injury. The early phase, with pain, swelling and increased skin temperature, is difficult to diagnose but potentially reversible.

After a period of weeks or months, a second, still painful, dystrophic phase develops, characterized by articular stiffness, cold skin and trophic changes, often with localized osteoporosis.

A late phase involves continued pain, skin and muscle atrophy, and muscle contractures, and is extremely disabling.

Diagnosis is clinical – a high index of suspicion and recognition of the unusual distribution of the pain. There are no specific or sensitive investigations, though demineralization may be seen on X-ray. Bone scan and MRI are not required to make the diagnosis.

Management

Management is difficult and the problem often very disabling. The evidence base for treatment is poor. Early diagnosis, effective pain relief and general care of the patient are essential. NSAIDs, tricyclic antidepressants, serotonin-norepinephrine reuptake inhibitors, and pregabalin or gabapentin are used in the early phase, together with active exercise of the limb, encouraged by a physiotherapist. Intravenous bisphosphonates can also be effective. Referral to a specialist pain clinic is essential. Nerve blocks were used in the past but are less common now. Intravenous immunoglobulins have been used in clinical trials but are not yet an accepted therapy.

ALGESIC AND ANTI-INFLAMMATORY DRUGS FOR MUSCULOSKELETAL PROBLEMS

The key to using drugs, particularly in chronic disorders and the elderly, is to balance risk and benefit and to review their appropriateness constantly. Box 18.18 shows the main drugs available.

Simple and compound analgesic agents

Simple agents, such as paracetamol, aspirin or codeine compounds (or combination preparations), used when necessary or regularly, relieve pain and improve function. Sleep may also be improved. Side-effects are relatively infrequent, although drowsiness and constipation occur with codeine preparations, especially in the elderly.

Stronger analgesics, such as dihydrocodeine, tramadol or morphine derivatives, should be used only for severe pain.

Non-steroidal anti-inflammatory drugs

Non-steroidal anti-inflammatory drugs (NSAIDs) have anti-inflammatory and centrally acting analgesic properties. They inhibit cyclo-oxygenase (COX), a key enzyme in the formation of prostaglandins, prostacyclins and thromboxanes (see p. 1176). There are two specific cyclo-oxygenase enzymes:

- COX-1 is the constitutive form present in many normal tissues.
- COX-2 is the form mainly induced in response to pro-inflammatory cytokines and is not found in most normal tissues.

### Analgesic and anti-inflammatory drugs for musculoskeletal problems

</tr>
</tbody>
</table>

### Non-steroidal anti-inflammatory drugs (NSAIDs)

Always to be taken with food. Slow-release preparations are used in inflammatory conditions or if more regular pain control is needed. Examples are shown.

- Ibuprofen: 200–400 mg, Every 6–8 h
- Ibuprofen slow-release: 600–800 mg, 12-hourly
- Diclofenac: 25–50 mg, 8-hourly
- Diclofenac slow-release: 75–100 mg, × 1–2 daily
- Naproxen: 250 mg, × 3–4 daily
- Naproxen slow-release: 550 mg, × 2 daily
- Celecoxib: 100–200 mg, × 2 daily

*In order of potency. *COX-2-specific NSAID (coxib).

### Effects and side-effects

Most of the older NSAIDs are non-specific and block both enzymes but with variable specificity (‘non-specific NSAIDs’, or nsNSAIDs). Their therapeutic effect depends on blocking COX-2 and their side-effects mainly on blocking COX-1. COX-1 protects the gastric mucosa and blocking it accounts for the majority of upper gastrointestinal side-effects.

The most common side-effects with non-specific NSAIDs are indigestion or skin rashes. More serious upper gastrointestinal side-effects are gastric erosions and peptic ulceration with perforation and bleeding. These occur more frequently in the elderly, in whom mortality is higher, in long-term use, and in those with high-risk factors: a history of ulcers, *Helicobacter pylori*, and concurrent corticosteroid or anticoagulant therapy. Ibuprofen, in combination with low-dose aspirin, significantly increases the risk of severe gastrointestinal bleeding. Practice guidelines recommend proton pump inhibitors in high-gastrointestinal-risk patients on non-specific NSAIDs. *H₂* blockers are less effective as gastroprotective agents. Prostaglandin E₂ analogues, such as misoprostol, reduce ulcer complications and are popular, but may cause nausea and diarrhoea. Lower gastrointestinal side-effects of non-specific NSAIDs are becoming more common.

COX-2 inhibitors (‘coxibs’) produce fewer gastrointestinal side-effects but these still occur. Coxibs are used in patients who have a high risk of gastrointestinal disease but are avoided in patients with cardiovascular risks. In fact, all NSAIDs except naproxen can cause an increase in risk of cardiovascular events, such as myocardial infarction or stroke. All these drugs, including naproxen, increase the risk of heart failure.

Coxibs and NSAIDs may reduce renal function, especially in the elderly (see Box 36.23).
### Uses

- **In musculoskeletal pain and in OA and spondylosis**, short courses of NSAIDs or coxibs are used but simple analgesia is often more appropriate.
- **In crystal synovitis**, NSAIDs and coxibs have a true anti-inflammatory effect.
- **In chronic inflammatory synovitis**, NSAIDs and coxibs do not alter the chronic inflammatory process or decrease the risk of joint damage, but they do reduce pain and stiffness.
- **In inflammatory arthritis and situations where more constant pain control is needed**, slow-release preparations are useful.
- **In chronic arthritis**, NSAID gels have some value.

The standard advice is to use NSAID in the lowest dose possible for the shortest time necessary to control pain. Be aware of the patient’s gastrointestinal and cardiac risks before prescribing NSAIDs or coxibs.

Diagnostic criteria for joint hypermobility syndrome: Beighton score ≥4; arthralgia for ≥3 months in ≥4 joints.

### Beighton score (Box 18.20)

The majority of hypermobile people suffer no adverse effects from the hypermobility but in some it can cause recurrent subluxations of individual joints and/or persistent widespread musculoskeletal pains. According to the 2017 classification, these people are classified into two groups; hypermobile Ehlers–Danlos syndrome (hEDS) for those who fulfill specific classification criteria and hypermobility spectrum disorder (HSD) for those who do not. Both groups may suffer other symptoms such as bowel disturbance, easy scarring and faintness on standing (postural orthostatic tachycardia syndrome; POTS), and the combination can be very disruptive to normal life. Treatment of the musculoskeletal symptoms relies on specialist physiotherapy to advise on exercises that take the patient’s hypermobility into account. Pain management programmes can be helpful in more severe cases. It is usually better to avoid surgery due to difficulties in healing.

### Other forms of Ehlers–Danlos syndrome

Whereas hEDS (EDS type 5) is the most common form of EDS and has no known genetic basis, there are 12 rarer forms that have all been linked to particular genes encoding collagen or collagen modifiers. EDS types 1, 4, 6 and 13 are autosomal dominant whereas the others are autosomal recessive (12 can be either). Note: numbering of these syndromes changed in 2017.

### Marfan’s syndrome

This condition is described on pages 1113–1115.

### Osteogenesis imperfecta

This is a heterogeneous group of disorders inherited mainly in autosomal dominant fashion with mutations in COL1A1 and COL1A2 genes. There are four main types of osteogenesis imperfecta and clinical subtypes are also described (V, VI and VII). The major clinical feature is bone fragility but other collagen-containing tissues are also involved, such as tendons, skin and eyes.

- **Type I**: mild bony deformities, blue sclerae, defective dentine, early-onset deafness, hypermobility of joints and heart valve disorders
- **Type II**: death in the perinatal period
- **Type III**: severe bone deformity and blue sclerae
- **Type IV**: fewer fractures, normal sclerae, normal lifespan but can also be severe, as in type III.
Management with daily oral risedronate in children improves BMD and reduces fracture risk. Intravenous pamidronate is another option. Prognosis is variable, depending on the severity of the disease. Stem cell therapy is being used. Types I and IV are associated with normal lifespan and people with these forms continue to have increased fracture risk into adulthood.

Achondroplasia
Achondroplasia (‘dwarfism’) is diagnosed in the first years of life. The disease is inherited in an autosomal dominant manner and is caused by a defect in the fibroblast growth factor receptor-3 gene. The trunk is of normal length but the limbs are very short and broad due to abnormal endochondral ossification. The vault of the skull is enlarged, the face is small and the nose bridge is flat. Intelligence is normal.

OSTEOARTHRITIS

Osteoarthritis (OA) is the most common type of arthritis. It results from damage to articular cartilage induced by an interaction of genetic, metabolic and biomechanical factors, leading to an inflammatory response affecting cartilage, subchondral bone, ligaments, menisci, synovium and capsule. Despite intense investigation, disease-modifying therapies remain elusive for this condition.

Epidemiology
Globally approximately 1 in 5 women and 1 in 10 men aged over 60 years have symptomatic OA, such that 80% have limitations in movement and 25% cannot perform major daily activities of life. Worldwide it has a variable pattern of presentation. For instance, hip OA is less common and knee OA more common in Asians than in Europeans. Beyond 55 years of age, women are affected more commonly than men by a familial pattern of inheritance in nodal and primary generalized forms of OA with variable patterns of distribution (Fig. 18.15). Resulting disabilities have major socioeconomic resource implications, particularly in the developed world where OA is one of the ten most disabling diseases in older adults.

Aetiology and pathogenesis
Cartilage is a matrix of water (>70%) and organic extracellular matrix components, mainly type II collagen and aggrecan or other proteoglycans (see p. 414); it has a smooth surface and shock-absorbing properties. OA is now considered a disease of the whole joint with alterations in subchondral bone, ligaments, capsule, synovial membrane as well as articular cartilage. Consequent structural changes include surface fibrillation and ulceration with loss of cartilage that exposes underlying bone to increased stress, producing microfractures and cysts leading to abnormal sclerotic subchondral bone and overgrowths at the joint margins, called osteophytes (Fig. 18.16). Inflammatory changes may also occur. This process produces a spectrum of OA, ranging from atrophic disease in which cartilage destruction occurs without any subchondral bone response, to hypertrophic disease with massive new bone formation at the joint margins.

Fig. 18.15 Typical distribution of affected joints in arthritis. (A) Primary generalized osteoarthritis. (B) Pyrophosphate arthropathy. Red circles indicate the more commonly affected sites, and blue the less commonly affected sites.

Various mechanisms have been suggested:
- Abnormal stress and loading, leading to mechanical cartilage damage.
- Obesity is a risk factor for developing OA of the hand and knee and thought to trigger metabolic inflammation via adipokines, released from adipose tissue, inducing pro-inflammatory cytokines that cause cartilage and bone damage.
- Matrix degradation by matrix metalloproteinase (MMP)-1, MMP-2, MMP-3, MMP-9, MMP-13, which are secreted by chondrocytes in an inactive form. Extracellular activation then leads to the degradation of both collagen and proteoglycans around chondrocytes.
- Tissue inhibitors of metalloproteinases (TIMPs) regulate the MMPs. Disturbance of this regulation may lead to an increase in cartilage degradation over synthesis and contribute to the development of OA.
- Osteoprotegerin (OPG), RANK and RANK ligand (RANKL) control subchondral bone remodelling. Their levels are significantly different in OA chondrocytes.
- Aggrecanase production is stimulated by pro-inflammatory cytokines, and aggrecan (the major proteoglycan) levels fall.
- Inflammatory mediator release (including interleukin-1, IL-1 and tumour necrosis factor-alpha, TNF-α) stimulates metalloproteinase production, and IL-1 inhibits type II collagen production. IL-6 and IL-8 may also be involved. The production of cytokines by macrophages and that of MMPs by chondrocytes in OA are dependent on the transcription factor nuclear factor kappa B (NF-κB).
• **Growth factors**, including insulin-like growth factor 1 (IGF-1) and transforming growth factor beta (TGF-β), are involved in collagen synthesis, and their deficiency may play a role in impairing matrix repair. Paradoxically, increased TGF-β may also cause increased subchondral bone density.

• **Cell derived and/or cartilage breakdown products**, such as alarmins, fibronectin fragments, hyaluronic acid fragments, collagen fragments, proteoglycan fragments and high mobility group box proteins, act to further deregulate chondrocyte function and contribute to cartilage degradation.

• **Vascular endothelial growth factor (VEGF)** from macrophages is a potent stimulator of angiogenesis and may contribute to inflammation and neovascularization in OA. Innervation can accompany vascularization of the articular cartilage.

• **A strong hereditary element** underlying OA is suggested by twin studies. The influence of genetic factors is estimated at 35–65%. To date, genome-wide association studies (GWAS) have identified several common variants associated with knee or hip OA, although the individual risk alleles exert only moderate to small effects. Loci that are associated with OA include genes encoding components of the TGF-β and bone morphogenetic factor 5 (BMP-5); type II iodothyronine deiodinase (DIO2), which regulates synthesis of triiodothyronine that is involved in cartilage maintenance and repair; proteins involved in apoptosis and mitochondrial damage; molecules that regulate the turnover of extracellular matrix components; and proteins that are associated with inflammation and immune responses.

• **In the Caucasian population**, there is an inverse relationship between the risk of developing OA and osteoporosis.

• **Gender.** In women, weight-bearing sports produce a twofold increase in risk of OA of the hip and knee. In men, there is an association between hip OA and certain occupations: farming and labouring. OA may flare after the female menopause or after cessation of hormone replacement therapy.

• **Periarticular enthesitis** is recognized in nodal generalized OA (NGOA) and may be difficult to distinguish from PsA at DIP joints. The term primary OA may be used when various predisposing factors (Box 18.21), occur in the absence of other conditions that may cause secondary OA (Box 18.22).

**Clinical features**

OA affects many joints, in diverse clinical patterns, typically causing mechanical pain with movement and/or loss of function. Hip and knee OA are major causes of disability. Early OA is rarely symptomatic, however, unless accompanied by a joint effusion, while advanced radiological and pathological OA is not always symptomatic.

Symptoms are usually gradual in onset and progressive. Episodic disease flare-ups may be inflammatory in nature, although typically ESR and/or CRP are normal. Radiological OA is not invariably progressive. Radiological improvement is uncommon but has been observed, suggesting that repair is possible.

---

**Box 18.21 Factors predisposing to osteoarthritis (OA)**

- **Obesity:** This predicts a later risk of radiological and symptomatic OA of the hip and hand in population studies
- **Heredity:** There is a familial tendency to develop nodal and generalized OA
- **Gender:** Polyarticular OA is more common in women; a higher prevalence after the menopause suggests a role for sex hormones
- **Hypermobility** (see p. 432): Increased range of joint motion and reduced stability lead to OA
- **Osteoporosis:** There is a reduced risk of OA
- **Diseases:** See Box 18.22
- **Trauma:** A fracture through any joint predisposes. Meniscal and cruciate ligament tears cause OA of the knee

- **Congenital joint dysplasia:** This alters joint biomechanics and leads to OA. Mild acetabular dysplasia is common and leads to earlier onset of hip OA
- **Joint congruity:** Congenital dislocation of the hip or a slipped femoral epiphysis or Perthes’ disease predispose; osteonecrosis of the femoral head (see p. 425s) in children and adolescents causes early-onset OA
- **Occupation:** Miners develop OA of the hip, knee and shoulder, cotton workers OA of the hand, and farmers OA of the hip
- **Sport:** Repetitive use and injury in some sports cause a high incidence of lower-limb OA
Osteoarthritis

18

Symptoms

- Joint pain with movement and/or weight-bearing.
- Short-lived morning joint stiffness.
- Functional limitation.

Signs

- Crepitus.
- Restricted movement.
- Bony enlargement.
- Joint effusion and variable levels of inflammation.
- Bony instability and muscle wasting.

Clinical subsets

Localized OA

Nodal OA

In nodal OA (Box 18.23), joints of the hand are usually affected one at a time over several years, with the DIPs more frequently involved than the PIPs. Nodal OA often begins around the female menopause, with inflammation causing painful, tender, swollen interphalangeal joints and impairment of hand function. At this stage, enthesitis can be seen on MRI. Intra-articular corticosteroid injections may be helpful at this stage. The inflammatory phase settles after some months or years, leaving painless bony swellings posterolaterally: Heberden’s nodes (DIPs) and Bouchard’s nodes (PIPs), along with stiffness and deformity (Fig. 18.17). Functional impairment is usually limited, although both hips may become involved in progressive disease.

Knee OA

The prevalence of symptomatic knee OA is 40% in individuals over 75 years of age and is more common in women. There is a strong relationship with obesity. The disease is generally bilateral and strongly associated with nodal OA of the hand in elderly women, or as part of generalized OA. The medial compartment is most commonly affected, leading to a varus (bow-legged) deformity. Often, retropatellar OA is also present. Previous trauma and meniscal and cruciate ligament tears are risk factors for developing knee OA. Bone marrow lesions seen on MRI predict disease progression and eventual joint replacement.

Primary generalized OA

This condition is rare and usually seen in combination with NGOA. Other affected areas include the knees, first MTP, hip and intervertebral (spondyloarthritis) joints. Its onset is often sudden and severe. There is a female preponderance and a strong familial tendency. Periarticular ligamentous pathology may have an important role in the phenotypic expression of NGOA.
Erosive OA

In this rare subgroup, the DIPs and PIPs are inflamed and equally affected, with a poor functional outcome. Radiologically, there is marked osteolysis. Destructive phases are followed by phases of remodelling.

Crystal-associated OA

This condition most commonly occurs with calcium pyrophosphate deposition (CPPD) in the cartilage. It increases in frequency with age and causes cartilage calcification (CC) on over 40% of knee X-rays in the over-eighties, but is usually asymptomatic. The joints most frequently affected are the knees (hyaline cartilage and fibrocartilage) and wrists (triangular fibrocartilage; see Fig. 18.15). There is patchy linear CC on X-ray (Fig. 18.18).

A chronic arthropathy (pseudo-OA) occurs, predominantly in elderly women with severe CC. There is a florid inflammatory component and marked osteophyte and cyst formation visible on X-rays that predominantly affects the knees, then wrists and shoulders. CC is associated with CPPD crystal-induced arthritis (see p. 451).

A rare, rapidly destructive arthritis in elderly women, affecting shoulders, hips and knees, is associated with the finding of crystals of calcium apatite in a bloody joint effusion. The outlook is poor and joints require early surgical replacement.

Investigations

- **Blood tests** lack specificity; the ESR is usually normal, although high-sensitivity CRP may be slightly raised. RFs and antinuclear antibodies are negative.
- **X-rays** are abnormal only when the damage is advanced. They are useful in preoperative assessments. For knees, a standing X-ray (stressed) is used to assess cartilage loss, and ‘skyline’ views in flexion are used for patello-femoral OA.
- **MRI** demonstrates meniscal tears, early cartilage injury and subchondral bone marrow changes (osteoochondral lesions).
- **Arthroscopy** reveals early fissuring and surface erosion of the cartilage.
- **Aspiration of synovial fluid** if there is a painful effusion shows a viscous fluid with few leucocytes (see p. 416).

Management

The guiding principle is to treat the symptoms and disability, not the radiological appearances; depression and poor quadriceps strength are better predictors of pain than radiological severity in OA of the knee. Patient education about the disease and its effects reduces pain, distress and disability, and increases compliance with treatment. Psychological or social factors alter the impact of the disease.

Physical measures

Weight management is recognized to reduce the risk of development of OA and slow its progression. Women who lost an average of 5 kg decreased their risk for knee OA by 50% in the Framingham study. As little as 1% change in body weight in obese adults modifies the rate of knee cartilage loss. Overall, maintenance of muscle mass and reduction of adiposity is central to OA management. Exercises for strength and stability are useful and land-based exercise programmes for the hip and knee improve physical function and pain. Hydrotherapy helps, especially in lower-limb OA. Insoles for flat feet and a walking stick help on the contralateral side to the affected lower limb joint are useful. Transcutaneous electrical nerve stimulation, acupuncture and thermotherapy may be adjuncts for treating OA but are not universally recommended due to their limited evidence of efficacy.

Medication

Topical, oral and injectable therapies are available and potential benefit must be balanced against potential side-effects, especially in the elderly. First-line therapies include topical or oral NSAIDs. Paracetamol has limited efficacy in OA (see Box 18.18). NSAIDs or coxibs should be used intermittently when possible due to their toxicities. Topical rubefacients, such as capsaicin, may be used as a supplementary analgesic. Opioids are a last resort and should be used cautiously in older patients.

Intra-articular corticosteroid injections produce short-term improvement when there is a painful joint effusion. Frequent injections into the same joint should be avoided. Heterogeneity of relevant studies of intra-articular hyaluronan preparations displays limited efficacy.

Glucosamine and chondroitin (sold as food supplements) have no clinically relevant effect on joint pain or joint space narrowing.

There are no proven agents that halt or reverse OA, although they are greatly needed.

Surgery

Arthroscopy for knee OA is rarely beneficial. Replacement arthroplasty, however, has transformed the management of severe OA to reduce pain, improve function, restore quality of life and regain independence. Increasing numbers of arthroplasties, particularly hip and knee, are being performed worldwide each year with shortened recovery times, improved durability and mortality. However, an increasing trend for hip or knee arthroplasty in patients less than 60 years of age is associated with an increased lifetime risk of revision surgery. Serious complications occur in less than 1%, with venous thromboembolism and infection being the most serious. These slight but definite risks make it essential for the patient to be certain that surgery is necessary. Resurfacing hip surgery has become popular but may have higher complication rates in women, particularly with metal on metal resurfacing. Uni-compartmental knee replacement is a less major procedure and may be appropriate in some cases.

Other surgical procedures include re-alignment osteotomy of the knee or hip, excision arthroplasty of the first MTP and base of the thumb, and fusion of a first MTP joint.
Box 18.24 The three main subgroups of inflammatory arthritis

1. Rheumatoid arthritis (associated with antibodies)
2. Spondyloarthritis (associated with human leucocyte antigen (HLA)-B27)
3. Metabolic arthritis (e.g. associated with crystals)

Box 18.25 Pattern of joint involvement in inflammatory arthritis

- Palindromic rheumatism

AxSpA, axial spondyloarthropathy; EA, enteropathic arthritis; EN, erythema nodosum; PsA, psoriatic arthritis; RA, rheumatoid arthritis; ReA, reactive arthritis. Italics indicate less common pattern of joint involvement.

INFLAMMATORY ARTHRITIS

Inflammatory arthritis is characterized by synovial inflammation. The three main subgroups of inflammatory arthritis are rheumatoid arthritis (RA), spondyloarthritis and crystal arthropathies (Box 18.24). The diagnosis of these conditions is helped by distinguishing:

- the number and pattern of joint involvement (symmetrical or asymmetrical, large or small) (Box 18.25)
- presence of any non-articular disease
- a past and family history
- periodicity of the arthritis (single acute, relapsing, chronic and progressive).

Certain non-articular diseases, such as psoriasis, iritis, IBD, non-specific urethritis or recent dysentery, suggest spondyloarthritis. There may be evidence of recent viral illness (rubella, hepatitis B or erythrovirus), rheumatic fever, or a tick bite and skin rash (Lyme disease). In early arthritis, it may not be possible to make a specific diagnosis until the disease has evolved from an undifferentiated arthropathy into a chronic form.

There is a distinct genetic separation of rheumatoid-pattern synovitis and spondyloarthritis; RA (see below) is associated with a genetic marker in the class II major histocompatibility complex (MHC) genes, while spondyloarthritis shares certain alleles in the B locus of class I MHC genes, usually B27 (see p. 448).

In general, the pain and stiffness of inflammatory arthritis are worse in the morning, often lasting for several hours and improving with activity, in contrast with the much shorter morning stiffness and mechanical pain with activity of OA. Inflammatory markers (ESR and CRP) are typically raised in inflammatory arthritis. Specific types of arthritis are discussed below.

Early inflammatory polyarthritis

Undifferentiated polyarthritis requires urgent referral to a rheumatologist for diagnosis and treatment, including the early introduction of disease-modifying agents when indicated (see p. 445). In persistent inflammatory arthritis, sustained remission depends on rapid diagnosis and intensive treatment. Poor prognostic features for undifferentiated polyarthritis are:

- polyarticular onset
- positive anti-citrullinated peptide antibodies (ACPA)
- positive rheumatoid factor
- joint erosion on X-ray at presentation
- disease for longer than 3–6 months.

RHEUMATOID ARTHRITIS

RA is a chronic inflammatory rheumatic disease. It has a multifactorial pathogenesis, with various genetic and environmental factors being implicated, giving rise to immune dysregulation with consequent joint inflammation and tissue damage. Patients typically develop a chronic symmetrical polyarthritis with systemic inflammation.

Epidemiology

RA has a worldwide distribution affecting 0.5–1% of the population (with a female preponderance of 3:1). The prevalence is low in black African and Chinese people. The incidence is falling. RA is the 42nd highest contributor to global disability just below malaria and just above iodine deficiency. It presents from early childhood (when it is rare) to late old age. The most common age of onset is between 30 and 50 years.

Aetiology and pathogenesis

There has been a greater understanding of genetic and environmental factors in the last two decades.

- Genetic factors. There is an increased incidence in first-degree relatives and a high concordance amongst monozygotic twins of up to 15%. Over 100 loci are associated with disease risk and progression. There is a strong association between susceptibility to RA and certain human leucocyte antigen (HLA) haplotypes: HLA-DR4, which occurs in 50–75% of patients and correlates with a poor prognosis, as does possession of certain shared alleles of HLA-DRB1*04. The possession of these shared epitope alleles in HLA-DRB1 (S2 and S3P) increases susceptibility to RA and may predispose to anti-cyclic citrullinated peptide antibody (ACPA) development against citrullinated antigens. Citrullination is a process that modifies antigens, allowing them to fit into the shared epitope on HLA alleles. A genome-wide association study in ACPA-positive RA found an association with loci near HLA-DRB1 and PTPN22 in people of European descent. These genes affect the presentation of autoantigens (HLA-DRB1), T-cell receptor signal transduction (PTPN22) and targets of ACPA (PAD14).

- Environment. Smoking and other forms of bronchial stress increase the risk of RA with HLA-DR4 and acts synergistically with HLA-DRB1 to increase the risk of having ACPA. Mucosal surfaces of the oral cavity, upper respiratory tract and gut are colonized by commensal microorganisms; a population known...
Alterations in the microbiome may facilitate developments in innate and adaptive immunity that predispose to RA, such as the association of periodontal disease and alterations in the gut microbiome with RA.

**Autoantibodies.** Rheumatoid factor (RF), autoantibodies to the Fc portion of immunoglobulin G, are found in 75–80% of RA patients and are relatively specific for diagnosis of RA but have little predictive value in the general population. In contrast, ACPA are more specific and sensitive to RA.

**Immunology**
RA is primarily a synovial disease, and synovitis occurs when chemoattractants produced in the joint recruit circulating inflammatory cells. Over-production of tumour necrosis factor-alpha (TNF-α) leads to synovitis and joint destruction. Interaction of macrophages and T and B lymphocytes drives this over-production. TNF-α stimulates over-production of IL-6, as well as other cytokines. The increased understanding of the immunopathogenesis of this disease has informed the development of targeted biological therapies (Fig. 18.19).

**Fig. 18.19 Pathogenesis of rheumatoid arthritis.** Environment–gene interactions promote citrullination of self proteins, which can then be detected by T and B cells; this leads to a loss of tolerance and promotion of the inflammatory response, resulting in joint damage. Targeted therapy is shown in yellow. ACPA, anti-citrullinated peptide antibody; APC, antigen-presenting cell; IL, interleukin; RANKL, receptor activator of nuclear factor kappa B ligand; RF, rheumatoid factor; Th, T helper; TNF, tumour necrosis factor.

Dysfunction of certain cell types are significant in immunopathogenesis:
- **Synovial cells** in chronic rheumatoid synovitis are predominantly fibroblast-like synoviocytes and macrophage-like synoviocytes that produce pro-inflammatory cytokines.
- **Osteoclasts** cause bone and cartilage destruction.
- **Synovial B cells,** activated by cytokine-activated macrophages and T cells, produce autoantibodies, of which IgM and IgA RF are the most typical in RA. As RFs bind the Fc portion of IgG, they have the potential for self-aggregation and immune complex formation in the synovium. These may then trigger macrophages via IgG Fc receptors to produce even more cytokines, including IL-1, IL-8, TNF-α and granulocyte–macrophage colony-stimulating factor, and fibroblasts to produce IL-6.
- **Synovial fibroblasts** have high levels of the adhesion molecule, vascular cell adhesion molecule (VCAM-1, a molecule that supports B-lymphocyte survival and differentiation), decay accelerating factor (DAF, a factor that prevents complement-induced cell lysis) and cadherin II (which mediates cell-to-cell interac-
Rheumatoid arthritis

T cells can be a part of the destructive process. The pro-inflammatory cytokine IL-17 is produced by a specific subset, Th17 helper cells (see p. 51), which produce IL-17, 21 and 22, and TNF-α. The normal regulatory T cells are suppressed by TGF-β and interleukins (produced by macrophages and dendritic cells), allowing Th17 helper cells to increase.

The triggering antigen, which leads to self-maintained inflammation in RA, remains unclear. Triggers for ACPA production include filaggrin, type II collagen and vimentin. There is little evidence that type II collagen is the triggering antigen, although it is a cause of arthritis in animal models of RA. Smoking is a potential trigger, particularly in ACPA-positive RA.

Pathology

RA is typified by widespread, persistent synovitis of joints, tendon sheaths or bursae. Normal synovium comprises a thin lining layer that contains fibroblast-like synoviocytes and macrophages overlying connective tissue. In RA, the synovium becomes greatly thickened, causing ‘boggy’ swelling around joints and tendons, with proliferation of the synovium into folds and fronds, and infiltration by a variety of inflammatory cells, including polymorphs, which transit through the tissue into the joint fluid, and lymphocytes and plasma cells. The normally sparse surface layer of lining cells becomes hyperplastic and thickened (Fig. 18.20). There is marked vascular proliferation. Increased permeability of blood vessels and the synovial lining layer leads to joint effusions containing lymphocytes and dying polymorphs.

The hyperplastic synovium spreads from the joint margins to the cartilage surface. This ‘pannus’ of inflamed synovium damages the underlying cartilage by blocking its normal route for nutrition and by the direct effects of cytokines on the chondrocytes. The cartilage becomes thinned and the underlying bone exposed. Local cytokine production and joint disuse combine to cause juxta-articular osteoporosis during active synovitis.

Fig. 18.20 Histological appearance of synovium in rheumatoid arthritis (RA). (A) Normal synovium. (B) Synovial appearances in established RA, showing marked hypertrophy of the tissues with infiltration by lymphocytes and plasma cells. (From Shipley M. Colour Atlas of Rheumatology, 3rd edn. London: Mosby–Wolfe; 1993, with permission.)

Fig. 18.21 Magnetic resonance imaging of erosions in rheumatoid arthritis. (From Elias-Jones C. Crash Course Orthopaedics and Rheumatology, 3rd edn. Edinburgh: Elsevier, 2015.)
Clinical features

Typical presentation

RA typically presents (~70%) as a progressive, symmetrical, peripheral polyarthritis, evolving over a period of a few weeks or months in patients between 30 and 50 years of age, although the disease can occur at any age. Less commonly (~15%), a rapid onset can occur over a few days (or explosively overnight), with a severe symmetrical, polyarticular involvement, especially in the elderly. Factors indicating a poor prognosis are listed in Box 18.26. The differential diagnosis of early RA is shown in Box 18.27.

Current classification criteria from 2010 are more suitable for assessing and diagnosing early arthritis than previous versions because they do not rely on later changes, such as erosions and extra-articular disease to distinguish RA (Box 18.28).

In early RA, the combination of at least one swollen joint for more than 6 weeks with no prior injury, no associated history or family history of spondyloarthritides or associated conditions such as psoriasis (see p. 664), and a positive ACPA test is the best way to select patients for earlier treatment to avoid joint damage. This evidence-based approach has been shown to reduce the risk of the development of damage and permanent joint deformities.

Symptoms and signs of early RA

Most patients complain of pain and stiffness of the small joints of the hands (MCPs, PIPs) and feet (MTPs). The DIPs are usually spared. Wrist, elbows, shoulders, knees and ankles are also affected. In most cases, multiple joints are involved, but 10% of patients present with a monoarthritis of the knee or shoulder or with carpal tunnel syndrome. The pain and stiffness are significantly worse in the morning. Sleep disturbance and fatigue are common complaints.

The joints are usually warm and tender with some joint swelling. There is limitation of movement and muscle wasting. Deformities and non-articular features develop if the disease cannot be controlled (see below).

RA in older patients may mimic polymyalgia rheumatica; the synovitis becomes apparent as the corticosteroid dose is reduced.

Other presentations

The variable presentations and progression of RA are shown in Box 18.29. Relapses and remissions occur either spontaneously or on drug therapy. Active disease, producing progressive joint damage, requires targeted treatment to induce remission.
Box 18.29 Presentations of rheumatoid arthritis

- **Palindromic**. Palindromic monoarticular attacks last 24–48 h; 50% progress to other types of RA.
- **Transient**. Disease is self-limiting, lasting <12 months and leaving no permanent joint damage. It is usually seronegative for IgM RF and ACPA. Some of these patients may have undetected postviral arthritis.
- **Rемitting**. There is a period of several years during which the arthritis is active but then remits, leaving minimal damage.
- **Chronic, persistent**. This is the most typical form; it may be seropositive or seronegative for IgM RF. The disease follows a relapsing and remitting course over many years. Seropositive (plus ACPA) patients tend to develop greater joint damage and long-term disability. They warrant earlier and more aggressive treatment with disease-modifying agents.
- **Rapidly progressive**. The disease progresses remorselessly over a few years and leads rapidly to severe joint damage and disability. It is usually seropositive (plus ACPA), has a high incidence of systemic complications and is difficult to treat.

**Seronegative RA** initially affects the wrists more often than the fingers and has a less symmetrical joint involvement. It has a better long-term prognosis but some cases progress to severe disability. This form can be confused with psoriatic arthropathy, which has a similar distribution (see p. 456).

**Palindromic rheumatism** is unusual (5%) and consists of 24–48-hour episodes of acute monoarthritis. The joint becomes acutely painful, swollen and red, but resolves completely. Further attacks occur in the same or other joints. About 50% of patients develop typical chronic rheumatoid synovitis after a delay of months or years. The rest remit or continue with acute episodic arthritis. Detection of RF or ACPA predicts conversion to chronic, destructive synovitis.

**Complications**

**Septic arthritis**

This serious complication has significant morbidity and mortality. In immunosuppressed patients, affected joints may not display the typical signs of inflammation with accompanying fever found in patients with an intact immune system. Treatment is with systemic antibiotics (see p. 455) and drainage.

**Amyloidosis**

Amyloidosis (see p. 1357) is found in a very small number of people with uncontrolled RA. RA is the most common cause of secondary AA amyloidosis. AL amyloidosis causes a polyarthritis that resembles RA in distribution and is also often associated with carpal tunnel syndrome and subcutaneous nodules.

**Joint involvement in RA**

These changes are seen in established disease or when early drug treatment has been ineffective.

**Hands and wrists**

In early disease, the fingers are swollen, painful and stiff. Inflamed flexor tendon sheaths increase functional impairment and may cause a carpal tunnel syndrome. Joint damage causes:

- **A combination of ulnar drift and palmar subluxation of the MCPs**. This change (Fig. 18.23) leads to unsightly deformity, but function may be preserved once the patient has learned to adapt and pain is controlled.
- **Fixed flexion** (buttonhole or boutonnière deformity) or **fixed hyperextension** (swan-neck deformity) of the PIP joints, which impairs hand function.

**Swelling and dorsal subluxation of the ulnar styloid**, which causes wrist pain. It may also cause rupture of the finger extensor tendons, leading to a sudden drop of the little and ring fingers that requires urgent surgical repair.

**Shoulders**

RA commonly affects the shoulders. Initially, the symptoms mimic rotator cuff tendonosis (see p. 419) with a painful arc syndrome and pain in the upper arms at night. Further joint damage leads to global stiffening; rotator cuff tears become more common and interfere with dressing, feeding and personal toilet.

**Elbows**

Synovitis of the elbows causes swelling and a painful fixed flexion deformity. In late disease, flexion may be lost and severe difficulties with feeding result, especially combined with shoulder, hand and wrist deformities.

**Feet**

One of the earliest manifestations of RA is painful swelling of the MTP joints.

- The foot becomes broader and a hammer-toe deformity develops.
- Exposure of the metatarsal heads to pressure by the forward migration of the protective fibrofatty pad (Fig. 18.24) causes pain.
- Ulcers or calluses may develop under the metatarsal heads and over the dorsum of the toes.
Rheumatoid arthritis causes a flat medial arch and loss of flexibility of the foot. The ankle often assumes a valgus position. Appropriate broad, deep, cushioned shoes are essential but rarely wholly adequate, and walking is often painful and limited. Podiatry helps and surgery may be required.

Knees
Massive synovitis and knee effusions occur but respond well to aspiration and steroid injection (see p. 416). A persistent effusion increases the risk of popliteal cyst formation and rupture (see p. 427). In later disease, erosion of cartilage and bone causes loss of joint space on X-ray and damage to the medial and/or lateral and/or retropatellar compartments of the knees. Depending on the pattern of involvement, the knees may develop a varus or valgus deformity. Secondary OA follows. Total knee replacement may be required to restore mobility and relieve pain.

Hips
The hips are occasionally affected in early RA but less commonly so than the knees at all stages of the disease. Pain and stiffness are accompanied by radiological loss of joint space and juxta-articular osteoporosis. The latter may permit medial migration of the acetabulum (protrusio acetabulae). Later, secondary OA develops. Hip replacement may be required.

Cervical spine
Painful stiffness of the neck in RA is often muscular, but it may be due to rheumatoid synovitis affecting the synovial joints of the upper cervical spine and the bursae, which separate the odontoid peg from the anterior arch of the atlas and its retaining ligaments. This synovitis leads to bone destruction, damages the ligaments and causes atlantoaxial or upper cervical vertebral instability. Subluxation and local synovial swelling may damage the spinal cord, producing pyramidal and sensory signs. MRI is the imaging of choice, but lateral flexed and extended neck X-rays can demonstrate instability. In late RA, difficulty walking that cannot be explained by articular disease, weakness of the legs or loss of control of bowel or bladder may be due to spinal cord compression and is a neurosurgical emergency.

Imaging of the cervical spine in flexion and extension is recommended in patients with RA before surgery or upper gastrointestinal endoscopy to check for instability and reduce the risk of cord injury during intubation.

Other joints
The temporomandibular, acromioclavicular, sternoclavicular, cricoarytenoid and any other synovial joint can be affected.

Non-articular manifestations
See Fig. 18.25.

Soft tissue surrounding joints
Subcutaneous nodules are firm and intradermal, generally occurring over pressure points: typically, the elbows, the finger joints and the Achilles tendon in patients with seropositive erosive disease. They can be removed surgically but they tend to recur.

The olecranon and other bursae may be swollen (bursitis). Tenosynovitis of flexor tendons in the hand can cause stiffness and occasionally a trigger finger. Swelling of the extensor tendon sheath over the dorsum of the wrist is common.

Muscle wasting around joints is common. Corticosteroid-induced myopathy occurs. Osteoporosis is more common in poorly controlled RA.

Less common non-articular manifestations
Non-articular complications are less common, probably because of more effective disease control.
Lungs
Findings in the lungs (see p. 992) include:
• airways disease: from predominant bronchiectasis (cough and daily sputum) to predominant obliterative bronchiolitis (progressive breathlessness)
• pleural disease: pleural effusion (asymptomatic to mildly breathless) and thickening
• interstitial lung disease: a combination of inflammation and basal lung fibrosis
• peripheral, intrapulmonary nodules: asymptomatic but may cavitate, especially with pneumoconiosis (Caplan’s syndrome)
• infective lesions, e.g. tuberculosis in patients on biological DMARDs.

Vasculitis
Vasculitis (see p. 464) is uncommon. Risk factors include high titres of RF and active extra-articular disease elsewhere. Findings include:
• widespread cutaneous vasculitis with necrosis of the skin
• mononeuritis multiplex (see p. 888).

Heart and peripheral vessels
Poorly controlled RA with a persistently raised CRP and high cholesterol is a cardiovascular risk factor, independent of traditional risk factors (i.e. high cholesterol and hypertension). Other cardiovascular problems include:
• pericarditis, which is rarely symptomatic
• endocarditis and myocardial disease, rarely symptomatic, found at postmortem in approximately 20% of cases.

Nervous system
• Peripheral sensory neuropathies: mononeuritis multiplex or symmetrical peripheral neuropathy – due to vasculitis of the vasa nervorum.
• Compression neuropathies: carpal or tarsal tunnel syndrome – due to synovitis.
• Cord compression: due to atlantoaxial subluxation (see earlier).

Eyes
• Sicca syndrome causes dry mouth and eyes (see Sjögren’s syndrome, p. 464).
• Scleritis and episcleritis occur in severe, seropositive disease, resulting in painful red eye.
• Scleromalacia perforans is a rare feature.

Kidneys
Amyloidosis causing proteinuria, nephrotic syndrome and chronic kidney disease occurs rarely in severe, longstanding RA, due to the deposition of highly stable serum amyloid A protein (SAP) in the intercellular matrix of a variety of organs (see p. 1357).

Spleen, lymph nodes and blood
Felty’s syndrome is splenomegalic and neutropenia in a patient with RA. Leg ulcers and sepsis are complications. HLA-DR4 is found in 95% of such patients, compared with 50–75% of people with RA alone.

Anaemia is almost universal and is usually normochromic and normocytic. It may be iron-deficient owing to gastrointestinal blood loss from NSAID ingestion, or rarely haemolytic (Coombs-positive). There may be a pancytopenia due to hypersplenism in Felty’s syndrome or as a complication of DMARD treatment. A high platelet count occurs with active disease.

Diagnosis and investigations
Diagnosis relies on the clinical features described earlier. The predictors of poor prognosis arthritis are listed in Box 18.26. Initial investigations include:
• Blood count may show a normochromic, normocytic anaemia.
• ESR and/or CRP are raised in proportion to the activity of the inflammatory process and are useful in monitoring treatment.
• Serology reveals ACPA positivity (see p. 416) that may be present early in the disease (and even predate it by many years), and in early inflammatory arthritis indicates the likelihood of progressing to RA. RF is present in approximately 75–80% of cases and ANA at low titre in 30%.
• X-rays show soft tissue swelling in early disease, but ultrasound and MRI (Fig. 18.26) are useful to demonstrate synovitis and early erosions.
• Aspiration of the joint may be needed if an effusion is present. The aspirate looks cloudy owing to white cells. In a suddenly painful joint, septic arthritis should be suspected (see p. 454).
• Musculoskeletal ultrasound is a very effective way of demonstrating persistent synovitis when deciding on the need for DMARDs or assessing their efficacy.

Other investigations will depend on the clinical picture, as outlined above. In severe disease, extensive imaging of joints may be required.

Management
See Box 18.30. The diagnosis of RA inevitably causes concern and fear in the patient and requires explanation and reassurance. Anyone with persistent arthritis should be referred urgently to a rheumatologist if small joints of hands or feet are affected, more than one joint is affected, or there has already been a delay of more than 3 months from symptom onset.

The doctor should have a positive approach and remind the patient that, with the help of drugs, most people continue to lead a more or less normal life, as the aim of therapy is disease remission. Furthermore, early therapy targeted at remission within 3 months of symptom onset is more likely to achieve sustained remission with subsequent drug tapering. People should be helped and encouraged to stay at work, as 30% lose their job within 2 years of
diagnosis. Patients adjust and cope remarkably with time and support from the specialist team in a rheumatology unit (including doctors, nurses, physiotherapists, podiatrists and psychologists) and from leaflets, websites and local patient groups.

Patients from socially deprived backgrounds and smokers have a worse prognosis. Due to the increased prevalence of cardiovascular risk in RA, aggressive management of traditional cardiac risk factors and suppression of disease are required.

**Drug therapy**

No curative agent exists for RA but early recognition and an intensified treat to target (T2T) regime, with regular review until remission occurs, improves outcomes. Less frequent review is then continued to assess disease activity, damage, function and co-morbidities.

The disease activity score DAS28 is widely used to measure disease activity in RA by counting the number of tender and swollen joints in 28 joints in the upper limbs and knees, combining these values with the ESR and the patient’s assessment of their general health on a visual analogue scale to generate a numerical score (Fig. 18.27). A DAS28 score of greater than 5.1 implies active disease, less than 3.2 low disease activity and less than 2.6 remission.

For newly diagnosed patients, treatment typically begins with a combination of fast-acting corticosteroid (its dose/duration limited to give benefit with minimal side-effects) and slow-acting conventional synthetic (cs)DMARDs. With regular and frequent review the T2T approach enables optimization and intensification of therapy with effective doses of csDMARDs, often in combination to prevent the long-term irreversible damaging effects of joint inflammation.

For patients who fail to achieve low disease activity or remission with csDMARDs biological therapies (bDMARDs) are then used to achieve the desired target. If efficacy is not achieved, or subsequently lost, then switching to an alternative bDMARD is indicated. A new therapeutic class of DMARDs that inhibit intracellular Janus kinase (JAK) enzymes are now licensed in RA. These drugs, known as targeted synthetic (ts)DMARDs, have oral bioavailability, rapid onset of action and efficacy similar to bDMARDs.

**Non-steroidal anti-inflammatory drugs and coxibs**

Most people with RA require an NSAID to relieve night pain and morning stiffness in addition to DMARDs. The individual response to NSAIDs varies greatly, so several different drugs may have to be tried for at least a week to find the most effective (see Box 18.18). The major side-effects of NSAIDs and the use of coxibs are discussed on page 431. If gastrointestinal side-effects are prominent, or the patient is over 65 years of age, add a proton pump inhibitor.

For additional relief, a simple analgesic is taken as required (e.g. paracetamol or a combination of codeine or dihydrocodeine and paracetamol).

**Corticosteroids**

The early use of corticosteroids slows down the course of the disease but intensive short courses in very early arthritis do not appear to stop progressive disease. Corticosteroids are a common cause of secondary osteoporosis; therefore, concomitant vitamin D and bisphosphonates are necessary to reduce fracture risk in patients expected to be on corticosteroid therapy for more than 3 months’ duration.

**Intra-articular injections** with semi-crystalline steroid preparations have a powerful but sometimes only short-lived effect.

**Intramuscular depot injections** (40–120 mg depot methylprednisolone) are used to help induce remission while waiting for DMARDs to work and to control severe disease flares.

**Oral corticosteroids** are powerful disease-controlling drugs but cause a number of problems (Box 18.31; see also Box 21.20); they are best avoided in the long term because side-effects are inevitable. Early intensive short-term regimens are often used to help induce remission. Corticosteroids are invaluable to people with
Patients are increasingly anxious about the use of corticosteroids because of adverse publicity about their potential side-effects. This must be discussed frankly and the risks of not using corticosteroids in treatment should be described and balanced against the risks posed by the drugs themselves.

- Patients must be warned to avoid sugars and saturated fats, and to eat less because of the risk of weight gain.
- The skin becomes thin and easily damaged.
- Patients should be monitored for diabetes and hypertension.
- Cataract formation may be accelerated.
- Osteoporosis develops within 3 months on doses above 7.5 mg daily. Monitor with DXA scan and treat with calcium, vitamin D and bisphosphonate (see p. 479).

DXA, dual-energy absorptiometry.

Box 18.31 Problems associated with the use of corticosteroids

- Osteoporosis develops within 3 months on doses above 7.5 mg daily.
- Cataract formation may be accelerated.
- Patients should be monitored for diabetes and hypertension.
- The skin becomes thin and easily damaged.
- Patients are increasingly anxious about the use of corticosteroids because of adverse publicity about their potential side-effects. This must be discussed frankly and the risks of not using corticosteroids in treatment should be described and balanced against the risks posed by the drugs themselves.

Disease-modifying anti-rheumatic drugs

Various DMARDs are listed in Box 18.32. Their beneficial effect is not immediate, taking 2–3 months to become apparent. As monotherapy, csDMARDs often have only a partial effect, achieving between 20% and 50% improvement by ACR criteria for disease remission (Box 18.33), and are frequently used in combination.

Early intervention with csDMARDs within 3 months of disease onset improves the outcome. Combinations of up to four drugs (steroids, sulfasalazine, methotrexate and hydroxychloroquine) may be used; the number of agents then reduced once remission has been achieved. Several DMARDs are contraindicated in pregnancy (see Box 38.9). Effective treatment with DMARDs including TNF-α blockers reduces the increased cardiovascular risk in RA.

Methotrexate

Methotrexate remains the anchor drug in RA therapy, although it should not be used in pregnancy. A screening history, chest X-ray and an interferon gamma release assay (IGRA) in high-risk patients are performed to exclude tuberculosis. Initial pneumococcal and annual influenza vaccinations are given. The starting weekly dose of 7.5–10 mg orally is increased up to 15–25 mg as necessary to T2T (see p. 444). It is well tolerated, although nausea or poor absorption may limit its efficacy, in which case it is given by subcutaneous injection. Oral folic acid reduces side-effects but may also lessen efficacy. Full blood counts and liver biochemistry should be monitored. Methotrexate usually works within 1–2 months. More patients remain on this agent than on most other DMARDs, indicating that it is effective and has relatively few side-effects.

Sulfasalazine

Sulfasalazine is well tolerated and can be used during pregnancy. The usual starting dose of 500 mg per day is increased to a maintenance dose of 2–3 g per day. Around 50% of patients respond in the first 3–6 months, but efficacy can be lost.

Hydroxychloroquine

A dose of 200–400 mg daily is well tolerated. It is used alone in mild disease or commonly as an adjunct to other DMARDs. Due to the risk of irreversible retinopathy with increasing dose and duration of use, baseline formal ophthalmic examination is now recommended within 1 year of commencing therapy. This initial screening is followed by annual ophthalmic review until 5 years of therapy are completed then annual ophthalmic assessment is required.

Leflunomide

This csDMARD prevents pyrimidine production in proliferating lymphocytes through blockade of the enzyme dihydro-orotate dehydrogenase, thus blocking clonal expansion of T cells. It has a long half-life of 4–28 days. A dose of 20 mg daily (10 mg if diarrhoea is a problem) is used. Diarrhoea diminishes with time. Blood monitoring is obligatory (full blood count, platelets, liver biochemistry). The onset of action is 4 weeks with some further improvement sustained at 2 years. Leflunomide works in some patients who have failed to respond to methotrexate. Its long half-life means that it is best avoided in women planning a family.

Biological therapies

These drugs are more expensive than csDMARDs. Costs, however, are being reduced by the introduction of biosimilar medicines – medicines that are highly similar to another (originator) drug and have been shown to have no clinically meaningful differences in quality, safety or efficacy from the originator compound.

TNF-α blockers

These agents are used after at least two csDMARDs (usually sulfasalazine and methotrexate) have failed. They are usually given in combination with methotrexate to reduce loss of efficacy due to anti-drug antibody formation.

- Etanercept is a fully humanized p75 TNF-α receptor IgG1 fusion protein given by self-administered subcutaneous injection. Around 65% of patients respond well. Some develop an injection reaction.
- Adalimumab is a fully human monoclonal antibody against TNF-α, given along with methotrexate.
- Infliximab is a monoclonal antibody against TNF-α, given intravenously and co-prescribed with methotrexate to prevent loss of efficacy because of antibody formation.
- Certolizumab pegol is a Fab fragment of a humanized TNF-α inhibitor monoclonal antibody that has polyethylene glycol (PEG) groups attached to reduce immunogenicity and prolong half-life. The presence of PEG and lack of Fc portion are likely responsible for its minimal transfer across the placenta and into breast milk. It is useful with or without methotrexate for severe active RA.
- Golimumab is a human IgG1-κ monoclonal antibody against TNF, which is given by subcutaneous injection once monthly for severe RA.

These products slow or halt erosion formation in up to 70% of people with RA and produce healing in a few. Malaise and tiredness improve in a manner that is not seen with csDMARDs. Secondary failure may occur with all in the first year; changing to another anti-TNF agent is justified and often regains control of the disease. Failure to respond to one does not predict failure to others. Currently, biosimilars exist for etanercept, infliximab and adalimumab.

Safety data. Various national registries exist to study adverse events, long-term outcomes and problems arising from biological therapies. To date, the results are reassuring. Infection rates are increased with TNF-α blockers, particularly in the first few months of treatment, but the rate then declines. There is a known association between RA and non-Hodgkin’s lymphoma (NHL) but, overall, registries have not shown an increased risk of NHL in patients with RA treated with TNF-α blockers, to date. There is no convincing evidence of any increased risk of other cancers. Reactivation of

old tuberculosis may occur but is probably less common with etanercept. A pre-treatment chest X-ray is recommended, with IGRA and specialist review for high-risk groups. Tuberculosis should be treated before these agents are prescribed, and a course of prophylaxis is used in latent disease. Hepatitis B and C infection requires risk analysis and regular aminotransferase monitoring if anti-TNF agents are prescribed. They should not be used in patients who have severe cardiac failure. To date, there is no evidence of an adverse effect on pregnancy outcome but care is essential (see Box 38.6).

Other biological agents

- **Rituximab** is a chimeric monoclonal antibody (see p. 67), directed against the CD20 receptor expressed on pre-B and mature B cells. Rituximab produces significant improvement in RF-positive RA for 8 months to several years when used alone or in combination with corticosteroids and/or methotrexate. This clinical improvement is associated with a 6–9-month B-cell lymphopenia. A re-flare is often accompanied by a return of peripheral B lymphocytes and rise in CRP. Repeated courses, with disease flare, are well tolerated and around 80% of RF-positive patients respond, with 50–60% showing persistent disease control; however, immunoglobulin levels should be monitored, as they may fall with repeated treatments. Rituximab is mainly used in patients who have failed to respond to anti-TNF agents and a biosimilar exists.

- **Abatacept** is a recombinant fusion protein of CTLA4 and the Fc portion of IgG1, which selectively modulates T-cell activation by co-stimulation blockade. It may be used in patients who do not respond to anti-TNF regimens.

- **Tocilizumab and sarilumab** are monoclonal antibodies against the anti-IL-6 receptor that may be used with methotrexate for moderate to severe RA, usually after at least one other biologic has failed, but may also be considered as a first-line biological therapy.

**Targeted synthetic DMARDs**

- **Tofacitinib and baricitinib** are oral JAK inhibitors that may be used in combination with methotrexate, or as monotherapy in patients who cannot take methotrexate, and have severe disease.

**Switching between DMARDs and tapering therapy**

Patients who fail to respond initially (primary failure) or subsequently lose efficacy (secondary failure) to a bDMARD over time will usually be switched to another bDMARD. In patients who lose response to a TNF-α blocker it is helpful to measure drug levels and for presence of neutralizing anti-drug antibodies (ADA), where possible. If the drug level is therapeutic then a non-TNF-α blocker is preferred. Alternatively, if the drug level is sub-therapeutic, non-adherence or the presence of ADA are likely explanations and switching to another TNF-α blocker or a different class of bDMARD are viable alternatives. If primary or secondary failure occurs to a subsequent bDMARD the switching process may be repeated multiple times. Switching to tsDMARDS may now be considered.

In patients who achieve sustained remission (>1 year) it is now commonplace to attempt dose reduction of DMARDs by either dose reduction or prolongation of dosing interval. Potential biomarkers of responsiveness are being explored to ensure a precision medicine approach to each individual patient.

**Physical measures**

Input is required from the multidisciplinary team. Physiotherapists advise a combination of rest for active arthritis and exercises to maintain joint range and muscle power. Exercise in a hydrotherapy pool is popular and effective. Occupational therapists help to manage activities of daily living despite the arthritis and provide functional adaptations in the home or at work. Family and friends should be involved. Podiatry, footwear advice and psychological support should also be offered to all people with RA.

**Surgery**

Surgery has a useful role in the long-term approach to patient management but is less frequently needed as therapeutic disease control becomes more effective. Its main objectives are prophylactic, to prevent joint destruction and deformity, and reconstructive, to restore function.

Surgical options in RA include: surgical synovectomy; tendon repair; osteotomy to realign weightbearing surfaces; joint fusion to stabilize damaged joints that are not easily replaced; small joint implant arthroplasty, e.g. metacarpophalangeal joints; excision arthroplasties of the metatarsals to reduce metatarsal pain; and total joint replacement arthroplasty of the shoulder, elbow, wrist, hip, knee and ankle. The main aim of joint arthroplasty is to reduce pain and improve function, requiring careful planning with explanation of risks and outcomes to the patient.

**Prognosis**

A poor prognosis is indicated by:

- **a clinical picture** of an insidious rather than an explosive onset of RA, female sex, increasing number of peripheral joints involved and the level of disability at the onset

- **blood tests** showing a high CRP/ESR, normochromic normocytic anaemia, and high titres of ACA and of RF

- **X-rays** with early erosive damage (note: ultrasound and MRI can show cartilage and bone damage prior to conventional X-rays).

Prognosis can be altered dramatically with early DMARD therapy and T2T regime (see p. 444) under expert supervision.

**SPONDYLOARTHRITIS**

The term spondyloarthritis (SpA) describes a group of conditions affecting the spine and peripheral joints with familial clustering and a link to certain type 1 HLA antigens (Box 18.34). These conditions share genetic factors and increasing implication of the IL-17 pathway in pathogenesis. Joint involvement differs from RA, being more

**Box 18.33 The 2011 ACR/EULAR definitions for disease remission in rheumatoid arthritis clinical trials**

- Tender joint count (including feet and ankles) ≤1
- Swollen joint count (including feet and ankles) ≤1
- C-reactive protein ≤1 mg/L
- Patient global assessment ≤1 (on a 10-cm visual analogue scale)

**Box 18.34 Spondyloarthritis**

- Axial spondyloarthritis, including ankylosing spondylitis
- Psoriatic arthritis
- Reactive arthritis (sexually acquired)
- Post-dysenteric reactive arthritis
- Enteropathic arthritis (ulcerative colitis/Crohn’s disease)
Rheumatology

limited with a different distribution and associated extra-articular features. These diseases occasionally present in childhood.

They may also be categorized according to their predominant clinical manifestation of axial (sacroiliac and/or spine) or peripheral arthritis, enthesitis and/or dactylitis) disease with possible overlap. Distinct SpA conditions exist (see Box 18.34).

Histologically, synovitis is similar to that of RA, but there is no production of RF or ACPA. Inflammation of the enthesis (junction of ligament or tendon and bone) and joint ankylosis develop more commonly than in RA. All are associated with an increased frequency of sacroiliitis and HLA-B27.

Aetiology

These disorders have a striking association with HLA-B27, particularly ankylosing spondylitis (AS). HLA type B27 is present in more than 90% of Caucasians with AS but only 8% of controls. HLA-B27 exhibits a number of unusual characteristics, including a high tendency to misfold. The types of arthritis that follow a precipitating infection are called reactive arthritis (see p. 450).

Axial spondyloarthritis

Axial spondyloarthritis (AxSpA) occurs in 1% of the general population. It is an inflammatory disorder primarily affecting sacroiliac joints or fibrous and synovial joints of the spine that are detectable on MRI. When radiographic changes at the sacroiliac joints are present, the term ankylosing spondylitis (AS) is used.

Ankylosing spondylitis

It is now recognized that AS forms part of the spectrum of AxSpA. It presents with inflammatory back pain and sacroiliac inflammation. It is seen in 0.2–0.5% of the population in Western Europe and approximately 0.5% in the USA, affecting mainly young adults (late teens to early thirties) and occurring worldwide, with a male to female ratio of 3:1. Women present later and are under-diagnosed. The frequency of AxSpA in different populations is roughly paralleled by the incidence of HLA-B27; Africans and Japanese have a low incidence of both HLA-B27 and AS, while the North American Haida Indians have a high incidence of both.

Aetiology

A combination of genetic and environmental features:

- Among white individuals with AS, 95% carry HLA-B27, in contrast to 8% of most white populations. Twin studies indicate a much higher disease concordance in HLA-B27-positive monozygotic twins (up to 70%) than in dizygotic twins (about 20–25%).
- Other genes lying within the MHC (the IL-1 gene cluster and CYP2D6) also influence susceptibility to AS but the disease is polygenic and GWAS have identified significant associations with the endoplasmic reticulum aminopeptidase (ERAP)-1 and IL-23 genes.
- The association of ERAP-1 with AxSpA may support the arthritogenic peptide hypothesis, whereby disease is triggered by presentation of peptide by HLA-B27 to CD8-positive T cells. Furthermore, misfolding of HLA-B27 leads to the production of IL-23, and T cells resident in entheses promote inflammation characteristic of SpA in response to IL-23.
- The finding of increased frequency of TH17 cells and various genetic association studies have implicated the IL-23-IL-17 axis in pathogenesis and this knowledge has been translated into therapies that target this pathway.

| Box 18.35 Back pain criteria for diagnosing axial/ankylosing spondylitis |
|-----------------|-----|
| **Age of onset** | <45 years |
| **Insidious onset** | |
| **Improvement of back pain with exercise** | |
| **No improvement of back pain with rest** | |
| **Pain at night** | with improvement on getting up |

The presence of four of the five criteria suggests ankylosing spondylitis with 80% sensitivity. All criteria have high sensitivity.

Clinical features

Initially, the diagnosis is often missed because the patient is asymptomatic between episodes and radiological abnormalities are absent.

- **Back pain** with episodic inflammation of the sacroiliac joints in the late teenage years or early twenties is the first manifestation of AxSpA.
- **Pain in one or both buttocks** and low back pain and stiffness are typically worse in the morning and relieved by exercise.
- **Retention of the lumbar lordosis during spinal flexion** is an early sign. Later, paraspinous muscle wasting develops.

**Criteria for classifying inflammatory back pain** as AxSpA are shown in Box 18.35. These criteria encompass the whole spectrum of disease, with evidence of sacroiliitis being based on radiographic or MRI evidence of disease. Spinal stiffness can be measured by Schober’s test; skin over the midline of the spine is marked 5 cm below and 10 cm above the dimples of Venus and the increase in distance between those marks during flexion is recorded. An increase of less than 5 cm implies spinal stiffness.

- **Non-spinal complications** (uveitis or costochondritis) suggest the diagnosis of SpA (Box 18.36).
- **Costochondral junction inflammation** causes anterior chest pain. Measurable reduction of chest expansion is due to costovertebral joint involvement.
- **Peripheral joint involvement** is asymmetrical and affects a few, predominantly large, joints. Hip involvement leads to fixed flexion deformities of the hips and further deterioration of posture. Young teenage boys occasionally present with a lower-limb monoarthritis, which later develops into AS.
- **Acute anterior uveitis** occurs in approximately 30% of patients with AxSpA and related diseases, and is occasionally the presenting complaint. Severe eye pain, photophobia and blurred vision are an emergency (see p. 921).
- **Other extra-articular features** include:
  - cardiovascular disease – aortic incompetence occurs in up to 1% of patients with established AS and cardiac conduction abnormalities in around 5%
respiratory disease – rarely, chest wall rigidity is associated with interstitial lung disease
renal impairment – reported in 10–35% of patients with AS and most commonly linked to chronic NSAID use
axial osteoporosis – occurs in approximately 25%, with vertebral fracture in 10%.

Overall clinical assessment of disease activity is based on a 1–10 score for levels of fatigue, spinal pain, arthralgia, swelling, localized tenderness, inflammation of tendons/enthesis, and duration and severity of morning stiffness. It is measured using the Bath Ankylosing Spondylitis Disease Activity Index (see Further reading).

Investigations
- **Blood.** ESR and CRP are usually raised.
- **HLA B27 testing.** This test is not definitive due to the high frequency of HLA-B27 in the population, but may strengthen or confirm suspected diagnoses.
- **X-rays.** The medial and lateral cortical margins of both sacroiliac joints lose definition owing to erosions and eventually become sclerotic (Fig. 18.28). Radiological appearances in the spine of blurring of the upper or lower vertebral rims at the thoracolumbar junction are caused by an enthesitis at the insertion of the intervertebral ligaments and may eventually affect the whole spine causing bony spurs (syndesmophytes), bony ankylosis and permanent stiffening. The sacroiliac joints eventually fuse, as may the costovertebral joints, reducing chest expansion. Calcification of the intervertebral ligaments and fusion of the spinal facet joints and syndesmophytes leads to what is often called a ‘bamboo’ spine (Fig. 18.29).
- **MRI.** MRI with gadolinium demonstrates sacroiliitis before it is seen on X-rays, as well as persistent enthesitis.

Management
- The key to effective management of AS is early diagnosis so that a regimen of preventative exercises is started before syndesmophytes have formed. Morning exercises aim to maintain spinal mobility, posture and chest expansion; regular NSAIDs to improve symptoms and signs of SpA are often required to achieve this goal.
- Failure to control pain and to encourage regular spinal and chest exercises leads to an irreversible dorsal kyphosis and wasted paraspinal muscles, which, along with stiffening of the cervical spine, makes forward vision difficult.
- When the inflammation is active and the morning pain and stiffness are too severe to permit effective exercise, an evening dose of a long-acting or slow-release NSAID or an NSAID suppository improves sleep, pain control and exercise compliance.
- Sulfasalazine, methotrexate and leflunomide may help peripheral arthritis but not spinal disease.
- When NSAIDs have failed, the TNF-α-blocking drugs adalimumab, etanercept, golimumab, certolizumab and infliximab (see Box 18.32) have all been shown to reduce symptoms of spinal
and peripheral joint inflammation substantially and to improve function, as well as quality of life. Evidence of reduction of bony progression, however, has not been found. Relapse occurs on stopping therapy but may be delayed by several months making intermittent treatment feasible.

- Other bDMARDs including the IL-12 and IL-23 blocker ustekinumab and the IL-17 blocker secukinumab are alternative options in SpA.

Prognosis

With exercise and pain relief, the prognosis is excellent and over 80% of patients are fully employed. The advent of bDMARD therapies has reduced the morbidity of severe disease, lowering the risk of permanent spinal stiffness and progressive peripheral joint disease.

Psoriatic arthritis

The prevalence of psoriasis is 2–3% worldwide; in this population, around 10% have arthritis, which precedes skin disease in around 15% of cases. A family history of psoriasis may be a clue to the diagnosis. The aetiology and pathogenesis are described on page 664.

Clinical features

Patterns of psoriatic arthritis include:

- **Mono- or oligoarthritis.**
- **Polyarthritis:** often begins with an asymmetrical pattern and progresses to be virtually indistinguishable from RA.
- **Spondylitis:** unilateral or bilateral sacroiliitis and early cervical spine involvement; only 50% are HLA-B27-positive.
- **Distal interphalangeal arthritis:** the most typical pattern of joint involvement in psoriasis, often with adjacent nail dystrophy (see p. 665) reflecting enthesitis extending into the nail root. Dactylitis, in which an entire finger or toe is swollen, with joint and tendon sheath involvement, is characteristic of this condition.
- **Arthritis mutilans:** affects about 5% of patients who have psoriatic arthritis and causes marked periarticular osteolysis and bone shortening (‘telescopic’ fingers) (Fig. 18.30).

Radiologically, psoriatic arthritis is erosive but the erosions are central in the joint, not juxta-articular, and produce a ‘pencil in cup’ appearance (Fig. 18.31). The skin and nail disease can be mild and may develop after the arthritis.

Management and prognosis

NSAIDs and/or analgesics help the pain but can occasionally worsen the skin lesions. Local synovitis responds to intra-articular corticosteroid injections. Sulfasalazine, methotrexate and leflunomide are commonly used in patients with persistent peripheral joint synovitis, although none has a proven effect on slowing the development of joint damage. Hydroxychloroquine is best avoided because it may rarely cause acute psoriatic skin reactions. Similarly, oral corticosteroids may destabilize skin disease; they are best avoided but are valuable when injected into a single inflamed joint.

Various bDMARDs and tsDMARDs are now available and highly effective for severe skin and joint disease in patients where csDMARDs, principally methotrexate, have failed. The bDMARDs include anti-TNF-α agents, such as etanercept and golimumab (see p. 445); IL-17 inhibitors, secukinumab and ilixizumab; and ustekinumab, an anti-IL-12/23 inhibitor. The tsDMARDs include apremilast, an oral PDE4 inhibitor and tofacitinib, a JAK inhibitor.

Reactive arthritis

Reactive arthritis is a sterile synovitis, which occurs following an infection. Spondyloarthritis develops in 1–2% of patients after an acute attack of dysentery, or after a sexually acquired infection – non-specific urethritis (NSU) in the male, non-specific cervicitis in the female. In males, positivity for HLA-B27 increases the risk of developing reactive arthritis after such an infection by 30–50-fold but not all patients are HLA-B27-positive. Women are less commonly affected.

Aetiology

A variety of organisms can be the trigger, including strains of *Salmonella* or *Shigella* spp. in bacillary dysentery. *Yersinia enterocolitica* causes diarrhoea and a reactive arthritis. In NSU, the organisms are *Chlamydia trachomatis* or *Ureaplasma urealyticum*.

People with reactive arthritis are not more susceptible to infection but appear to respond differently. Bacterial antigens or bacterial DNA have been found in the inflamed synovium of affected joints,
suggesting that this persistent antigenic material is driving the inflammatory process. The methods by which HLA-B27 increases susceptibility to reactive arthritis include:

- T-cell receptor repertoire selection
- molecular mimicry causing autoimmunity against HLA-B27 and/or other self antigens
- mode of presentation of bacteria-derived peptides to T lymphocytes.

There are other organisms that also trigger reactive arthritis but have a different genetic basis; see post-streptococcal arthritis (p. 544), gonococcal arthritis (p. 455), and brucellosis (p. 456). In these conditions, the line between reactive arthritis and septic arthritis is more indistinct and they can cause both.

Clinical features
Typically an acute, asymmetrical, lower-limb arthritis, this occurs days to weeks after the infection. The arthritis may be the presenting complaint if the infection is mild or asymptomatic. Enthesitis is common, causing plantar fasciitis or Achilles tendon enthesitis (see p. 428), and dactylitis may also occur (Fig. 18.32); 70% of patients recover fully within 6 months but many have a relapse.

In susceptible individuals with reactive arthritis, sacroiliitis and spondylitis may also develop. Sterile conjunctivitis occurs in 30%. Acute anterior uveitis complicates more severe or relapsing disease but is not synchronous with the arthritis.

The skin lesions resemble psoriasis:
- **Circinate balanitis** in the uncircumcised male causes painless superficial ulceration of the glans penis. In the circumcised male, the lesion is raised, red and scaly. Both heal without scarring.
- **Keratoderma blennorrhagica** involves the skin of the feet and hands, which develops painless, red and often confluent raised plaques and pustules that are histologically similar to pustular psoriasis.
- **Nail dystrophy** occurs.

Management
Treating persisting infection with antibiotics alters the course of the arthritis, once it has developed. Cultures should be taken and any infection treated. Sexual partners must be screened.

Pain responds well to NSAIDs and locally injected or oral corticosteroids. The majority of individuals with reactive arthritis have a single attack that settles, but a few develop a disabling relapsing and remitting arthritis. Relapsing cases are sometimes treated with sulfasalazine or methotrexate (see Box 18.32).

Enteropathic arthritis associated with inflammatory bowel disease
Enteropathic synovitis occurs in up to 10–15% of patients who have ulcerative colitis or Crohn’s disease (see p. 1198). The link between the bowel disease and the inflammatory arthritis is not clear. The arthritis is asymmetrical and predominantly affects lower-limb joints. An HLA-B27-associated sacroiliitis or spondylitis also occurs. The joint symptoms may predate the development of bowel disease and lead to its diagnosis.

Remission of ulcerative colitis or total colectomy usually leads to remission of the joint disease, but arthritis can persist even in well-controlled Crohn’s disease.

Crystal arthritis
Aetiology
The two main types of crystal-induced arthritis are caused by sodium urate and calcium pyrophosphate crystals, which are distinguished by their different shapes and refringence properties under polarized light with a red filter (Fig. 18.33). Rarely, crystals of calcium apatite (see p. 436) or cholesterol cause acute synovitis.

![Fig. 18.33 Crystal arthritis. (A) Needle-shaped urate crystals (arrowed). (B) A small, intracellular pyrophosphate crystal (arrowed). Both are viewed under polarized light with a red filter.](image-url)
Gout and hyperuricaemia

Gout is an inflammatory arthritis associated with hyperuricaemia and intra-articular urate crystals.

Epidemiology

The prevalence of gout has increased in recent decades to 2.5% in the UK and 3.9% in the USA. Asian populations are also increasingly at risk as their diet becomes more Western. This rising prevalence is due to changing diets with purine-rich foods, high saturated fats and fructose-containing drinks; alcohol misuse; increasing co-morbidities that promote hyperuricaemia; and suboptimal management. Gout is more common in men than women (5:1); it rarely occurs before young adulthood (when it suggests a specific genetic defect), and seldom in pre-menopausal females. Some 85–90% of cases are idiopathic. Hyperuricaemia is common in certain ethnic groups (e.g. Maoris).

The last two steps of purine metabolism in humans are the conversion of hypoxanthine to xanthine, and of xanthine to uric acid, catalysed by the enzyme xanthine oxidase. Serum uric acid (SUA) levels are higher in men than in women. Pathological hyperuricaemia is defined as a SUA level of 408 μmol/L above which monosodium urate crystal formation occurs in vitro at physiological pH and temperature, although it may occur in peripheral joints with lower tissue pH and temperature, e.g. 360 μmol/L at 35°C and 300 μmol/L at 30°C. Hyperuricaemia is mostly asymptomatic, although OA joints are more prone to attacks of gout. The range of SUA for individuals with gout is higher than in healthy controls. SUA levels increase with age, obesity, a ‘Western’ diet (see earlier) and combined hyperlipidaemia, diabetes mellitus, ischaemic heart disease and hypertension (metabolic syndrome; see p. 1250). Gout is often familial.

Pathogenesis of hyperuricaemia and gout

Uric acid is the final product of endogenous and dietary purine metabolism in humans, and SUA depends on the balance between purine synthesis, ingestion of dietary purines and the elimination of urate by the kidney (66%) and intestine (33%).

Some 90% of people with gout have impaired excretion of uric acid (10% have increased production due to high cell turnover and <1% due to an inborn error of metabolism). Renal excretion is coordinated by a group of secretory and reabsorptive renal tubular urate transport molecules, some of which are targets of urate-lowering drugs. These molecules can be grouped into reabsorptive urate anion exchangers (URAT1/SLC22A12, OAT4/SLC22A11 and OAT10/SLC22A3), the resorptive GLUT9/SLC2A9 urate transporter, secretory anion-exchange transporters (OAT1, OAT2 and OAT3) and sodium-phosphate transporter proteins (NPT1/SLC17A1 and NPT4/SLC17A3), and the ATP-driven secretory pump MRP4/SLC17A3 (Fig. 18.34). The secretory transporter ABCG2 is significant in the gut, with reduced functioning contributing to extrarenal under-excretion. GWAS have identified prominent loci encoding urate transporters: primarily SLC2A9 and ABCG2; with a second tier dominated by genes encoding SLC22A11, SLC22A12, SLC17A1 and SLC17A3. Causes of hyperuricaemia are shown in Box 18.37.

Gout as an autoinflammatory disease

The involvement of the innate immune system and inflammasomes indicates that gout is an autoinflammatory disease, similar to the hereditary periodic fevers (see p. 452). This response is initiated when monosodium urate crystals interact with resident macrophages to form and activate NLRP3 inflammasome. Caspase 1 is recruited by the activated inflammasome (see p. 46) leading to activation of IL-1β and cellular activation, which triggers an IL-8-mediated influx of neutrophils. Ingestion by polymorphonuclear leucocytes of monosodium urate crystals causes the release of pro-inflammatory cytokines, particularly IL-1β and complement. Colchicine inhibits the microtubule formation that is necessary for this process to occur.

Clinical features

Hyperuricaemia may be asymptomatic or may cause:

- **Acute gout**, followed by an asymptomatic intercritical phase; a second acute attack is likely within 2 years.
- **Chronic interval gout**, with acute attacks superimposed on low-grade inflammation and potential joint damage.
- **Chronic polyarticular tophaceous gout**, which is rare and characterized by chronic joint pain, activity limitation, structural joint damage and frequent flares.
- **Urate renal stone** formation (see p. 1373).

**Acute gout** presents typically in a middle-aged male with a sudden onset of agonizing pain, swelling and redness of the first MTP joint. The attack may be precipitated by excess food, alcohol, dehydration or diuretic therapy. Untreated attacks last about 7 days. Recovery is typically associated with desquamation of the overlying
skin. In 25% of attacks, a joint other than the great toe is affected. Triggers for flares include acute medical or surgical illness, dehydration, or dietary factors such as alcohol intake or purine-rich foods.

In severe attacks, overlying crystal cellulitis makes gout difficult to distinguish clinically from infective cellulitis. A family or personal history of gout and the finding of a raised SUA suggest the diagnosis but, if in doubt, blood and joint fluid cultures should be taken to exclude sepsis.

**Chronic tophaceous gout** is described below.

**Investigations**

The clinical picture is often diagnostic, as is the rapid response to NSAIDs or colchicine.

- **Joint fluid microscopy** is the most specific and diagnostic test but is technically difficult.
- **Serum uric acid** is usually raised (>600 μmol/L). If it is not, it should be rechecked several weeks after the attack, as levels fall immediately after an acute episode. Acute gout rarely occurs with SUA in the lower half of the normal range below the saturation point of 360 μmol/L.
- **Serum urea, creatinine** and estimated glomerular filtration rate (eGFR) are monitored for signs of renal impairment.

**Management**

The use of NSAIDs or coxibs in high doses rapidly reduces the pain and swelling. The first dose should be taken at the first indication of an attack:

- **naproxen**: 750 mg immediately, then 500 mg every 8–12 hours
- **diclofenac**: 75–100 mg immediately, then 50 mg every 6–8 hours.

After 24–48 hours, reduced doses are given for a further week. **Caution**: NSAIDs may cause renal impairment. In individuals with renal impairment or a history of peptic ulceration, alternative treatments include:

- **Colchicine**: loading doses will cause diarrhoea or colicky abdominal pain, so 500 μg 2–3 times per day is usually sufficient to terminate attacks without side-effects.
- **Corticosteroids**: oral prednisolone or intramuscular or intra-articular depot methylprednisolone is used.

**Dietary advice**

The first attacks may be separated by up to 2 years and are managed symptomatically. Recognition and prompt treatment, including lifestyle modifications, are paramount. Advice to reduce alcohol intake, especially beer, which is high in purines and fructose, and consumption of non-diet carbonated soft drinks, also high in fructose, is essential; other dietary changes include reduction of total calorie and cholesterol intake, and avoidance of purine-rich foods, such as offal, red meat, shellfish and spinach. These modifications can reduce serum urate by 15% and delay the need for drugs that reduce serum urate levels. Dietary advice is readily available on the Internet.

**Treatment with agents that reduce serum uric acid levels**

The aim of treatment is to reduce and maintain the uric acid level below 360 μmol/L in all patients, and in those with severe gout, such as tophi or frequent attacks, a lower level below 300 μmol/L is required to achieve clinical remission.

**Allopurinol**

Allopurinol should only be used when the attacks are frequent and severe (despite dietary changes), or associated with renal impairment or tophi, or when the patient finds NSAIDs or colchicine difficult to tolerate. Allopurinol is a xanthine oxidase inhibitor, which reduces SUA levels rapidly; it is relatively non-toxic but should be used at low doses (50–100 mg) in renal impairment. It should never be started within a month of an acute attack and always under cover of NSAIDs or colchicine for the first 2–4 weeks before and 4 weeks after starting allopurinol, as it may induce acute gout. The dose can be increased gradually from 100 mg every few weeks until the uric acid level is below the 360 μmol/L level. Skin rashes and gastrointestinal intolerance are the most common side-effects. A hypersensitivity reaction is the most serious but rare adverse event, as is bone marrow suppression.

**Febuxostat**

Febuxostat (80–120 mg) is a non-purine analogue inhibitor of xanthine oxidase that is well tolerated and as effective as allopurinol. It is safer in renal impairment, as it undergoes hepatic metabolism rather than renal excretion, and is helpful in patients who cannot tolerate allopurinol. All-cause mortality and cardiovascular mortality, however, are higher with febuxostat than with allopurinol. Allopurinol remains the drug of first choice, unless there are strong contraindications to its use.

**Pegloticase**

Pegloticase, a pegylated recombinant uricase given intravenously, lowers urate levels dramatically but is typically reserved for patients with severe, refractory gout in whom target serum urate concentrations are not achieved or who cannot tolerate oral urate-lowering therapy (ULT).

**Uricosuric agents**

These also lower the SUA but their use is restricted throughout Europe by the very rare occurrence of serious hepatotoxicity. **Benzbromarone** acts on the URAT1 transporter and is well tolerated. Sulfinpyrazone and probenecid are best avoided in renal impairment. Availability of these drugs varies between countries – in the UK, benzbromarone and probenecid can be obtained for treating named patients.

**Losartan**

Losartan is an angiotensin I receptor antagonist and is uricosuric in hypertensive patients with gout. It may reduce the risk of gout in patients with the metabolic syndrome.

**Targeted therapies**

The IL-1 receptor inhibitor, anakinra, canakinumab (an anti-human IL-1β monoclonal antibody) and rilonacept (a dimeric fusion protein consisting of portions of IL-1R and the IL-1R accessory protein linked to the Fc portion of IgG1) have shown efficacy. The high cost of these agents, however, means they may only be considered in patients resistant to standard therapy. Lesinurad, a URAT1 inhibitor, is now licensed but its unfavourable cost-effectiveness ratio limits its availability.

**Chronic tophaceous gout**

Individuals with persistently high levels of uric acid can present with chronic tophaceous gout, as sodium urate forms smooth white deposits (tophi) in skin and around joints, on the ear, fingers (Fig. 18.35) or the Achilles tendon. Large deposits are unsightly and ulcerate. There is chronic joint pain and sometimes superimposed acute gouty attacks.
Periarticular deposits lead to a halo of radio-opacity and clearly defined (‘punched out’) bone cysts on X-ray.

Tophaceous gout is often associated with renal impairment and/or the long-term use of diuretics. There may be acute or chronic urate nephropathy or renal stone formation. Whenever possible, diuretics should be stopped or changed to less urate-retaining ones, such as bumetanide. Treatment is with allopurinol and/or uricosuric agents (see above). Pegloticase is used in people undergoing chemotherapy for malignancies (to prevent tumour lysis syndrome), and in those rare individuals who have refractory tophaceous gout.

**Calcium pyrophosphate dihydrate deposition arthropathy (CPPD)**

Deposition of calcium pyrophosphate dehydrate (CPP) crystals in hyaline and fibrocartilage is the most common cause of cartilage calcification. Previous terms, including pseudogout, have been unified into calcium pyrophosphate dihydrate deposition (CPPD) arthropathy. CPPD-associated arthritis is the third most common inflammatory arthritis, which increases with age, OA, joint trauma/injury and metabolic disease (hyperparathyroidism, haemochromatosis, hypomagnesaemia), and has a familial predisposition. Shedding of crystals into a joint precipitates acute synovitis that resembles gout, except that it is more common in elderly women and usually affects the knee or wrist.

**Diagnosis**

Diagnosis is made by detecting rhomboidal, weakly positively birefringent crystals in joint fluid (see Fig. 18.33), or is deduced from the presence of cartilage calcification on X-ray. Joint fluid looks purulent so should be sent for culture to exclude septic arthritis, as the attacks may also be associated with fever and a raised white blood cell count.

**Management**

There is no specific treatment to eliminate calcium pyrophosphate crystals. Therefore, management is focused on symptom control and treatments overlap with those for gout and OA. An evidence base is lacking in this condition, however, and there have been no randomized controlled clinical trials of acute management. Aspiration of the joint reduces the pain dramatically and usually affects the knee or wrist.

**Basic calcium phosphate deposition disease**

Basic calcium phosphate (BCP) crystals, including hydroxyapatite, tricalcium phosphate and octacalcium phosphate, can be deposited in any tissues, particularly at intra-articular and periarticular locations. Crystal formation is thought to be partly regulated by the effects of extracellular inorganic phosphate on chondrocytes and is linked with the development of OA. BCP crystals cause joint damage through induction of fibroblast proliferation, inflammatory cytokines (IL-1β and TNF-α), nitric oxide and metalloproteinases.

BCP crystal deposits in periarticular soft tissue may be asymptomatic or can cause acute calcific periartthritis (particularly in the supraspinatus tendon), tendinitis, bursitis and enthesitis. Less frequently, they can cause arthritis. In acute attacks, periarticular tissues or joints can be swollen, tender and hot. This presentation may mimic cellulitis, gout, CPPD disease and septic arthritis. Periarticular or articular BCP crystal deposits are also found in an extremely destructive chronic arthropathy of the elderly that occurs most often in shoulders (Milwaukee shoulder) or other large joints, such as the hips and knees, and in erosive OA of the fingers.

**Diagnosis**

The diagnosis is made clinically and septic arthritis should be excluded. A neutrophilia with elevation of ESR and CRP may occur during an acute attack. Intra- and/or periarticular calcifications, with or without erosive, destructive or hypertrophic changes, may be seen on X-ray. Alizarin red S staining is not specific for BCP crystals in synovial fluid and other calcium-containing particulates are also stained by this method.

**Management**

Management of acute attacks is similar to that of CPPD disease with NSAIDs, oral colchicine, aspiration of effusions and/or intra-/periarticular injection of steroids to try to shorten the duration of symptoms. In patients with underlying progressive articular changes, the response to medical therapy is usually less rewarding. Total joint replacement may be required for patients with severe destructive arthropathy in large joints.

**Further reading**

infection, intravenous drug use, alcoholism and prior intra-articular corticosteroid injection.

**Septic arthritis**

The organism that most commonly causes septic arthritis is *Staphylococcus aureus*. Other organisms include streptococci, other species of staphylococcus, *Neisseria gonorrhoeae*, *Haemophilus influenzae* in children, and these and other Gram-negative organisms in the elderly or complicating RA.

**Clinical features**

Suspected septic arthritis is a medical emergency. In young and previously fit people, the joint is hot, red, swollen and agonizingly painful; it is held immobile by muscle spasm. In contrast, the onset may be insidious with a lack of systemic symptoms in the elderly, the immunosuppressed and patients with RA, and a high index of suspicion is needed. In 20% of patients, the sepsis affects more than one joint.

**Investigations**

- **Aspirate** the joint and send the fluid for urgent Gram-staining and culture. The fluid is usually frankly purulent. The culture techniques should include those for gonococci and anaerobes.
- **Blood cultures** are often positive.
- **Leucocytosis** is usual, unless the person is severely immunosuppressed.
- **X-rays** are of no value in diagnosis in acute septic arthritis.
- **Skin wound swabs, sputum and throat swab or urine** may be positive and indicate the source of infection.

**Management**

There are no RCTs to guide management in adults. The prognosis is similar for patients with a proven microbiological diagnosis to those with a suspected but not proven diagnosis; therefore, it is vital to treat on the basis of clinical suspicion, probability (with subsequent confirmed identity) of organism, local pattern of antibiotic sensitivity and microbiological advice.

Therapy should be started immediately before culture results are available because joint destruction may occur within weeks.

- The joint should be aspirated and then immobilized initially, followed by early physiotherapy to prevent stiffness and muscle wasting.
- Intravenous antibiotics should be given for 2 weeks and then oral antibiotics for a further 4 weeks. Response is monitored clinically and with ESR and CRP.

**Empirical treatment in septic arthritis**

Empirical regimens vary according to local advice and index of suspicion. For suspected Gram-positive infection first-line therapy is vancomycin, with clindamycin or cephalosporin second-line. For suspected Gram-negative infection first-line therapy is a third-generation cephalosporin with IV ciprofloxacin second-line. In confirmed methicillin-sensitive *Staphylococcus aureus* (MSSA) primary options include fluclaxacinil alone or combined with fusidic acid or gentamicin, while penicillin-allergic patients should receive clindamycin or a third-generation cephalosporin. In cases of methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin is the drug of choice. Antibiotics should be altered according to sensitivities. Drainage of the joint and/or arthroscopic joint washouts are required in all cases.

**Management of infected protheses**

Long-term goals of prosthetic joint infection are to eradicate the infection, reduce pain and restore function. Two-stage surgery is required to remove the prosthesis followed by treatment with appropriate IV antibiotics for 4–6 weeks before a new prosthesis is inserted. A 2–6-week course of pathogen-directed IV antibiotics followed by 3–6 months of oral antibiotics are also given.

**Specific types of bacterial arthritis**

**Gonococcal arthritis**

Disseminated gonococcal infection occurs in 0.5–3% of patients infected with *Neisseria gonorrhoeae*. It is a common cause of acute arthritis in previously fit young adults, with increasing rates in men in general and men who have sex with men.

Patients present with a fever and characteristic pustules on the distal limbs, often in association with polyarthralgia and tenosynovitis. Blood cultures are reportedly positive in up to 70% of cases, particularly those with skin lesions, tenosynovitis and polyarthralgia. Nucleic acid amplification tests may be positive even when cultures are negative. Patients should be screened for other STIs. Later, large-joint mono- or pauciarticular arthritis may follow. Culture is usually positive from the genital tract, although the joint fluid may be sterile. It is not clear whether this joint inflammation is simply a septic arthritis (which responds rapidly to antibiotics), or whether there is also a reactive element to a variety of virulence and growth factors specific to *N. gonorrhoeae*.

**Management** consists of initial IV ceftriaxone (or cefotaxime or cefpodoxime) repeatedly until clinical improvement occurs, plus a single oral dose of azithromycin or alternatively a week of doxycycline. In the absence of purulent arthritis after 2–3 days of improvement a 7-day course of therapy may be completed with intramuscular ceftriaxone. Purulent arthritis, however, often requires 7–14 days of IV therapy and joint drainage.

**Tuberculous arthritis**

Around 1% of people with tuberculosis develop joint and/or bone involvement. It occurs as the primary disease in children. In adults, it is usually due to haematogenous spread from secondary pulmonary or renal lesions. The onset is insidious and diagnosis often delayed.

The organism invades the synovium or intervertebral disc. There are caseating granulomas and rapid destruction of cartilage and adjacent bone. Some patients develop a reactive polyarthritis (Poncet’s disease).

Osteoarticular TB most commonly affects the spine (50%), hip (12–15%), knee (10%) and ribs (10%). Patients become febrile with night sweats, anorexia and weight loss. The usual risk factors for tuberculosis apply – debility, excess alcohol use or immunosuppression. HIV-positive/AIDS patients are at particular risk.

**Investigations** should include culture of fluid, and culture and biopsy of the synovium. *Mycobacterium tuberculosis* is the usual organism but atypical mycobacteria are occasionally implicated. A chest X-ray should be performed. Initially, joint or spinal X-rays may be normal but joint-space reduction and bone destruction develop rapidly if treatment is delayed. MRI shows the abnormality earlier in the spine and CT-guided biopsy from the affected disc is often necessary to obtain cultures.
**Management** is as for pulmonary tuberculosis with therapy for 9 months. The joint should be rested and the spine immobilized in the acute phase.

**Meningococcal arthritis**

Joint inflammation may complicate meningococcal septicaemia, presenting as a migratory polyarthritis. Organisms are rarely cultured from the joint and most cases are due to immune-complex deposition. Treatment is urgent with immediate penicillin therapy.

**Infective endocarditis**

This condition may present with arthralgia, polyarthritis rheumat- atica-like symptoms or an infective arthritis (see p. 1103).

**Lyme arthritis**

About 25% of people with Lyme disease develop arthralgia, less commonly an acute pauciarticular arthritis (see p. 549); this usually resolves but 10% of untreated cases go on to develop a chronic arthritis. There are no positive markers of an ongoing infection in these patients.

*Diagnosis* is by the detection of IgM antibodies against the spirochaete *Borrelia burgdorferi*.

*Treatment* with antibiotics (amoxicillin or doxycycline) is highly effective in early disease.

**Brucellosis**

Brucellosis (see p. 548) has a worldwide distribution. The most common cause of chronic brucellosis and of arthritis is *Brucella melitensis*. There is usually a migratory large-joint mono- or oligoarticular arthritis, which is septic or reactive. Arthritis is more common in chronic infections of more than 6 months.

**Leprosy**

Acute or chronic symmetrical polyarthritis resembling RA, swollen hands and feet due to lepra reactions, tenosynovitis and thickened nerves with or without cutaneous manifestations are seen in leprosy (see p. 550).

**Arthritis in viral disease**

A transient polyarthritis or arthralgia can occur before, during or after many viral illnesses. These include infectious mononucleosis, chickenpox, mumps, adenovirus, rubella, erythrovirus B19, hepatitis B and C, arboviral infections and HIV. In most of these, it is due to a direct toxic effect or immune-complex deposition.

**Rubella**

In rubella (see p. 518), the virus can occasionally be isolated from the joint. This arthritis is rare in countries where rubella vaccination is routine. It occurs in up to 50% of young adult females a few days after rubella infection (6% of men). It is a symmetrical polyarthritis involving the MCP or PIP joints most commonly, but many joints can be affected. It closely resembles RA. IgM rubella antibodies are present. It resolves within a few weeks in most cases. A mild arthritis occurs rarely 2–4 weeks after rubella vaccination.

**Erythrovirus B19**

Erythrovirus B19 (see p. 519) causes an acute, self-limiting arthritis and is associated with erythema infectiosum (‘slapped cheek disease’).

**Hepatitis**

In hepatitis B infection (see p. 1277), a sudden, symmetrical polyarthritis of the small joints of the hands occurs in approximately one-third of patients, often in the prodromal phase, and mostly resolves before the onset of jaundice. Hepatitis C infection causes type II mixed cryoglobulinaemia (see p. 1368).

**Arbovirus**

Arbovirus infections (see p. 522), which are endemic in many parts of the world, give rise to an arthralgia and/or arthritis. For example, the Ross River virus causes an epidemic polyarthritis in Australia and the South Pacific; it involves the small joints of the hands and clear in 2–4 weeks. Other viral infections causing epidemic arthritis include chikungunya (see p. 524) and o’nyong-nyong.

**Musculoskeletal aspects of infection with HIV and AIDS**

Musculoskeletal manifestations are common in these patients and are often caused by triggers such as opportunistic infections and drug therapy rather than HIV itself. Infective arthritis seen in these immunosuppressed patients often has minimal symptoms and signs. Certain of the antiviral agents cause an acute arthritis, possibly because of crystallization in the joint.

Arthralgia is common in AIDS. There is a seronegative, pre-dominantly lower-limb arthritis, similar to psoriasis or Reiter’s disease. *Spondylitis* also occurs but is not associated with HIV.

Arthralgia or osteoarthritis with or without deformity can occur in chronic HIV infection. Septic arthritis is common in HIV infection. Septic arthritis is less common in patients who are aware of HIV infection.

**Fungal infections**

Fungal infections of joints occur rarely. Bone abscesses may be seen. Destructive joint lesions can also occur with blastomycosis. A benign polyarthritis accompanied by erythema nodosum occasionally occurs in coccidioidomycosis and histoplasmosis. Culture of purulent synovial fluid and skin tests for fungi may help the diagnosis.

**Further reading**

Systemic lupus erythematosus

Systemic lupus erythematosus (SLE) is an inflammatory, multisystem autoimmune disorder with arthralgia and rashes as the most common clinical features, and cerebral and renal disease as the most serious problems.

Epidemiology

SLE occurs worldwide and is about nine times as common in women as in men, with a peak age of onset between 20 and 40 years. The prevalence varies between ethnic groups, being highest (at 1:250) in African/Caribbean women. In other populations, the prevalence varies between 1:1000 and 1:10000.

Aetiology

The cause is unknown but there are several predisposing factors:

- **Heredity.** There is a higher concordance rate in monozygotic twins (up to 25%) compared with dizygotic twins (3%). First-degree relatives have a 3% chance of developing the disease but approximately 20% have autoantibodies.

- **Genetics.** Three whole-genome analyses have led to the identification of approximately 20 genes linked to the development of SLE. These include some HLA genes, as well as genes involved in T- and B-lymphocyte function and genes related to autophagy and interferon function. Homozygous deficiencies of the complement genes C1q, C2 or C4 are very rare but convey a high risk of developing SLE.

- **Sex hormone status.** Pre-menopausal women are most frequently affected.

- **Drugs.** Drugs such as hydralazine, isoniazid, procarbamide and penicillamine can induce a form of SLE that is usually mild, in that the kidneys and central nervous system are not affected.

- **Ultraviolet light.** This can trigger flares of SLE, especially in the skin.

- **Exposure to Epstein–Barr virus.** This has been suggested as a trigger for SLE.

### Pathogenesis

When cells die by apoptosis, the cellular remnants appear on the cell surface as small blebs that carry self antigens. These antigens include nuclear constituents (e.g. DNA and histones), which are normally hidden from the immune system. In people with SLE, removal of these blebs by phagocytes is inefficient, so that they are transferred to lymphoid tissues, where they can be taken up by antigen-presenting cells. The self antigens from these blebs can then be presented to T cells, which in turn stimulate B cells to produce autoantibodies directed against these antigens (see p. 64). It has been shown that, in some patients, the autoantibodies are present in stored blood samples that were taken years before the patient developed clinical features of SLE. The combination of availability of self antigens and failure of the immune system to inactivate B cells and T cells that recognize these self antigens (i.e. a breakdown of tolerance; see p. 64) leads to the following immunological consequences.

- Development of autoantibodies that either form circulating complexes or deposit by binding directly to tissues.

- Activation of complement and influx of neutrophils, causing inflammation in those tissues.

- Abnormal cytokine production: increased blood levels of IL-10 and interferon-alpha are particularly closely linked to high activity of inflammation in SLE. However, no form of anticytokine biological therapy has yet been adopted routinely in the treatment of SLE.

More recently, other cells have been implicated in the pathogenesis of SLE. These include dendritic cells, which are activated by immune complexes containing nucleic acids to produce interferon, and invariant natural killer T cells (iNKT cells), which are reduced in number and function in patients with SLE.

### Pathology

SLE of the skin and kidneys is characterized by deposition of complement and IgG antibodies, and by influx of neutrophils and lymphocytes. Biopsies of other tissues are carried out less frequently but can show vasculitis affecting capillaries, arterioles and venules. The synovium of joints can be oedematous and may contain immune complexes. Hae-matoxylin bodies (rounded, blue, homogeneous haematoxylin-stained deposits) are seen in inflammatory infiltrates and are thought to result from the interaction of antinuclear antibodies and cell nuclei.

The pathology of lesions in other organs is described in the appropriate chapters.

### Clinical features

The manifestations of SLE vary greatly between patients. Most patients suffer fatigue, arthralgia and/or skin problems. Involvement of major organs is less common but more serious (Fig. 18.36).

#### General features

Fever is common in exacerbations. Patients complain of marked malaise and tiredness, and these symptoms do not correlate with disease activity or severity of organ-based complications.

#### Joints and muscles

Joint involvement is the most common clinical feature (>90%). Patients often present with symptoms resembling RA with symmetrical small joint arthralgia. Joints are painful but characteristically appear clinically normal, although sometimes there is slight soft tissue swelling surrounding the joint. Deformity because of joint capsule and tendon contraction is rare, as are bony erosions. Rarely, major joint deformity resembling RA (known as Jaccoud’s arthropathy) is seen. Avascular necrosis affecting the hip or knee is a rare complication of the disease or of treatment with corticosteroids.

ds-DNA, double-stranded DNA; RNP, ribonuleoprotein; Ro, La, first two letters of name of patients; Sm, Smith, patient’s name; SS-A, SS-B, Sjögren’s syndrome A and B; SSc, systemic scleroderma; SLE, systemic lupus erythematosus.
Myalgia is present in up to 50% of patients but a true myositis is seen in only less than 5%. If myositis is prominent, the patient may well have an overlap ARD with both polymyositis and SLE.

**Skin**

The skin (see p. 682) is affected in 85% of cases. Erythema, in a ‘butterfly’ distribution on the cheeks of the face and across the bridge of the nose (see Fig. 22.40), is characteristic. Vasculitic lesions on the fingertips and around the nail folds, purpura and urticaria occur. In 40–50% of cases, there is photosensitivity (especially in patients positive for anti-Ro antibodies). Prolonged exposure to sunlight can lead to exacerbations of the disease. Livedo reticularis, palmar and plantar rashes, pigmentation and alopecia are seen. Scarring alopecia can lead to irreversible bald patches. Raynaud’s phenomenon (see p. 1131) is common and may precede the development of other clinical problems by years.

Discoid lupus is a benign variant of lupus in which only the skin is involved. The rash is characteristic and appears on the face as well-defined erythematos plaques that progress to scarring and pigmentation (see p. 681). Subacute cutaneous lupus erythematosus, a rare variant, is described on page 682.

**Lungs**

Up to 50% of patients will have lung involvement at some time during the course of the disease (see p. 992). Recurrent pleurisy and pleural effusions (exudates) are the most common manifestations and are often bilateral. Pneumonitis and atelectasis are seen; in some patients a restrictive lung defect develops, with loss of lung volumes and raised hemidiaphragms. This ‘shrinking lung syndrome’ is poorly understood but may have a neuromuscular basis. Rarely, pulmonary fibrosis occurs, more commonly in overlap syndromes (see p. 463). Intrapulmonary haemorrhage associated with vasculitis is a rare but potentially life-threatening complication.

**Heart and cardiovascular system**

The heart is involved in 25% of cases. Pericarditis, with small pericardial effusions detected by echocardiography, is common. A mild myocarditis also occurs, giving rise to arrhythmias. Aortic valve lesions and a cardiomyopathy can rarely be present. A non-infective endocarditis involving the mitral valve (Libman–Sacks syndrome) is very rare. Raynaud’s, vasculitis, and arterial and venous thromboses can occur, especially in association with the antiphospholipid syndrome (see below). There is an increased frequency of ischaemic heart disease and stroke in people with SLE, which is partly due to altered levels of common risk factors such as hypertension and lipid levels, but the presence of chronic inflammation over many years may also be contributory. It is not known whether intensive treatment of cardiovascular risk factors or use of statins in SLE will alter the risk of developing coronary disease or stroke.

**Kidneys**

A classification of types of nephritis is given on page 1353. Post-mortem studies suggest that histological changes are very frequent, but clinical renal involvement occurs in only approximately 30% of cases. All patients should have regular screening of urine for blood and protein. An asymptomatic patient with proteinuria may be in the early stages of lupus nephritis, and treatment may prevent progression to renal impairment. Proteinuria should be quantified and haematuria should prompt examination for urinary casts or fragmented red cells that suggest glomerulonephritis. Renal biopsy is used to define the type and severity of nephritis. Renal vein thrombosis can occur in nephrotic syndrome or in association with antiphospholipid antibodies.

**Nervous system**

Involvement of the nervous system occurs in up to 60% of cases and symptoms often fluctuate. There may be a mild depression, but occasionally, more severe psychiatric disturbances occur. Epilepsy, migraines, cerebellar ataxia, aseptic meningitis, cranial nerve lesions, cerebrovascular disease or a polyneuropathy may be seen. The pathogenic mechanism for cerebral lupus is complex. Lesions may be due to vasculitis or immune complex deposition, thrombosis or non-inflammatory microvasculopathy. In people with cerebral lupus, infection should be excluded, or treated in parallel with administration of corticosteroids and immunosuppression.

**Eyes**

Retinal vasculitis can cause infarcts, which appear as hard exudates, and haemorrhages. There may be episcleritis, conjunctivitis or optic neuritis, but blindness is uncommon. Secondary Sjögren’s syndrome is seen in about 15% of cases.

**Gastrointestinal system**

Mouth ulcers are common and may be a presenting feature. These may be painless or become secondarily infected and painful. Mesenteric vasculitis can produce inflammatory lesions involving the small bowel (infarction or perforation). Liver involvement and pancreatitis are uncommon.
Investigations

Blood

- A full blood count may show a leucopenia, lymphopenia and/or thrombocytopenia. Anaemia of chronic disease or autoimmune haemolytic anaemia also occurs. The ESR is raised in proportion to the disease activity. In contrast, the CRP is usually normal but may be high when the patient has lupus pleuritis or peritonitis, arthritis or a coexistent infection.

- Urea and creatinine only rise when renal disease is advanced. Low serum albumin or high urine albumin/creatinine ratio are earlier indicators of lupus nephritis.

- Autoantibodies of many different types may be present in SLE but the most significant are ANA, anti-dsDNA, anti-Ro, anti-Sm and anti-La (see Box 18.38). Antiphospholipid antibodies are present in 25–40% of cases but not all of these patients develop antiphospholipid syndrome (see later).

- Serum complement C3 and C4 levels are often reduced during active disease. The combination of high ESR, high anti-dsDNA and low C3 may herald a flare of disease. All these markers tend to return towards normal as the flare improves, but in some patients, anti-dsDNA levels will remain high even during clinical remission.

Histology

Characteristic histological and immunofluorescent abnormalities (deposition of IgG and complement) are seen in biopsies from the kidney and skin.

Diagnostic imaging

CT scans of the brain sometimes show infarcts or haemorrhage with evidence of cerebral atrophy. MRI can detect lesions in white matter that are not seen on CT. However, it can be very difficult to distinguish true vasculitis from small thrombi.

Management

General measures

The disease and its management should be discussed with the patient, particularly the effect upon the patient’s lifestyle: for example, appearance and debility due to fatigue. Patients are advised to avoid excessive exposure to sunlight and it is also necessary to reduce cardiovascular risk factors.

Symptomatic treatment

Arthralgia, arthritis, fever and serositis all respond well to standard doses of NSAIDs (see p. 431). Topical corticosteroids are effective and widely used in cutaneous lupus. Antimalarial drugs (chloroquine or hydroxychloroquine) help mild skin disease, fatigue and arthralgias that cannot be controlled with NSAIDs, but patients require regular eye checks because of potential retinal toxicity. It is now thought that retinal changes occur in up to 7.5% of patients on long-term treatment with hydroxychloroquine, with increased risk in those taking more than 5 mg/kg per day.

Corticosteroids and immunosuppressive drugs

Single intramuscular injections of long-acting corticosteroids or short courses of oral corticosteroids are useful in treating severe flares of arthritis, pleuritis or pericarditis. In some cases, these symptoms can only be kept under control using long-term oral corticosteroids.

Renal or cerebral disease and severe haemolytic anaemia or thrombocytopenia must be treated with high-dose oral corticosteroids, and the first two of these require immunosuppressive drugs in addition. Cyclophosphamide was most commonly used to achieve remission in these severe forms of lupus but has largely been replaced by mycophenolate mofetil, which has fewer side-effects. Azathioprine is also used to maintain remission. Newer agents, which specifically target cells or cytokines in the immune system, are coming into use, especially in refractory cases. These include rituximab (anti-CD20) and belimumab, which are both monoclonal antibodies acting against B lymphocytes. Other drugs, such as anti-interferon agents, are being investigated in large clinical trials.

Prognosis

An episodic course is characteristic, with exacerbations and complete remissions that may last for long periods. However, SLE can also be a chronic persistent condition. The mortality rate in SLE has fallen dramatically over the last 50 years; the 10-year survival rate is about 90%, but this is lower if major organ-based complications are present. Deaths early in the course of disease are mainly due to renal or cerebral disease or infection. Later, coronary artery disease and stroke become more prevalent. Chronic progressive destruction of joints, as seen in RA and OA, occurs rarely, but a few patients develop deformities such as ulnar deviation. People with SLE have an increased long-term risk of developing some cancers, especially lymphoma.

Pregnancy and SLE

Fertility is usually normal, except in severe disease, and there is no major contraindication to pregnancy. Recurrent miscarriages can occur, especially in women with antiphospholipid antibodies. Exacerbations can arise during pregnancy and are frequent postpartum. The patient’s medications should be reviewed. Mycophenolate should be stopped, whereas azathiopeine, hydroxychloroquine and low-dose oral corticosteroids are safe. Hypertension must be controlled. People with anti-Ro or anti-La antibodies have a 2% risk of giving birth to babies with neonatal lupus syndrome (rash, hepatitis and fetal heart block).

Antiphospholipid syndrome

Patients who have thrombosis (arterial or venous) and/or recurrent miscarriages (see p. 1471), and who also have persistently positive blood tests for antiphospholipid antibodies (aPL), have the antiphospholipid syndrome (APS). Antiphospholipid antibodies can be detected by several different tests:

- The anticardiolipin test, which detects antibodies (IgG or IgM) that bind the negatively charged phospholipid, cardiolipin.
- The lupus anticoagulant test, which detects changes in the ability of blood to clot in a test tube. Despite the name, it is not a test for lupus. It is a test for APS. The anticoagulant effect caused by aPL in the test tube causes an opposite procoagulant effect inside the body because the balance of factors stimulating thrombosis is different there.
- The anti-β2-glycoprotein I test, which detects antibodies that bind β2-glycoprotein I, a molecule that interacts closely with phospholipids.

A persistently positive test (i.e. positive on at least two occasions ≥12 weeks apart) in one or more of these assays is needed to diagnose APS. However, some people who test positive for aPL will never develop APS; that is, not all aPLs are harmful. APS can present in patients who already have another ARD, especially SLE. APS can also occur on its own (primary APS).

New diagnostic tests for APS are being developed and include anti-prothrombin assays, tests for IgA aPL and tests for antibodies to the N-terminal domain of β2-glycoprotein I. Although not currently
used in clinical practice, these tests may soon be helpful for assessing the overall thrombosis risk of a patient with APS, or for diagnosing patients with ‘seronegative’ APS who have typical clinical features but test negative for anticardiolipin, lupus anticoagulant and anti-β2-glycoprotein I.

**Pathogenesis**

Negatively charged phospholipids and β-glycoprotein I are present on the outer surface of apoptotic blebs, and so aPLs are believed to arise by a similar mechanism to the lupus autoantibodies described above. Pathogenic aPLs bind to the N-terminal domain of β2-glycoprotein I. Changes in the oxidation state of β2-glycoprotein I in patients with APS enhance the availability of this domain to bind aPLs, and this interaction is facilitated when the protein is bound to phospholipid on the surface of cells such as endothelial cells, platelets, monocytes and trophoblasts. This change alters the functioning of those cells, leading to thrombosis and/or miscarriage.

**Clinical features**

Ischaemic strokes occur in about 20% of patients and deep vein thrombosis in about 40%. Unlike most causes of thrombophilia, APS can cause either arterial or venous thrombosis (though rarely both in the same patient). Some 27% of women who have had two or more spontaneous miscarriages have APS.

Large studies, however, show that people with APS can also have many other features, including:
- thrombocytopenia
- chorea, migraine and epilepsy
- valvular heart disease
- cutaneous manifestations (e.g. livedo reticularis)
- positive Coombs test
- renal impairment due to ischaemia in the small renal vessels.

Catastrophic APS is a rare variant (about 1% of cases) in which multiple infarcts in different organs of the body cause failure of multiple organs simultaneously. There is a high mortality from catastrophic APS.

**Management**

In people with APS who have had one thrombosis or more, the recommended treatment to prevent further thrombosis is long-term anticoagulation with warfarin. The target INR is lower in people with a history of venous compared to arterial thrombosis. Pregnant women with APS are given oral aspirin and subcutaneous low-molecular-weight heparin from early in gestation. This therapy reduces the chance of a miscarriage but pre-eclampsia and poor fetal growth remain common. There are no definite guidelines for managing people with aPL who have never had thrombosis. Aspirin or clopidogrel is sometimes given prophylactically, especially in those with high-IgG aPL. Warfarin is given much more rarely in these circumstances, but may be indicated in patients at particularly high risk; for example, those who test positive for all three of anticardiolipin, lupus anticoagulant and anti-β2-glycoprotein I.

Anti-coagulants that act against specific clotting factors are replacing warfarin in some clinical situations and may come into use in APS. An example is the factor X inhibitor rivaroxaban, which has been the subject of two clinical trials in APS, though its place in management of APS is not yet clear.

**Systemic sclerosis (scleroderma)**

Systemic sclerosis (SSc, or scleroderma; see p. 681) is a multisystem disease and is distinct from localized scleroderma syndromes, such as morphea, that do not involve internal organ disease and are rarely associated with vasospasm (Raynaud’s phenomenon). SSc has the highest case-specific mortality of any of the autoimmune rheumatic diseases. It occurs worldwide but there may be racial or ethnic differences in clinical features. For example, renal involvement is less frequent in Japanese cases.

The incidence of SSc is 10/million population per year with a 3:1 female to male ratio. The peak incidence is between 30 and 50 years of age. It is rare in children.

Environmental risk factors for scleroderma-like disorders include exposure to vinyl chloride, silica dust, adulterated rapeseed oil and trichloroethylene. Drugs such as bleomycin also produce a similar picture. Although unusual, familial cases are reported and twin cohorts suggest higher concordance in monozygotic pairs, consistent with genetic determinants of aetiology.

**Pathology and pathogenesis**

**Vascular features**

Widespread vascular damage involving small arteries, arterioles and capillaries is an early lesion. There is initial endothelial cell damage with release of cytokines, including endothelin-1, which causes vasoconstriction. There is continued intimal damage with increasing vascular permeability, leading to cellular activation and activation of adhesion molecules (E-selectin, VCAM, intercellular adhesion molecule 1 (ICAM-1)), with migration of cells into the extracellular matrix. Migrating lymphocytes are IL-2-producing cells, expressing surface antigens such as CD3, CD4 and CD5. All these factors cause release of other mediators (e.g. IL-1, 4, 6 and 8, TGF-β and platelet-derived growth factor) with activation of fibroblasts. Plasma levels of the chemokine CXCL4 are elevated in SSc and correlate with skin and lung fibrosis.

The damage to small blood vessels also produces widespread obliterator arterial lesions and subsequent chronic ischaemia.

**Fibroblasts features**

Fibroblasts synthesize increased quantities of collagen types I and III, as well as fibronectin and glycosaminoglycans, producing fibrosis in the lower dermis of the skin as well as the internal organs. It is possible that antibodies to platelet-derived growth factor receptor, which have been found in blood of people with SSc, stimulate fibroblasts to cause fibrosis.

**Clinical features**

See Fig. 18.37.

**Raynaud’s phenomenon**

Raynaud’s phenomenon is seen in almost all cases and can precede the onset of the full-blown disease by many years.

**Limited cutaneous scleroderma (LcSSc): 70% of cases**

This condition usually starts with Raynaud’s phenomenon many years (up to 15) before any skin changes. The skin involvement is limited to the hands, face, feet and forearms. The skin is tight over the fingers and often produces flexion deformities of the fingers. Involvement of the skin of the face produces a characteristic ‘beak’-like nose and a small mouth (microstomia). Painful digital ulcers and telangiectasia with dilated nail-fold capillary loops are seen. Digital ischaemia may lead to gangrene. Gastrointestinal tract involvement is common. Pulmonary hypertension develops in 21% of people with LcSSc and pulmonary interstitial disease also occurs.
Diffuse cutaneous scleroderma (DcSSc): 30% of cases

Initially oedematous in onset, skin sclerosis rapidly follows. Raynaud’s phenomenon usually starts just before or concomitant with the oedema.

Diffuse swelling and stiffness of the fingers is rapidly followed by more extensive skin thickening, which can involve most of the body in the severest cases. Later, the skin becomes atrophic. Early involvement of other organs occurs with general symptoms of lethargy, anorexia and weight loss.

- **Gastrointestinal involvement** includes heartburn, reflux or dysphagia due to oesophageal involvement (see p. 1168), which is almost invariable. Anal incontinence occurs in many patients. Malabsorption from bacterial overgrowth due to dilatation and atony of the small bowel is not infrequent; more rarely, dilatation and atony of the colon occurs. Pseudo-obstruction is a known complication.
- **Renal involvement** is acute or chronic (see p. 1368). Acute hypertensive renal crisis used to be the most common cause of death in systemic sclerosis. Angiotensin-converting enzyme (ACE) inhibitors and better care, along with dialysis and renal transplantation, have changed this.
- **Lung disease**, both fibrosis (in 41% of cases) and pulmonary hypertension (17% of cases), contributes significantly to mortality in SSc. Pulmonary hypertension can be isolated or secondary to fibrosis, and high plasma levels of endothelin-1 are seen.
- **Myocardial fibrosis** leads to arrhythmias and conduction defects. Pericarditis is found occasionally. Sometimes, these systemic features occur without skin involvement (SSc sine scleroderma).

**Investigations**

- **Full blood count.** A normochromic, normocytic anaemia occurs and a microangiopathic haemolytic anaemia is seen in some people with renal disease.
- **Serum creatinine and electrolytes.** Urea and creatinine rise in acute kidney injury.
- **Autoantibodies** (see Box 18.38):
  - In LcSSc: speckled, nucleolar or anti-centromere antibodies (ACAs) occur in 70% of cases. Anti-Th/To antibodies target small nuclear ribonucleoproteins and are found in up to 7% of cases of LcSSC.
  - In DcSSc: there are anti-topoisomerase-1 antibodies (called anti-Scl-70) in 30% of cases, and anti-RNA polymerase (I, II and III) antibodies in 20–25%. Anti-Scl-70 is highly specific for DcSSC. Anti-RNA polymerase positivity is associated with an increased risk of renal involvement. Anti-U3RNP antibodies bind a small nuclear ribonucleoprotein called fibrillarin and are present in up to 6% of patients with SSc – more common in DcSSc than LcSSc.
  - **RF** is positive in 30%.
  - **ANA** is positive in 95%.
  - **Urine** microscopy and, if there is proteinuria, the urine albumin/creatinine ratio should be measured.
- **Imaging:**
  - **Chest X-ray:** to exclude other pathology, for changes in cardiac size and established lung disease.
  - **Hands:** deposits of calcium around the fingers (in severe cases, erosion and absorption of the tufts of the distal phalanges, termed ‘acro-osteolysis’).
  - **Barium swallow:** generally confirms impaired oesophageal motility. Scintigraphy, manometry, impedance and upper gastrointestinal endoscopy are also valuable.
  - **Echocardiogram and lung function tests** should be carried out annually to monitor for development of pulmonary fibrosis or pulmonary hypertension.
  - **High-resolution CT:** to demonstrate fibrotic lung involvement.
- **Other investigations** of gastrointestinal tract, lung, renal and cardiac as appropriate.

**Management**

Treatment should be organ-based in order to try to control the disease. Currently, there is no cure. In contrast to many other ARDs, corticosteroids and immnosuppressants are rarely used in SSc, with the exception of SSc-related pulmonary fibrosis.

- **Education**, counselling and family support are essential.
- **Regular exercises** and skin lubricants may limit contractures but no treatment has proven efficacy in reducing skin fibrosis.
- **Raynaud’s phenomenon** may be improved by hand warmers and oral vasodilators (calcium-channel blockers, ACE inhibitors, angiotensin receptor blockers). In severe cases, parenteral vasodilators (prostacyclin analogues and calcitonin gene-related peptide) are used. Lumbar sympathectomy can help foot symptoms. Radical micro-arteriolysis (digital sympathectomy) can be used where individual fingers or toes are severely ischaemic, and thoracic sympathectomy under video-assisted thoracic surgery is now performed.
- **Oesophageal symptoms** can almost always be improved by proton pump inhibitors but prokinetic drugs are rarely helpful.
- **Symptomatic malabsorption** requires nutritional supplements and rotational antibiotics to treat small intestinal bacterial overgrowth.
Rheumatology

- Renal involvement requires intensive control of hypertension. The first drug of choice is an ACE inhibitor. Vigilance for hypertensive scleroderma renal crisis (SRC) is critical, especially in early-stage dcSSc with rapidly progressive skin and tendon friction rubs. High-dose corticosteroids (above 10 mg prednisolone daily) may increase the risk of SRC.

- Pulmonary hypertension is treated with oral vasodilators, oxygen and warfarin. Advanced cases should receive prostacyclin therapy (inhaled, subcutaneous or intravenous) or the oral endothelin-receptor antagonist, bosentan. Right heart failure is treated conventionally and transplantation (heart-lung or single lung) is used in eligible cases.

- Pulmonary fibrosis is currently treated with immunosuppression, most often with cyclophosphamide or azathioprine combined with low-dose oral prednisolone.

**Prognosis**

In limited cutaneous scleroderma, the disease is often milder, with much less severe internal organ involvement and a 70% 10-year survival. Pulmonary hypertension is a significant later cause of death. Lung fibrosis and severe gut involvement also determine mortality. In diffuse disease, where organ involvement is often severe at an earlier stage, many patients die of pulmonary, cardiac or renal involvement. Overall, pulmonary involvement (vascular or interstitial) accounts for around 50% of scleroderma-related deaths.

Localized forms of scleroderma occur either in patches (morphea; see p. 681) or linear forms. These are more commonly seen in children and adolescents, and do not convert into systemic forms, although ANA may occur in localized scleroderma and, very occasionally, localized and systemic forms coexist.

**Polymyositis and dermatomyositis**

Polymyositis (PM) is a rare disorder of unknown cause, in which the clinical picture is dominated by inflammation of striated muscle, causing proximal muscle weakness. When the skin is involved, it is called ‘dermatomyositis’ (DM). The incidence is about 2–10/million population per annum and it occurs in all races and at all ages. The aetiology is unknown, although viruses (e.g. Coxsackie, rubella, influenza) have been implicated and persons with HLA-B8/DR3 appear to be genetically predisposed.

**Clinical features**

**Adult polymyositis**

Women are affected three times more commonly than men.

The onset can be insidious, over months, or acute. General malaise, weight loss and fever can develop during the acute phase, but the cardinal symptom is proximal muscle weakness. The shoulder and pelvic girdle muscles become wasted but are not usually tender. Face and distal limb muscles are not usually affected. Movements such as squatting and climbing stairs become difficult. As the disease progresses, involvement of pharyngeal, laryngeal and respiratory muscles can lead to dysphonia and respiratory failure. These severe complications are rare if the disease is treated early.

**Adult dermatomyositis**

This condition is also more common in women. Apart from muscle weakness, these patients often suffer from myalgia, polyarthritis and Raynaud’s phenomenon, but DM is primarily distinguished from PM by the characteristic rash. This typically affects the eyelids, where heliotrope (purple) discoloration is accompanied by periorbital oedema, and the fingers, where purple-red, raised vasculitic patches are seen. These patches occur over the knuckles (Gottron’s papules; Fig. 18.38) in 70% of patients, and this appearance is highly specific for DM. Ulcerative vasculitis and calcinosis of the subcutaneous tissue are seen in 25% of cases. In the long term, muscle fibrosis and contractures of joints occur.

**Antisynthetase syndrome**

Some 20–30% of people with PM or DM have antibodies to tRNA synthetase enzymes. These people are more likely to develop pulmonary interstitial fibrosis, Raynaud’s phenomenon, arthritis, and hardening and fissuring of skin over the pulp surface of the fingers (mechanic’s hands). This variant of PM/DM is sometimes called antisynthetase syndrome and often has a poor outcome. Respiratory muscles are affected in PM/DM and this compounds the effects of interstitial fibrosis. Dysphagia is seen in about 50% of patients owing to oesophageal muscle involvement.

**Association with other ARDs**

There is an association with other ARDs (e.g. SLE, RA and SSc) and their associated clinical features, such as deforming arthritis, malar rash and skin sclerosis.

**Association with malignancies**

The relative risk of cancer is 2.4 for male and 3.4 for female patients, and a wide variety of cancers have been reported. The onset and clinical picture do not differ in malignancy-associated disease from those of typical DM/PM. The associated cancer may not become apparent for 2–3 years, and recurrent, refractory or ANA-negative DM should prompt a search for occult malignancy.

Malignancy (e.g. lung, ovary, breast, stomach) can also predate the onset of myositis, particularly in males with DM.

**Childhood dermatomyositis**

This variant most commonly affects children between the ages of 4 and 10 years. The typical rash of DM is usually accompanied by muscle weakness. Muscle atrophy, subcutaneous calcification and contractures may be widespread and severe. Ulcerative skin vasculitis is common and recurrent abdominal pain due to vasculitis is also a feature. Adults who have suffered from childhood DM may have chronic damage (e.g. contractures) or show effects of long-term corticosteroid or immunosuppressive therapy.
Investigations

- **Serum creatine kinase (CK)**, aminotransferases, lactate dehydrogenase (LDH) and aldolase are usually raised and are useful guides to muscle damage, but may not reflect activity.
- **ESR** and **CRP** may be raised.
- **Serum autoantibody studies** include antinuclear antibody testing, which is usually positive in people with DM. RF is present in up to 50%, and many **myositis-specific antibodies** (MSAs) have been recognized and correlate with certain subsets. Antisyntethase antibodies have been described above.
- **Electromyography (EMG)** shows a typical triad of changes with myositis: spontaneous fibrillation potentials at rest, polyphasic or short-duration potentials on voluntary contraction, and salvos of repetitive potentials on mechanical stimulation of the nerve.
- **MRI** can be used to detect abnormally inflamed muscle.
- **Needle muscle biopsy** shows fibre necrosis and regeneration in association with an inflammatory cell infiltrate with lymphocytes around the blood vessels and between muscle fibres. Open biopsy allows more thorough assessment.
- **Screening for malignancy** is usually limited to relatively non-invasive investigations such as chest X-ray, mammography, pelvic/abdominal ultrasound and CT scanning, urine microscopy and a search for circulating tumour markers.
- **PET** scanning can detect malignancy.

Management

Bed rest may be helpful but must be combined with an exercise programme. Prednisolone is the mainstay of treatment: 0.5–1.0 mg/kg body weight as initial therapy, continued until at least 1 month after myositis has become clinically and enzymatically inactive. Tapering of steroids must be slow. Early intervention with steroid-sparing agents, such as methotrexate, azathioprine, ciclosporin, cyclophosphamide and mycophenolate motefitol, is common, especially where there is clinical relapse or a rise in CK as the dose of steroids is reduced. Intravenous immunoglobulin therapy (IVIG) is helpful in some recalcitrant cases. Treatment of childhood DM tends to be more intensive, with earlier use of immunosuppressive agents. Use of biological agents such as rituximab has been described. Rituximab is more likely to be effective in autoantibody-positive cases.

Inclusion body myositis

Inclusion body myositis is an idiopathic inflammatory myopathy usually occurring in men over 50 years. Weakness of the pharyngeal muscles causes difficulty in swallowing in over 50%. It is a slowly progressive weakness of mainly distal muscles. In contrast to polymyositis, the CK is only slightly elevated; the EMG shows both myopathic and neuromyopathic changes. On MRI, the changes are often more distal but can be similar to those of polymyositis. A muscle biopsy shows inflammation and basophilic rimmed vacuoles with diagnostic filamentous inclusions and vacuoles on electron microscopy. A trial of corticosteroids is worthwhile but generally the response is poor.

Sjögren’s syndrome

The syndrome of dry eyes (keratoconjunctivitis sicca) in the absence of RA or any of the autoimmune diseases is known as ‘primary Sjögren’s syndrome’. There is an association with HLA-B8/DR3. Dryness of the mouth, skin or vagina may also be a problem. Salivary and parotid gland enlargement is seen. In the majority of cases, dryness and fatigue are the only symptoms, and Sjögren’s syndrome is irritating and inconvenient rather than dangerous. However, in a minority there may be systemic symptoms such as:

- **arthralgia and occasional non-progressive polyarthritis, like that seen in SLE (but much less common)**
- **Raynaud’s phenomenon**
- **dysphagia and abnormal oesophageal motility, as seen in systemic sclerosis (but less common)**
- **other organ-specific autoimmune disease, including thyroid disease, myasthenia gravis, primary biliary cirrhosis, autoimmune hepatitis and pancreatitis**
- **renal tubular defects (uncommon) causing nephrogenic diabetes insipidus and renal tubular acidosis**
- **pulmonary diffusion defects and fibrosis**
- **polyneuropathy, fits and depression**
- **vasculitis**
- **increased incidence of non-Hodgkin’s B-cell lymphoma.**

Pathology and investigations

Biopsies of the salivary gland or of the lip show a focal infiltration of lymphocytes and plasma cells.

- **Schirmer tear test.** A standard strip of filter paper is placed on the inside of the lower eyelid; wetting of less than 10 mm in 5 minutes indicates defective tear production.
- **Rose Bengal staining.** Staining of the eyes shows punctate or filamentary keratitis.
- **Laboratory abnormalities.** These include raised immunoglobulin levels, circulating immune complexes and autoantibodies. RF is usually positive. Antinuclear antibodies are found in 80% of cases and anti-mitochondrial antibodies are found in 10%. Anti-Ro (SSA) antibodies are found in 60–90%, compared with 10% of cases of RA and secondary Sjögren’s syndrome.

Management

Symptomatic treatment is with artificial tears and saliva replacement solutions. Hydroxychloroquine may help fatigue and arthralgia. Corticosteroids are rarely needed but are used to treat persistent salivary gland swelling or neuropathy. A trial of rituximab in Sjögren’s syndrome did not demonstrate efficacy and this drug is not used.

‘Overlap’ syndromes and undifferentiated autoimmune rheumatic disease

An **overlap syndrome** is one where the patient shows the characteristic clinical features of more than one ARD. Treatment of each ARD is usually the same as when they occur separately.

**Undifferentiated ARD** is a term used for the condition of patients who have evidence of autoimmunity (e.g. positive autoantibody test) and some clinical features of such diseases (commonly, Raynaud’s phenomenon and/or arthralgia) but not enough to make a clear diagnosis of any individual ARD. These patients sometimes develop a clearer ARD over time, but some always remain undifferentiated and tend to have relatively mild disease without major organ problems.

Rheumatology

### SYSTEMIC INFLAMMATORY VASCULITIS

Vasculitis is a histological term describing inflammation of the vessel wall. Vasculitis can be seen in many diseases (Boxes 18.39 and 18.40). The group of diseases described in this section (systemic inflammatory vasculitides) is characterized by widespread vasculitis leading to systemic symptoms and signs, generally requiring treatment with corticosteroids and/or immunosuppressive drugs. Two main features are helpful in classifying these vasculitides: the size of the blood vessels involved and the presence or absence of anti-neutrophil cytoplasmic antibodies (ANCA) in the blood. Revisions in the commonly used terms for various vasculitides have been proposed to reflect increased pathophysiological understanding of these conditions (Fig. 18.39 and see Box 18.39).

- **Large vessel vasculitis** refers to the aorta and its major tributaries.
- **Medium-vessel vasculitis** refers to medium- and small-sized arteries and arterioles.
- **Small-vessel vasculitis** refers to small arteries, arterioles, venules and capillaries.

#### Large-vessel vasculitis

Polymyalgia rheumatica and giant cell (temporal) arteritis are systemic illnesses of the elderly. Both are associated with the finding of a giant cell arteritis on temporal artery biopsy.

#### Polymyalgia rheumatica

Polymyalgia rheumatica (PMR) causes a sudden onset of severe pain and stiffness of the shoulders and neck, and of the hips and lumbar spine: a limp girdle pattern. These symptoms are worse in the morning, lasting from 30 minutes to several hours. The clinical history is usually diagnostic and the patient is always over 50 years old. Up to 25% of patients may have some inflammation of peripheral joints.

Approximately one-third of patients develop systemic features of tiredness, fever, weight loss, depression and occasionally nocturnal sweats, especially if PMR is not diagnosed and treated early. A differential diagnosis is shown in Box 18.41.

#### Investigation of PMR

- A raised ESR and/or CRP is a hallmark of this condition. It is rare to see PMR without an acute-phase response. If it is absent, the diagnosis should be questioned and the tests repeated a few weeks later before treatment is started.
- **Serum alkaline phosphatase and γ-glutamyl-transpeptidase** may be raised as markers of the acute inflammation.
- **Anaemia** (mild normochromic, normocytic) is often present.
- **Temporal artery biopsy** shows giant cell arteritis in 10–30% of cases, but is rarely performed unless giant cell arteritis is also suspected.

#### Giant cell arteritis

Giant cell arteritis (GCA) is inflammatory granulomatous arteritis of large cerebral arteries, which occurs in association with PMR. The patient may have current PMR or a history of recent PMR, or may be on treatment for PMR. It is extremely rare under 50 years of age. Presenting symptoms of GCA include severe headaches, tenderness of the scalp (combing the hair may be painful) or of the temple, claudication of the jaw when eating, and tenderness and swelling of one or more temporal or occipital arteries. The most feared manifestation is sudden, painless, temporary or permanent loss of vision in one eye due to involvement of the ophthalmic artery (see p. 852). Systemic manifestations of severe malaise, tiredness and fever occur.

#### Investigations in GCA

- Normochromic, normocytic anaemia.
- ESR is usually raised (in the region of 50–120 mm/h) and the CRP very high.
- Liver biochemistry may be abnormal, as in PMR. The albumin may be low.
- A temporal artery biopsy from the affected side is the definitive diagnostic test. This should be taken before, or within 7 days of starting, high doses of corticosteroids. The lesions are patchy and the whole length of the biopsy (>1 cm long) must be examined; even so, negative biopsies occur.
- Ultrasound scanning of the temporal arteries is increasingly used – if diagnostic features are seen, biopsy can be avoided. The histological features of GCA are:
  - Cellular infiltrates of CD4+ T lymphocytes, macrophages and giant cells in the vessel wall. Note that giant cells are not visible in all cases.
  - Granulomatous inflammation of the intima and media.
  - Breaking up of the internal elastic lamina.
  - Giant cells, lymphocytes and plasma cells in the internal elastic lamina.
Management of PMR or GCA

Corticosteroids produce a dramatic reduction of symptoms of PMR within 24–48 hours of starting treatment, provided the dose is adequate. If this improvement does not occur, the diagnosis should be questioned and an alternative cause sought, such as RA, vasculitis, infection or malignancy. Corticosteroid treatment should reduce the risk of patients who have PMR developing GCA. NSAIDs are less effective and should not be used.

In GCA, corticosteroids are obligatory because they significantly reduce the risk of irreversible visual loss and other focal ischaemic lesions, but much higher doses are needed than in PMR. If GCA is suspected, it may not be possible to arrange an ultrasound scan or temporal artery biopsy rapidly. In these circumstances, treatment should not be delayed, especially if there have already been episodes of visual loss or stroke.

Starting daily doses of prednisolone are:
- **PMR**: 15 mg prednisolone as a single dose in the morning
- **GCA**: 60–100 mg prednisolone, usually in divided doses.

The dose should then be reduced gradually in weekly or monthly steps. While the dose is above 20 mg, the step reductions are 5 mg, reducing the evening doses first. Below 20 mg the reduction can be in 2.5-mg steps, but below 10 mg the rate should be slower and the steps of 1 mg each. Most patients will eventually be able to stop corticosteroids after 12–18 months but up to 25% may need low doses long term. Steroid-sparing immunosuppressive agents are used in refractory cases where it is hard to reduce the corticosteroid dose without causing a flare of disease or a rise in ESR or CRP. A clinical trial showed that a combination of the anti-interleukin receptor 6 receptor agent tocilizumab with corticosteroid gave higher remission rates than corticosteroid alone.

Calcium and vitamin D supplements, and sometimes bisphosphonates, are necessary to prevent osteoporosis while high-dose steroids are being used (see p. 479).
manifestations, and its occasional association with hepatitis B antigenaemia suggests a vasculitis secondary to the deposition of immune complexes. Pathologically, there is fibrinoid necrosis of vessel walls with microaneurysm formation, thrombosis and infarction.

Clinical features
These include fever, malaise, weight loss and myalgia. These initial symptoms are followed by dramatic acute features that are due to organ infarction.
- **Neurological.** Mononeuritis multiplex is due to arteritis of the vasa nervorum.
- **Abdominal.** Pain is due to arterial involvement of the abdominal viscera, mimicking acute cholecystitis, pancreatitis or appendicitis. Gastrointestinal haemorrhage occurs because of mucosal ulceration.
- **Renal.** Presentation is with haematuria and proteinuria. Hypertension and acute/chronic kidney disease occur.
- **Cardiac.** Coronary arteritis causes myocardial infarction and heart failure. Pericarditis also occurs.
- **Skin.** Subcutaneous haemorrhage and gangrene occur. A persistent livedo reticularis is seen in chronic cases. Cutaneous and subcutaneous palpable nodules occur but are uncommon.
- **Lung.** Involvement is rare.

Investigations and management
- **Blood count.** Anaemia, leucocytosis and a raised ESR occur.
- **Biopsy.** Material from an affected organ shows features listed above.
- **Angiography.** Microaneurysms in hepatic, intestinal or renal vessels can be demonstrated if necessary.
- **Other investigations.** These are performed as appropriate (e.g. echocardiogram and abdominal ultrasound), depending on the clinical problem. ANCA is positive only rarely in classic PAN.

**Treatment** is with corticosteroids, usually in combination with immunosuppressive drugs such as azathioprine.

**Kawasaki’s disease**
Kawasaki’s disease is an acute systemic vasculitis involving medium-sized vessels, affecting mainly children under 5 years of age. It is very frequent in Japan and an infective trigger is suspected. Fewer than 10% of cases occur in adults.

Clinical features and management
The characteristic clinical features are fever lasting longer than 4 days, bilateral conjunctival congestion, dry red lips and oral cavity, cervical lymphadenopathy, rash and redness of the palms and soles.

Cardiovascular changes in the acute stage include pancarditis and coronary arteritis, leading to aneurysms or dilatation visible on echocardiography, MRI or angiography.

**Treatment** is with a single dose of high-dose intravenous immunoglobulin (2 g/kg), which prevents the coronary artery disease, followed after the acute phase by aspirin 200-300 mg daily. There is no evidence that steroid treatment improves the outcome.

**Primary central nervous system vasculitis** is a very rare condition (incidence 2–4 cases per million person years) characterized by clinical features confined to the central nervous system and characteristic appearances on angiography or cerebral biopsy. The most common clinical features are headache, altered cognition, focal weakness and stroke. Blood tests, including inflammatory markers and autoantibodies, are usually normal but a normal cerebral MRI essentially excludes the diagnosis.

Management of small-cell vasculitis
The treatment depends on the organs involved. Vasculitis confined to the skin may not require systemic treatment, whereas involvement of major organs (e.g. lungs or kidneys in GPA) requires high-dose corticosteroids, immunosuppression and, sometimes, plasma exchange. Clinical trials have shown that depletion of B cells with rituximab is as effective as cyclophosphamide in treating AAV and can help reduce the dose of corticosteroids required to maintain remission. In EPGA, the anti-interleukin 5 agent mepolizumab has been found to be effective in a clinical trial.

**Behçet’s disease**
Behçet’s disease is an inflammatory disorder of unknown cause. There is a striking geographical distribution, it being most common in Turkey, Iran and Japan. The prevalence per 100,000 is 10–15 in Japan and 80–300 in Turkey. There is a link to the HLA-B51 allele, with a relative risk of 5–10; this association is not seen in patients in the USA and Europe.

Clinical features
The cardinal clinical feature is recurrent oral ulceration. The international criteria for diagnosis require oral ulceration and any two of the following:
- genital ulcers
- defined eye lesions, including an anterior or posterior uveitis or retinal vascular lesions
- defined skin lesions – erythema nodosum, pseudofolliculitis and papulopustular lesions
- positive skin pathergy test (see below)
- oral ulcers – aphthous or herpetiform.

Other manifestations include a self-limiting peripheral mono- or oligoarthritis affecting knees, ankles, wrists and elbows; gastrointestinal symptoms of diarrhoea, abdominal pain and anorexia;
pulmonary and renal lesions; thrombophlebitis (especially in the legs); vasculitis; and a brainstem syndrome, organic confusional states and a meningoencephalitis. All the common manifestations are self-limiting except for the ocular attacks. Repeated attacks of uveitis can cause blindness.

The pathergy reaction is highly specific to Behçet’s disease. Skin injury – by a needle prick, for example – leads to papule or pus-tule formation within 24–48 hours. Blood tests usually show raised ESR and CRP but not autoantibodies.

Management
Corticosteroids, immunosuppressive agents and ciclosporin are used for chronic uveitis and the rare neurological complications. Colchicine helps erythema nodosum and joint pain. Thalidomide may be useful in some cases, although side-effects of drowsiness and peripheral neuropathy are common. It should not be used in pregnant women because of phocomelia (limb abnormalities). Anti-TNF agents can be used to control severe uveitis and serious manifestations such as neurological and gastrointestinal Behçet’s disease.

Further reading

ARTHRITIS IN CHILDREN

Joint and limb pains are common in children but arthritis is, fortunately, rare. Babies and young children may present with immobility of a joint or a limp, but the diagnosis can be extremely difficult. Fig. 18.40 summarizes the differential diagnosis.

Juvenile idiopathic arthritis

A full description of juvenile idiopathic arthritis (JIA) is beyond the scope of this textbook. A brief account is provided below.

JIA is classified according to the extent and type of joint involvement. A particularly severe form, systemic onset JIA (Still's disease) presents with high fever (>39°C), rash, lymphadenopathy, hepatosplenomegaly and/or serositis. Joint involvement is often not the most prominent symptom. High-dose corticosteroids and immunosuppressants such as methotrexate are used for treatment.

In contrast, patients with oligoarticular (<5 joints involved) and polyarticular (≥5 joints) JIA complain mainly of joint pain and swelling.

The oligoarticular form is more common. In childhood, these patients can develop uveitis and require regular screening by slit lamp examination. Outlook is usually good but approximately 25% develop an extended form where more joints can be involved over time leading to destructive arthritis persisting into adulthood.

Polyarticular JIA is divided into RF-positive and RF-negative subtypes, of which the RF-positive form is more aggressive.

Enthesitis-related arthritis tends to affect teenage and younger boys, mainly involves lower limb joints and entheses and is associated with HLA-B27 positivity.

RHEUMATOLOGICAL PROBLEMS SEEN IN OTHER DISEASES

Gastrointestinal and liver disease

- Enteropathic synovitis (see p. 451).
- Autoimmune hepatitis (see p. 1286) may be accompanied by an arthralgia similar to that seen in SLE. Joint pain occurs in a bilateral, symmetrical distribution, predominantly affecting the small joints of the hands. Joints usually look normal but sometimes there is a slight soft tissue swelling. These patients often have positive tests for antinuclear antibodies.
- Primary biliary cholangitis patients occasionally have a symmetrical arthropathy.
- Hereditary haemochromatosis is associated with arthritis in 50% of cases, which is often the first sign of the disease and cartilage calcification is common.
- Whipple’s disease (see p. 1194) is accompanied by fever and arthralgia.

Respiratory disease

Sarcoidosis

- Sarcoidosis (see p. 985) is a multisystem granulomatous disease associated with erythema nodosum in 20% of cases at or soon after the onset of the disease. A chest X-ray shows hilar lymphadenopathy in 80% of cases. The serum ACE may be raised.
Several patterns of arthritis occur later in the disease. These include a transient rheumatoid-like polyarthritis and an acute monoarthritis that can be mistaken for gout. Bone cysts can also develop.

**Treatment** is with NSAIDs; if these fail to control the symptoms, corticosteroids are usually very effective.

### Malignant disease

It is not uncommon for malignant diseases to present with muscular-skeletal symptoms. Gout occurs in conditions such as chronic myeloid leukaemia. Neoplastic disease of bone is described on page 485.

**Hypertrophic pulmonary osteoarthropathy**

Hypertrophic pulmonary osteoarthropathy (HPO) is a paraneoplastic, non-metastatic complication, frequently associated with carcinoma of the bronchus. It may be the presenting feature of the disease. It rarely occurs with other conditions that also cause clubbing, presenting most often in middle-aged men with pain and swelling of the wrists and ankles. Other joints are occasionally involved. Primary HPO is a hereditary condition involving a mutation in the HPGD gene that degrades prostaglandin E2 (PGE2), thus allowing over-production of PGE2, which may cause clubbing.

The diagnosis is made on the presence of clubbing of the fingers (usually gross in primary HPO) and periosteal new bone formation along the shafts of the distal ends of the radius, ulna, tibia and fibula on X-ray. A chest X-ray usually shows the malignancy.

**Management** should be directed at the underlying carcinoma; if this can be removed, the arthropathy disappears. NSAIDs relieve the symptoms.

**Paraneoplastic polyarthritis**

This condition is seen with carcinoma of the breast in women and of the lung in men, and also with renal cell carcinoma. The neoplasm may be occult at onset and the diagnosis is then difficult to make.

### Skin disease

**Psoriatic arthritis**

This disease is discussed on page 450.

**Erythema nodosum**

Erythema nodosum (see p. 677) is accompanied by arthritis in over 50% of cases. The knees and ankles are particularly affected, being swollen, red and tender. The arthritis subsides, along with the skin lesions, within a few months. Treatment is with NSAIDs or occasionally steroids.

### Neurological disease

**Neuropathic (Charcot’s) joints**

These are damaged by trauma as a result of the loss of the protective pain sensation. The site of the neuropathic joint depends on the localization of the pain loss:

- In tabes dorsalis, the knees and ankles are most often affected.
- In diabetes mellitus, the joints of the tarsus are involved.
- In syringomyelia, the shoulder is involved.

Neuropathic joints are not painful, although there may be painful episodes associated with crystal deposition. Presentation is usually with swelling and instability. Eventually, severe deformities develop.

The characteristic finding is a swollen joint with abnormal but painless movement, in association with neurological findings that depend on the underlying disease (e.g. dissociated sensory loss in syringomyelia or polyneuropathy in diabetes). X-ray changes are characteristic, with gross joint disorganization and bony distortion.

**Treatment** is symptomatic. Surgery may be required in advanced cases.

### Blood disease

Arthritis due to haemarthrosis is a common presenting feature of people with haemophilia (see p. 375). Attacks begin in early childhood in most cases and are recurrent. The knee is the most commonly affected joint but the elbows and ankles are sometimes involved. The arthritis can lead to bone destruction and disorganization of joints. Apart from replacement of factor VIII, affected joints require initial immobilization followed by physiotherapy to restore movement and measures to prevent and correct deformities.

**Sickle cell crises** (see p. 345) are often accompanied by joint pain that particularly affects the hands and feet in a bilateral, symmetrical distribution. Affected joints usually look normal but are occasionally swollen. This condition may also be complicated by avascular necrosis (see p. 425) and by osteomyelitis.

Arthritis can also occur in acute leukaemia (see p. 388); it may be the presenting feature in childhood. The knee is particularly affected and is very painful, warm and swollen. Treatment is directed at the underlying leukaemia. Arthritis may also occur in chronic leukaemia, with leukaemic deposits in and around the joints.

Individuals with transfusion-dependent thalassaemia (see p. 343) are living longer and are presenting with back pain due to premature disc degeneration, secondary spondylosis and crush fractures caused by osteoporosis. There is marked discal calcification.

### Endocrine and metabolic disorders

**Hypothyroid** patients may complain of pain and stiffness of proximal muscles, resembling polymyalgia rheumatica. They may also have carpal tunnel syndrome. Less often, there is an arthritis accompanied by joint effusions, particularly in the knees, wrist and small joints of the hands and feet. These problems respond rapidly to thyroxine.

**Hyperparathyroidism** may be complicated by cartilage calcification and acute CPPD.

In acromegaly, arthralgia occurs in about 50% of patients, particularly the small joints of the hands and knees. There may be a carpal tunnel syndrome.

In Cushing’s disease, back pain is common.

Joint disorders related to diabetes mellitus are described on page 735.

**Familial hypercholesterolaemia** is associated with oligo- or polyarthritis, usually with tendon xanthomata. Arthritis also occurs in combined hyperlipidaemia.

### MISCELLANEOUS ARTHROPATHIES

**Familial Mediterranean fever**

Periodic fever syndromes are a group of autoinflammatory disorders that present with recurrent attacks of fever in childhood and adult life.
Familial Mediterranean fever (FMF) is the most common inherited autoinflammatory disease. It is an autosomal recessive condition recognized worldwide but most prevalent in populations originating from the eastern Mediterranean. Mutations in the MEFV gene on chromosome 16 that encodes for pyrin, a suppressor of the activation of caspase 1, leads to increased biosynthesis of IL-1β and inflammation in FMF.

Symptoms of FMF are recurrent episodes of fever, arthritis and serositis. Peritonitic abdominal pain occurs in 80% of attacks. Pleuritic chest pain occurs in 15% of cases and is unilateral. Arthritis is rare and usually monoarticular, lasting up to 1 week. The CRP is markedly raised during the attacks. The condition may be mistaken for palindromic rheumatism (see p. 441), but such attacks are not usually accompanied by fever.

The diagnosis can be made by PCR, if available, but is based on the clinical picture and exclusion of other conditions.

**Treatment** involves lifelong colchicine 1000–1500 μg daily, which can usually prevent the attacks. In resistant patients, IL-1 inhibitors (anakinra and canakinumab) are licensed. In general, the disorder is benign, but in 25% of cases, renal amyloidosis develops (see p. 1357).

Other periodic fevers are being increasingly recognized. These include tumour necrosis factor receptor-associated periodic syndrome (TRAPS), mevalonate kinase deficiency (MKD), cryopyrin-associated periodic syndrome (CAPS), and periodic fever, aphthous stomatitis, pharyngitis and adenitis (PFAPA).

**SAPHO (synovitis, acne, palmoplantar pustulosis, hyperostosis, osteitis)**

This rare autoinflammatory disorder, linked to various HLA associations, dysregulation of IL-1 and *Cutibacterium acnes* infection, is considered on a spectrum with SpA, autoinflammatory disorders and pustular dermatoses. It produces chronic multifocal osteitis with anterior chest wall pain and peripheral synovitis. There is inflammatory cytokine release and global neutrophil activation. NSAIDs, methotrexate or TNF inhibitors (see pp. 444–445) may help.

**Osteochondromatosis**

In this condition, focci of cartilage form within the synovial membrane. These focci become calcified and then ossified (osteochondromas). They may give rise to loose bodies within the joint. The condition occurs in a single joint of a young adult and X-rays are usually diagnostic.

**Management** involves removal of loose bodies and synovectomy.

**Pigmented villonodular synovitis**

This is characterized by exuberant synovial proliferation that occurs either in joints or in tendon sheaths. The main manifestation in joints is recurrent haemarthrosis. It may produce progressive local bone destruction. A malignant form is seen occasionally.

**Management** is synovectomy or radiotherapy for more widespread cases or those that have failed surgery.

**Relapsing polychondritis**

Relapsing polychondritis is a rare inflammatory condition of cartilage. It occurs equally in males and females, usually the elderly. Tenderness, inflammation and eventual destruction of cartilage occur, mainly in the ear, nose, larynx or trachea. A seronegative polyarthritis occurs, as well as episcleritis and evidence of a vasculitis (e.g. glomerulonephritis). The diagnosis is clinical with laboratory evidence of acute inflammation.

**Treatment** involves corticosteroids and immunosuppressive agents.

**Further reading**

Bone disease is common in the general population, although frequently undiagnosed and often asymptomatic. Some 50% of women and 25% of men will suffer an osteoporotic fracture in their lifetime. Bone diseases are even more prevalent in those with coexisting medical conditions and the elderly. Bone disease specialists work in a variety of disciplines including general practice, rheumatology, endocrinology and medicine for the elderly, dividing their time between outpatient bone health clinics and inpatient fracture liaison services. Specialist nurses, radiographers, orthopaedic surgeons and allied health professionals all have important roles in helping to care for patients with bone disease.

Key learning objectives in bone disease include:

- understanding osteoporosis – its causes, diagnosis and treatment
- knowing when to investigate for other bone disorders, including bone infections and malignancy
- understanding ‘bone profile’ blood tests, dual X-ray absorptiometry (DXA) scanning and fracture risk assessment tools.

Learning opportunities in bone health include attending specialist bone health clinics, and attending fracture liaison service ward rounds where the underlying causes of fragility fractures are addressed.

### CLINICAL SKILLS FOR BONE DISEASE

#### History

**Clinical features**

- Bone disease such as osteoporosis is often asymptomatic.
- **Severe, acute-onset pain** suggests a fracture (Box 19.1), which can occur with minimal trauma if the bone is fragile due to osteoporosis or malignancy.
- **Progressive localized bone pain** may suggest primary or secondary malignancy, or localized Paget’s disease.

**Risk factors for osteoporosis:**

- Increased age.
- Early menopause without use of hormone replacement therapy.
- Hypogonadism in men.
- Corticosteroid use.
- Intestinal malabsorption.
- Obesity.
- Immobility.

#### Examination

Bone disease often presents with no physical signs, particularly in developed countries where good diet, early diagnosis and effective management of infectious disease prevent serious abnormalities. The commonest anatomical sites for various diseases of bone to occur are shown in the diagram; physical signs will vary from severe acute deformity and pain (if fracture occurs), through varying levels of tenderness, swelling and deformity in slowly progressive disease, to no observable changes in clinically silent disease.
Biochemical tests

A number of biochemical tests can be used to investigate the presence of bone disease. These are best described by their use in different clinical settings: in a patient with a fracture, or in patients with bony pain, or no symptoms at all (when these abnormalities may be picked up incidentally during routine or screening blood tests) (Boxes 19.2 and 19.3).

### Box 19.1 Evaluation of a patient with a fracture

#### Why has fracture occurred?
- Traumatic – high impact trauma
- Fragility – force equivalent to fall from less than standing height – implies osteoporosis or other bone disorder
- Pathological – consider when multiple fractures, systemic symptoms, unusual sites.

#### Investigations of fragility fracture
- Calcium/phosphate/magnesium
- 1,25 dihydroxyvitamin D/parathyroid hormone/alkaline phosphatase
- Myeloma screening – serum electrophoresis, serum and urine free light chains, immunoglobulins
- Dual X-ray absorptiometry (DXA) scanning.

#### Treatment of fragility fracture
- Fracture risk assessment
- Most patients with fragility fracture have osteoporosis and warrant treatment
- Calcium/vitamin D if required
- Oral bisphosphonate
  - Denosumab is alternative
  - Consider recombinant parathyroid hormone (PTH) if very high risk.

ANATOMY AND PHYSIOLOGY OF BONE

Bone is a specialized connective tissue serving three major functions:
• **mechanical** – supplying structure and muscle attachment for movement
• **metabolic** – providing the body’s primary store of calcium and phosphate
• **protective** – enclosing the marrow and other vital organs.

This chapter covers the connective tissue functions of bone; bone marrow function is discussed in Chapter 16.

Bone structure

Bone comprises cells and a matrix of organic protein and inorganic mineral. Long bones (femur, tibia, humerus) and flat bones (skull, scapula) have different embryological templates, with varying proportions of cortical and trabecular bone.
- **Cortical (compact or lamellar) bone** forms the shaft of long bones and the outer shell of flat bones. Formed of concentric rings of bone, it is particularly adapted to withstand bending strain.
- **Trabecular (cancellous) bone** is found at the ends of long bones and inside flat bones. Comprising a network of interconnecting rods and plates of bone, it offers resistance to compressive loads. It is also the main site of bone turnover for mineral homeostasis.
- **Woven bone** lacks an organized structure. It appears in the first few years of life, at sites of fracture repair and in high-turnover bone disorders such as Paget’s disease.

Matrix components

- **Type I collagen** is the main protein, forming parallel lamellae of differing density (which impairs spreading of cracks). In cortical
bone, concentric lamellae form around a central blood supply (Haversian system), which communicates via transverse (Völkmann’s) canals.

- **Non-collagen proteins** include osteopontin, osteocalcin and fibronectin.
- **Bone mineral** largely consists of calcium and phosphate in the form of hydroxyapatite.

**Bone cells**

**Osteoblasts**

Derived from local mesenchymal stem cells, these cells synthesize matrix (osteoid) and regulate its mineralization. After bone formation, the majority of osteoblasts are removed by apoptosis, others remaining at the bone/marrow interface as lining cells or within the bone as osteocytes. Osteoblasts regulate bone resorption through the balance in expression of the stimulatory receptor activator of nuclear factor kappa B ligand (RANKL) and its antagonist, osteoprotegerin (OPG). Osteoblasts are rich in alkaline phosphatase and express receptors for parathyroid hormone (PTH), oestrogen, glucocorticoids, vitamin D, inflammatory cytokines and the transforming growth factor-beta (TGF-β) family, all of which may therefore influence bone remodelling.

**Osteocytes**

These small cells, derived from osteoblasts, are embedded in bone and interconnected with each other and with bone-lining cells through cytoplasmic processes. They respond to mechanical strain by undergoing apoptosis or through altered cell signalling, which in turn activates bone formation with or without prior resorption. As osteocytes also express RANKL and OPG, the relative importance of osteocytes and osteoblasts in bone resorption function continues to be explored.

**Osteoclasts**

These cells have the unique capacity to resorb bone and are derived from haemopoietic precursors of the macrophage lineage. In response to RANKL, macrophage colony stimulating factor (M-CSF) and local adhesion factors (integrins), osteoclasts attach to bone, creating a ruffled border that forms a number of extracellular lyosomal compartments. Hydrogen ions are actively secreted into these spaces and the acid environment removes the mineral phase before specialized cysteine proteases (e.g. cathepsin K) resorb the collagen matrix.

**Bone growth and remodelling**

Longitudinal growth occurs at the epiphyseal growth plate, a cartilage structure between the epiphysis and metaphysis (Fig. 19.1). Cartilage production is tightly regulated, with subsequent mineralization and growth finally arrested at 18–21 years, when the epiphysis and metaphysis fuse.

In adults, bone is regularly remodelled to ensure repair of microdamage and turnover of calcium and phosphate for homeostasis. This remodelling cycle is carried out by the basic multicellular unit (BMU; Fig. 19.2). Signals initiating resorption include osteocyte apoptosis and altered signalling (sclerostin, prostaglandins, RANKL and other molecules), resulting in localized retraction of bone-lining cells and binding of multinucleate osteoclasts to the bone surface, followed by bone resorption. Bone formation involves reciprocal effects of wnt versus dickkopf (Dkk) and sclerostin on the LRP5/6-β-catenin pathway. The switch from resorption to formation may rely on osteocyte signalling or on release of signals from the bone matrix, such as TGF-β. Bone remodelling is said to be coupled when formation follows resorption, but may be unbalanced when the amount of bone removed is not replaced with an equal amount. Examples of bone remodelling include:

- Myeloma cells have dual lytic effects, with enhanced expression of RANKL and Dkk
- In rheumatoid arthritis, RANKL and Dkk are increased
- In spondyloarthritis (characterized by new bone formation alongside erosion) Dkk is inhibited, with the increased wnt activity also increasing OPG relative to RANKL
- Corticosteroids may increase osteocyte SOST expression, and stimulate expression of Dkk.

**Calcium homeostasis and its regulation**

Calcium homeostasis is regulated by the effects of PTH and 1,25-dihydroxyvitamin D₃ on gut, kidney and bone. Calcium-sensing receptors are present in the parathyroid glands, kidney and brain.

**Calcium absorption and distribution**

Daily calcium consumption (Fig. 19.3), primarily from dairy foods, is 20–25 mmol (800–1000 mg). The combined effect of calcium and vitamin D deficiency contributes to the bone fragility seen in some older people. Intestinal absorption of calcium is reduced by vitamin D deficiency and in malabsorption states (see p. 1245).

**Vitamin D metabolism**

The primary source of vitamin D (Fig. 19.4) in humans is photoactivation in the skin of 7-dehydrocholester to cholecalciferol, which
is then converted first in the liver to 25-hydroxyvitamin D (25(OH) D₃) and subsequently in the kidney (by the enzyme 1α-hydroxylase) to 1,25-dihydroxyvitamin D₃. (This step can occur in lymphomatous and sarcoid tissue, resulting in hypercalcaemia.) Regulation of the latter step is by PTH, phosphate and feedback inhibition by 1,25-dihydroxyvitamin D₃.

**Parathyroid hormone**

Parathyroid hormone (PTH), an 84-amino-acid hormone, is secreted from the chief cells of the parathyroid gland, which have calcium-sensing and vitamin D receptors. PTH increases renal phosphate excretion and increases plasma calcium by:

- increasing osteoclastic activity in bone (a rapid response)
- increasing intestinal absorption of calcium (a slower response)
- increasing 1α-hydroxylation of vitamin D (the rate-limiting step)
- increasing renal tubular reabsorption of calcium.

Hypomagnesaemia can suppress the normal PTH response to hypocalcaemia.

**Calcitonin**

Calcitonin is produced by thyroid C cells. Although calcitonin inhibits osteoclastic bone resorption and increases the renal excretion of calcium and phosphate, neither excess calcitonin (seen in medullary carcinoma of the thyroid) nor its deficiency following thyroidectomy has significant skeletal effects in humans.

**Further reading**

http://courses.washington.edu/bonephys/ Bone physiology.
Bone disease

**Plasma PTH**

*Normal range is 10–65 pmol/L (1.3–7.6 ng/mL).* The PTH assay measures the intact hormone. In hypercalcaemia not due to hyperparathyroidism, serum PTH levels are suppressed. Lithium toxicity may be associated with raised PTH levels; in familial hypocalciuric hypercalcaemia (FHH), serum PTH may be normal or marginally elevated.

**Serum 25-hydroxyvitamin D**

Vitamin D status is best assessed using serum 25-hydroxyvitamin D, as 1,25-dihydroxyvitamin D₃ has a short half-life and does not accurately reflect true vitamin D status. *Vitamin D deficiency* is defined as <25 nmol/L (10 ng/mL) and *vitamin D insufficiency* as less than 75 nmol/L (30 ng/mL). Rickets and osteomalacia occur with prolonged vitamin D deficiency.

The significance of vitamin D insufficiency is uncertain but it has been linked to a wide range of conditions, including ischaemic heart disease, multiple sclerosis and a variety of cancers. Recent evidence suggests that racial differences are present in the assessment of vitamin D status. Black Americans have consistently lower levels of 25-hydroxyvitamin D₃ than white Americans but also lower levels of vitamin D-binding protein, resulting in equivalent bioavailable 25-hydroxyvitamin D₃.

**24-hour urinary calcium**

*Normal range 2.5–7.5 mmol/24 h (100–300 mg/24 h).* This is increased where renal tubular reabsorption of calcium is decreased, and in hypercalcaemia. One exception is FHH, where the genetic defect leads to inappropriately reduced calcium excretion. Measurement of 24-hour urinary calcium excretion should be performed in the assessment of hypercalcaemic patients.

**Biochemical markers of bone formation and resorption**

The clinical use of these biochemical markers is limited by large biovariability and measurement variance. Serial measurements at the same time of day in individual patients are useful in assessing response to treatment of metabolic bone diseases.

- **Bone-specific alkaline phosphatase.** Circulating alkaline phosphatase is derived from bone, liver, neutrophils and placenta. The bone-specific isoenzyme can be measured as a marker of formation, although there is some overlap with the liver isoenzyme. Elevated serum levels occur during bone growth: for example, in adolescents, fracture repair and high-bone-turnover states.
- **Type 1 collagen pro-peptides.** These are by-products of collagen synthesis. Serum levels of both the carboxyterminal (P1CP) and aminoterminal (P1NP) pro-peptides reflect bone formation.
- **Serum osteocalcin.** This is another bone formation marker.
- **Serum or urine levels of N-terminal (NTX) and C-terminal (CTX) cross-linked telopeptides.** These reflect bone resorption. They may change rapidly in response to anti-resorptive drugs or in disease states, and have been used to assess fracture risk.

**Diagnostic imaging**

- **Plain radiographs.** These identify fractures, tumours and infections. Other specific features may be seen (see following sections).
- **Radionucleotide imaging.** The uptake of a ⁹⁹ᵐTc-labelled bisphosphonate in bone reflects bone turnover and blood flow. Increased uptake is therefore seen in fractures, tu-
Osteoporosis is defined as ‘a disease characterized by low bone mass and micro-architectural deterioration of bone tissue, leading to enhanced bone fragility and an increase in fracture risk’.

Using bone densitometry at the hip or spine measured by dual X-ray absorptiometry (DXA), the World Health Organization (WHO) also defines osteoporosis as a bone density of 2.5 standard deviations (SDs) below the young healthy adult mean value (T-score ≤ −2.5) or lower. Values between −1 and −2.5 SDs below the young adult mean are termed ‘osteopenia’. The rationale for this definition is the inverse relationship between bone mineral density (BMD) and fracture risk in postmenopausal women and older men. However, this definition should not be applied to younger populations.

Fractures due to osteoporosis are a major cause of morbidity and mortality in elderly populations, with osteoporotic fractures of the spine causing acute pain or deformity and postural back pain. One in two women and one in five men aged 50 years will have an osteoporotic fracture during their remaining lifetime. As the risk of fracture increases with age, changing population demographics will increase the burden of disease.

Pathogenesis

Osteoporosis results from increased bone breakdown by osteoclasts and decreased bone formation by osteoblasts, leading to loss of bone mass.

Bone mass decreases with age (Fig. 19.6) but will depend on the “peak” mass attained in adult life and on the rate of loss in later life. Genetic factors are the single most significant influence on peak bone mass. Multiple genes are involved, including collagen type 1A1, vitamin D receptor and oestrogen-receptor genes. Nutritional factors, sex hormone status and physical activity also affect peak mass. Not all causes of osteoporosis affect bone remodelling and architecture in the same way.

Oestrogen deficiency results in increased numbers of remodelling units, premature arrest of osteoblastic synthetic activity and perforation of trabeculae, with a loss of resistance to fracture that is not fully reflected in the bone density measurement.
**Bone disease**

*Glucocorticoids* induce a high-turnover state initially, with increased fracture risk evident within 3 months of starting therapy. More prolonged use leads to a reduced-turnover state but with a net loss due to reduced synthesis (through inhibition of the wnt-LRP5/6 axis).

*Aging* results in increased turnover at the bone/vascular interface within cortical bone, resulting in structural weakness (trabecularization of cortical bone).

**Risk factors**

Risk factors for fracture may exert their effect through reducing BMD, or they may increase risk over that attributable to BMD (BMD-independent) ([Box 19.4](#)). Oestrogen deficiency is a major factor in the pathogenesis of accelerated bone loss due to a normal or premature menopause, or amenorrhea in patients with anorexia nervosa and in athletes. In the elderly, vitamin D insufficiency and consequent hyperparathyroidism reduce BMD. However, previous fracture, increasing age, glucocorticoid therapy, smoking and falls increase the risk of fracture at any given BMD. For instance, 10% of women who are 65 years old and have a T-score of –2 at the hip would be expected to sustain a fracture over the next 10 years; if similar women had a Colles’ fracture, smoked and had prolonged exposure to steroids, their risk would be closer to 26% in the same period.

**Box 19.4 Risk factors for fragility fractures**

**Bone mineral density-dependent**
- Female sex
- Caucasian/Asian ethnicity
- Gastrointestinal disease
- Hypogonadism
- Immobilization
- Chronic liver disease
- Chronic kidney disease
- Low dietary calcium intake
- Vitamin D insufficiency
- Chronic obstructive pulmonary disease
- Cushing’s syndrome
- Hyperthyroidism
- Hyperparathyroidism
- Diabetes mellitus
- Mastocytosis
- Multiple myeloma
- Osteogenesis imperfecta

**Drugs**
- Heparin
- Calcineurin inhibitors, e.g. ciclosporin
- Anticonvulsants
- Thiazolidinediones
- Aromatase inhibitors
- Anti-androgens
- Gonadotrophin-releasing hormone (GnRH) analogues
- Proton pump inhibitors
- Selective serotonin reuptake inhibitors

**Bone mineral density-independent**
- Increasing age
- Previous fragility fracture
- Family history of hip fracture
- Low body mass index
- Smoking
- Excess alcohol use
- Glucocorticoid therapy
- High bone turnover
- Increased risk of falling
- Rheumatoid arthritis

BMD-dependent risk factors respond to bone-directed treatment. BMD-independent risk factors benefit from additional targeted intervention (e.g. reduction of falls risk – see p. 306).

**Clinical features**

Fracture is the only cause of symptoms in osteoporosis. *Vertebral fracture* is suggested by the sudden onset of severe back pain. However, two in every three vertebral fractures are asymptomatic. Pain from mechanical derangement, increasing kyphosis, height loss and abdominal protuberance may follow vertebral fracture. *Colles’ fractures* typically follow a fall on an outstretched arm. *Fractures of the proximal femur* usually occur in older individuals falling on their side or back.

Other causes of low-trauma fractures must not be overlooked, including metastatic disease and myeloma.

**Investigations**

*Plain X-rays* (Fig. 19.7) may show fractures including previously asymptomatic vertebral fractures. Such clinically silent fractures may also be detected during Dxa scanning with an additional analysis (called *vertebral fracture assessment*, [Box 19.5](#)) carried out with a much lower radiation dose than conventional imaging. Increased bone radiolucency suggests low BMD but requires confirmation with DXA.

**Bone density**

*DXA* measures areal bone density (mineral per surface area rather than a true volumetric density), usually of the lumbar spine and proximal femur. It is precise and accurate, uses low doses of radiation and is the “gold standard” in diagnosis of osteoporosis (Fig. 19.8). Because of osteophytes, spinal deformity and vertebral fractures, spinal values may be artefactually elevated and should be interpreted with caution in the elderly.

**Associated disease and risk factors**

Investigations to exclude other diseases or identify contributory factors associated with osteoporosis should be performed and are particularly necessary in men, in whom secondary causes are more common (see [Box 19.4](#)).

**Selection of individuals for treatment: risk assessment**

The goal of osteoporosis treatment is to reduce fracture risk ([Box 19.6](#)). Thus, assessment of absolute fracture risk should be made in every case. A previous fracture is the strongest risk factor for further fractures. DXA is useful in guiding treatment decisions ([Box 19.7](#); Fig. 19.8). Patients with a previous fragility fracture or a BMD T-score less than or equal to –2.5 should be considered for treatment. It is vital to recognize, however, that the majority of fragility fractures occur in women with a T-score better than –2.5 (Fig. 19.9). In these patients an assessment for future fracture risk should be made; this can be performed using clinical judgement by an experienced physician or using formal risk calculators, for example FRAX ([Box 19.8](#)). The threshold for recommending treatment in this setting will be determined by the cost-effectiveness of treatment in a particular healthcare setting and by clinical judgement. For example, in the USA, the National Osteoporosis Foundation recommends treatment if the 10-year probability of hip fracture is more than or equal to 3% or if major osteoporotic fracture is more than or equal to 20%.
Prevention and management

- **Symptomatic management.** New vertebral fractures may require bed rest for 1–2 weeks with strong analgesia and gradual physiotherapy to restore confident mobilization (see p. 424). Non-spinal fractures should be treated by conventional orthopaedic means. In fractured neck of femur, early surgical intervention, and early mobilization post-surgery, are associated with improved outcomes.

- **Calcium and vitamin D.** Daily intakes of 800–1200mg of calcium and 400–800IU of vitamin D are recommended throughout life for optimum bone health. Dietary intake of calcium, and vitamin D from sunshine and diet, are preferable. For those not meeting calcium intake targets, or those with low serum 25-hydroxyvitamin D₃ levels, supplements are recommended (Box 19.9).

- **Lifestyle measures.** Weight-bearing exercise for 30 minutes three times a week may increase BMD, while gentle exercise in the elderly may reduce the risk of falls and improve the protective responses to falling (see p. 306). Smoking and excess alcohol use should be avoided.

**Pharmacological intervention**

Most interventions (see Fig. 19.5) act by inhibiting bone resorption (anti-resorptives), the exception being PTH peptides, which stimulate bone formation. The impression from bone turnover markers that strontium ranelate may have both anti-resorptive and stimulatory effects remains poorly understood.

The evidence base for the **anti-fracture efficacy** of interventions varies. Treatments with proven efficacy at all major fracture

**Box 19.6 Management of osteoporosis: summary**

*Treatment is guided by risk of fracture, not BMD alone.*

Fracture risk assessment should be performed, either using clinical judgement or a formal risk assessment calculator (e.g., http://www.shef.ac.uk/FRAX and many others; see Box 19.8).

Do not under-estimate the risk from steroids or previous fracture.

**Oral bisphosphonates** (alendronate, risedronate) are first-line treatment in many cases. Other options include:

- **denosumab**:
  - difficulty taking bisphosphonate
  - poor adherence to treatment
  - failing BMD on bisphosphonate
  - new fracture on a bisphosphonate
  - after 5–10 years on bisphosphonate
- **teriparatide** if there are multiple vertebral fractures or very low BMD
- **i.v. zoledronate** after hip fracture.

**BMD monitoring** is recommended in:

- all treated patients to monitor therapy
- all untreated cases if a BMD reduction would lead to treatment.

BMD, bone mineral density; DXA, dual-energy X-ray absorptiometry.

---

**Box 19.7 DXA scanning**

**Indications for DXA scanning**

- Women aged ≥65
- Men aged ≥70
- Frailty fracture
- Women <65 with risk factors (see Box 19.4)
- Men <70 with risk factors (see Box 19.4)
- Monitoring of BMD in those on treatment

**Features of DXA scanning**

- Low-dose radiation X-ray
- Measures a real BMD
- Gives BMD in g/cm², which is difficult to interpret so translated to T or Z score
- T-score generated by comparing result with female, white, aged 20–29 years taken from the NHANES III study database.
- Z score generated by comparing result with person of same age and ethnicity and used to report to report BMD in pre-menopausal women and men aged <50

**Interpretation of DXA**

BMD measured at lumbar spine, total hip, femoral next (+ radius)

In postmenopausal women and men aged ≥50:

- T-score ≤−2.5 = osteoporosis
- T-score ≤−1.0 to −2.5 = osteopenia/low BMD
- T-score >−1.0 = normal BMD
- Z scores ≤−2.0 is ‘low BMD for age’

Interpretation of Z scores is complex and beyond the scope of this text.

BMD, bone mineral density; DXA, dual-energy X-ray absorptiometry.

---

**Box 19.8 Fracture risk assessment**

Fracture risk assessment:

- Should be performed in all patients
- Can be performed clinically or using risk assessment calculators. FRAX is one of a number of fracture risk assessment tools available:
- Treatment is generally indicated if a 10-year major fracture risk ≥20% or hip fracture risk ≥3%
- These tools enable quantification of fracture risk and guide treatment decisions
- They provide estimates of fracture risk based on a set number of variables
- In certain situations they will not accurately estimate fracture risk so must be used in combination with clinical judgement

---

**Box 19.9 Management of vitamin D deficiency**

**Treatment phase**

- Vitamin D 50 000 iu weekly PO × 6–8 weeks or vitamin D 30 000 iu IM × 2 doses

**Maintenance phase**

- Vitamin D 800–1000 iu daily PO × lifelong

---

Bisphosphonates are generally well tolerated but may be associated with upper gastrointestinal side-effects such as oesophagitis, particularly if the dosing instructions are not closely followed. Bisphosphonates should be used with careful monitoring in patients who have chronic kidney disease (stage 4 or 5). Osteonecrosis of the jaw is a rare complication of high-dose intravenous bisphosphonates in patients who have malignant disease. It is associated with poor dental hygiene. As prolonged suppression of bone turnover is linked with atypical femoral fractures, it is currently advised to reassess bisphosphonate
treatment after 5 years. Only those with vertebral fractures and a T-score at the neck of femur below −2.5 at this 5-year scan appear to have a reduced risk of fracture with continued treatment.

Denosumab

Denosumab is a fully human monoclonal antibody to RANKL administered as a single subcutaneous injection every 6 months. It is an anti-resorptive agent that increases BMD and reduces fractures at the spine, hip and other non-vertebral sites. Fracture risk reduction is equivalent to that of bisphosphonates. Unlike bisphosphonates, the benefit of denosumab is rapidly lost on cessation, therefore if stopped it should be replaced by an alternative agent. Adverse effects are infrequent: most commonly dysuria, rarely cellulitis. Osteonecrosis of the jaw and atypical femoral fractures have also been reported.

Strontium ranelate

This is rarely used due to concerns over cardiovascular and thromboembolic adverse events. It has weak anti-resorptive activity whilst maintaining bone formation. It reduces the risk of vertebral fractures in postmenopausal women with osteoporosis, and the risk of hip and other non-vertebral fractures in high-risk subgroups (women with previous fracture and T-scores at the hip of −2.4 or less).

Selective oestrogen-receptor modulators

Selective oestrogen-receptor modulators (SERMs) include raloxifene and bazedoxifene. They are rarely used to treat osteoporosis. They have no stimulatory effect on the endometrium but activate oestrogen receptors in bone. Both prevent BMD loss at the spine and hip in postmenopausal women but have been found to reduce only vertebral fracture rates. Leg cramps and flushing may occur, and the risk of thromboembolic complications is also increased to a degree similar to that seen with hormone replacement therapy (HRT; see p. 1468 and Box 39.3). The use of SERMs is associated with a small increase in the risk of stroke.

Recombinant human parathyroid hormone

Recombinant human PTH peptide 1–34 (teriparatide) and recombinant human PTH 1–84 are anabolic agents that stimulate bone formation. Teriparatide reduces vertebral and non-vertebral fractures in postmenopausal women with established osteoporosis, although data on hip fracture are not available. It is given by daily subcutaneous injection for 24 months. Recombinant human PTH 1–84 is also administered by once-daily subcutaneous injection but has been shown to reduce only vertebral fractures. An anti-resorptive drug should be given on completion of PTH peptide therapy to maintain the increase in BMD. Non-osteoporotic bone diseases, such as osteomalacia, should be excluded prior to treatment. PTH peptide therapy is difficult for patients to take and associated with more adverse events than other agents and therefore is mainly indicated in severe cases of vertebral osteoporosis or in those who fail to respond to other therapies. Teriparatide may cause mild transient hypercalcaemia but routine monitoring is not required. Nausea and head ache may occur. Recombinant human PTH 1–84 is associated with a higher incidence of hypercalcaemia and hypercalciuria, and routine monitoring is advised. Neither agent should be used in people with skeletal metastases or osteosarcoma.

**Hormone replacement therapy**

Because of its adverse effects on breast cancer and cardiovascular disease risk, HRT is not indicated for osteoporosis except in early postmenopausal women who also have significant perimenopausal symptoms.

**Calcitriol (1,25-dihydroxyvitamin D₃) and calcitonin**

These may reduce vertebral fracture rate, although the data are inconsistent.

**Combination therapies**

Combination therapies, either with two anti-resorptive agents, or an anti-resorptive and an anabolic agent, often produce larger increases in BMD than monotherapy but have not been shown to result in greater fracture reduction.

**Surgery**

This is very rarely indicated in osteoporotic vertebral fractures. Percutaneous vertebroplasty and balloon kyphoplasty are discussed on page 424. Hip fractures are dealt with by hip replacements or stabilization with pins.

**Treatment of specific conditions**

**Glucocorticoid-induced osteoporosis**

Individuals requiring continuous oral glucocorticoid therapy for 3 months or more (at any dose) should be assessed for coexisting risk factors (age, previous fracture, hormone status). Postmenopausal women, men aged over 50 years and any individuals who have sustained a fragility fracture should receive treatment without waiting for DXA scanning. DXA results and fracture risk assessment guide treatment for other patients (see Boxes 19.5, 19.7 and 19.8). Bisphosphonates, denosumab and teriparatide are approved in this setting.

**Osteoporosis in men**

Alendronate, risedronate, denosumab and teriparatide are approved for use in men. In men with osteoporosis who have clinical and biochemical evidence of hypogonadism, testosterone replacement is also used.

**Further reading**

OSTEONECROSIS

This is also known as aseptic, avascular or ischaemic necrosis of bone. Over 80% of cases are attributed to glucocorticoid treatment or alcohol excess. Less frequent causes include sickle cell disease, systemic lupus erythematosus (SLE), deep-sea diving (Caisson’s disease), endocrine disorders (e.g. Cushing’s, diabetes mellitus), trauma, human immunodeficiency virus (HIV) infection and irradiation.

Osteonecrosis usually presents with joint pain, the shoulder or hip being most commonly affected, but can be asymptomatic, particularly on the opposite side in the same person. It may only be recognized when it results in collapse of the articular bone.

MRI best confirms the diagnosis by showing bone marrow oedema. If advanced, it can be seen on plain X-rays.

Management is mainly symptomatic. Surgical options include drilling through the bone cortex (decompression), vascularized bone grafts, or rotation of the affected bone away from the load-bearing area; however, joint replacement is often required. Bisphosphonates may reduce pain, and progression has been reduced with statin therapy in steroid-associated osteonecrosis.

PAGET’S DISEASE OF BONE

Paget’s disease of bone is a focal disorder of bone remodelling. Increased osteoclastic bone resorption is followed by a compensatory increase in new bone formation, increased local bone blood flow and fibrous tissue in adjacent bone marrow. Ultimately, formation exceeds resorption but the new woven bone is weaker than normal bone, which leads to deformity and increased fracture risk. Paget’s disease does not spread but can become symptomatic at previously silent sites.

Epidemiological studies are difficult because most affected individuals are asymptomatic. Paget’s disease is most often seen in Europe and particularly in northern England. It affects men and women (2:3) over the age of 40 years. The incidence approximately doubles per decade thereafter, with up to 10% of individuals radiologically affected by the age of 90. For unknown reasons, the incidence and severity of Paget’s disease have decreased in recent years.

Aetiology and pathogenesis

Genetic factors are implicated in Paget’s disease. A positive family history is noted in about 15%. Mutations in SQSTM1, which encodes the osteoclast mediator protein p62, have been reported in up to 10% of cases. Intracellular inclusions in the osteoclasts in pagetic lesions are believed to be paramyxovirus nucleocapsid (e.g. canine distemper virus, measles or respiratory syncytial virus). However, similar inclusions are seen in other bone disorders, and theories of a viral aetiology in Paget’s remain contentious. Altered expression of c-fos (an oncogene) is one suggested mechanism linking viral infection with the pathogenic changes in osteoclasts, which are more numerous and contain an increased number of nuclei (up to 100).

Clinical features

Clinical features are summarized in Fig. 19.10A. Between 60% and 80% of people with radiologically identified Paget’s disease are asymptomatic. Diagnosis often follows the finding of an asymptomatic elevation of serum alkaline phosphatase, or a plain X-ray performed for other indications. The disease may involve one bone (monostotic, in 15%) or many (polystotic). The most common sites, in order of frequency, are pelvis, femur, lumbar spine, skull and tibia (see Fig. 19.10C). Small bones of the feet and hands are rarely involved.

![Fig. 19.10 Paget's disease. (A) Clinical features. (B) X-ray appearance of the pelvis, showing osteolytic (thin arrow) and osteosclerotic (thick arrow) lesions. (C) Legs showing bowing of the tibia caused by increased bone growth. Note the erythema ab igne on the medial aspect of the thigh.](image-url)
Symptoms and complications include:

- bone pain
- joint pain when an involved bone is close to a joint, leading to cartilage damage and osteoarthritis
- deformities, in particular bowed tibia and skull changes
- neurological complications – nerve compression (deafness from VIIIth cranial nerve involvement; cranial nerves II, V and VII may also be involved); spinal stenosis; hydrocephalus due to blockage of the aqueduct of Sylvius
- high-output cardiac failure and myocardial hypertrophy due to increased bone blood flow (rarely seen with modern management)
- hypercalcaemia – rarely seen outside the setting of fracture
- pathological fractures
- osteosarcoma – occurs in fewer than 1% of cases of Paget’s and may be heralded by an increase in bone pain or swelling in a previous pagetic bone area.

**Investigations**

- **Increased serum alkaline phosphatase** with normal serum calcium and phosphate reflects increased bone turnover. Levels may be normal with limited or monostotic Paget’s disease. Levels are reduced with treatment and increased during relapse.
- **Vitamin D** should be measured, as deficiency is frequent in the age group affected by Paget’s disease and should be corrected (see Box 19.9) to avoid hypocalcaemia following bisphosphonate treatment.
- **X-ray** features (see Fig. 19.10B) vary from predominantly lytic lesions (osteoporosis circumspecta in the skull is characteristic), through a mixed phase, to a mainly sclerotic phase of bone expansion, cortical thickening and coarsening of the trabecular pattern.
- **Isotope bone scans** are useful to determine the extent of skeletal involvement but are unable to distinguish between Paget’s disease and sclerotic metastatic carcinoma (especially breast and prostate).

**Management**

Bisphosphonates are the mainstay of treatment. New bone formed after treatment is lamellar, not woven (reflecting normalization of bone turnover rather than a direct effect on osteoblasts). Repeat treatment courses are guided by recurrence of symptoms and by rising alkaline phosphatase. In addition to treatment of symptomatic patients, treatment of asymptomatic lesions is appropriate if there is a significant risk of potential complications, such as fracture in weight-bearing long bones or the spine, nerve entrapment or deafness with skull involvement, and before orthopaedic procedures in involved bone (to reduce vascularity).

**Intravenous bisphosphonates**

**Zoledronate** is the most commonly used agent for Paget’s disease, administered as a single infusion over 15 minutes. **Pamidronate** is an alternative but takes longer to infuse and is less potent; some patients develop drug resistance for unknown reasons. Both drugs can be associated with a first-dose reaction characterized by ‘flu-like’ symptoms, including transient pyrexia over 24–48 hours, which can be ameliorated with paracetamol.

**Oral bisphosphonates**

Oral bisphosphonates are used at doses higher than those for osteoporosis (e.g. 30 mg risedronate daily for 2 months, or 40 mg alendronate daily for 6 months) and are less effective than intravenous zoledronic acid.

**Surgery**

Joint replacement or osteotomy is sometimes necessary to correct deformity or pain due to associated degenerative joint disease. Neurosurgery may be needed where there is spinal disease. Osteosarcoma usually requires amputation, though wide excision and limb salvage can be successful at distal sites.

**Further reading**

**RICKETS AND OSTEOMALACIA**

Osteomalacia is defective mineralization of newly formed bone matrix or osteoid. Rickets is defective mineralization at the epiphyseal growth plate and is found in association with osteomalacia in children.

**Aetiology**

Many factors can result in defective mineralization of the osteoid. For normal mineralization, adequate levels of vitamin D, calcium and phosphate, adequate activity of alkaline phosphatase, a normal pH at the osteoid surface and normal osteoid composition are all necessary (Box 19.11).

The most common cause of osteomalacia is hypophosphataemia due to hyperparathyroidism secondary to vitamin D deficiency. The most common cause of vitamin D deficiency worldwide is dietary deficiency. Bread, milk and cereals in high-income countries are now fortified with vitamin D. This has led to a much-reduced incidence of osteomalacia and rickets.

Vitamin D is produced in the skin through the action of sunlight on 7-dehydrocholesterol (see Fig. 19.4). Lack of sun exposure can lead to vitamin D deficiency, especially in individuals living in temperate regions who keep large parts of the skin covered throughout the year.

---

**Box 19.11 Causes of rickets/osteomalacia**

**Deficient intake or absorption of vitamin D**

- Inadequate sun exposure or deficient synthesis in skin
- Low dietary intake
- Malabsorption: coeliac disease, Crohn’s disease, gastrectomy, bariatric surgery, primary biliary cirrhosis

**Defective 1α-hydroxylation**

- Chronic kidney disease
- Vitamin D-dependent rickets type I – due to deficiency of 1α-hydroxylase

**Primary renal phosphate wasting**

- Renal tubular acidosis (also by causing metabolic acidosis)
- Hereditary hypophosphataemic rickets (vitamin D-resistant rickets)
- Dent’s disease
- Fanconi’s syndrome
- Multiple myeloma
- Tumour-induced osteomalacia

**Inhibitors of mineralization**

- Fluoride, aluminium, bisphosphonates
- Metabolic acidosis

**Defective vitamin D receptors**

- Hereditary vitamin D-resistant rickets (previously known as vitamin D-dependent rickets type II)
Vitamin D is a fat-soluble vitamin, so gastrointestinal disease can result in malabsorption. Gastrectomy, various forms of bariatic surgery, cystic fibrosis, coeliac disease, Crohn’s disease and primary biliary cirrhosis are well-recognized causes.

Due to the intimate involvement of the kidney in phosphate balance, a number of causes of osteomalacia are mediated by the kidney (see p. 1394). Primary renal phosphate wasting occurs in tumour-induced osteomalacia, multiple myeloma and Fanconi’s syndrome. Proximal (type 2) renal tubular acidosis can cause osteomalacia due to both renal phosphate wasting and abnormal osteoid pH secondary to metabolic acidosis.

Clinical features
Osteomalacia may be asymptomatic and identified incidentally on routine investigations following a fragility fracture. When symptomatic, it characteristically causes muscle weakness and widespread bone pain. Muscle weakness is due to a multifactorial proximal myopathy, with low vitamin D, hypophosphataemia and high PTH levels all contributing. It results in a characteristic waddling gait with difficulty climbing stairs and getting out of a chair. Generalized bone pain and tenderness are thought to be caused by hydration of the demineralized matrix, resulting in periosteal distension. The pain is typically a dull ache that is worse on weight-bearing and walking. It can be reproduced by pressure on the sternum or tibia. Insufficiency fractures can occur when the quality of the bone is insufficient to handle the stress of weight-bearing.

At birth, neonatal rickets may present as craniotubes (a thin, deformed skull). In the first few years of life, there may be widened epiphyses at the wrists and beading at the costochondral junctions, producing the ‘rickety rosary’, or a groove in the rib cage (Harrison’s sulcus). In older children, lower limb deformities are seen. A myopathy may also occur. Hypocalcaemic tetany may occur in severe cases.

Investigations
- **Serum alkaline phosphatase** is elevated in 90% of cases.
- **Low serum calcium, low phosphate** and elevated PTH are each present in approximately half of the cases.
- **Serum** 25-hydroxyvitamin D₃ is low, usually less than 25 nmol/L (10 ng/mL).
- **Serum FGF-23** is elevated in many people with tumour-induced osteomalacia and in hypophosphataemic rickets.
- **Plain radiographs** demonstrate decreased bone mineralization. The characteristic finding in osteomalacia is Looser's pseudofractures. These are narrow radiolucent lines with sclerotic borders running perpendicular to the cortex. They can be found at any site but are most commonly seen in the femur and pelvis.
- **Tetracycline-labelled bone biopsy** is the gold standard diagnostic test. This is not practical in most clinical settings and is used mainly in research studies.

Management
Vitamin D replacement is the cornerstone of treatment. Treatment involves two stages: an initial loading stage to replenish body stores of vitamin D, and a subsequent maintenance phase to avoid repeat deficiency (see Box 19.9). All patients should also receive supplementary calcium of 1000–1200 mg/day. In nutritional deficiency, recommended initial replacement is with vitamin D 50,000 units per week orally. The initial replacement dose should be continued for 6–8 weeks. Vitamin D is also available as an intramuscular injection; two doses of 300,000 units are usually enough to replenish body stores. Adequacy of vitamin D replacement should be confirmed by repeat measuring of vitamin D levels. This should be followed by maintenance supplementation with 800–1000 units of vitamin D per day.

Doses for children are lower and are age-dependent. People with gastrointestinal disease and vitamin D deficiency due to malabsorption need higher doses of 10,000–50,000 units per day of vitamin D.

**Tumour-induced osteomalacia** is best treated by removal of the causative neoplasm, which is usually occult and frequently benign. This leads to rapid resolution of symptoms.

**Further reading**
Pearce SH, Cheetham TD. Diagnosis and management of vitamin D deficiency. BMJ 2010; 340:b5664.

**BONE INFECTIONS**

**Acute and chronic osteomyelitis**
Osteomyelitis is more common in children and arises due to haematogenous spread to the vascular metaphysis. In high-income countries, it occurs in around 8 per 100,000 children per year; but it is more common in low-income countries, with boys affected twice as often as girls. In adults it generally occurs in the setting of other medical conditions, such as type 2 diabetes mellitus and chronic skin ulceration where it infiltrates the bone through direct spreading.

*Staphylococcus* is the organism responsible for 90% of cases of acute osteomyelitis. Other organisms include *Haemophilus influenzae* and *Salmonella*; infection with the latter may occur as a complication of sickle cell disease. The classic presentation is with fever and localized bone pain with overlying tenderness and erythema.

**Diagnosis**
- **Imaging:**
  - Plain X-ray is not sensitive in early infection but demonstrates chronic damage.
  - MRI is highly sensitive in early disease.
  - Nuclear medicine bone scans are also helpful.
- **Blood cultures** may be positive.
- **Bone biopsy and culture** identifies the organism and sensitivities.

**Management**
Treatment of osteomyelitis is with intravenous antibiotics. Switching to oral antibiotics can be considered after 2 weeks with continuation for a further 4 weeks. Choice of antibiotic is determined by the causative agent and local guidelines. Surgical drainage and removal of dead bone (sequestrum) may be necessary but recurrence is common.

Delayed treatment leads to chronic osteomyelitis. In chronic osteomyelitis, sinus formation is common. Subacute osteomyelitis is associated with a chronic abscess within the bone (Brodie’s abscess).

**Tuberculous osteomyelitis**
This is usually due to haematogenous spread from a reactivated primary focus in the lungs or gastrointestinal tract. The disease starts in intra-articular bone. The spine is commonly involved (Pott’s disease), with damage to the bodies of two neighbouring vertebrae leading to vertebral collapse and acute angulation of the spine (gibbus). Later, an abscess forms (‘cold abscess’). Pus can track along tissue planes...
and discharge at a point far from the affected vertebrae. Symptoms consist of local pain and later swelling if pus has collected. Systemic symptoms of malaise, fever and night sweats occur.

Management is as for pulmonary tuberculosis but extended to 9 months (see p. 969), together with initial immobilization.

**NEOPLASTIC DISEASE OF BONE**

Bone pain may be due to multiple myeloma, lymphoma, a primary tumour of bone or secondary deposits. The pain is typically unremitting and worse at night, and there are other clinical clues such as weight loss or ill-health.

**Malignant tumours** of bone are shown in **Box 19.12**. The most common tumours are metastases from the bronchus, breast and prostate. Metastases from kidney and thyroid are less common. Primary bone tumours are rare and most commonly seen in children and young adults.

Symptoms are usually related to the anatomical position of the tumour, with local bone pain. Systemic symptoms (e.g. malaise and pyrexia) and aches and pains occur and may be related to hypercalcaemia. The diagnosis of metastases may be evident from the history and examination, particularly in the setting of a known primary tumour. Symptoms from bony metastases may also be the first presenting feature of a malignancy, however.

**Investigations**
- **Skeletal isotope scans** show bony metastases as ‘hot’ areas.
- **X-rays** may show metastases as osteolytic areas with bony destruction. Osteosclerotic metastases are characteristic of prostatic carcinoma.
- **MRI** is used particularly for vertebral lesions.
- **CT and computed tomography-positron emission tomography (CT-PET)** are useful.
- **Serum alkaline phosphatase** may be raised.
- **Hypercalcaemia** occurs in 10–20% of patients who have metastatic malignancies, or can be due to ectopic parathormone or PTH-related protein secretion.
- **Prostate-specific antigen** (PSA) and serum acid phosphatase are raised in the presence of prostatic metastases.

**Management**

Treatment is usually with analgesics and anti-inflammatory drugs. Local radiotherapy to bone metastases relieves pain and reduces the risk of pathological fracture. Some tumours respond to chemotherapy; others are hormone-dependent and respond to hormonal therapy. Bisphosphonates (see p. 483) can help symptomatically. Occasionally, pathological fractures require internal fixation.

**SCHUEERMANN’S DISEASE**

This disease predominantly occurs in adolescent boys. The main feature is a progressive dorsal kyphosis of the thoracic spine. Pain may or may not be present. The cause is unknown. A genetic predisposition, exacerbated by excessive exercise prior to epiphyseal fusion, is one suggested explanation. Older patients with kyphosis may be referred with suspected osteoporotic fractures but found to have long-standing kyphosis due to Scheuermann’s. Management is focused on postural exercises and avoidance of precipitants. Surgery may be undertaken to correct kyphosis in severe cases.

CORE SKILLS AND KNOWLEDGE

Most infections are either self-managed or cared for by community services. Hospital-based infection services manage patients with complicated or severe infections that require expertise from trained infection specialists, in settings that vary from outpatient clinics (for example, those that treat patients with chronic infections such as tuberculosis), to critical care units.

There are two main clinical infection subspecialties, although increasingly the dividing line is blurred. Clinical microbiologists and virologists predominantly provide specialist infectious diseases advice concerning patients in the care of other doctors, and also manage the microbiology laboratory. Infectious disease specialists are often trained as general physicians, and may treat patients directly under their care or provide a ‘laboratory liaison service’ for doctors working in other teams.

Key skills to master in infectious diseases include:
- taking a comprehensive history from patients in order to draw up a thorough account of their presentation and risk factors
- understanding the geographical distribution of different types of infectious agent and their varied clinical presentations
- being familiar with the role of laboratory-based experts in interpreting complex microbiological investigations.

The best way to learn about infectious diseases is by following patients as the story of their illness unfolds. Assess patients in the clinical environment where they present (often the emergency department), review available and subsequent investigations, and discuss them with the healthcare professionals caring for these individuals. Reflect on whether the initial assessment, investigations and management were appropriate in light of any problems that emerged (e.g. adverse drug reactions or the need to intensify therapy), and review the subsequent processes of care (e.g. de-escalation of antibiotic therapy) and the final infection diagnosis.

CORE CONTENT

Although it is necessary for doctors to be aware of a wide range of infectious diseases, it is easy for students reading chapters on the subject to lose themselves among rare and exotic diagnoses and struggle to prioritize key content. The lists in Box 20.1 represent an attempt to identify infections, emergencies and pathogens that doctors need not just to know about, but to know well.

Box 20.1 Key infections, emergencies, pathogens and concepts in infectious diseases

'Top 10' infections
- Respiratory infections, including pneumonia
- Diarrhoeal diseases
- Tuberculosis
- HIV infection
- Hepatitis B and C
- Malaria
- Urinary tract infection
- Skin and soft tissue infections
- Meningitis
- Staphylococcus aureus and Escherichia coli bacteraemia (see Ch. 8)

'Top 10' infection emergencies
- Sepsis
- Severe community-acquired pneumonia
- The ill returning traveller
- The severely ill HIV-positive patient
- Meningitis and encephalitis
- Endocarditis
- Necrotizing fasciitis
- Native joint septic arthritis
- Infection control for highly pathogenic transmissible diseases (e.g. Ebola, avian influenza, etc., see p. 507)
- Neutropenic sepsis (see p. 116)

'Top 10' pathogens to know about
- Streptococcus pneumoniae
- Influenza A virus
- Mycobacterium tuberculosis
- HIV
- Plasmodium falciparum
- Escherichia coli
- Staphylococcus aureus (including meticillin-resistant)
- Multi-resistant Gram-negative organisms (see p. 167)
- Candida albicans
- Hepatitis B and C viruses

'Top 10' concepts in infection care
- Sepsis
- Infection source control
- Finding the focus in bloodstream infections (bacteraemia)
- Multidisciplinary infection care
- Confidentiality in infection care
- Infection prevention and control measures
- Outbreak control
- Immunization
- Net state of immunosuppression
- Oral rehydration solution
Many patients with infectious diseases present with symptoms that are obviously suggestive of a particular type of infection. Others do not, and may present with non-specific symptoms (e.g. fever, malaise, vomiting or a rash). Taking a full history is critical in reaching a diagnosis (Box 20.2). A detailed description of how to ask about different risk factors is given later in this chapter (see p. 492), but a basic summary can be based around the crucial question ‘Why has this patient, from this place, presented at this time, with these symptoms?’

### History

<table>
<thead>

<tr>
<td>‒ Where a diagnosis is unclear, taking time to revisit the history and ask about any unusual activities or exposures is sometimes helpful. Activities that may not be common in a particular setting, e.g. caving, cleaning aquariums, art restoration or repairing air-conditioning systems, all carry risks for developing particular infectious diseases. Unless you ask, you may never find out.</td>
</tr>
</tbody>
</table>

### Place

| A detailed travel history is essential (see p. 492): |
| • Travel to tropical and subtropical countries may be a risk factor for a wide range of infectious diseases, including malaria, dengue and typhoid. |
| • Chronic infectious diseases, such as tuberculosis or viral hepatitis, may have been acquired during a childhood spent in endemic regions and then present in adulthood. |
| • Recent geographically localized epidemics, such as Middle Eastern respiratory syndrome (MERS) or Ebola (Central Africa), should be borne in mind. |
| • Contact with healthcare settings: |
| ‒ Nursing or residential home residents are at risk of developing infectious diseases that are usually associated with hospital inpatients (such as ‘hospital acquired pneumonia’ or *Clostridium difficile* infection). |
| ‒ There are significant global differences in antibiotic resistance rates, so patients who have been inpatients in, or travelled to, other countries may present with multi-resistant organisms not usually seen in their country of residence. |

### Time

| It is often helpful to produce a timeline describing the development (and perhaps resolution) of different symptoms over time. |
| • Symptoms of many acute viral and bacterial infectious diseases emerge over several days. |
| • Symptom duration of more than 2 weeks suggests chronic infection (e.g. tuberculosis, leishmaniasis, brucellosis, human immunodeficiency virus (HIV) or a non-infectious (e.g. autoimmune or malignant) disease process. |
| • Abrupt onset of severe symptoms suggests a highly virulent organism and may imply the need for urgent and empirical treatment before a diagnosis is made. |
| • Some diseases have characteristic time courses, e.g. the biphasic febrile response in dengue, or the initial ‘Katayama fever’ followed by haematuria seen in *Schistosoma haematobium* infection. |

### Symptoms

| Producing a clear account of the different general and organ-specific symptoms experienced by the patient is crucial. |
| • Sepsis is a physiological state that must not be missed, as it always requires empirical antibiotic therapy (see Ch. 8). |
| • Some symptoms suggest the involvement of a particular anatomical site or organ system, such as localized pain, jaundice or the bloody diarrhoea of dysentery. |
| • Other symptoms, such as headache, and vomiting or watery diarrhoea, often occur non-specifically in various infectious and non-infectious diseases, and should not be presumed to imply neurological or gastrointestinal disease, respectively. |
| • Some infectious diseases have unique pathological features that, if properly described, are highly suggestive of a particular diagnosis, e.g. the ‘erythema migrans’ rash of Lyme disease, or the progressive phases of typhoid. |
**Examination**

A full examination is essential in patients presenting with fever or other signs of infectious disease. Where the site of infection is not clear from the history, signs found on examination can help form a diagnosis. The figure shows pathogens commonly affecting different organ systems, allowing a move from a clinical syndrome to a likely microbial diagnosis.

- **Sinuses/nose**
  - Strep. pneumoniae
  - H. influenzae
  - Staphylococci / MSSA / MRSA

  - Staph. aureus
  - E. coli
  - Meningococcus
  - Strep. pneumoniae

- **Large and small intestine**
  - Gram-negative organisms, e.g. E. coli, Klebsiella
  - Campylobacter
  - Salmonella
  - C. difficile
  - Bacteroides / anaerobes

- **Joints**
  - Staphylococci
  - Streptococci
  - Neisseria gonorrhoeae
  - Haemophilus in children
  - Kingella in young children (≤5 years old)

- **Bones**
  - Staphylococci
  - Salmonella
  - Streptococci
  - Gram-negatives

MRSA, meticillin-resistant Staphylococcus aureus; MSSA, meticillin-susceptible Staphylococcus aureus; RSV, respiratory syncytial virus.
INTRODUCTION

‘Infection’ is defined as the process of pathogenic organisms invading and multiplying in or on a host’s tissues. The term should be reserved for situations in which this results in harm, rather than when a microorganism simply colonizes the host without ill effect. The majority of microbes cause no harm. The relationship between the nature of colonizing microorganisms and human health is increasingly being recognized in studies of the human microbiome (see p. 504). Some microbes, however, including colonizing bacteria (e.g. *Staphylococcus aureus*) have the potential to cause disease in the right circumstances.

Infectious agents

The causative agents of infectious diseases can be divided into four groups:

**Prions** are the simplest infectious agents, consisting of a single protein molecule. They contain no nucleic acid and therefore no genetic information; their ability to propagate within a host relies on inducing the conversion of endogenous prion protein PrP$^{c}$ into an abnormal protease-resistant isoform referred to as PrP$^{Sc}$ or PrP$^{Res}$. Prion diseases are described on page 535.

**Viruses** contain both protein and nucleic acid, and so carry the genetic information for their own reproduction. However, they lack the apparatus to replicate autonomously, relying instead on ‘hijacking’ the cellular machinery of the host. They are small (usually <300 nanometres (nm) in diameter) and each virus possesses only one type of nucleic acid (either RNA or DNA).

**Bacteria** are usually larger than viruses. They are enclosed by a cell membrane and most have a cell wall, although some (e.g. *Mycoplasma* spp.) have only a cell membrane. This makes them naturally resistant to cell-wall-acting antibacterial agents (e.g. β-lactam antibiotics, including penicillin, and glycopeptide antibiotics, such as vancomycin; see Chapter 8).

**Eukaryotes** are the most sophisticated infectious organisms and include unicellular protozoa, fungi (which can be unicellular or filamentous) and multicellular parasitic worms. Other higher classes, such as the insects and the arachnids, also contain species that can envenom, injure or parasitize humans and cause disease; these are discussed in more detail in the topic pages online.

The figure on page 490 provides an overview of common microorganisms that cause infections. **Fig. 20.1** shows the approximate global distribution of selected human pathogens in 2019.

**Fig. 20.1** Approximate global distribution of selected human pathogens (2019). This map is not exhaustive or geographically precise, and should not be used to guide clinical practice; a reliable travel health source (e.g. Travel Health Pro) should always be consulted. Avian I, avian influenza; C, Chikungunya virus; CRE, carbapenem-resistant Enterobacteriaceae; D, dengue virus; HIV*, human immunodeficiency virus (global distribution but highest prevalence in Africa); MDRTB, multi-drug-resistant tuberculosis; MERS, Middle East respiratory syndrome coronavirus; PF, *Plasmodium falciparum* malaria; T, typhoid fever; YF, yellow fever; Z, Zika virus.
Infectious disease

CLINICAL APPROACH TO THE PATIENT WITH A SUSPECTED INFECTION

Fever is the cardinal feature of infection, but not all febrile illnesses are infections and not all infections present with a fever. Fig. 20.2 provides an outline of the approach to the patient with acute (undifferentiated) fever of unclear cause. Fever is usually intermittent, so may not be present at the time of presentation, and occurs less commonly in elderly patients. Infection can also present with hypothermia (temperature <36°C), which is a poor prognostic sign. The biological behaviours of the pathogen and the consequent host responses are responsible for the clinical expression of disease, which sometimes allows clinical recognition. Knowledge of the incubation period following exposure can be helpful (e.g. up to 21 days for chickenpox). The site and distribution of a rash may be diagnostic (e.g. shingles), while symptoms of cough, sputum and pleuritic chest pain may suggest lobar pneumonia. Fever and neck stiffness characterize meningitis but do not inform about the microbial cause or management.

The three critical points in the assessment and management of a patient with fever, suspected infection or sepsis are:

- **Physiological assessment** (severity of illness), predominantly based on systematic examination of key physiological markers at initial presentation and subsequently.
- **Diagnostic assessment**, predominantly based on history-taking, examination and interpretation of those diagnostic tests available at presentation and subsequently performed (see later) in the context of the history and examination.
- **Management assessment**, based on linking physiological and diagnostic assessments to key interventions. Decisions will be based on the seriousness of the underlying infection and the likely cause. Interventions may include, for example, the use of antimicrobials and, when required, intravenous fluids or oxygen; infection source control (e.g. drainage of an abscess); infection prevention and control measures (see later); and use of advanced physiological support.

A detailed history can be taken in a physiologically stable patient, but may need to be delayed until after a patient is stabilized in the presence of sepsis, or taken after isolating the patient if a highly transmissible infection is suspected. The recognition and management of sepsis are considered in Chapter 8.

Diagnostic assessment

History-taking, examination and investigations aim to identify the site(s) of infection and also the likely causative organism(s). Boxes 20.3-20.5 outline the links between symptoms, risk factors, examination findings and potential infection diagnoses. Box 20.6 shows the different components of an infection diagnosis and how and why these are ascertained.

History

The history is the most important component of diagnostic assessment. A detailed, systematic history is taken with specific questions about the nature, timing and periodicity of symptoms (see Box 20.1), in particular in relation to any infection exposures and other risk factors (see Box 20.4). If symptoms started after the upper limit of the incubation period of any potential transmissible infection exposure identified, the diagnosis is unlikely. Consideration of the incubation period is irrelevant for many infections, however: for example, when the invading pathogen is often a colonizer of the host, such as in *Staph. aureus* bloodstream infections, or when a specific exposure history cannot be identified, or the patient’s history and examination signs are not diagnostic.

Symptoms are often non-specific (e.g. a 3-day history of lethargy, loss of appetite and shivers), but may lead to a diagnosis or differential diagnosis through careful interpretation and problem-solving (e.g. by linking the patient’s symptoms to their exposures and risk factors and then to potential clinical infection diagnoses and causal pathogens; examination findings and any available test results also need to be considered). In patients with sepsis, a full history should be obtained after, or at the same time as, initiating emergency medical management (see p. 157) to avoid therapeutic delay. If the patient is confused, the history may have to be obtained from a relative or friend. With some exceptions, patients with short, acute symptom histories are more likely to have infections due to microbes that tend to cause acute presentations (e.g. *Streptococcus pneumoniae* infection in a patient with a 3-day history of shivers, cough with production of green sputum, and right-sided pleuritic chest pain). Patients with longer symptom histories are more likely to have infections due to microbes that tend to cause chronic presentations (e.g. pulmonary tuberculosis in a patient with a 2-month history of sweats, weight loss and cough productive of blood-stained sputum, and who has recently returned from living in sub-Saharan Africa).

Key diagnostic information in the patient’s history includes:

**Age**

Older patients are more prone to some infections (e.g. *Clostridium difficile* infection or pneumonia). Some infections (e.g. glandular fever, chickenpox) are less common in older adults but are sometimes more severe.

**Sex**

Some diagnoses are sex-specific, such as epididymo-orchitis or prostatitis in men, and pelvic inflammatory disease or tampon-related toxic-shock syndrome in women.

**Occupational history**

The potential links between occupation and infection are sometimes significant. Healthcare workers may be exposed to certain infections: for example, by air-borne (e.g. chickenpox, tuberculosis), person-to-person (e.g. rotavirus) and needle-stick injury (e.g. blood-borne viruses) routes of transmission. Teachers may be exposed to the common infections of childhood. Those who work with animals may be exposed to zoonoses.

**Symptoms**

See Box 20.3 for examples of how symptoms can be linked to a diagnosis or differential diagnosis.

**Human infection contact**

Contact with other persons who have an infection diagnosis or symptoms of an infectious disease should be discussed. A patient with a new vesicular rash, for example, is asked about contact with chickenpox or shingles within the previous 21 days (the upper limit of the incubation period). A patient with gastroenteritis is asked about contact with other people with similar symptoms, when that contact was with respect to the start of symptoms, and the social context of that contact. A patient with recurrent skin abscesses is asked about contact with other persons with recurrent skin infections (e.g. to assess the risk of transmission of Panton–Valentine–leukocidin (PVL) producing *Staph. aureus* skin infections).
Clinical approach to the patient with a suspected infection

**Risk factors/Exposures**
- Age
- Occupation
- Human contact
- Animal contact
- Travel
- Food and drink
- Sexual exposure
- Pregnancy
- Drug use and needle exposure
- Leisure activities

**Symptom history**
- Timeline / chronicity / periodicity
- Fever, sweats, shivers, rigors
- Rash / glands / masses (abscesses)
- Headache / agitation / confusion / seizures
- Ear pain/discharge; runny/congested nose; eye symptoms; sinus pain; throat; mouth; swallowing (e.g. candidiasis)
- Cough / sputum (colour/blood) / shortness of breath / pleuritic chest pain
- Abdominal pain / symptoms (nature/location/radiation) / diarrhoea
- Urinary – dysuria / frequency / urgency / haematuria, etc.
- Genital – discharge (and nature) / itching / ulceration, etc.
- Limb pain, swelling, warmth, redness
- Bone/joint/spine pain, swelling, warmth, redness

**General investigations**
- Full blood count
- Urea / electrolytes
- Liver enzymes
- C-reactive protein
- Other biomarkers (e.g. procalcitonin) as indicated or used nationally/locally
- Lactate (sepsis)
- Coagulation (sepsis, hepatitis)
- CD4 count / viral load in HIV patients
- Other tests as appropriate (e.g. autoantibodies, thyroid tests, ferritin)
- ECG (e.g. pericarditis)

**Radiology**
- Chest X-ray
- Ultrasound
- Echocardiography
- CT
- MRI
- Nuclear imaging as available/appropriate after discussion with radiologist

**Examination**
- Temperature (repeat regularly)
- Skin – rash, splinter haemorrhages, wounds, ulcers (remove dressings)
- Device / prosthesis / implant sites (e.g. i.v. lines, cardiac devices, urinary catheters, etc.)
- Neck stiffness
- Eyes – conjunctivitis, photophobia
- Mouth and throat, ears and nose
- Lymph nodes
- Murmurs (other signs of endocarditis)
- Focal chest signs
- Abdomen
- Genitourinary / rectal
- Lower limbs / bone / joints / spine
- Sites of inflammation – redness, warmth, swelling, pain

**Medical history**
- Previous infections
- Co-morbidities
- Immunosuppressing conditions – net state of immunosuppression
- Devices / protheses
- Vaccination history
- Medications – recent antimicrobials – immunosuppression – acid suppression – HIV / hepatitis, etc.
- Allergies / intolerances

**Microbiology / Virology**
- Blood cultures x2 for all patients; x3 if endocarditis or other ‘deep’ site of infection suspected
- Urine culture (if patient has symptoms or is unable to give history; only a negative urine dip test for leucocytes/nitrites is useful)
- Malaria film and/or rapid diagnostics (as indicated)
- Pus; do not swab clean, uninfected wounds
- Screening swabs (for MRSA and/or CRE)
- Sputum (culture, rapid respiratory diagnostics; x3 if TB suspected; induced or BAL if required)
- Throat / nasopharyngeal swab / sample (culture, rapid respiratory diagnostics)
- Cerebrospinal fluid (microscopy, culture, protein, glucose, virology)
- Aspiration / biopsy / operative tissue for histology and/or microscopy and culture; may need to be radiologically guided
- Faeces (tests depend on differential diagnosis)
- Nucleic acid amplification tests (e.g. PCR)
- Immunodiagnostics (e.g. serology)

**Infection prevention and control**

**Problem-solving**

**Differential diagnosis**

**Diagnosis**

**Management**
- Multidisciplinary care
- Shared decision-making with patient
- Antimicrobials / medications, etc. (as appropriate)
- Source control (e.g. drainage of abscess)
- Foci of bloodstream infections (e.g. endocarditis)
- Re-evaluation from top if diagnosis unclear or patient does not respond / improve or deteriorates

Fig. 20.2 Clinical approach to the patient with fever of unclear cause but without sepsis. For patients with sepsis, see Chapter 8. BAL, bronchoalveolar lavage; CRE, carbapenem-resistant Enterobacteriaceae; CT, computed tomography; ECG, electrocardiogram; HIV, human immunodeficiency virus; MRE, magnetic resonance enterography; MRI, magnetic resonance imaging; MRSA, meticillin-resistant *Staphylococcus aureus*; PCR, polymerase chain reaction; TB, tuberculosis.
Animal contact

Domestic (e.g. cats and Toxoplasma gondii infection), farm (e.g. sheep and Coxiella burnetii infection) and wild animal (e.g. bats and rabies) contact is discussed.

Travel history

Some diseases are more prevalent in certain geographical locations. A detailed travel itinerary, including any flight stopovers, should be taken from anyone who is unwell after arriving from another country. Previous travel should also be covered, as some infections may be chronic or recurrent (e.g. Plasmodium vivax malaria). It is necessary to find out not only which countries were visited but also the type of environment and length of stay; a prolonged stay in a remote jungle village carries much higher health risks than a short holiday in an air-conditioned coastal holiday resort, even in the same country. Food and water consumption, bathing and swimming, animal and insect contact, and contact with human illness need to be established. Enquiry should be made about sexual contacts, drug use and medical treatment (especially parenteral).

In some parts of the world, a high-proportion of professional sex workers are human immunodeficiency virus (HIV)-positive, and hepatitis B and C (HBV/HCV) are very common in some parts of Africa and the Middle East. A travel history should also be covered, as some infections may be chronic or recurrent (e.g. Plasmodium vivax malaria). It is necessary to find out not only which countries were visited but also the type of environment and length of stay; a prolonged stay in a remote jungle village carries much higher health risks than a short holiday in an air-conditioned coastal holiday resort, even in the same country. Food and water consumption, bathing and swimming, animal and insect contact, and contact with human illness need to be established. Enquiry should be made about sexual contacts, drug use and medical treatment (especially parenteral).

Asia. Special tests may be needed, depending on the epidemiological risks and clinical signs, and malaria rapid antigen diagnostic tests and thick/thin blood films are mandatory in anyone who is unwell after being in a malarious area. A reliable resource such as Travel Health Pro (see Further reading) is consulted regarding current infectious disease alerts and endemic risks for the countries visited. Some of the more common causes of a febrile illness in returning travellers are listed in Box 20.7.

**Food and drink history**
Exposure to unclean water and uncooked, unpasteurized or contaminated foods or drinks (e.g. *Listeria monocytogenes* infection from soft cheeses), and illness in other people also exposed, should be asked about.

**Sexual activity**
The sexual history is often omitted or poorly taken, but is essential if diagnoses, such as HIV infection, are not to be missed. Sexual exposure is common in travellers. Sexually transmitted infections are discussed in Chapter 37.

**Pregnancy**
Pregnant women may be more susceptible to some infections (e.g. malaria, HIV infection, and listeriosis) and may be at higher risk of severe infections (e.g. disseminated herpes simplex virus (HSV) infection/hepatitis, hepatitis E, influenza, malaria and measles).

**Intravenous drug use and needle exposure**
As well as blood-borne viruses (mostly HIV, HBV and HCV), drug injectors are susceptible to a wide variety of bacterial and fungal infections, in particular those due to *Staph. aureus* and *Streptococcus pyogenes* (group A streptococcus), as a result of contamination of the injecting equipment or inoculation from the patient’s colonized skin. Abscesses (e.g. in the psoas or other muscles) and soft tissue infections at the site of injection are common, especially in the groin, and may involve adjacent vascular structures (e.g. to form pseudoaneurysms) and bones (osteomyelitis). Bloodstream and haematogenously spread infections, including endocarditis (often right-sided), spinal infections and bone/joint infections, are also common. Other needle exposures, such as tattooing, body piercing, needle-stick injury and receipt of blood products (especially outside of developed countries), are also risk factors for blood-borne infections.

**Leisure activities**
Certain pastimes (e.g. open-water swimming and leptospirosis) may predispose to water-borne infections or zoonoses.

**Previous infections**
Previous infections are reviewed. This may provide a useful clue to both the organ/system and microbiological/virological diagnoses (see Box 20.6); previous microbiological results, especially for the prior 12 months, are reviewed for any pathogens isolated and associated antimicrobial susceptibilities in order to guide

BSI, bloodstream infection; CRP, C-reactive protein; CXR, chest X-ray; RTI, respiratory tract infection; TTE, transthoracic echocardiogram; UTI, urinary tract infection; WCC, white cell count.
empirical antimicrobial therapy if required. This is particularly useful in patients with a history of colonization/infection by meticillin-resistant Staph. aureus (MRSA) or other resistant microbes, or of recurrent respiratory or urinary tract infection. Some infections, such as chickenpox, rarely occur for a second time due to waning immunity, although chickenpox may recrudesce from latency in the form of shingles (zoster). Patients who are infected with dengue virus for a second time are at higher risk of developing severe forms of the infection.

Co-morbidities
The potential association between co-morbid illnesses and infections is considered (e.g. haematological malignancy and medication-related immune suppression are risk factors for invasive pneumococcal disease, and opportunistic infections, such as *Pneumocystis jirovecii* infection).

Devices/prostheses/implants
Symptoms relating to any recently inserted or longstanding devices, prostheses or implants are discussed (e.g. increasing pain in a total hip replacement; swelling and warmth over a pacemaker insertion site).

Vaccination history
Patients who have not received certain childhood (e.g. measles, mumps) or pre-travel (e.g. typhoid) vaccines are at higher risk if exposed.

Medications
Some medications increase the risk of certain infections (e.g. proton pump inhibitors and histamine₂ antagonists may predispose to gastrointestinal infections, including, for example, *Salmonella* spp. gastroenteritis and *C. difficile* infection, but not norovirus, which is not acid-sensitive). The patient’s recent antimicrobial exposure should also be ascertained; it is well known, for example, that individuals recently exposed to an antimicrobial are more likely subsequently to harbour microorganisms resistant to that antimicrobial (and possibly to other antimicrobials too) and this may influence prescribing decisions.

Allergies/intolerances
The detailed nature of any prior allergies and/or intolerances should be determined with respect to antimicrobials or infection-related drugs (e.g. HIV medications).

Immunosuppression
Increasing age and co-morbidity, as well as advances in medical treatment over recent decades, have led to a huge increase in the number of patients living with immunodeficiency states of varying degrees. Cancer chemotherapy, immunosuppressive drugs, including the increasing use of monoclonal antibody-based biologic therapy (e.g. infliximab), and the worldwide HIV epidemic have all contributed. Given that, in modern medicine, a patient’s immunosuppression status is often multifactorial because of age, co-morbidity and therapy, for example, an assessment of the patient’s net state of immunosuppression is an important concept in determining the nature of the infections of which a patient is at risk. For example, an otherwise well 60-year-old on low-dose maintenance prednisolone for polymyalgia rheumatica is considerably less immunosuppressed, and hence at lower risk of infections, than an 82-year-old with diabetes, rheumatoid arthritis and a past history of a renal transplantation, who is taking a variety of immunosuppressant and disease-modifying medications. The temporality of immunosuppression is also a factor: patients within 6 months of solid organ transplantation, for example, are at higher risk, as this period corresponds to the most intense time of immunosuppression. Patients who do not have a spleen (or a functional spleen) are at risk of infections caused by encapsulated bacteria (i.e. pneumococci, *Haemophilus* spp. and meningococci; see p. 357).

The presentation may be atypical in the immunocompromised patient, with few, if any, localizing symptoms or signs. Infection can be due to organisms that are not usually pathogenic, including environmental bacteria and fungi (opportunistic microbes). The normal physiological responses to infection (e.g. fever, neutrophilia) may be diminished or absent. The onset of symptoms may be sudden and the course of the illness fulminant. A high index of suspicion for infections in immunosuppressed individuals is required, with early investigation (e.g. computed tomography (CT) thorax for invasive pulmonary aspergillosis in a patient receiving highly immunosuppressant cancer chemotherapy and with new chest X-ray shadowing) and rapid intervention. Common causes of infection in immunosuppressed patients are shown in Box 20.8. For neutropenic sepsis, see page 116.

**Clinical examination**
A careful and systematic examination covering all systems is required in order to avoid missing subtle signs, such as splinter haemorrhages in endocarditis or the petechial rash of early meningococcal disease. The examination is used to support or refute likely differential diagnoses based on the history and may also help guide the approach to investigations; new differential diagnoses may also emerge based on examination findings.
Clothes and dressings should be removed to inspect underlying skin, wounds (including historic wounds) and invasive devices (e.g. pacemaker sites). Skin rashes (Fig. 20.3) and lymphadenopathy are common features of infectious diseases but can occur in non-infectious conditions, such as lymphoma. The ears (e.g. necrotizing otitis externa), nose (e.g. common cold), eyes (e.g. Roth’s spots in endocarditis), mouth (e.g. Koplik’s spots in measles) and throat (e.g. tonsillitis) should all be inspected carefully. Infections commonly associated with a rash are listed in Box 20.9. Auscultation of the heart, for murmurs, is critical in patients with fever of unknown cause, bloodstream infections and other potential signs of endocarditis. Likewise, examination of the musculoskeletal system, including palpation of the spine (i.e. discitis), is performed in patients with bloodstream infection, especially that due to *Staph. aureus*, and fever/pyrexia of unknown cause.

Abdominal examination, including the renal angles (i.e. pyelonephritis, see p. 1383), should be performed in patients with Gram-negative bloodstream infection (e.g. that due to *Escherichia coli*, *Klebsiella pneumoniae*, *Proteus mirabilis*, etc.) as the urinary tract (most commonly), intra-abdominal sites and the liver/biliary tract (liver enzymes are often elevated) are the most common underlying foci of infection. Rectal, vaginal and penile examinations are required in those at risk of sexually transmitted infections (see pp. 411–412).

The fever pattern may occasionally be helpful – for example, the tertian fever of *falciparum* malaria – but in most patients fever is non-specific and not diagnostic. Box 20.5 outlines the potential links between some examination findings and diagnoses of infection.

</table>
The results of investigations are used to support, confirm or refute likely differential diagnoses based on the history and examination findings, and may also lead to new differential diagnoses and the need for further investigations. In some infections, such as chickenpox, the clinical presentation is so distinctive that no investigations are necessary to confirm the diagnosis. In other mild and self-limiting infections, such as those frequently managed in primary and ambulatory care settings (e.g. minor skin infections, upper respiratory tract infections, cystitis, etc.), extensive investigations will not change management and are therefore unwarranted, as the diagnosis and treatment are clear. Some patients, especially when they are being managed in secondary care or when an antibiotic prescription may be avoidable, require further tests to determine the organ/system/site of infection and microbiological cause, and thereby to guide required intervention(s). A shared decision-making approach should be taken with the patient to avoid tests, treatments or procedures that are unlikely to be of benefit (see p. 11).

**General investigations**

**Box 20.10** shows general investigations for a patient with acute fever or suspected infection of unclear cause. It is vital to review at presentation any tests that have been performed previously, including prior microbiological tests. Treating a patient known to harbour resistant microorganisms with an antibiotic to which those organisms are resistant may be unwise, depending on clinical circumstances: for example, a patient presenting with pyelonephritis should not be treated with co-amoxiclav if *E. coli* resistant to co-amoxiclav were recently grown from a mid-stream urine specimen. The exact tests performed will vary, depending on clinical presentation and differential diagnoses, severity of illness and available resources:

**General blood tests**

These provide clues to the diagnosis or organ/system involved (e.g. raised liver enzymes in liver or biliary tract infection), but in general are non-specific and non-diagnostic. Helpful tests may include:

- **The full blood count and differential white cell count.** In adults, lymphopenia is commonly associated with various viral infections, whereas neutrophilia, particularly if marked, is more likely to be associated with bacterial infections, although such associations are far from being a precise science in clinical practice.
- **The erythrocyte sedimentation rate (ESR), plasma viscosity and/or C-reactive protein (CRP).** These may be raised in infection and other inflammatory states.
- **Liver biochemistry and function.**
- **Serum creatinine and electrolytes.** These assess for infection-related acute kidney injury.
- **Coagulation screen** (in suspected sepsis and hepatitis).
- **Serum lactate** (in suspected sepsis).

CRP is a non-specific marker of inflammation and is raised in many different infections, and in acute and chronic non-infection conditions associated with inflammation (e.g. rheumatoid arthritis). It is more useful in monitoring response to treatment than in making a diagnosis, although it is sometimes used as a point-of-care test in primary or ambulatory care to guide the need for antibiotic therapy in acute bronchitis (using cut-offs of 100 mg/L for an antibiotic prescription, 20–100 mg/L for a delayed prescription and <20 mg/L for no antibiotic).

The exact role of procalcitonin in the diagnostic and prognostic assessment of bacterial infections is controversial; it may have a useful role in antibiotic stewardship (see p. 159) when used within algorithms, particularly for respiratory tract infections and in the critical care environment, to determine when it is safe to start or stop antibiotic therapy.

**Radiological imaging**

X-ray (e.g. pneumonia), ultrasound (e.g. abscess), echocardiography (endocarditis), computed tomography (CT; e.g. intra-abdominal infection) and magnetic resonance imaging (MRI; e.g. bone and spinal infections) are used to identify and localize infections. Positron emission tomography (PET) and single-photon emission computed tomography (SPECT) have also proved useful in localizing infection, especially when combined with CT scanning, when the focus of infection is unclear. Biopsy or aspiration of tissue for microbiological examination is often facilitated by ultrasound or CT guidance. Indium- or technetium-labelled white cell scans (using white cells harvested from the patient prior to the test) may also help to localize infection. When possible, cases are discussed with a radiologist before ordering tests – for example, PET or white cell scans – to ensure that patients receive the optimal investigations in the context of their individual clinical presentation and prior investigations.

**Microbiological investigations**

It is often helpful to discuss the clinical problem with an infection specialist to ensure that appropriate tests are performed to identify the causative organism and that specimens are collected and transported correctly. Accurate completion of the request form, including clinical information, antimicrobial history, epidemiological and risk

factor details (e.g. onset and duration or symptoms, recent travel, etc.) enable laboratory staff to add or delete tests appropriately.

Microscopy

The most widely utilized microscopic technique is the Gram stain, which determines the shape (cocci or bacilli) and Gram status (positive or negative) of bacteria. This allows most pathogenic bacteria to be classified into four groups: Gram-positive cocci, Gram-negative cocci, Gram-positive bacilli and Gram-negative bacilli. To some extent, this then dictates empirical antibacterial therapy, if appropriate. Box 20.11 shows some key bacterial causes of bloodstream infections in the UK, along with their shape and Gram status, and how bacterial identity links to potential foci of infection.

Culture

Specimens for culture should, ideally, be taken prior to administration of, or a change in, antibiotic therapy. Once antibiotics are commenced, however, there will be an impact on the microbiome (see p. 504), including infecting pathogens, resulting in potentially misleading results. Culture techniques can be applied to a wide variety of bacteria, fungi, protozoa and viruses. However, some organisms are difficult to grow and may require special culture media and/or conditions. Viruses are particularly difficult (and, in many cases, impossible) to culture in the laboratory. Antimicrobial susceptibility testing is performed on isolates thought to be clinically significant. Increasingly, traditional culture techniques are combined with new technologies, such as fluorescence in situ hybridization (FISH), matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectroscopy, morphokinetic cellular analysis, polymerase chain reaction (PCR) testing of identifier genes, and whole-genome sequencing (WGS) of pathogenic organisms. This reduces the time to identification of pathogens, informs subsequent antimicrobial susceptibility testing (including whether a pathogen produces an extended-spectrum β-lactamase (ESBL) or carbapenemase – associated with multidrug resistance in Gram-negative bacteria) and enables linkage of bacteria and patients in outbreaks. In the future, new technologies may be applied directly to blood samples, possibly replacing the current culturing process.

Specimens sent for microscopy and/or culture (Box 20.12) are described here.

- **Blood** is sent for bacterial culture in hospitalized patients if systemic infection is suspected, regardless of whether fever is present at the time of presentation. Additional blood cultures are taken if fever subsequently occurs. In patients with suspected endocarditis or cardiac device infection or other ‘deep’ foci of infection (e.g. psoas abscess, discitis, etc.), at least three sets of blood cultures are taken.

- **Urine** is sent for microscopy and culture in patients with urinary tract symptoms, and also in patients unable to provide a clear history when urinary tract infection (UTI)/sepsis is suspected. Urine culture is not indicated in asymptomatic patients able to provide a clear history, regardless of whether they are catheterized or not.

- **Cerebrospinal fluid (CSF)** (meningitis, encephalitis), **sputum** (e.g. pneumonia, tuberculosis), **articular fluid** (e.g. septic arthritis, prostatic joint infection), **pus** (e.g. abscess) and **biopsy** (e.g. of a lymph node) specimens are sent when clinically indicated.

- **Swabs** of clean wounds, without pus or surrounding cellulitis, are avoided because of the risk of identifying colonizing bacteria and encouraging inappropriate antibiotic prescribing. Infection doctors prefer a specimen rather than a swab of a specimen; tissues, aspirates and fluids are usually preferred. Vaginal swabs are useful, however, to identify *Candida* spp., *Trichomonas vaginalis* and other bacterial causes of vaginitis; nucleic acid amplification techniques (see next section) are more commonly used to screen for *Neisseria gonorrhoeae* and *Chlamydia* spp.

- **Special culture techniques or prolonged culture** are required for *Mycobacteria* spp., slow-growing bacteria, such as *Actinomyces* spp. and *Brucella* spp., and sometimes fungi; the laboratory must be informed of patients with suspected unusual infections or infections due to fastidious microbes.

- **Faecal culture** should be reserved for cases of suspected bacterial gastroenteritis or dysentery, especially when there may be public health implications. Faecal culture for viruses is not helpful; antigen or nucleic acid detection techniques (see next section) are more appropriate, especially in the investigation of an outbreak of diarrhoea and vomiting (e.g. norovirus). Protozoa (e.g. amoebiasis, giardiasis) may be a cause of diarrhoea in returning travellers, immunocompromised patients, toddlers, men who have sex with men, and farm workers, and in any case of prolonged unexplained diarrhoea; antigen or PCR-based tests are a useful adjunct to traditional microscopy. Detection of a specific clostridial toxin is a more reliable test for *C. difficile* infection than culture.

Nucleic acid detection

Specific genes from many pathogenic microorganisms have been cloned and sequenced. Nucleic acid probes can be designed to detect these sequences, identifying pathogen-specific nucleic acid in body fluids or tissue. The use of nucleic acid amplification techniques (NAATs), such as PCR, has increased the power of these tests to detect very small quantities of microbial material. Such techniques not only are exquisitely sensitive, but also enable quantitation (e.g. viral load testing in HIV and hepatitis B and C) and subspeciation (e.g. at genotype level). NAAT tests have been widely used for viral infections (e.g. for influenza infection), but increasingly PCR-based bacterial identification is also employed in clinical practice. This allows ‘screening’ of clinical samples from sterile sites for a wider range of organisms, but because of the risk of detecting contaminating, colonizing or multiple bacteria, results must be interpreted carefully in the context of clinical findings.

Immunodiagnostic tests

These can be divided into two types:

- tests that detect **microbial components** (antigens), using a polyclonal antiserum or a monoclonal antibody (e.g. hepatitis B surface antigen, galactomannan in *Aspergillus* spp. infections)
- tests that detect an **antibody response** to infection (serological tests).

These investigations are valuable in the identification of organisms that are difficult to culture, especially viruses, atypical bacteria and fungi, and can also be helpful when antibiotics have been administered before samples were obtained. Elevated antibody titres on a single occasion (especially of immunoglobulin (Ig) G) are rarely diagnostic and it may be difficult to distinguish between past and acute infection. Paired serological tests taken a few weeks apart to observe IgG seroconversion, or specific assays for IgM antibodies (indicating an acute infection), are useful retrospectively to confirm the diagnosis, but rarely change the acute management of the patient. Avidity testing may also enable recent infection (low-avidity antibodies) and historical infection (high-avidity antibodies)
to be distinguished. Numerous serological tests are available; they should be used only in light of the clinical presentation and exposure/risk history.

**Pyrexia of unknown origin**

History, clinical examination and simple investigation will reveal the cause of a fever in many patients. In a small number, no diagnosis is apparent, despite continuing symptoms. The term pyrexia of unknown origin (PUO) is sometimes used to describe this problem. Various definitions have been suggested for PUO; a useful one is ‘a fever persisting for more than 2 weeks, with no clear diagnosis despite intelligent and intensive investigation’. Patients who are known to have HIV or other immunosuppressive conditions are normally excluded from the definition of PUO, as the investigation and

NAAT, nuclear acid amplification test; PCR, polymerase chain reaction; STI, sexually transmitted infection; TB, tuberculosis.

A detailed history and examination is essential, including a medication (the commencement of medications in relation to symptoms) and family history, and breast, spine and testicular examinations. Examination should be repeated on a regular basis to identify new signs as they appear. It is also worth retaking the history intermittently, as previously undisclosed important information, particularly about sexual exposures, may emerge. Investigative findings to date should be reviewed, obvious omissions amended and abnormalities followed up (e.g. raised serum liver enzymes trigger further thought about and possible investigation for liver and biliary tract abnormalities; raised serum creatine kinase may suggest myositis or a medication-related adverse effect; a markedly elevated serum ferritin may suggest adult-onset Still's disease). Confirmation should be sought that the patient does have objective evidence of a raised temperature; this may require admission to hospital if the patient is not already under observation. Some people have an exaggerated circadian temperature variation (usually peaking in the evening), which is asymptomatic and not pathological.

The range of tests available has already been discussed. Investigation is guided by the history and particular abnormalities on examination or initial test results, but in some cases “blind” investigation is necessary. Some investigations, especially blood cultures (at least three are taken), should be repeated regularly and prolonged culturing may be justified, depending on epidemiological exposure (e.g. *Brucella* spp.). Serial monitoring of inflammatory markers such as CRP allows assessment of progress. Ultrasound, echocardiography, CT, MRI, PET and labelled white-cell scanning can all help establish a diagnosis if used appropriately; the temptation to scan all patients with PUO from head to toe as a first measure should be avoided. Imaging may also be useful for identifying an appropriate site for biopsy. Biopsy of the bone marrow (and, less frequently, liver) may be useful, and temporal artery biopsy is used to confirm suspected temporal arteritis (see p. 464). Bronchoscopy is used to obtain samples for microbiological and histological examination if sputum specimens are inadequate or absent and a respiratory diagnosis is suspected. Molecular and serological tests have greatly improved the diagnosis of infectious causes of PUO, but these tests should be ordered and interpreted only in the context of the patient’s presentation and exposure/risk history. Some non-infection conditions (e.g. lymphoma) can be challenging to diagnose and may, for example, require more than one lymph node biopsy.

### Management

Management of a patient with a persistent fever is aimed at the underlying cause. If possible, only symptomatic treatment should be given until a clear diagnosis is made. Blind antibiotic therapy may make diagnosis of an occult infection more difficult, and empirical steroid therapy may cause deterioration of an infection or mask an inflammatory response without treating the underlying cause. In a few patients, no cause of fever is found, despite many months of investigation and follow-up. In most of these individuals, symptoms settle spontaneously, and if no definite cause has been identified after 2 years, the long-term prognosis is good.

### Non-antimicrobial principles of infection care

See Box 20.2 for other important concepts in infection and page 158 for infection source control (e.g. draining of an abscess) and finding the underlying focus in bloodstream infections.
Multidisciplinary infection care

It has increasingly been recognized that complex infections and infectious diseases cannot be managed singlehandedly by a lone specialist clinician, regardless of experience. Many infections require multidisciplinary teams to provide optimal care and clinical outcomes. A good example is that of orthopaedic infections. These require the expertise of multiple doctors (e.g. orthopaedic surgeons, plastic surgeons, infection doctors and radiologists), nurses (e.g. specialist outpatient parental antibiotic therapy (OPAT) staff), pharmacists and professionals allied to medicine, such as physiotherapists. Care plans are discussed at multidisciplinary meetings and/or clinics, which all attend. There are many other infections and situations for which the multidisciplinary team approach is necessary, such as HIV infection, tuberculosis, hepatitis, diabetic foot infection, OPAT, infection prevention and control, and antimicrobial stewardship. A weekly multidisciplinary infection meeting to discuss outpatients or inpatients with complicated infections is a standard of good departmental practice for adequately resourced infection departments.

Shared decision-making

Infection practice is often ‘grey’. Patients frequently present with non-specific histories and examination findings, and tests are often not diagnostic. The degree of investigation and intervention is determined by the severity or seriousness of the clinical presentation. A clear diagnosis is not always possible, and it is therefore important to use a shared patient-healthcare professional decision-making approach to avoid tests, treatments or procedures that are unlikely to be of benefit. Discussing the following four questions with patients may be useful in determining appropriate investigation and management strategies:

- What are the benefits?
- What are the risks?
- What are the alternatives?
- What if I do nothing?

Confidentiality

Many infections (e.g. hepatitis, HIV and tuberculosis) continue to be associated with social stigma. It is important to maintain patient confidentiality about the diagnosis at all times. Case notes should not be left lying around and electronic patient records should not be visible in public areas. The patient’s permission is always sought prior to discussion with spouses, partners, relatives or friends, or communication with their primary care physician, although the latter is always encouraged to facilitate high-quality integrated care. Confidentiality is broken only when there is an overwhelming individual or public health risk, although multidisciplinary discussion and legal advice are usually sought beforehand.

Re-evaluation

Patients with sepsis and other serious infections need to be evaluated regularly, sometimes several times a day. Whether as an outpatient or inpatient, those who remain symptomatic without a clear diagnosis are re-evaluated by retaking the history and performing repeat examinations and appropriate investigations using a shared decision-making approach. If the patient’s clinical condition deteriorates or does not respond to therapy, or if adverse effects occur on intervention, careful re-evaluation is essential. Such patients are discussed at the hospital’s multidisciplinary infection meeting.

Infectious Diseases Society of America. Laboratory Diagnosis of Infectious Disease; https://www.idsociety.org/practice-guideline/laboratory-diagnosis-of-infectious-diseases/.

EPIDEMIOLOGY AND PREVENTION OF INFECTIONS

Infectious diseases remain one of the main causes of morbidity and mortality in humans, particularly in low- and middle-income countries (LMICs), where they are associated with poverty and overcrowding. In high-income countries, increasing prosperity and hygiene (most importantly), along with universal immunization and antibiotics, have reduced the prevalence of infections. Increasingly, difficult-to-treat, antibiotic-resistant microorganisms are being isolated, however, and diseases such as HIV infection, influenza viruses, malaria, measles and Middle East respiratory syndrome (MERS) continue to be problematic. Ebola and Zika viruses have recently emerged as much greater concerns than they were historically.

Increased population mobility

There is increased global mobility, both enforced (as a result of war, civil unrest and natural disaster) and voluntary (for tourism
and economic benefit). This has aided the spread of infectious diseases and allowed previously localized pathogens to be imported and to establish themselves across much wider territories (e.g. New Delhi metallo-β-lactamase (NDM)-producing Gram-negative bacteria). Greater movement of livestock and animals has enabled the spread of zoonotic diseases, while changes in farming and food-processing methods have contributed to an increase in the incidence of food- and water-borne diseases. Deteriorating social conditions in the inner city areas of major conurbations have facilitated the resurgence of tuberculosis and other infections. Prisons and refugee camps, where large numbers of people are forced to live in close proximity, often in poor conditions, also continue to provide breeding grounds for devastating epidemics of infectious disease. There are ongoing concerns about the deliberate release of infectious agents, such as anthrax, by terrorist groups or national governments.

### Changing patterns of disease

In LMICs, successes such as the eradication of smallpox, the near-eradication of Guinea worm infection (dracunculiasis) and reductions in leprosy have been balanced or outweighed by new problems. Communicable, maternal, neonatal and nutritional conditions, for example, were still responsible for 56% of deaths in the World Health Organization (WHO) African region in 2015. Although the leading causes of death globally are increasingly non-communicable diseases, lower respiratory tract infections, diarrhoeal diseases and tuberculosis are still the fourth, ninth and tenth most common causes of death, respectively (Box 20.14).

- New or relapsed cases of tuberculosis remain common at 140 per 100 000 population, with 600 000 cases of rifampicin-resistant (the most important anti-tuberculosis antibiotic) and 490 000 cases of multidrug-resistant tuberculosis diagnosed globally each year. Progress in reducing malaria has stalled, with funding being the main barrier; in 2016, there were 216 million patients with malaria globally, compared to 237 million in 2010 and 210 million in 2013.

- Some 325 million people live with hepatitis B or C, although the incidence of hepatitis B in those <5 years old has decreased from 4.7% in the pre-vaccine era to 1.3% in 2015.

- In 2016, approximately 1 million people (12% of whom were children) still died of HIV-related disease (compared to 1.9 million in 2005), despite the availability of effective therapy; globally, only half of those living with HIV receive anti-retroviral therapy. Global HIV incidence has fallen, however, from 0.4 per 1000 uninfected population in 2005 to 0.26 per 1000 uninfected population in 2016, but remains high in Africa (1.24 per 1000 population). Neglected tropical diseases, such as filariasis, onchocerciasis and trachoma, remain problematic, with 1.5 billion persons requiring mass or individual treatment in 2016 (versus 2 billion in 2010); 409 million persons were from low-income countries, which account for just 9% of the total global population.

### Factors limiting control of infectious diseases in LMICs

Infections are often multiple and there is synergy between different infections (e.g. tuberculosis and HIV) and other factors such as malnutrition. Many of the infectious diseases affecting LMICs are preventable or treatable, but continue to thrive due to lack of money, infrastructure and political will. The surveillance of infectious diseases is generally poor in such countries, resulting in a slow response to emerging problems (e.g. Ebola in the West Africa region in 2013). It seems likely that the ongoing emergence of highly drug-resistant Gram-negative bacterial infections will affect the poor and vulnerable disproportionately. The impact of global warming on the spread and incidence of infections remains uncertain. Both natural climatic events and the gradual global change in weather conditions can affect the spread and transmission of infectious diseases. Changes in temperature directly influence the behaviour of insect vectors, while changes in rainfall have an effect on water-borne disease. Climate change also triggers population movement and migration, indirectly affecting infection transmission.

### Goals in international development

The WHO set eight Millennium Development Goals (MDGs, see p. 278) that were meant to have been achieved by 2015, including combating HIV, malaria and other diseases; these have now evolved into 17 Sustainable Development Goals (SDGs). While a lot has been achieved by public/private partnerships and other charitable funders, it is clear that there is still much to be done, as is demonstrated by ongoing malaria transmission.

### Acquisition of infection

Many infections are acquired from other people, who may be symptomatic or asymptomatic carriers. Some bacteria, like the meningococcus, are common transient commensals but cause invasive disease in a small minority of those colonized, sometimes after other infections such as influenza. Infections with other organisms, such as hepatitis B virus, can be followed in some cases by an asymptomatic but potentially infectious carrier state.
Zoonoses are infections that can be transmitted from wild or domestic animals to humans. Infection can be acquired in a number of ways:
- direct contact with the animal
- ingestion of meat or animal products
- contact with animal urine or faeces, aerosol inhalation
- via an arthropod vector
- by inoculation of saliva in a bite wound.

Many zoonoses can also be transmitted from person to person. Some zoonoses are listed in Box 20.15.

Most microorganisms do not have a vertebrate or arthropod host but are free-living in the environment. The vast majority of these environmental organisms are non-pathogenic but some can cause human disease (Box 20.16). Person-to-person transmission of these infections is rare. Some parasites may have a stage of their life cycle that is environmental (e.g. the free-living larval stage of *Strongyloides stercoralis* and the hookworms), even though the adult worm requires a vertebrate host. Other pathogens can survive for periods in water or soil and are transmitted from host to host via this route (see later); these should not be confused with true environmental organisms.

### Routes of transmission

#### Endogenous infection

The body’s own endogenous flora (often called the **microbiome**) can cause infection if the organism gains access to a usually sterile site. This can happen by simple mechanical transfer, such as when colonic bacteria enter the female urinary tract. The non-specific host defences may be breached, for example, by cutting or scratching the skin and allowing surface commensals to gain access to deeper tissues; this is frequently the aetiology of cellulitis. There may be more serious defects in host immunity owing to disease or chemotherapy, allowing normally harmless skin and bowel flora to produce invasive disease.
Air-borne spread

Many respiratory tract pathogens are spread from person to person by aerosol or droplet transmission. Secretions containing the infectious agent are coughed, sneezed or breathed out and are then inhaled by a new host. Some enteric viral infections may also be spread by aerosols of faeces or vomit. Environmental pathogens, such as Legionella pneumophila, and zoonoses, such as ornithosis, are also acquired by aerosol inhalation, while rabies virus may be inhaled in the dust from bat droppings.

Faeco-oral spread

Transmission of organisms by the faeco-oral route occurs by direct transfer, by contamination of clothing or household items or, most commonly, via contaminated food or water. Human and animal faecal pathogens enter the food supply at any stage. Raw sewage is used as fertilizer in many parts of the world, contaminating growing vegetables and fruit. Poor personal hygiene can result in contamination during production, packaging, preparation or serving of food. In the Western world, centralization of the food supply and increased processing of food have allowed the potential for relatively minor episodes of contamination to cause widely disseminated outbreaks of food-borne infection.

Water-borne faeco-oral spread is usually the result of inadequate access to clean water and safe sewage disposal, and is common throughout the developing world. Worldwide, 5.2 billion people (71% of the global population) have access to clean water, but only 39% have access to safe sanitation. An estimated 870,000 deaths globally each year are due to unsafe water and sanitation and suboptimal hygiene.

Vector-borne disease

Many tropical infections, including malaria, are spread from person to person or from animal to person by an arthropod vector. Vector-borne diseases are also found in temperate climates but are relatively uncommon, although they may become more prevalent due to climate change. In most cases, part of the parasite life cycle takes place within the body of the arthropod and each parasite species requires a specific vector. Some vector-borne diseases are shown in Box 20.17.

Direct person-to-person spread

Organisms can be passed on directly in a number of ways. Sexually transmitted infections are dealt with in Chapter 37. Skin infections such as ringworm, and ectoparasites such as scabies and head lice, can be spread by simple skin-to-skin contact. Other organisms are passed on by transmission from blood (or, occasionally, some other body fluid) to blood. Blood-to-blood transmission can occur during sexual contact; from mother to infant, either transplacentally or in the peripartum; between intravenous drug users sharing any part of their injecting equipment; when infected medical or other (e.g. tattoo needles) equipment is reused; if infected blood or blood products are transfused; or in any sporting or accidental contact when blood is spilled. Ingestion of infected breast milk is another route of person-to-person spread for some infections (e.g. HIV), although in LMICs breastfeeding is still recommended when HIV-positive women are taking antiretroviral therapy.
Indirect person-to-person spread

Many organisms can be spread from person to person indirectly by contamination of fomites (e.g. door handles), which are subsequently touched by another person. Common examples include respiratory viruses, such as influenza, and healthcare-associated pathogens, such as MRSA and the spores of *C. difficile*. This is sometimes an overlooked route of transmission; minimization requires, for example, hand-washing immediately after sneezing or coughing and when moving from ward to ward in a hospital, and optimal cleaning regimens in institutions.

Direct inoculation

Infection can occur when pathogenic organisms breach the normal mechanical defences by direct inoculation (e.g. environmental contamination of bone after an open fracture, leading to subsequent osteomyelitis). Some of the circumstances in which this can occur are covered under endogenous infection and blood-to-blood transmission, described earlier. Some environmental organisms may be inoculated by accident; this is a common mode of transmission of tetanus and certain fungal infections. Rabies virus is inoculated by the bite of an infected animal.

Consumption of infected material

Although many food-related zoonotic infections are due to contamination of food with animal faeces (and are thus spread by the faeco-oral route), several diseases are transmitted directly in animal products. These include some strains of *Salmonella* (eggs, chicken meat), brucellosis ( unpasteurized milk), *E. coli*, and the prion diseases kuru and variant Creutzfeldt–Jakob disease (vCJD; neural tissue).

**Classification of outbreaks**

The type of outbreak has a bearing on the public health measures that need to be instituted for its control.

- **Person-to-person** is where infection is passed from one infected individual to another and outbreaks of infection are separated by the incubation period. Control measures may include hand and personal hygiene (a sensible early control measure in any outbreak), immunization (e.g. influenza, measles) and antiviral agents (e.g. influenza).

- **Point source** is where there is a single source of infection, e.g. food eaten at a social function. All those infected will develop symptoms at the same time, around the expected incubation period. If the point source is temporary or removed, and provided there is no person-to-person or other mode of transmission, new cases decline after the incubation period.

- **Common source** is where there is a single source of infection but infections are spread over a period of time, e.g. a contaminated food preparation facility or restaurant. Many people may be exposed over a potentially long period of time. Once the source is identified, control measures may include cleaning and disinfecting the facility, closing the facility or restaurant, recalling food, and informing the public on how to make food safe (such as by cooking it) or to avoid or throw food away.

- **Epidemic** is when there is an increased and unusually widespread infection in the community, causing waves of infection. Epidemics spread through communities and may affect those who have no active immunity to that infection.

- **Pandemic** is an epidemic, as defined above, occurring worldwide or over a very wide geographical area and crossing international boundaries, usually affecting a large number of people. Some infectious diseases should be notified to the public health authorities, so that they are aware of cases and outbreaks, and can respond accordingly. Diseases that are notifiable in England and Wales are listed in Box 20.18 (see also Further reading for the List of Notifiable Organisms (Causative Agents) in the UK).

The prevention of and response to epidemics and pandemics is complex and depends on the underlying cause, but will be multifactorial in approach and may include:

- routine and enhanced disease surveillance
- identification and tracing of contacts, including rapid diagnostics, and epidemiological investigation
- public awareness campaigns (e.g. focused on hand and personal hygiene and/or other control measures; to provide reassurance)
- enhanced infection prevention and control procedures
- isolation or cohort nursing in healthcare facilities admitting patients and other institutions (e.g. nursing homes)
- use of mass antimicrobials (e.g. antiviral agents in influenza epidemics) and immunization as appropriate and available.

Efficient coordination of such responses by local, regional, national (e.g. Public Health England) or international organizations
Infection prevention and control

Relatively few patients with infections present a serious risk to healthcare workers and other contacts or patients. The appearance of diseases such as strains of influenza with high mortality, the occasional importation of Lassa fever or Ebola (see p. 532), ongoing concerns about the bioterrorist use of microbes, and the emergence of extensively drug-resistant bacterial infections (e.g. tuberculosis and Gram-negative bacteria, especially carbapenemase-producing or carbapenemase-resistant *E. coli* and *K. pneumoniae*) mean that the potential remains for unexpected outbreaks of life-threatening or almost untreatable infections, including within healthcare settings.

During the worldwide outbreak of severe acute respiratory syndrome (SARS) in 2003, scrupulous infection control procedures reduced the spread of infection. However, in the ‘inter-epidemic’ period, it is difficult to maintain a high level of alert. Healthcare workers should remain vigilant because the early symptoms of many of these diseases are non-specific. Methods of preventing infection depend on the source and route of transmission.

Healthcare-associated infections

The burden of morbidity, mortality and costs attributed to healthcare-associated infection (HAI) has been highlighted in many high-income countries. Although data from LMICs are sparse, the impact of HAI is likely to be even greater. *C. difficile*, *Staph. aureus* (especially MRSA), vancomycin-resistant enterococci and the increasingly difficult-to-treat, multi- and extensively drug-resistant Gram-negative infections are all strongly associated with healthcare contact and remain a problem in hospitals worldwide. In 2011 the proportion of inpatients with an HAI in acute hospitals in England was 6.4%. In Europe, 1 in 18 inpatients have an HAI at any one time. The most frequent HAI s affect the respiratory and urinary tracts, as well as surgical sites. There has been a notable decline, however, in the incidences of, and mortality caused by, MRSA bloodstream and *C. difficile* infections in the UK. This has been due to higher standards of basic infection prevention and control, including rapid isolation of patients, hospital cleaning and universal MRSA screening (and decolonization therapy, if positive) on entry to acute hospitals and prior to surgery, and improved care of intravenous access devices.

**HAI prevention and control measures**

Poor infection control practice in hospitals and other healthcare environments can cause the transfer of infection from person to person. It is essential for all healthcare workers to wash or clean their hands before and after patient contact; whenever necessary, they should wear gloves, aprons and other protective equipment. This is particularly important when they are performing invasive procedures, dealing with infected wounds or manipulating indwelling devices. Care should also be taken when in contact with patients known to be colonized or infected with a resistant organism (e.g. carbapenemase-producing *K. pneumoniae*), those infected by communicable pathogens with high mortality (e.g. Ebola, for which high-security isolation and extreme care are mandatory), or those with diarrhoea (e.g. *C. difficile* infection).

Interventions that health workers should focus on to prevent and control HAIs are described here.

**Care bundle approach**

There is a set (typically 3–5) of simple actions – ideally, highly evidence-based – that healthcare professionals should always implement in a certain situation (e.g. inserting a urinary catheter) to minimize the risk of a negative outcome. As an example, see the Matching Michigan approach to reducing infections associated with central intravenous catheters (see Further reading).

**Hand hygiene**

The WHO’s ‘Five Moments for Hand Hygiene’ (see Further reading) are applied before and after all patient contacts, including before and after aseptic procedures, and after contact with body fluids and the patient environment. Soap and water (rather than an alcohol-based rub) should be used after visible contamination of hands and when patients are vomiting or have diarrhoea, even if gloves are used. In low-income settings, in the absence of soap and water, alcohol-based hand rub should be used if available.

**Personal protective equipment**

Gloves should be worn for all invasive procedures, including venesection, and contact with sterile sites, mucous membranes, bodily fluids or non-intact skin. Disposable plastic aprons should be used when there is a risk of contamination of clothing or skin; if there is a risk of extensive contamination, surgical gowns should be worn. Respiratory protection should be worn for patients with high-consequence respiratory-spread pathogens, such as avian influenza and MERS.

**Aseptic technique**

This should be adopted for all invasive procedures, when using and manipulating invasive devices, and when in contact with all wounds.

**Urinary catheters**

These should be inserted only when it is essential to do so and then removed as soon as is possible; they must be inserted using an aseptic technique. A clear care plan should be in place for longer-term catheters. Overuse or poor care of urinary catheters increases the risk of *E. coli* bloodstream infection, a current target for HAI reduction in the UK.

**Vascular access devices**

Insert a vascular catheter only when there is a clear plan to use it; check the device daily and remove as soon as is possible. Use 2% chlorhexidine gluconate in 70% isopropyl alcohol for skin decontamination prior to insertion and to clean the access port or hub prior to use. Ensure that a clear care plan is in place for medium- or long-term devices.

**Adequate hydration**

Dehydrated patients are at higher risk of urinary tract infections. Oral hydration is preferred to intravenous if possible (there is a lower risk of infection with an intravenous device), and patients should be encouraged to drink a variety and an adequate quantity of fluids.

**Communication**

This is essential when transferring patients with transmissible infections (e.g. chickenpox, MERS, and infections caused by multi- and extensively drug-resistant bacteria) between admission areas, wards, hospitals and institutions, including residential and nursing homes.
Isolation

The appropriateness of isolation, if available, should be considered. Infections with a high risk to public health (e.g. Ebola and MERS) are isolated within high-security, hospital-based, negative-pressure isolation facilities using enhanced respiratory, personal protective equipment and decontamination procedures. In the UK there are only two such sites for the management of suspected Ebola infection. Patients hospitalized with highly infectious respiratory-spread pathogens, such as chickenpox and measles, are isolated in negative-pressure isolation facilities. Patients with high-consequence pathogens spread by direct or indirect person-to-person contact (colonization or infection), such as C. difficile and multi-drug-resistant Gram-negative bacteria, are, ideally, housed in side-rooms with en suite toileting facilities and appropriate contact precautions (hand hygiene and personal protective equipment). If there are few such facilities available, then risk assessment is essential (i.e. patients posing the highest risk to the health of the public, other patients and healthcare staff are housed in the available isolation facilities). If no such facilities exist, then basic precautions (hand hygiene, personal protective equipment, etc.) are still applied and cohort isolation is considered (i.e. patients with the same microbiologically confirmed infection are housed on the same ward).

Other infection prevention and control measures (non-HAI)

Although effective antimicrobial chemotherapy is available for many diseases, the ultimate aim of any infectious disease control programme is to prevent infection occurring. This is achieved either by:

• eliminating the source or mode of transmission of an infection (see p. 504), or
• reducing host susceptibility to environmental pathogens:

Eradication of reservoir

In a few diseases, for which humans are the only natural reservoir of infection, it may be possible to eliminate disease by an intensive programme of case-finding, treatment and immunization (as in the case of smallpox). If there is an animal or environmental reservoir, complete eradication is unlikely but local control methods may decrease the risk of human infection (e.g. killing of rodents to control plague, leptospirosis and other diseases).

For arthropod- or vector-borne infections

It may be possible to destroy the vector species and/or to take measures to avoid being bitten (e.g. insect repellent sprays, impregnated netting).

For food-borne infections

Improvements in food handling and preparation result in less contamination during processing, transport or preparation. Organisms that are intrinsically present in food can be killed by appropriate preparation and cooking. Improved surveillance and regulation of the food industry, as well as better health education for the public, are necessary.

For faeco-oral infections

Improvements in water supply and sanitation (recognized in the WHO’s SDGs) could dramatically decrease the prevalence of faeco-oral infections.

For blood-borne infections

Blood transfer may be prevented by optimal use of medical equipment. Donated blood is routinely tested for infection in most high-income countries.

For infections spread by air-borne and direct contact

Some air-borne respiratory infections and some infections spread by direct contact can be controlled by isolating patients, although this is often difficult. Positive pressure isolation (in which the flow of air is from the patient’s room into the ward) is useful in uninfected patients with severe immunodeficiency to protect them from infection. Neuraminidase inhibitors may reduce the transmission of influenza viruses to at-risk persons.

Immunization, immunoprophylaxis and immunotherapy

Immunization has changed the course and natural history of many infectious diseases. Passive immunization by administering preformed antibody, in the form of either immune serum or purified normal immunoglobulin, provides short-term immunity and has been effective in both the prevention (immunoprophylaxis) and the treatment (immunotherapy) of a number of bacterial and viral diseases (Box 20.19). The active immunization schedule currently recommended is summarized in Box 20.20. Long-lasting immunity is achieved only by active immunization with a live attenuated or an inactivated organism, or a subunit thereof (Box 20.21). Active immunization may also be performed with microbial toxin (either native or modified): that is, a toxoid. Immunization should be kept up to date, with booster doses being given throughout life according to the vaccines booster schedule. Travellers to LMICs, especially if visiting rural areas for prolonged periods, should enquire about further specific immunizations.

In 1974 the WHO introduced the Expanded Programme on Immunization (EPI). By 1994, more than 80% of the world’s children had been immunized against tuberculosis, diphtheria, tetanus, pertussis, poliomyelitis and measles. It is hoped that poliomyelitis will be eradicated worldwide in the near future, matching the past success of global smallpox eradication. Introduction of conjugate vaccines against *Haemophilus influenzae* type b (Hib) and *Strep. pneumoniae* has proved highly effective in controlling invasive *H. influenzae* infections, notably meningitis, and reducing invasive pneumococcal disease, and can have a positive effect on antibiotic resistance (Fig. 20.4). The incidence of group C meningococcal infections in the UK is now so low that the childhood immunization schedule has been modified. A safe and immunogenic vaccine against *Neisseria meningitidis* serogroup B has now been included in the childhood

For more detailed advice about childhood immunization, consult The Green Book (see Further reading). A model scheme for all children; different schedules and/or additional vaccines are recommended in some locations: https://www.who.int/immunization/policy/Immunization_routine_table2.pdf?ua=1. BCG, bacille Calmette–Guérin; DPT, diphtheria, tetanus, pertussis; Tetanus triple vaccine; HBV, hepatitis B vaccine; Hib, Haemophilus influenzae type b; HPV, human papillomavirus vaccine; PCV, pneumococcal conjugate vaccine; PV, polio vaccine. Mumps vaccine is also given in many developing countries.

**Box 20.21** Examples of active immunization available

- **Live attenuated vaccines**
  - Oral polio (Sabin) (not recommended, used only for outbreaks)
  - MMR (measles, mumps, rubella)
  - Rotavirus
  - Varicella zoster
  - Yellow fever
  - BCG
  - Typhoid

- **Inactivated and/or conjugate vaccines**
  - Hepatitis A
  - Pertussis
  - Typhoid – whole-cell and Vi antigen
  - Polo (Salk) for routine use
  - Influenza
  - Human papillomavirus (HPV)
  - Cholera (oral) – includes toxoid
  - Meningococcosis groups A, B, C, W135 and Y
  - Rabies
  - Anthrax
  - Tick-borne encephalitis
  - Japanese encephalitis
  - Pneumococcal
  - Haemophilus influenzae type b

- **Recombinant vaccines**
  - Hepatitis B

Individual vaccines for measles, mumps and rubella are not licensed in the UK. BCG, bacille Calmette–Guérin.

**PRINCIPLES AND MECHANISMS OF INFECTION**

**Host–organism interactions, including the human microbiome**

Each of us is colonized by huge numbers of microorganisms (10^{14} bacteria, plus viruses, fungi, protozoa and worms), with which we coexist. Many mucosal surfaces and organs (e.g. skin, lungs, and
gastrointestinal and genitourinary tracts) in humans have their own unique community of microbes, often called the microbiome. Within our gastrointestinal tract (GIT), for example, there are approximately $10^{11}$–$10^{12}$ microbes per gram of content with each person carrying at least 160 species, but often many more. A very high proportion of the GIT microbiome bacteria are anaerobic, which means that antibiotics with anti-anaerobic activity (e.g. clindamycin) can profoundly disrupt the nature of this microbial community. The human microbiome also acts as a reservoir for antimicrobial resistance, with many antimicrobials promoting the emergence of resistance through microbiome effects.

The development of the human microbiome is complex; normal vaginal delivery (or not Caesarian section), breast-feeding, diet and the living environment, for example, may have an impact on it. The effect of change in the human microbiome, particularly of the GIT, on host metabolism and immunity is increasingly associated with health states, including, for example, cancer (where it has been shown to change the patient’s response to chemotherapy), diabetes and other metabolic diseases, host metabolism of medications, inflammatory bowel disease, mental health and rheumatological diseases. Early use of antibiotics, or disruption of the microbiome by other means, may therefore have a prolonged impact on microbiome community structure and, through that, on health and disease states later in life. On the other hand, it may be possible to protect and manipulate the microbiome therapeutically to the benefit of health, and not just infectious diseases; existing examples, not necessarily widely implemented in current clinical practice, include the use of probiotics and faecal transplantation to prevent and treat recurrent C. difficile infection, respectively, and selective decontamination of the digestive tract to prevent infections in critically ill patients.

Most microbiome microorganisms are commensal or symbiotic, living on or within humans without causing harm, but some are potentially pathogenic in the right circumstances: ‘the right bug in the wrong place’. Infection and illness may be caused by microbes that are usually harmless evading the body’s defences and infecting abnormal sites (e.g. Staphylococcus epidermidis and prosthetic joint infection). Endogenous GIT commensals may also cause disease in the host, either because they physically transfer to an inappropriate site (e.g. the bowel coliform E. coli causing urinary tract infection, sometimes called uropathogenic E. coli) or because the host immune response or the protective nature of endogenous bacteria has been reduced (e.g. oral candidiasis in an immunocompromised host and following exposure to antibiotics). Alternatively, disease may be caused by exposure to exogenous pathogenic organisms that are not part of the human microbiome (e.g. Legionella spp., rabies virus).

The symptoms and signs of infection are a result of the interaction between host and pathogen. In some cases, such as the early stages of influenza, symptoms are almost entirely due to killing of host cells by the invading organism. Usually, however, the harmful effects of infection are caused by a combination of direct microbial pathogenicity and the body’s immune response to infection. In meningococcal bloodstream infection, for example, much of the tissue damage is caused by cytokines released in an attempt to fight bacteria.

### Specificity of microorganisms

When the wrong microbes reach the right place, they are often highly specific with respect to the organ or tissue they infect (see p. 490). For example, a number of viruses are hepatotropic, such as those responsible for hepatitis A, B, C and E, and for yellow fever. This predilection for specific sites in the body relates partly to the presence of appropriate receptors on different cell types, partly to the immediate environment in which the organism finds itself,
and partly to the nature of the organism. *Staph. epidermidis*, for example, is a facultative anaerobe (i.e. can live in oxygenated and non-oxygenated environments) that usually lives on the human skin, an aerobic environment, but which has a predilection to forming biofilms on medical devices (e.g. of central venous lines and hip replacements) in less aerobic environments when it reaches the right place. Other important facultative anaerobes include *E. coli*, other staphylococcal species and streptococci species. In contrast, *Mycobacterium tuberculosis* is an obligate aerobe (i.e. it needs oxygen) and *Bacteroides* spp. (found in the human GIT) and *Clostridium* spp. are obligate anaerobes (i.e. cannot live in atmospheric conditions), which partly explains the nature of the infections these bacteria cause. *Clostridium* spp. form spores, however, that enable survival in atmospheric conditions, and thereby their spread to the GIT of other human hosts.

Even within a species of bacterium there are sometimes clear differences between strains with regard to their ability to cause certain clinical presentations. There are many different strains of *Streptococcus pneumoniae*, for example, with some asymptomatically colonizing the nasopharyngeal microbiome, some more likely to invade and cause pneumococcal bloodstream infection, and certain different invasive strains more likely to cause empyema or meningitis, while other strains are more likely to cause pneumonia without bloodstream infection. Likewise, some strains of *E. coli* (enterotoxin-producing strains) are more likely to cause gastrointestinal disease (see p. 539), whereas uropathogenic *E. coli* are more likely to cause UTI.

### Pathogenesis

*Fig. 20.5* summarizes some of the steps that are followed during the pathogenesis of infection. Pathogens have developed a variety of mechanisms to evade host defences. For example, some produce toxins directed at phagocytes – *Staph. aureus* (α-toxin), *Strep. pyogenes* (streptolysin) and *Clostridium perfringens* (α-toxin) – while others can survive within macrophages. Several pathogens possess a capsule that protects against complement activation (e.g. *Strep. pneumoniae*). Antigenic variation can also help evasion of host defences – for example, antigenic shift and drift in influenza – which is the reason why influenza vaccines are modified from year to year.

#### Epithelial attachment

Many bacteria attach to epithelium cells using the adhesion molecules (called adhesins) of specific organelles called pili (or fimbriae). Enterotoxigenic and uropathogenic *E. coli* use fimbriae, for example, to attach to enterocytes and urothelial cells, respectively. Following attachment, some bacteria, such as *Staph. epidermidis* and *Pseudomonas aeruginosa*, may produce an extracellular ‘slime’ layer and recruit additional bacteria to form a ‘protective’ biofilm. Biofilms are difficult to eradicate and are frequently associated with medical devices and persistent infections. Many viruses and protozoa (e.g. *Plasmodium* spp., *Entamoeba histolytica*) attach to specific epithelial target-cell receptors, while others have attachment organs (e.g. the buccal plates of hookworms) that firmly grip the intestinal epithelium.

#### Colonization and invasion

Following epithelial attachment, pathogens may remain on the surface epithelium or tissue invasion may follow.

#### Tissue dysfunction or damage

Microorganisms produce disease by a number of mechanisms, as described here.
The presence of replicating viruses may interfere with host-cell metabolism, resulting in cell death.

Exotoxins and endotoxins

- **Exotoxins** have many diverse actions, including inhibition of protein synthesis (diphtheria toxin), neurotoxicity (*Clostridium tetani* and *Clostridium botulinum*) and enterotoxicity, which results in intestinal secretion of water and electrolytes (*E. coli*, *Vibrio cholerae*).
- **Endotoxin** is a lipopolysaccharide (LPS) in the cell wall of Gram-negative bacteria. It is responsible for many of the features of sepsis (see p. 156). The effects of endotoxin are mediated predominantly by release of tumour necrosis factor (TNF).

The clinical expression of disease caused by *Staph. aureus* varies according to site, invasion and toxin production (Box 20.23). Furthermore, host susceptibility to infection may be linked to genetic or acquired defects in host immunity that may complicate intercurrent infection, injury, ageing and metabolic disturbances (Box 20.24).

Host response to infection

Natural defences

The natural host defences to infection are those of an intact surface epithelium with local production of secretions, antimicrobial enzymes (e.g. lysozyme in the eye) and, in the stomach, gastric acidity. The latter is reduced by proton pump inhibitors, increasing the risk of some gastroenteric infections, including *C. difficile* infection. The mucociliary escalator of the large airways is destroyed by smoking.

Immunological defences

The immunological response to infection is described in Chapter 3.

**Metabolic and immunological consequences of infection**

**Fever**

Body temperature is controlled by the thermoregulatory centre in the anterior hypothalamus and is usually maintained at approximately 36.8°C in health, with diurnal and inter-individual variation of about ±1.0°C. Gram-negative bacteria contain LPS and peptidoglycan; the latter is also a component of Gram-positive bacterial cell walls. Monocytes and dendritic cells recognize these, leading to the formation of inflammatory cytokines, such as interleukin (IL)-1, IL-6, IL-12, tumour necrosis factor alpha (TNF-α) and many others. These act on the thermoregulatory centre by increasing prostaglandin (PGE₂) synthesis. The antipyretic effect of salicylates is brought about, at least in part, through their inhibitory effects on prostaglandin synthase.

Fever production has a positive effect on the course of infection. However, for every 1°C rise in temperature, there is a 13% increase in resting metabolic rate and oxygen consumption. Fever leads to
increased energy requirements, therefore, at a time when anorexia leads to decreased food intake, resulting in an increase in skeletal muscle breakdown to provide energy. Fever in non-infection conditions can be deleterious.

The inflammatory response

The inflammatory response is a fundamental biological response to a variety of stimuli, including microorganisms or their products, such as endotoxin, which acts on monocytes and macrophages. Non-phagocytic cells (lymphocytes, natural killer cells) are also involved. The release of cytokines – notably, TNF-α, IL-1, IL-6 and interferon gamma (IFN-γ) – leads to the release of a cascade of other mediators involved in inflammation and tissue remodelling, such as interleukins, prostaglandins, leukotrienes and corticotropin. See Further reading for more information about the pathogenesis of infection by some key human bacterial, viral and protozoan pathogens.

Further reading

VIRAL INFECTIONS

Viruses are much smaller than other infectious agents and carry their genome as either DNA or RNA (but never both). Details of the structure, size and classification of human DNA and RNA viruses are shown in Boxes 20.25 and 20.26, respectively. Since viruses are metabolically inert, they must live intracellularly, using the host cell for synthesis of viral proteins and nucleic acid. Viruses have a central nucleic acid core (genome) surrounded by a protective protein coat (capsid) that is antigenically unique for a particular virus.

The capsid imparts a helical or icosahedral structure to the virus. Some viruses also possess an outer envelope consisting of lipid and protein.

OUTCOMES OF VIRUS INFECTION OF A CELL

Replication of viruses within a cell may result in sufficient distortion of normal cell function to result in cell death: a lytic or cytolysic infection. However, acute cell death is not an inevitable consequence of virus infection of a cell. In a chronic, or persistent, infection, virus replication continues throughout the lifespan of the cell but does not interfere with the normal cellular processes necessary for cell survival. Hepatitis B and C viruses may interact with cells in this way. Some viruses, such as those of the herpesvirus family, are able to go latent within a cell; in such a state, the virus genome is present within the cell, but there is very little, if any, production of viral proteins and no production of mature virus particles. Finally, some viruses are able to transform cells, leading to uncontrolled cell division: for example, Epstein–Barr virus infection of B lymphocytes, resulting in the generation of an immortal lymphoblastoid cell line.

VIRUS INFECTIONS OF THE SKIN AND MUCOUS MEMBRANES

Many virus infections are associated with skin rashes (exanthems) or eruptions on the mucous membranes (exanthems) (see Box 20.9), and so clinical syndromes based on the nature of the rash (which may be vesicular (i.e. consisting of fluid-filled vesicles) or maculopapular) are often highly specific to the causative agent.

Vesicular viral rashes

Herpes simplex virus infection

Members of the Herpesviridae family of viruses cause a wide range of human diseases (Box 20.27). The hallmark of all herpesvirus
infections is the ability of the viruses to establish latent infections that persist for the life of the individual.

Two types of herpes simplex virus (HSV; Fig. 20.6) have been identified: HSV-1 is the major cause of herpetic stomatitis, herpes labialis (‘cold sore’), keratoconjunctivitis and encephalitis, whereas HSV-2 causes genital herpes and may also be responsible for systemic infection in the immunocompromised host. These divisions are not rigid, however, for HSV-1 can give rise to genital herpes and HSV-2 can cause infections in the mouth. The site of latency for both HSV-1 and 2 is the nerve cell body.

**HSV-1**

The portal of entry of HSV-1 infection is usually via the mouth or, occasionally, the skin. The primary infection may go unnoticed, or may produce a severe inflammatory reaction with vesicle formation leading to painful ulcers (gingivostomatitis; Fig. 20.7). Latent virus may be reactivated from the trigeminal ganglion by stress, trauma, febrile illnesses and ultraviolet radiation, producing the recurrent form of the disease known as herpes labialis (‘cold sore’). Approximately 70% of the population is infected with HSV-1 and recurrent infections occur in one-third of individuals. Reactivation often produces localized paraesthesiae in the lip before the appearance of a cold sore. Complications of HSV-1 infection include transfer to the eye (dendritic ulceration, keratitis), acute encephalitis (see p. 871), nail-bed infections (herpetic whitlow) and erythema multiforme (p. 678).

**HSV-2**

The clinical features, diagnosis and management of genital herpes are described on page 1421. The virus remains latent in the sacral ganglia and, during recurrence, can produce a radiculomyelopathy, with pain in the groin, buttocks and upper thighs. Primary anorectal herpes infection is common in men who have sex with men.
Virus infections of the skin and mucous membranes

Neonates may develop primary HSV infection following vaginal delivery in the presence of active genital HSV infection in the mother, particularly if the maternal disease is a primary, rather than a recurrent, infection. The disease in the baby varies from localized skin lesions (about 10–15%) to widespread visceral disease most often affecting the lungs, liver and brain, with a poor prognosis. Caesarean section should therefore be performed if active genital HSV infection is present during labour.

Immunocompromised patients, such as those receiving intensive cancer chemotherapy or those with acquired immunodeficiency syndrome (AIDS), may develop disseminated HSV infection involving many of the viscera. In severe cases, death may result from hepatitis and encephalitis. Eczema herpeticum is a serious complication in individuals with eczema, where the non-intact skin allows spread of lesions across large areas and bloodstream access, which may lead to herpetic involvement of internal organs.

**Diagnosis and management**

Confirmation of clinical diagnosis is most commonly obtained by detection of HSV DNA in vesicle fluid by genome amplification. Treatment of HSV-associated disease is with aciclovir and derivatives.

**Varicella (chickenpox) and herpes zoster (shingles)**

Infection with varicella zoster virus (VZV), another herpesvirus, produces two distinct diseases: varicella (chickenpox) and herpes zoster (shingles). The *primary infection*, chickenpox, usually occurs in childhood, the virus entering through the mucosa of the upper respiratory tract. In some countries (e.g. the Indian subcontinent), a different epidemiological pattern exists, with most infections occurring in adulthood. Chickenpox is rarely contracted twice by the same individual. Infectious virus is spread from the throat and from fresh skin lesions by air-borne transmission or direct contact. The period of infectivity in chickenpox extends from 2 days before the appearance of the rash until the skin lesions are all at the crusting stage. Following recovery from chickenpox, the virus remains latent in dorsal root and cranial nerve ganglia. *Reactivation* of infection results in shingles.
Clinical features of chickenpox

Some 14–21 days after exposure to VZV, a brief prodromal illness of fever, headache and malaise heralds the eruption of chickenpox, characterized by the rapid progression of macules to papules to vesicles to pustules in a matter of hours (Fig. 20.8). In young children the prodromal illness may be very mild or absent. The illness tends to be more severe in older children and can be debilitating in adults. The lesions occur on the face, scalp, trunk and, to a lesser extent, the extremities. It is characteristic to see lesions at all stages of development on the same area of skin. Fever subsides as soon as new lesions cease to appear. Eventually, the pustules crust and heal without scarring.

Complications include pneumonia, which generally begins 1–6 days after the skin eruption, and bacterial superinfection of skin lesions. Pneumonia is more common in adults than in children, and cigarette smokers are at particular risk. Pulmonary symptoms are usually more striking than the physical findings, although a chest X-ray usually shows diffuse changes throughout both lung fields. Central nervous system (CNS) involvement occurs in about 1 per 1000 cases and most commonly presents as an acute truncal cerebellar ataxia. The immunocompromised are susceptible to disseminated infection, with multiorgan involvement. Women in pregnancy are prone to severe chickenpox and, in addition, there is a risk of intrauterine infection with structural damage to the fetus (if maternal infection is within the first 20 weeks of pregnancy, the risk of varicella embryopathy is 1–2%).

Clinical features of shingles

Shingles (see p. 672) arises from the reactivation of VZV latent within the dorsal root or cranial nerve ganglia. It may occur at any age but is most common in the elderly, producing skin lesions similar to those of chickenpox, although classically they are unilateral and restricted to a sensory nerve (i.e. dermatomal) distribution (Fig. 20.9). The onset of a shingles rash is usually preceded by severe dermatomal pain, indicating the involvement of sensory nerves in its pathogenesis. Virus is disseminated from freshly formed vesicles and may cause chickenpox in susceptible contacts.

The most common complication of shingles is post-herpetic neuralgia (PHN; see p. 672). Occurrence of PHN is related to age (more likely in the elderly) and the intensity of the original shingles rash.

Diagnosis

The diseases are usually recognized clinically but can be confirmed by detection of VZV DNA within vesicular fluid, electron microscopy, immunofluorescence or culture of vesicular fluid, and serology.

Prevention and management

Chickenpox usually requires no treatment in healthy children and infection results in life-long immunity. Aciclovir and derivatives are licensed for this indication in the USA. However, the disease may be fatal in the immunocompromised, who should therefore be offered protection after exposure to the virus, with zoster-immune globulin (ZIG) and high-dose aciclovir at the first sign of development of the disease.

Antiviral therapy with aciclovir or a similar drug may be offered to patients over the age of 16 years, if they present within 72 hours of onset. Prophylactic ZIG is recommended for susceptible pregnant women exposed to VZV and, if chickenpox develops, aciclovir treatment should be given but the drug is not licensed for use in pregnancy. If a woman has chickenpox at term, her baby should be protected by ZIG if delivery occurs within 7 days of the onset of the mother’s rash. An effective live attenuated varicella vaccine is licensed as a routine vaccination of childhood in the USA; it is available on a named patient basis in the UK and for susceptible healthcare workers.

Shingles involving motor nerves – for example, the VIIth cranial nerve, leading to facial palsy – is also treated with aciclovir (or derivatives). Antiviral therapy has been shown to reduce the burden of PHN when treatment is given in the acute phase, and is therefore recommended for shingles in the over-65s. Shingles involving the ophthalmic division of the trigeminal nerve has an associated 50% incidence of acute and chronic ophthalmic complications. Early treatment with aciclovir reduces this to 20% or less. As for chickenpox, all immunocompromised individuals should be given aciclovir at the onset of shingles, no matter how mild the attack appears when it first presents.

Both recombinant and live attenuated vaccines have been shown to reduce shingles-related morbidity and PHN. Vaccination is recommended for all adults over the age of 60 (USA) or 70 (UK).

+++ indicates a likely animal reservoir. The virus was introduced into the USA in 2003 via small West African mammals illegally imported as pets. Widespread infection of prairie dogs resulted and there were 37 laboratory-confirmed cases in humans. Two imported cases were reported in the UK in 2018, with spread to a third case who was a healthcare worker.

Poxvirus infections

Smallpox (variola)
This disease was eradicated in 1977 following an aggressive vaccination policy. Its possible use in bioterrorism has resulted in the re-introduction of smallpox vaccination in some countries.

Monkeypox
This rare zoonosis occurs in small villages in tropical rainforests in several countries of West and Central Africa. Its clinical effects, including a generalized vesicular rash, are indistinguishable from those of smallpox, but person-to-person transmission is unusual. Most infections occur in children who have not been vaccinated against smallpox. Disease can be severe, with mortality rates of 10–15% in unvaccinated individuals. Serological surveys indicate that several species of squirrel are the likely animal reservoir. The virus was introduced into the USA in 2003 via small West African mammals illegally imported as pets. Widespread infection of prairie dogs resulted and there were 37 laboratory-confirmed cases in humans. Two imported cases were reported in the UK in 2018, with spread to a third case who was a healthcare worker.

Cowpox
Cowpox produces large vesicles that are classically found on the hands of individuals in contact with infected cows. The lesions are associated with regional lymphadenitis and fever. Cowpox virus has been found in a range of species, including domestic and wild cats, and the reservoir is thought to exist in a range of rodents.

Vaccinia virus
This laboratory virus does not occur in nature in either humans or animals. Its origins are uncertain but it has been invaluable in its use as the vaccine to prevent smallpox.

Orf
This poxvirus causes contagious pustular dermatitis in sheep and hand lesions in humans (see p. 672).

Molluscum contagiosum
This is discussed on page 672.

Human papillomavirus infections
These cause warts (see p. 672) and cervical cancer (p. 130).

Maculopapular viral rashes

Measles (rubeola)
Measles virus is a paramyxovirus (see Box 20.26). Measles is a highly communicable disease that occurs worldwide. With the introduction of aggressive immunization policies, the global incidence of and mortality from measles fell by 80% between 2000 and 2017, but there were still approximately 110,000 measles-related deaths in 2017, mostly in children under the age of 5 and largely in Africa and South-east Asia. It is spread by droplet infection, and the period of infectivity is from 4 days before until 2 days after the onset of the rash.

Clinical features
The incubation period is 8–14 days. Two distinct phases of the disease can be recognized.
Typical measles

- **Pre-eruptive and catarrhal stage**, the stage of viraemia and viral dissemination. Malaise, fever, rhinorrhea, cough, conjunctival suffusion and the pathognomonic Koplik’s spots – small, greyish, irregular lesions surrounded by an erythematous base, found in greatest numbers on the buccal mucous membrane opposite the second molar tooth – are present during this stage.

- **Eruptive or exanthematous stage**, characterized by the presence of a maculopapular rash that initially occurs on the face, chiefly the forehead, and then spreads rapidly to involve the rest of the body (Fig. 20.10). At first, the rash is discrete but later it may become confluent and patchy, especially on the face and neck. It fades in about 1 week and leaves behind a brownish discoloration.

The most feared complication in an immunocompetent child is post-measles encephalomyelitis, occurring within 2 weeks of the rash in 1/1000–1/5000 cases of measles. This is most likely an autoimmune disorder triggered by the measles infection, as virus is not present in the brain substance. Prognosis is poor, with a high mortality (30%), and severe residual damage in survivors.

Measles carries a high mortality in the malnourished and those who have other diseases. Complications are common in such individuals and include bacterial pneumonia, bronchitis, otitis media and severe diarrhoea. Less commonly, myocarditis, hepatitis and encephalomyelitis occur. In the malnourished or those with defective cell-mediated immunity, the classical maculopapular rash may not develop and there may be widespread desquamation. The virus also causes the rare condition subacute sclerosing panencephalitis, which may follow measles infection occurring early in life (<18 months of age). Persistence of the virus with reactivation before puberty results in accumulation of virus in the brain, progressive mental deterioration and a fatal outcome (see p. 872).

Maternal measles, unlike rubella, does not cause fetal abnormalities. It is, however, associated with spontaneous abortions and premature delivery.

**Diagnosis and management**

Most cases of measles are diagnosed clinically but detection of measles-specific IgM in blood or oral fluid, or genome or antigen detection from nasopharyngeal aspirates or throat swabs, should be used to confirm the diagnosis.

Management is supportive. Antibiotics are indicated only if secondary bacterial infection occurs. Vitamin A supplements lower the number of deaths from measles by 50%, and also reduce eye damage and blindness, and therefore two doses of vitamin A supplements given 24 hours apart are recommended for all children with measles.

**Prevention**

A previous attack of measles confers a high degree of immunity and second attacks are uncommon. Normal human immunoglobulin given within 5 days of exposure effectively aborts an attack of measles. It is indicated following exposure for previously unimmunized children below 3 years of age, for pregnant women and for those with debilitating disease.

**Active immunization**

Children in the UK are immunized with the combined mumps/measles/rubella (MMR) vaccine (see Box 20.20). In developing countries, the first measles vaccination is given at 9 months.

**Rubella**

Rubella (‘German measles’) is caused by a spherical, enveloped RNA virus of the *Rubivirus* genus belonging to the family of togaviruses. While the disease can occur sporadically, epidemics are not uncommon. It has a worldwide distribution. Spread of the virus is via droplets; maximum infectivity occurs before and during the time the rash is present.

**Clinical features**

The incubation period is 14–21 days, averaging 18 days. The clinical features are largely determined by age, symptoms being mild or absent in children under 5 years.

During the prodrome, the patient may develop malaise, fever, mild conjunctivitis and lymphadenopathy involving particularly the suboccipital, post-auricular and posterior cervical groups of lymph nodes. Small petechial lesions on the soft palate (Forchheimer spots) are suggestive but not diagnostic. Splenomegaly may be present.

The eruptive or exanthematous phase usually occurs within 7 days of the initial symptoms. The rash first appears on the forehead and then spreads to involve the trunk and limbs. It is pinkish red, macular and discrete, although some of these lesions may coalesce (Fig. 20.11). It usually fades by the second day and rarely persists beyond 3 days after its appearance.
Complications
Complications are rare. They include superadded pulmonary bacterial infection, arthralgia (more common in females), haemorrhagic manifestations due to thrombocytopenia, and encephalitis. Maternal infection in pregnancy may result in the congenital rubella syndrome. Rubella affects the fetuses of up to 90% of all women who contract the infection during the first trimester of pregnancy. The incidence of congenital abnormalities diminishes in the second trimester and no ill-effects result from infection in the third trimester.

Congenital rubella syndrome is characterized by the presence of fetal cardiac malformations (especially patent ductus arteriosus and ventricular septal defect), eye lesions (especially cataracts), microcephaly, mental retardation and deafness. Hepatosplenomegaly, myocarditis, interstitial pneumonia and metaphyseal bone lesions also occur.

Diagnosis and management
Laboratory diagnosis is essential, especially in pregnancy, to distinguish the illness from other virus infections (e.g. erythrovirus B19, echovirus) and drug rashes. This is achieved by detection of rubella-specific IgM by enzyme-linked immunosorbent assay (ELISA) in an acute serum sample, preferably confirmed by demonstration of IgG seroconversion (or a rising titre of IgG) in a subsequent sample taken 14 days later. Viral genome can be detected in throat swabs (or oral fluid samples), urine and, in the case of intrauterine infection, the products of conception.

Management is supportive.

Prevention
Several live attenuated rubella vaccines have been used and have had great success in preventing this illness. They have been successfully combined with measles and mumps vaccines in the MMR vaccine. Use of the vaccine is contraindicated during pregnancy or if there is a likelihood of pregnancy within 3 months of immunization. Inadvertent use of the vaccine during pregnancy has not, however, revealed a risk of teratogenicity.

Erythrovirus infections
Human erythrovirus (also known as parvovirus) B19 causes erythema infectiosum (fifth disease), a common infection in schoolchildren. The rash is typically on the face (the ‘slapped cheek’ appearance). The patient is well and the rash can recur over weeks or months. Asymptomatic infection occurs in 20% of children. Non-specific respiratory tract illness may also occur. In adults, the rash may be clinically indistinguishable from that of rubella. Moderately severe self-limiting polyarthropathy is common if infection occurs in adulthood, especially in women (this is also true of rubella). The virus infects bone marrow cells, and aplastic crisis may occur in patients with chronic haemolytic anaemia (e.g. sickle cell disease). Chronic infection with anaemia occurs in immunocompromised subjects. Hydrops fetalis (3% risk) and spontaneous abortion (9% risk) may result from maternal infection in the first and second trimesters of pregnancy.

Diagnosis of acute infection is by detection of parvovirus-specific IgM and/or DNA.

Human herpesvirus types 6 and 7 infection
These human herpesviruses occur worldwide and exist as latent infections in over 85% of the adult population. They are spread by contact with oral secretions. Human herpesvirus type 6 (HHV-6) causes roseola infantum (exanthem subitum), which presents as a high fever followed by a generalized macular rash in infants. HHV-6 is a common cause of febrile convulsions, and aseptic meningitis or encephalitis is a rare complication.

The full spectrum of disease due to HHV-7 has not yet been fully characterized but, like HHV-6, it may cause roseola infantum in infants. Both viruses have been associated with encephalitis in heavily immunosuppressed patients, such as bone marrow transplant recipients.

Management
Supportive management is recommended for the common infanilte disease. Ganciclovir can be used in the immunocompromised.

Further reading

Virus infections of the respiratory tract
Many viruses can cause upper respiratory tract infection (URTI); for example, in the nose (rhinitis), throat (tonsillitis, pharyngitis), sinuses (sinusitis), ear (otitis media), eye (conjunctivitis) or larynx (laryngitis) (Box 20.29). Infections below the larynx are referred to as lower respiratory tract infections (LRTIs). URTIs are common but relatively trivial; LRTIs are less common but may result in hospitalization and even death.

Upper respiratory tract infections
The common cold – coryza, rhinitis
Rhinovirus infection is the most common cause of the common cold (see p. 945). Peak incidence rates occur in the colder months,

especially spring and autumn. There are multiple rhinovirus serotypes (>100), which explains why infection occurs throughout life and makes vaccine control impracticable. In contrast to enteroviruses, which replicate at 37°C, rhinoviruses grow best at 33°C (the temperature of the upper respiratory tract), which explains the localized disease characteristic of common colds.

Human coronaviruses were first isolated in the mid-1960s and the majority of isolates (related to the reference strains 229E and OC43) have been associated with common colds. In 2004 and 2005, two new coronavirus infections of humans were described: NL63 and HKU1. These are also associated with coryzal symptomatology. Coronaviruses have recently become of interest owing to the discovery of three new viruses causing life-threatening LRTI (see later).

Parainfluenza
Parainfluenza is caused by the parainfluenza viruses types I–IV; these have a worldwide distribution and cause acute respiratory disease.

Parainfluenza is essentially a disease of children and presents with features similar to those of the common cold. When infection is severe, a brassy cough with inspiratory stridor and features of laryngotracheitis (croup) are present. Fever usually lasts for 2–3 days and may be more prolonged if pneumonia develops. The development of croup is due to submucosal oedema and consequent airway obstruction in the subglottic region. This may lead to cyanosis, subcostal and intercostal recession and progressive airway obstruction. Infection in the immunocompromised is usually prolonged and may be severe. Management is supportive with oxygen, humidification and sedation when required. The role of steroids and the antiviral agent ribavirin is controversial.

Adenovirus infection
Over 50 adenovirus serotypes have been identified as human pathogens, infecting a number of different cell types and therefore resulting in different clinical syndromes. Adenovirus infection commonly presents as an acute pharyngitis, and extension of infection to the larynx and trachea in infants may lead to croup. By school age, the majority of children show serological evidence of previous infection. Certain subtypes produce an acute conjunctivitis associated with pharyngitis. In adults, adenovirus causes acute follicular conjunctivitis and, rarely, pneumonia that is clinically similar to that produced by Mycoplasma pneumoniae (see p. 963). Adenoviruses 40 and 41 cause gastroenteritis (see p. 529) without respiratory disease, and adenovirus infection may be responsible for acute mesenteric lymphadenitis in children and young adults, which may lead to intussusception in infants. Infection in an immunocompromised host, such as a bone marrow transplant recipient, may result in multisystem failure and fatal disease.

Other viral causes of URTI
Human erythrovirus B19 infection may present as a URTI. Bocavirus is a recently identified parovirus, which accounts for around 3–5% of respiratory tract infections in young children. Enteroviruses, such as Coxsackie and echoviruses, are occasionally found in respiratory tract secretions of young babies, and there has been much interest recently in EV D-68, which appears to infect the respiratory tract predominantly. WU and KI polyomaviruses may be associated with respiratory tract infections in young children.

Lower respiratory tract infections
Viral infections resulting in life-threatening LRTIs are influenza, respiratory syncytial virus and the Middle East respiratory syndrome and severe acute respiratory syndrome (SARS)-associated coronaviruses. However, other causes of viral pneumonia occasionally arise (see Box 20.29), and at the time of going to press, a novel coronavirus (SARS-CoV2) has been identified as the causative agent of an outbreak originating in Wuhan, China, which has spread throughout the world.

Influenza
Influenza viruses belong to the family of orthomyxoviruses, having a segmented negative-strand RNA genome. The influenza virus is a spherical or filamentous enveloped virus. Haemagglutinin (H), a surface glycoprotein, aids attachment of the virus to the surface of susceptible host cells at specific sialic acid receptor sites. Release of progeny viruses from the cell surface, effected by budding through the cell membrane, is facilitated by the enzyme neuraminidase (N), which is also present on the viral envelope. Three types of influenza virus are recognized – A, B and C – distinguishable by the nature of their internal proteins. In addition, 18 H subtypes (H1–H18) and 11 N subtypes (N1–N11) have been identified for influenza A viruses but only H1, H2, H3, N1 and N2 have established stable lineages in the human population since 1918.

- **Influenza A** is generally responsible for pandemics and epidemics.
- **Influenza B** often causes smaller or localized, milder outbreaks but can also result in severe disease and mortality. There are no subtypes of influenza B.
- **Influenza C** rarely produces disease in humans.

**Antigenic shift** generates new influenza A subtypes carrying different H and/or N proteins on their surface, which emerge at irregular intervals and give rise to influenza pandemics. Possible mechanisms include:

- Genetic reassortment of the eight RNA segments of the virus with that of an avian influenza virus. This requires co-infection of a host with both human and avian viruses. Pigs are thought to be the likely mixing vessel, although this could theoretically also occur in humans.
- Trans-species transmission of an avian influenza virus to humans. Viruses transmitted in this way are usually not well adapted to growth in their new host but adaptation may occur as a result of spontaneous mutations, leading to the emergence of a pandemic strain.

**Antigenic drift** (minor changes in influenza A and B viruses) results from Darwinian evolution, with randomly occurring point mutations leading to amino acid changes in the two surface glycoproteins, haemagglutinin and neuraminidase, against the selection pressure of previously existing humoral immunity. This enables the virus to evade previously induced immune responses and is the process whereby annual influenza epidemics arise.

Thus, changes due to antigenic shift or drift render the individual’s immune response less able to combat the new variant.

Incidence increases during the winter months. Spread is mainly by droplet infection but fomites and direct contact have also been implicated. Influenza pandemics of the 20th century are listed in Box 20.30.

In 1997, avian influenza A/H5N1 viruses were first isolated from humans in Hong Kong, raising the spectre of another pandemic. Since then, the virus has spread across Asia, Europe and Africa. There have been several hundred human cases, with a mortality...
approaching 50%. While this virus is highly pathogenic to humans, due to the induction of a cytokine storm within the lungs, it still has not evolved to replicate well in human cells and human-to-human spread is unusual. However, anxieties remain that either genetic reassortment will occur in a human co-infected with human A(H1N1)pdm09 or A(H3N2) virus, or adaptive mutations will occur within infected human hosts, such that a truly pandemic strain will emerge.

In April 2009, a novel influenza A virus, now referred to as A(H1N1)pdm09, was identified in patients with severe respiratory illness in Mexico and North America. The virus quickly spread across the world, with the WHO declaring an official pandemic in June 2009. The virus was the end-product of several reassortments between pre-existing swine, avian and human virus lineages, with the swine H1 protein showing around 20% amino acid sequence divergence from previously circulating human seasonal H1N1 influenza viruses. Although unquestionably highly transmissible (with estimates of millions of infections worldwide within 1 year), this pandemic virus was, perhaps fortunately, not especially virulent. Most infections occurred in children; adults over 50 years of age had evidence of pre-existing protective immunity. A minority of infections resulted in serious disease, with an estimated 200 000 deaths worldwide. Risk factors for serious disease included pre-existing underlying medical conditions, age below 5 years, obesity and pregnancy. The pandemic was declared officially over by the WHO in August 2010, the virus now behaving as a normal seasonal influenza virus and replacing the previously circulating A(H1N1) virus.

Novel influenza viruses may continue to infect humans sporadically, raising the possibility of a new pandemic. In 2013, over 100 cases of infection with an H7N9 virus were reported from China. As of December 2018, there had been 1567 confirmed cases, with 615 deaths. Most cases gave a history of exposure to live animals, including chickens.

Purified haemagglutinin and neuraminidase from recently circulating strains of influenza A and B viruses are incorporated in current vaccines.

The clinical features, diagnosis, treatment and prophylaxis of influenza are discussed on page 947.

Respiratory syncytial virus infection

Respiratory syncytial virus (RSV) is a paramyxovirus that causes many respiratory infections in epidemics each winter. It is a common cause of bronchiolitis in infants, complicated by pneumonia in approximately 10% of cases. The infection normally starts with upper respiratory symptoms. After an interval of 1–3 days, a cough and low-grade fever may develop. The onset of bronchiolitis is characterized by dyspnoea and hyperexpansion of the chest with subcostal and intercostal recession. The disease may be severe and potentially fatal in babies with underlying cardiac, respiratory (including prematurity) or immunodeficiency disease. The virus undergoes antigenic drift and, consequently, re-infection occurs throughout life. RSV is occasionally the cause of outbreaks of influenza-like illness or pneumonia in the elderly (in residential homes) and the immunocompromised.

Transfer of infection between children in hospital (hospital-acquired infection) commonly occurs unless infected patients are isolated or cohorted. Meticulous attention to hand-washing and other infection control measures reduces the risk of transmission by staff members (see p. 292).

Diagnosis and management

Genome detection or immunofluorescence on nasopharyngeal aspirates is the usual way of confirming the diagnosis.

Management is generally supportive but aerosolized ribavirin can be given to severe cases, particularly those with underlying cardiac or respiratory disease.

Prevention

No vaccine is currently available for RSV but high-risk children (including those with bronchopulmonary dysplasia and congenital heart disease) can be protected against severe disease by monthly administration of either a hyperimmune globulin against RSV, or a humanized monoclonal antibody (palivizumab) during the winter months.

Metapneumovirus

Human metapneumovirus (hMPV) belongs to the same virus family as RSV and causes approximately 10% of LRTIs in infants and young children. Infection is clinically indistinguishable from that caused by RSV.

Coronavirus infection – severe acute respiratory and Middle East respiratory syndromes

In November 2002, an apparently new viral LRTI occurred in China and spread rapidly in other parts of the Far East and, from there, across the world. This disease, of which bronchopneumonia is a major feature, is known as ‘severe acute respiratory syndrome’ (SARS); it is caused by a previously unknown coronavirus (SARS-CoV). Similarity of this virus to coronaviruses isolated from civet cats, raccoons and ferret badgers indicates that SARS is a zoonotic disease. Bats are the likely host species. The epidemic was finally brought under control in the summer of 2003, by which time there had been more than 8000 cases with approximately 800 deaths. Naturally acquired infection has not been reported since.

In 2012, a new coronavirus, Middle East respiratory syndrome coronavirus (MERS-CoV), was identified in a patient who died of acute respiratory failure in Saudi Arabia. There have been over 2200 cases since, across 27 countries, although mostly in the Middle East; mortality is around 35%. The most likely source is from dromedary camels. Person-to-person spread within healthcare settings is another major source, with the largest outbreaks in Saudi Arabia, United Arab Emirates and the Republic of Korea.

In December 2019, yet another coronavirus was identified in an outbreak of severe respiratory disease in Wuhan, China. This virus is now known as SARS Coronavirus 2 (SARS-CoV-2), and the associated disease is Coronavirus Disease 2019 (COVID 19). Whilst mortality is not as high as with SARS-CoV (current estimates are of the order of 1-5%), this virus is clearly more transmissible and has spread explosively around the world. As of May 2020, there are approaching 5 million cases and 300,000 deaths recorded globally. It is feared that many more people will become infected over the next year or so, with millions of deaths.

SYSTIC VIRAL INFECTIONS

Dengue

This is the most common arthropod-borne viral infection in humans, whose global incidence has increased dramatically in recent years; over 100 million cases occur every year in the tropics, with over 100 000 deaths from severe dengue (previously known as haemorrhagic fever)
Infectious disease

Dengue is caused by a flavivirus. The disease is endemic in all tropical regions, including northern Australia, most South-east Asian countries, tropical Africa and the Middle East, and Caribbean countries. Cases of dengue are also imported into the continental USA and Europe (e.g. Italy) via tourists returning from endemic countries.

Viruses spread by insects are collectively referred to as arthropod-borne viruses, or arboviruses (Boxes 20.31 and 20.32). Four different antigenic serotypes of dengue virus are recognized and all are transmitted by the daytime biting mosquito *Aedes aegypti*, which breeds in standing water in refuse dumps in inner cities. *A. albopictus* is a less common transmitter. Humans are infective during the first 3 days of the illness (viraemic stage; Fig. 20.13). Mosquitoes become infective about 2 weeks after feeding on an infected individual and remain so for life. The disease is usually endemic. Heterotypic immunity between serotypes after the illness is partial and lasts only a few months, although homotype immunity is life-long.

**Clinical features**
The incubation period is 5–6 days following the mosquito bite. Asymptomatic or mild infections are common. Two clinical forms are recognized (see Fig. 20.14).

**(Fig. 20.12).** Global dengue burden.

---

**Defining features of arboviruses**
- Arboviruses are zoonotic viruses, transmitted through the bites of insects, especially mosquitoes and ticks
- >385 viruses are classified as arboviruses
- Most are members of the families of togaviruses, flaviviruses and bunyaviruses (see Box 20.32)
- *Culex, Aedes* and *Anopheles* mosquitoes account for transmission of the majority of these viruses

**Clinical features of arbovirus infection**
- Most arbovirus diseases are generally mild; epidemics are frequent, and when these occur, the mortality is high
- In general, the incubation period is short (<10 days). Common features include a biphasic illness, pyrexia, conjunctival suffusion, a rash, retro-orbital pain, myalgia and arthralgia. Lymphadenopathy is seen in dengue
- **Haemorrhage** (from increased vascular permeability, capillary fragility, consumptive coagulopathy) is a feature of some arbovirus infections (see Box 20.37)
- **Encephalitis** resulting from cerebral invasion may be prominent in some arbovirus fevers

---

**Classic dengue fever**
Classic dengue fever is characterized by the abrupt onset of fever, malaise, headache, facial flushing, retrobulbar pain that worsens on eye movements, conjunctival suffusion and severe backache, which is a prominent symptom. Lymphadenopathy, petechiae on the soft palate and transient, morbilliform skin rashes may also appear on the limbs with subsequent spread to involve the trunk. Desquamation occurs subsequently. Cough is uncommon. The fever subsides after 3–4 days, the temperature returning to normal for a couple of days, after which the fever returns, together with the features already mentioned, but milder. This biphasic or ‘saddleback’ pattern is considered characteristic. Severe fatigue, a feeling of being unwell and depression are common for several weeks after the fever has subsided.

**Severe dengue**
Severe dengue is potentially deadly and is believed to arise from two or more sequential infections with different dengue serotypes. It is characterized by the capillary leak syndrome, thrombocytopenia, haemorrhage, hypotension and shock. It is characteristically a disease of children, occurring most commonly in South-east Asia. The disease has a mild start, often with symptoms of an URTI. This
is followed by the abrupt onset of shock and haemorrhage into the skin and ear, epistaxis, haematemesis and melaena, known as the dengue shock syndrome, which has a mortality of up to 44%. Serum complement levels are depressed and there is laboratory evidence of disseminated intravascular coagulation (DIC, see p. 377).

Diagnosis and management

- Isolation of dengue virus by tissue culture, or detection of viral RNA by genome amplification in sera obtained during the first few days of illness, is diagnostic.
- Detection of virus-specific IgM antibodies, or of rising IgG titres in sequential serum samples, confirms the diagnosis.
- Blood tests show leucopenia and thrombocytopenia.

Management is supportive, with analgesics and adequate fluid replacement. Corticosteroids are of no benefit and convalescence can be slow. In dengue haemorrhagic fever blood transfusion may be necessary, as well as intensive care support.

Prevention

Travellers should be advised to sleep under impregnated nets but this is not very effective, as the mosquito bites in the daytime. Topical insect repellents should be used. Adult mosquitoes should be destroyed by sprays, and breeding sites, such as small pools of stagnant water, should be eradicated. A live recombinant tetravalent dengue vaccine has been licensed, although concerns have arisen that vaccination of seronegative
individuals may paradoxically increase the risk of severe dengue. Several other vaccines are in clinical trials.

**Zika virus infection**

Zika virus, a flavivirus closely related to dengue viruses, came to prominence in 2016 following an explosive pandemic throughout South and Central America, and the Caribbean. Like dengue, Zika is an arbovirus, transmitted to humans by Aedes mosquitoes. Illness, when it arises, is usually unremarkable, with fever, myalgia, eye pain, prostration and maculopapular rash, with spontaneous resolution. However, the epidemiological association of Zika virus outbreaks with subsequent dramatic increases in the number of cases of microcephaly in infants (e.g. Brazil reported a 20-fold increase in incidence from 2014 to 2015) led the WHO to declare Zika a public health emergency of international concern. Precise data on the magnitude of the risk of congenital brain abnormalities in a Zika-affected pregnancy are not yet available. The WHO has also concluded that Zika virus is a trigger of the Guillain–Barré syndrome. Accurate diagnosis of infection is complicated by serological cross-reactivity with dengue viruses. Further research on the consequences of infection with Zika virus is urgently needed.

**Chikungunya**

Chikungunya virus is an alphavirus, a genus within the family of togaviruses. There are eight alphaviruses that result in human disease and all are arboviruses, transmitted by mosquitoes. They are globally distributed and tend to acquire their names from the location where they were first isolated (such as Ross River, Eastern Venezuelan and Western equine encephalitis viruses) or from the local expression for a major symptom caused by the virus (such as chikungunya, meaning ‘doubled up’). Chikungunya infection is characterized by fever, headache, maculopapular skin rash, arthralgia, myalgia and sometimes encephalitis. After 1 year, at least 20% of patients still suffer recurrent joint pains. Mortality is approximately 0.1%, mostly in the elderly or very young.

Major epidemics of chikungunya, spread via A. aegypti or A. albopictus, were reported in India, Sri Lanka and islands in the Indian Ocean (including Reunion, Mauritius and the Seychelles) in 2005 and 2006, with at least 1 million cases and several hundred deaths. The severity of these epidemics is possibly due to a viral strain, with mutations resulting in a higher neurovirulence. Several European countries reported cases of chikungunya in returning travellers, including 133 cases in the UK in 2006. The increased numbers of infected returning travellers may result in the local Aedes mosquito population becoming infected, giving rise to outbreaks in countries where it has not previously been described: for example, in Italy (2007) and the French mainland (2010). In 2013, an outbreak in the Caribbean islands spread to contiguous Central and South American countries, and over 200 cases were reported in 2014 in the USA.

A number of chikungunya vaccines are currently undergoing clinical trials.

**Infectious mononucleosis: Epstein–Barr virus infection**

Globally, most individuals are infected with the herpesvirus Epstein–Barr virus (EBV) at an early age (0–5 years), at which time clinical symptoms are unusual. Infection at an older age is associated with an acute febrile illness known as infectious mononucleosis (glandular fever), which occurs worldwide in adolescents and young adults. EBV is probably transmitted in saliva and by aerosol.

**Clinical features**

The predominant symptoms of infectious mononucleosis are fever, headache, malaise and sore throat. Palatal petechiae and a transient macular rash are common, the latter occurring in 90% of patients who have received ampicillin (inappropriately) for the sore throat. Cervical lymphadenopathy, particularly of the posterior cervical nodes, and splenomegaly are characteristic. Mild hepatitis is common, resulting in clinical jaundice in 10% of young adults, but other complications such as myocarditis, meningitis, encephalitis, mononeuropathy multiplex, cerebellar ataxia and mesenteric adenitis are rare. Splenic rupture may occur in the first 3 weeks of illness and contact sport should be avoided during this period. Some young adults may remain debilitated and depressed for some months after infection.

The site of EBV latency is resting memory B lymphocytes. Evidence for reactivation of latent virus in healthy individuals is controversial, although this is thought to occur in immunocompromised patients. Severe, often fatal, infectious mononucleosis may result from a rare X-linked lymphoproliferative syndrome affecting young boys. Those who survive have an increased risk of hypogammaglobulinaemia and/or lymphoma. EBV is the cause of oral hairy leukoplakia in AIDS patients and is intimately linked to the generation of a number of malignancies (see later). EBV is a cause of haemophagocytic lymphohistiocytosis (HLH), a rare condition presenting with fever, rash, jaundice, hepatosplenomegaly and enlarged lymph nodes. Blood tests show cytopenia and a high ferritin, and the bone marrow shows haemophagocytosis. HLH can be primary (inherited) or secondary (e.g. to EBV), and has a high mortality.

**Diagnosis**

EBV infection should be strongly suspected if atypical mononuclear cells (activated CD8-positive T lymphocytes) are found in the peripheral blood in large numbers. It can be confirmed during the second week of infection by a positive Paul–Bunnell reaction, which detects heterophile antibodies (IgM) that agglutinate sheep erythrocytes, in around 90% of cases. False-positives can occur in other conditions, such as viral hepatitis, Hodgkin lymphoma and acute leukaemia. The Monospot test is a sensitive and easily performed screening test for heterophile antibodies. Specific EBV IgM antibodies indicate recent infection by the virus. Clinically similar illnesses are produced by cytomegalovirus, toxoplasmosis and acute HIV infection (the so-called seroconversion illness) but these can be distinguished serologically.

**Management**

The majority of cases require no specific treatment and recovery is rapid. Corticosteroid therapy is advised when there is neurological involvement (e.g. encephalitis, meningitis, Guillain–Barré syndrome), marked thrombocytopenia or haemolysis, or tonsillar enlargement that is so marked as to cause respiratory obstruction.

**Cytomegalovirus infection**

Clinically significant cytomegalovirus (CMV) infection arises in two patient groups in particular:

- fetuses who acquire the infection transplacentally and are born congenitally infected
- patients who are immunocompromised, such as transplant recipients or people with HIV infection.

As with all herpesviruses, CMV persists for life, usually as a latent infection in cells of the monocyte/macrophage lineage, and so may become reactivated, especially in immunocompromised patients. Over 50% of the adult population has serological evidence of latent CMV infection.
Clinical features

In healthy children and adults, CMV infection is usually asymptomatic but occasionally may result in a glandular fever-like illness, with fever, lymphocytosis with atypical lymphocytes, and hepatitis with or without jaundice. The Paul–Bunnell test for heterophile antibody is negative. Infection may be spread in saliva (accounting for extensive person-to-person spread in childcare units), sexual intercourse or blood transfusion, and transplacentally to the fetus. In an immunocompromised patient (see Ch. 40), CMV infection may involve multiple organ systems, common manifestations being retinitis, pneumonitis, diffuse involvement of the gastrointestinal tract and encephalitis.

Intrauterine infection may arise from either primary or reactivated maternal infection. CMV is, by far, the most common congenital infection; in developed countries, 0.3–1% of all babies are born congenitally infected with CMV. Around 5–10% of such babies have severe disease evident at birth, with a poor prognosis (cytomegalic inclusion disease). CNS involvement may cause microcephaly and motor disorders. Jaundice and hepatosplenomegaly are common and thrombocytopenia and haemolytic anaemia also occur. Periventricular calcification is seen on skull X-ray. A further 5–10% of infected babies are normal at birth but developmental abnormalities become apparent later: for example, sensorineural nerve deafness. The remaining 80–85% of infected babies are normal at birth and develop normally.

Diagnosis

Serological tests can identify latent (IgG) or primary (IgM) infection. However, most infections are now diagnosed by detection and quantification of CMV DNA or RNA using molecular amplification techniques, in blood or other body fluid samples. The virus can also be identified in tissues by the presence of characteristic intranuclear ‘owl’s eye’ inclusions (Fig. 20.14) on histological staining and by direct immunofluorescence.

Management

In the immunocompetent, infection is usually self-limiting and no specific treatment is required. In the immunosuppressed, ganciclovir reduces retinitis and gastrointestinal damage, and can eliminate CMV from blood, urine and respiratory secretions. It is less effective against pneumonitis. In patients who are continually immunocompromised, maintenance therapy may be necessary. Drug resistance may arise during long-term therapy, such as in transplant recipients.

Mumps

Mumps virus is a paramyxovirus. It is spread by droplet infection, by direct contact or through fomites. Humans are the only known natural hosts. The peak period of infectivity is 2–3 days before the onset of the parotitis and for 3 days afterwards.

Clinical features

The incubation period averages 18 days. Although no age is exempt, this is primarily a disease of school-age children and young adults; it is uncommon before the age of 2 years. The prodromal symptoms are non-specific and include fever, malaise, headache and anorexia. This is usually followed by severe pain over the parotid glands, with either unilateral or bilateral parotid swelling (Fig. 20.15). The enlarged glands obscure the angle of the mandible and may elevate the ear lobe, which does not occur in cervical lymph node enlargement. Trismus due to pain is common at this stage. Submandibular gland involvement occurs less frequently.

Complications

CNS involvement is the most common extra-salivary gland manifestation of mumps. Clinical meningitis occurs in 5% of all infected patients, and 30% of patients with CNS involvement have no evidence of parotid gland involvement.

Epididymo-orchitis develops in about one-third of patients who develop mumps after puberty. Bilateral testicular involvement results in sterility in only a small percentage of these patients. Pancreatitis, oophoritis, myocarditis, mastitis, hepatitis and polyarthritis may also occur.
DIAGNOSIS AND MANAGEMENT

The diagnosis of mumps is on the basis of the clinical features. Viral RNA can be demonstrated by genome detection assays in saliva, throat swabs, urine and CSF. Serological demonstration of a mumps-specific IgM response in an acute blood or oral fluid sample is also diagnostic.

Treatment is supportive. Attention should be paid to adequate nutrition and mouth care. Analgesics should be used to relieve pain.

PREVENTION

Children in the UK are immunized with the live attenuated MMR vaccine (see Box 20.20) and the mumps vaccine is given in most developing countries. Vaccination is contraindicated in immunosuppressed individuals, pregnant women or those with severe febrile illness.

HIV INFECTIONS

The human immunodeficiency viruses (HIV) belong to the family of retroviruses (Box 20.33), and are characterized by their ability to replicate through a DNA intermediate using the enzyme reverse transcriptase.

HIV-1 and the related virus, HIV-2, are further classified as lentiviruses (‘slow’ viruses) because of their slowly progressive clinical effects. They give rise to the acquired immunodeficiency syndrome (AIDS) and are discussed in Chapter 37.

HUMAN T-CELL LEUKAEMIA/LYMPHOTROPIC VIRUS INFECTION

Human T-cell leukaemia/lymphotropic virus type 1 (HTLV-1) causes adult T-cell leukaemia/lymphoma and tropical spastic paraparesis.

MYOCARDITIS AND SKELETAL MUSCLE INFECTION

Enterovirus infection is a cause of acute myocarditis and pericarditis (see Box 20.28), from which, in general, there is complete recovery. However, these viruses can also cause chronic congestive cardiomyopathy and, rarely, constrictive pericarditis. Skeletal muscle involvement, particularly of the intercostal muscles, is a feature of Bornholm disease, a febrile illness usually due to Coxsackie B viruses. The pain may be of such intensity as to mimic pleurisy or an acute abdomen. The infection affects both children and adults, and may be complicated by meningitis or cardiac involvement. Myocarditis and pericarditis are also discussed on pages 1118 and 1125.

POSTVIRAL/CHRONIC FATIGUE SYNDROME

Many viral infections have been implicated aetiologically, including EBV, Coxsackie B viruses, echoviruses, CMV and hepatitis A virus. Non-viral causes, such as allergy to Candida spp., have also been proposed. Only a minority of patients have an identifiable precipitating infectious illness (see also p. 770).

VIRUS INFECTIONS OF THE NERVOUS SYSTEM

ACUTE FLACCID PARALYSIS, INCLUDING POLIOMYELITIS

A number of enteroviruses may infect the nervous system (see Box 20.25), with different clinical outcomes. Infection with polioviruses 1, 2 and 3, classified within enterovirus species C, may result in acute flaccid paralysis (AFP). Polioviruses are excreted in faeces and spread via the faecal–oral route. They have a propensity for the nervous system, especially the anterior horn cells of the spinal cord and cranial motor neurones.

CLINICAL FEATURES

The incubation period is 7–14 days. Although polio is essentially a disease of childhood, no age is exempt. The clinical manifestations vary considerably. The most common outcome (95% of individuals) is asymptomatic seroconversion. AFP, also known as paralytic poliomyelitis, arises in only approximately 0.1% and 1% of infected children and adults, respectively. It follows about 4–5 days after an initial illness of fever, sore throat and myalgia. Meningeal irritation and muscle pain occur and are followed by the onset of asymmetric flaccid paralysis without sensory involvement. Factors predisposing to the development of paralysis include male sex, exercise early in the illness, trauma, surgery or intramuscular injection, which localise the paralysis, and recent tonsillectomy (bulbar poliomyelitis).

Aspiration pneumonia, myocarditis, paralytic ileus and urinary calculi are late complications of poliomyelitis.

AFP may also arise from infection with a number of other enteroviruses, and indeed, AFP is now more commonly caused by these viruses than by polioviruses. EV A71, more usually associated with hand, foot and mouth disease, has a particular predilection for neuromuscular invasion. Epidemics of EV A71 are not infrequent; an estimated 6 million cases have occurred globally since 2009, with over 2000 deaths from a variety of serious neuromotor syndromes. Inactivated EV A71 vaccines have been approved for clinical use in China. Acute flaccid myelitis has also been associated recently with outbreaks of EV D68 infection in the USA and UK.

DIAGNOSIS

All cases of AFP must be investigated to exclude poliovirus infection. Diagnosis is by detection of EV RNA in a throat swab, faecal sample or CSF, followed by sequencing to identify precisely which EV is present. Sequencing also enables a distinction to be made between wild poliovirus and vaccine strains.

MANAGEMENT

Management is supportive. Bed rest is essential during the early course of the illness. Respiratory support with intermittent positive-pressure respiration is required if the muscles of respiration are involved.
Prevention and control of poliomyelitis

In 1988, the World Health Assembly adopted the goal of eliminating poliomyelitis worldwide. Since then, the estimated 350,000 cases arising annually in 125 countries have been reduced by over 99%, with only Pakistan, Nigeria and Afghanistan never having terminated indigenous transmission. Only 33 cases of wild-type poliomyelitis were documented in 2018. The eradication campaign has relied on improvements in sanitation, hygiene and the widespread use of polio vaccines. However, spread of infection via travel from endemic countries has led to the disease reappearing in a number of states, including China, Cameroon, Syria and Somalia, and in 2014 the WHO declared the spread of poliomyelitis to be a global public health emergency. The creation of a poliomyelitis-free world remains the goal, and there is a revised strategic plan to achieve this by 2023. Vaccination remains the bedrock of the campaign. New preparations of inactivated intramuscular poliovirus vaccine (IPV) have greater potency than the original Salk IPV. The greater reliability of IPV in hot climates and the scientific and ethical problems of continuing to use oral polio vaccine (OPV) in countries free from poliomyelitis mean that IPV has replaced OPV in the routine immunization schedules in many countries.

Meningitis

Enteroviruses are the most common viral cause of aseptic meningitis, although a number of other viruses may also result in this syndrome (Box 20.34).

Encephalitis

Encephalitis may arise by direct virus invasion of nervous tissue, or by induction of an aberrant cross-reactive immune response (post-infectious encephalitis). While HSV is the most common cause of sporadic encephalitis worldwide (see p. 871), a number of other virus infections may also present with an encephalitic illness.

Japanese encephalitis

Japanese encephalitis is a mosquito-borne encephalitis caused by a flavivirus. It has been reported most frequently in the rice-growing countries of South-east Asia and the Far East. Culex tritaeniorhynchus is the usual vector and this feeds mainly on pigs, as well as birds such as herons and sparrows. Humans are accidental hosts.

The incubation period is 5–15 days. Most infections are asymptomatic. When disease arises, the onset is heralded by severe rigors. Fever, headache and malaise last 1–6 days. Weight loss is prominent. In the acute encephalitic stage the fever is high (38–41°C), neck rigidity occurs and neurological signs, such as altered consciousness, hemiparesis and convulsions, develop. Mental deterioration occurs over a period of 3–4 days and culminates in coma. Mortality varies from 7% to 40% and is higher in children. Residual neurological defects, such as deafness, emotional lability and hemiparesis, occur in about 70% of patients who have had CNS involvement. Convalescence is prolonged. Antibody detection in serum and CSF by IgM capture ELISA is a useful rapid diagnostic test. Vaccines containing formalin-inactivated viruses derived from mouse brain are available and effective. Management is supportive.

West Nile encephalitis

West Nile virus was first recognized in the Western hemisphere (New York, USA) in 1999, having been previously reported in Africa, Asia and parts of Europe. By the end of 2009, the US outbreak had resulted in over 25,000 human cases and over 1100 deaths. The vast majority of infections are asymptomatic. In a minority of cases, infection presents as a febrile illness with a maculopapular rash, 1% resulting in severe encephalitis. Disease severity and mortality are age-related, being greatest in the elderly. The primary hosts of infection are birds. It is spread by mosquitoes (Culex spp.) and may also infect humans and horses. It can also be transmitted by blood transfusions, breastfeeding and organ donation from an infected individual. Diagnosis is by genome detection in appropriate samples, or specialized serology for the detection of IgM virus-specific antibodies.
Tick-borne encephalitis

This arises from infection with a flavivirus (actually a series of closely related viruses) transmitted by Ixodes spp. ticks. It occurs in an area extending from Western Europe to Japan. The tick is the main reservoir for the virus, which is transmitted when it feeds on mice and other rodents.

The disease starts 4–28 days after a bite from an infected tick and is biphasic in 80% of patients. After a symptom-free period of about 7 days, fever, malaise, headache and fatigue are followed by encephalitis. There may be associated limb paralysis, which is due to anterior horn cell involvement, mainly of the cervical region. Cranial nerve involvement also occurs. Tick-borne encephalitis virus (TBEV) IgM and IgG antibodies are present and the virus can be detected in blood by genome detection assays. Overall mortality is about 1% (but can be considerably higher for certain strains); 30% of cases have impairment in neurological function with persistent paralysis in 6%. A preventative vaccine is available.

Lymphocytic choriomeningitis

This is a zoonosis, the natural reservoir of lymphocytic choriomeningitis (LCM) virus (an arenavirus; see Box 20.26) being the house mouse. Infection is by inhalation from urine-contaminated rubbish and is characterized by:

- non-nervous-system illness, with fever, malaise, myalgia, headache, arthralgia and vomiting
- meningitis in addition to the above symptoms.

Occasionally, a more severe form occurs, with encephalitis leading to disturbance of consciousness.

This illness is generally self-limiting and requires no specific treatment.

Hendra and Nipah virus infection

Hendra and Nipah viruses cause zoonotic infections in humans who have been in contact with infected animals (horses and pigs, respectively). The viruses are named after the locations where they were first isolated: Hendra in Australia and Nipah in Malaysia. Both are classified as paramyxoviruses, and fruit bats are their natural hosts. Hendra virus has caused severe respiratory distress in horses and humans, and Nipah virus caused a major outbreak of viral encephalitis (265 cases and 105 deaths) in Malaysia between September 1998 and April 1999; subsequent outbreaks have been reported in India and Bangladesh. Management of these conditions is supportive and no vaccines are currently available.

Rabies

Rabies is a major problem in some countries, with an estimated 55,000 deaths per year worldwide. Established infection is almost invariably fatal; there are only a handful of recorded cases of survival from clinical rabies. It is caused by the rabies virus, a single-stranded RNA virus of the lyssavirus genus within the family of rhabdoviruses. The virus is bullet-shaped and has spike-like structures arising from its surface containing glycoproteins that cause the host to produce neutralizing, haemagglutination-inhibiting antibodies. The virus has a marked affinity for nervous tissue and the salivary glands. It exists in two major epidemiological settings:

- **Urban rabies** is most frequently transmitted to humans through rabid dogs and, less frequently, cats.
- **Sylvan (wild) rabies** is maintained in the wild by a host of animal reservoirs such as foxes, skunks, jackals, mongooses and bats.

With the exception of Australia, New Zealand and the Antarctic, human rabies has been reported from all continents. Transmission is usually through the bite of an infected animal. However, the percentage of rabid bites leading to clinical disease ranges from 10% (on the legs) to 80% (on the head). Other forms of transmission, if they occur, are rare.

The virus replicates in the muscle cells near the entry wound. It penetrates the nerve endings and travels in the axoplasm to the spinal cord and brain. In the CNS, the virus again proliferates before spreading to the salivary glands, lungs, kidneys and other organs via the autonomic nerves.

**Clinical features**

The incubation period is variable, ranging from a few weeks to several years; on average, it is 1–3 months. In general, bites on the head, face and neck have a shorter incubation period than those elsewhere. In humans, two distinct clinical varieties of rabies are recognized:

- **Furious rabies** – the classic variety. The only characteristic feature in the prodromal period is the presence of pain and tingling at the site of the initial wound. Fever, malaise and headache are also present. About 10 days later, marked anxiety and agitation or depressive features develop. Hallucinations, bizarre behaviour and paralysis may also occur. Hyperexcitability, the hallmark of this form of rabies, is precipitated by auditory or visual stimuli. Hydrophobia (fear of water) is present in 50% of patients and is due to severe pharyngeal spasms on attempting to eat or drink. Aerophobia (fear of air) is considered pathognomonic of rabies. Examination reveals hyper-reflexia, spasticity and evidence of sympathetic overactivity indicated by pupillary dilation and diaphoresis. The patient goes on to develop convulsions, respiratory paralysis and cardiac arrhythmias. Death usually occurs in 10–14 days.
- **Dumb rabies** – the paralytic variety. This presents with a symmetrical ascending paralysis that resembles the Guillain–Barré syndrome.

**Diagnosis**

The diagnosis of rabies is generally made clinically. Skin-punch biopsies are used to detect antigen with an immunofluorescent antibody test on frozen section. Viral RNA can be detected by genome amplification. Isolation of virus from saliva or the presence of antibodies in blood or CSF may establish the diagnosis. Negri bodies are detected at postmortem in 90% of all patients with rabies: these are eosinophilic, cytoplasmic, ovoid bodies, 2–10nm in diameter, seen in greatest numbers in the neurones of the hippocampus and the cerebellum. The diagnosis should be made pathologically on the biting animal using genome amplification, immunofluorescence on brain tissue using fluorescently labelled anti-rabies antibody or tissue culture of the brain.

**Management**

Once CNS disease is established, therapy is symptomatic, as death is virtually inevitable. The patient should be nursed in a quiet, darkened room. Nutritional, respiratory and cardiovascular support may be necessary.

Drugs such as morphine, diazepam and chlorpromazine should be used liberally in patients who are excitable.

**Prevention and control**

**Pre-exposure prophylaxis**

This is given to individuals with a high risk of contracting rabies, such as laboratory workers, animal handlers and veterinarians. Three doses of human diploid (HDCV) or purified chick embryo
cell vaccine (PCEV), given by deep subcutaneous or intramuscular injection on days 0, 7 and 28, provide effective immunity. A reinforcing dose is given after 12 months and additional reinforcing doses are given every 3–5 years, depending on the risk of exposure. Vaccines of nervous tissue origin are still used in some parts of the world. These, however, are associated with significant side-effects and should not be used if HDCV is available.

**Post-exposure prophylaxis**

The wound should be cleaned carefully and thoroughly with soap and water, and left open. Human rabies immunoglobulin should be given immediately (20IU/kg); half should be injected around the area of the wound and the other half should be given intramuscularly. Five 1.0mL doses of HDCV should be given intramuscularly: the first dose is given on day 0 and is followed by injections on days 3, 7, 14 and 28. Reaction to the vaccine is uncommon. Protection mediated by this protocol is almost 100%.

**Control**

Domestic animals should be vaccinated if there is any risk of rabies in the country. In the UK, control has been by quarantine of imported animals for 6 months and no indigenous case of rabies has been reported for many years. The Pet Travel Scheme (PETS) enables certain pet animals to enter or re-enter Great Britain without quarantine if they come from qualifying countries via designated routes, are carried by authorized transport companies and meet the conditions of the scheme. Wild animals in ‘at-risk’ countries must be handled with great care.

**Progressive multifocal leucoencephalopathy**

JC virus, a polyomavirus, is the cause of progressive multifocal leucoencephalopathy (PML), which presents as dementia in the immunocompromised and is due to multiple foci of demyelination in cerebral white matter. Virus replicates in the nucleus of oligodendrocytes, resulting in cell lysis and breakdown of the myelin sheath. The virus is usually acquired in childhood, and may reactivate if the host immune system becomes compromised in later life (see p. 1446). Reactivation of JC virus and development of PML have recently been described in multiple sclerosis patients treated with the monoclonal antibody, natalizumab, directed against the cell adhesion molecule, α4 integrin.

**VIRUS INFECTIONS OF THE GASTROINTESTINAL TRACT**

Virus infections that commonly result in acute gastroenteritis (diarrhoea and vomiting) are listed in **Box 20.35**.

### Rotavirus infection

Rotaviruses are a major cause of infantile gastroenteritis worldwide. The virus (Latin *rota* = wheel) is so named because of its electron microscopic appearance with a characteristic circular outline and radiating spokes (**Fig. 20.16**). It belongs to the reoviruses family, which have double-stranded RNA segmented genomes. More than 200,000 infected children under the age of 5 years are estimated to die annually in resource-deprived countries. The prevalence is higher during the winter months in non-tropical areas. Asymptomatic infections are common and bottle-fed babies are more likely to be symptomatic than those that are breast-fed.

Adults may become infected with rotavirus but symptoms are usually mild or absent. The virus may, however, cause diarrhoea in immunosuppressed adults, or outbreaks in patients on care of the elderly wards.

**Clinical features**

The illness is characterized by vomiting, fever, diarrhoea and the metabolic consequences of water and electrolyte loss.

**Diagnosis and differential diagnosis**

The diagnosis can be established by genome amplification, or ELISA for the detection of rotavirus antigen in faeces and by electron microscopy of faeces. Histology of the jejunal mucosa in children shows shortening of the villi, with crypt hyperplasia and mononuclear cell infiltration of the lamina propria.

**Management and prevention**

Management is directed at overcoming the effects of water and electrolyte imbalance with adequate oral rehydration therapy and, when indicated, intravenous fluids (**Box 20.36**). Antibiotics should not be prescribed.

**Rotavirus vaccines**

Despite a major setback when the first licensed rotavirus vaccine was rapidly withdrawn from the market in 1999 following reports of increased rates of intussusception, two live vaccines have been developed and are now used in many countries. One (Rotarix) contains an attenuated human strain, the relevant antigens being P[8] and G1; the other (Rotateq) is based on a bovine parent strain and comprises five single-gene reassortants, each containing a human-strain outer capsid gene encoding the most common human antigenic...

In children under 5, zinc supplements (10 mg daily under 6 months, 20 mg daily over 6 months) should ideally be given along with ORS. ORS should be administered by encouraging the patient to take small, regular sips of fluid. If vomiting occurs, administration should be paused for 10 min and then cautiously restarted. ORS can be administered via a nasogastric tube if swallowing is impaired. If patients are severely dehydrated, intravenous fluids are preferred. Contains Ca²⁺ 2 mM/l and HCO₃⁻ (as lactate).

Calicivirus infection

The caliciviruses are an extensive virus family, named after the cup-shaped (Latin calyx = cup) indentations on their viral surface seen by electron microscopy. The family contains four genera, two of which, the noroviruses and sapoviruses, infect humans and cause gastroenteritis.

Norovirus is the major cause of acute non-bacterial gastroenteritis, causing outbreaks in nursing homes, hospitals, schools, leisure centres and restaurants, and on cruise ships. In countries that have adopted routine rotavirus vaccination of infants, norovirus has become the leading cause of clinically significant acute gastroenteritis in children. Transmission is mostly faecal–oral, with outbreaks suggesting a common source, such as food and water, and fomites. Aerosol transmission also occurs and noroviruses can be detected in vomit. Illness is usually self-limiting (12–48 h) and mild, consisting of nausea, headache and abdominal cramps, followed by diarrhoea and vomiting, which may be the only feature (winter vomiting). Diagnosis is by demonstration of viral nucleic acid or antigen in diarrhoeal faeces. Treatment is with oral rehydration solutions. Prevention can be difficult but hand-washing and good hygiene food preparation are required.

Sapovirus causes gastroenteritis, mainly in children.

VIRUSES AND MALIGNANT DISEASE

Around 15–20% of all human malignant disease arises from infection. Recognition of the infectious cause of a particular cancer raises the possibility of developing an anti-cancer vaccine, as has now happened for both hepatitis B virus and human papillomavirus.

Hepatitis viruses and primary hepatocellular carcinoma

Globally, hepatocellular carcinoma is the second most common cause of death due to malignant disease. A high percentage arises in patients infected with either hepatitis B or C viruses (see pp. 126 and 1308).

Human papillomaviruses and cancer of the uterine cervix

Papillomaviruses tend to produce chronic infections (see also p. 672). Human papillomaviruses (HPVs), of which there are at least 100 types, are responsible for the common skin and genital warts, and certain types (mainly 16 and 18) are the cause of carcinoma of the cervix, cancers in other genital areas (vagina, vulva, penis, anus) and some oral cancers (type 16). Vaccines against HPV types 16 and 18 are available. The current recommendations in many countries are for vaccination of all girls at age 9–14 years, although some countries (including the UK) are increasingly opting to vaccinate both boys and girls. (For anogenital warts, see p. 1420.)

Epstein–Barr virus and malignant disease

EBV infection has been associated with a number of malignant diseases, including Burkitt lymphoma, undifferentiated nasopharyngeal carcinoma, post-transplant lymphoma, the immunoblastic lymphoma of AIDS patients, some forms of Hodgkin lymphoma and gastric cancer. Different levels of expression of EBV latency genes occur in these proliferative conditions, and various co-factors are

VIRAL HEPATITIS

A number of distinct virus infections may result in inflammation of the liver (hepatitis). The viruses belong to different virus families, are spread by different routes, and may have differing clinical consequences (see Box 34.7). Viral hepatitis is discussed further in Chapter 34.
Viral haemorrhagic fevers

These comprise infection with a range of different viruses (Box 20.37), which have in common the clinical feature of haemorrhagic manifestations.

Yellow fever

Yellow fever, caused by a flavivirus, is an illness of widely varying severity. It is confined to Africa (90% of cases) and South America between latitudes 15°N and 15°S. For poorly understood reasons, yellow fever has not been reported from Asia, despite the fact that climatic conditions are suitable and the vector, Aedes aegypti, is common. The infection is transmitted in the wild by A. africanus in Africa and the Haemagogus species in South and Central America. Extension of infection to humans (via the mosquito from monkeys) leads to the occurrence of ‘jungle’ yellow fever. A. aegypti, a domestic mosquito that lives in close relationship to humans, is responsible for human-to-human transmission in urban areas (urban yellow fever). Once infected, a mosquito remains so for life.

Clinical features

The incubation period is 3–6 days. Mild infection is indistinguishable from other viral fevers such as influenza or dengue.

Three phases are recognized in the severe (classical) illness. Initially, the patient presents with a high fever of acute onset, usually 39–40°C, which then returns to normal in 4–5 days. During this time, headache is prominent. Retrobulbar pain, myalgia, arthralgia, a flushed face and suffused conjunctivae are common. Epigastric discomfort and vomiting are present when the illness is severe. Relapse is not uncommon and may occur. Coma, which is usually a result of uraemia or haemorrhagic shock, occurs for a few hours preceding death. The mortality rate is up to 40% in severe cases. Liver pathology shows mid-zone necrosis and eosiophilic degeneration of hepatocytes (Councilman bodies; see p. 1275).

Diagnosis and management

The diagnosis is established by a history of travel and vaccination status, and by isolation of the virus (when possible) from blood during the first 3 days of illness. Serodiagnosis is possible but in endemic areas cross-reactivity with other flaviviruses is a problem.

Management is supportive. Bed rest (under mosquito nets), analgesics and maintenance of fluid and electrolyte balance are required.

Prevention and control

Yellow fever is an internationally notifiable disease. It is easily prevented by using the attenuated 17D chick embryo vaccine. Vaccination is not recommended for children under 9 months, pregnant women or immunosuppressed patients, unless there are compelling reasons. For the purposes of international certification, immunization is valid for 10 years, but protection lasts much longer than this and probably for life. The WHO Expanded Programme of Immunization includes yellow fever vaccination in endemic areas.

Infectious disease

Congo–Crimean haemorrhagic fever
Congo–Crimean haemorrhagic fever (CCHF) virus belongs to the Nairovirus genus of the family Bunyaviridae. This family contains more than 200 viruses, grouped into a number of genera, most of which are arthropod-borne.

CCHF disease is found mainly in Asia and Africa. The primary hosts are cattle and hares, and the vectors are Hyalomma ticks. Following an incubation period of 3–6 days, there is an influenza-like illness with fever and haemorrhagic manifestations. The mortality is 10–50%.

Hantavirus infection
Hantaviruses belong to the Hantavirus genus of the Bunyaviridae and are enzootic viruses of wild rodents, which are spread by aerosolized excreta and not by insect vectors. The most severe form of this infection is Korean haemorrhagic fever (also known as haemorrhagic fever with renal syndrome, HFRS). This condition has a mortality of 5–10% and is characterized by fever, shock and haemorrhage followed by an oliguric phase. Milder forms of the disease are associated with related viruses (e.g. Puumala virus) and may present as nephropathia epidemica, an acute fever with renal involvement, seen in Scandinavia and other European countries in people who have been in contact with bank voles. In the USA a hantavirus (transmitted by the deer mouse) termed Sin Nombre was identified as the cause of outbreaks of acute respiratory disease (hantavirus pulmonary syndrome, HPS) in adults. Other hantavirus types and rodent vector systems have been associated with this syndrome.

Diagnosis of hantavirus infection is made by ELISA detection of specific antibodies.

Rift Valley fever
Rift Valley fever, caused by a virus from the Phlebovirus genus of the Bunyaviridae, is primarily an acute febrile illness of livestock: sheep, goats and camels. It is found in southern and eastern Africa. The vector is Culex pipiens in East Africa and Aedes caballus in southern Africa, but disease can be transmitted by the bite of an infected animal. Following an incubation period of 3–6 days, the patient has an acute febrile illness that is difficult to distinguish clinically from other viral fevers. The temperature pattern is usually biphasic. The initial febrile illness lasts 2–4 days and is followed by a remission and a second febrile episode. Complications are indicative of severe infection and include retinopathy, meningoencephalitis, haemorrhagic manifestations and hepatic necrosis. Mortality approaches 50% in severe forms. Management is supportive. Animals can be vaccinated.

Lassa fever
Lassa fever virus belongs to the family Arenaviridae. Arenaviruses are pleomorphic, round or oval viruses with diameters ranging from 50 to 300 nm. The virion surface has club-shaped projections and the virus itself contains a variable number of characteristic electron-dense granules that represent residual, non-functional host ribosomes. Lassa fever illness was first documented in the town of Lassa, Nigeria, in 1969 and is confined to sub-Saharan West Africa (Nigeria, Liberia and Sierra Leone). The multimammate rat, Mastomys natalensis, is known to be the reservoir. Humans are infected by ingesting foods contaminated by rat urine or saliva containing the virus. Person-to-person spread by body fluids also occurs. Only 10–30% of infections are symptomatic. Related arenaviruses are the causative agents of Argentinian and Bolivian haemorrhagic fevers.

Clinical features
The incubation period is 7–18 days. The disease is insidious in onset and characterized by fever, myalgia, severe backache, malaise and headache. A transient maculopapular rash may be present. A sore throat, pharyngitis and lymphadenopathy occur in over 50% of patients. In severe cases, there may be epistaxis and gastrointestinal bleeding: hence the classification of Lassa fever as a viral haemorrhagic fever. The fever usually lasts 1–3 weeks, and recovery within 1 month of the onset of illness is usual. However, death occurs in 15–20% of hospitalized patients, usually from irreversible hypovolaemic shock.

Diagnosis
The diagnosis is established by serial serological tests (including the Lassa virus-specific IgM titre) or by genome detection in throat swab, serum or urine.

Management
Management is supportive. In addition, clinical benefit and a reduction in mortality can be achieved with ribavirin therapy, if given in the first week.

In non-endemic countries, strict isolation procedures should be used, the patient ideally being nursed in a flexible-film isolator. Specialized units for the management of Lassa fever and other haemorrhagic fevers have been established in the UK. As Lassa fever virus and other causes of haemorrhagic fever (Marburg/Ebola and Congo–Crimean haemorrhagic fever viruses; see Box 20.37) have been transmitted from patients to staff in healthcare situations, great care should be taken in handling specimens and clinical material from these patients.

Marburg virus disease and Ebola virus disease
These severe, haemorrhagic, febrile illnesses are discussed together because their clinical manifestations are similar, and the causative negative-strand RNA viruses belong to the same virus family, the Filoviridae, so called because the viruses have a filamentous appearance on electron microscopy. The diseases are named after Marburg in Germany and the Ebola river region in the Sudan and Zaire, where these viruses first appeared. Their natural reservoir has not been identified and the precise mode of spread from one individual to another has not been elucidated. The genus Ebolavirus contains five defined species, which vary in terms of case fatality rates: less than 40% for Bundibugyo, 50% for Sudan and 40–90% for Ebola viruses. There has been only one (non-fatal) case of Tai Forest virus infection. Reston virus, the only Asian species, has not been associated with human mortality.

Epidemics have occurred periodically in recent years, mainly in sub-Saharan Africa. Filoviruses are zoonotic pathogens, with fruit bats thought to be the natural host. The illness is characterized by the acute onset of severe headache, myalgia, vomiting and high fever, followed by prostration. On about the fifth day of illness a non-pruritic maculopapular rash develops on the face and then spreads to the rest of the body. Diarrhoea is profuse and associated with abdominal cramps and vomiting. Haematemesis, melena or haemoptysis may occur between days 7 and 16. Hepatosplenomegaly and facial oedema are usually present. In Ebola virus disease, chest pain and a dry cough are prominent symptoms.

In August 2014 the WHO declared the ongoing outbreak of Ebola virus infection in West Africa a public health emergency of international concern, with an estimated several thousand
Antiviral drugs

Deaths. Guinea, Sierra Leone and Liberia were the worst affected countries. As of early 2020, an outbreak in the Democratic Republic of Congo has involved over 3000 cases, with over 2000 deaths.

Treatment is symptomatic, although a number of experimental therapies, including monoclonal antibodies (e.g. Mab114) and the antivirals remdesivir and favipiravir, are being tried. Experimental vaccines are also being developed. In the absence of effective therapy, accurate diagnosis and infection control precautions are the only intervention strategies. Lack of infrastructure to support rapid molecular diagnostic techniques, and to allow institution of the meticulous patient isolation necessary to interrupt human-to-human transmission of infection, has contributed to generating the recent large outbreaks. Asymptomatic people may be infected but have a low viral count, making transmission unlikely.

ANTIVIRAL DRUGS

Drugs for HIV infection are discussed on page 1435, and the treatment of hepatitis C and B virus infections on page 1281.

Anti-herpesvirus drugs

Nucleoside analogues
Aciclovir. Aciclovir (Fig. 20.17A; also known as acycloguanosine) is an acyclic nucleoside analogue that acts as a chain terminator of herpesvirus DNA synthesis. This drug is converted to aciclovir monophosphate by a virus-encoded thymidine kinase produced by the alpha herpesviruses, herpes simplex types 1 and 2, and varicella zoster virus (Box 20.38). Conversion to the triphosphate is then achieved by cellular enzymes. Aciclovir triphosphate acts as a potent inhibitor of viral (but not cellular) DNA polymerase and also competes with deoxyguanine triphosphate for incorporation into the growing chains of herpesvirus DNA, thereby resulting in chain termination.

in chain synthesis termination due to its acyclic structure. This highly specific mode of activity, targeted only to virus-infected cells, means that aciclovir has very low toxicity. Crystallization in the renal tubules is a well-recognized adverse effect and patients should be well hydrated, particularly when high-dose intravenous therapy is being used. Intravenous, oral and topical preparations are available for the treatment of herpes simplex and varicella zoster virus infections. Treatment does not eliminate latent virus and so relapses do occur.

Valaciclovir. This is an oral prodrug of aciclovir. Coupling of valine to the acyclic side-chain of aciclovir allows better intestinal absorption. The valine is removed by enzymic action and aciclovir is released into the circulation. A similar prodrug of a related nucleoside analogue (penciclovir) is the antiviral drug famciclovir. The mode of action and efficacy of famciclovir are similar to those of aciclovir.

Ganciclovir. This guanine analogue is structurally similar to aciclovir, with extension of the acyclic side-chain by a carboxymethyl group. It is active against herpes simplex viruses and varicella zoster virus by the same mechanism as aciclovir. In addition, phosphorylation by a protein kinase, encoded by the UL97 gene of cytomegalovirus, renders it potently active against this virus. Thus, ganciclovir is currently the first-line treatment for cytomegalovirus disease. Intravenous and oral preparations are available, as is an oral prodrug, valganciclovir. Unlike aciclovir, ganciclovir has a significant toxicity profile, including neutropenia, thrombocytopenia and, rarely, sterilization by inhibition of spermatogenesis. It is therefore reserved for the treatment or prevention of life- or sight-threatening cytomegalovirus infection in immunocompromised patients.

Nucleotide analogues

Cidofovir. This is a phosphonate derivative of an acyclic nucleoside that acts as a viral DNA polymerase inhibitor (Fig. 20.17B). Phosphorylation to the active triphosphate moiety is entirely by host cell enzymes. It is administered intravenously for the treatment of severe cytomegalovirus infections when other drugs are inappropriate. It is given with probenecid and, as it is nephrotoxic, particular attention should be paid to hydration and monitoring of renal function.

Brincidofovir. This drug consists of cidofovir bound to a lipid moiety, enabling an oral route of administration and avoiding renal toxicity; it has shown great promise in clinical trials.

Pyrophosphate analogues

Foscarnet (sodium phosphonoformate). This is a simple pyrophosphate analogue that inhibits viral DNA polymerases. It is active against herpesviruses and its main role is as a second-line treatment for severe cytomegalovirus disease and in the treatment of aciclovir-resistant herpes simplex infection. It is given intravenously but the potential for severe side-effects, particularly renal damage, limits its use.

Novel anti-herpesvirus agents

New drugs undergoing clinical trials include pritelivir, an inhibitor of the herpes simplex viral helicase-primase enzyme complex; maribavir, an inhibitor of the product of the UL97 gene of cytomegalovirus, which plays a key role in allowing viral egress from an infected cell; and betamovir, an inhibitor of the cytomegalovirus terminase enzyme complex, which cuts the string of cytomegalovirus genomes synthesized in an infected cell into unit-length genomes for packaging in the capsid.

Anti-influenza drugs

Adamantanes

Amantadine. The use of amantadine and derivatives in the treatment and prophylaxis of influenza has largely been superseded by the neuraminidase inhibitors. Amantadine is active prophylactically and therapeutically against influenza A (but not B) virus. CNS side-effects, such as insomnia, dizziness and headache, may occur and the drug is poorly tolerated, especially in the elderly.

Neuraminidase inhibitors

Zanamivir (administered by inhalation) and oseltamivir (an oral preparation). These drugs inhibit the action of the neuraminidase of influenza A and B. Both have been shown to be effective in reducing the duration of illness in influenza if given within the first 48 hours. Oseltamivir is also available for the prophylaxis of influenza among contacts of an index case. Intravenous peramivir and zanamivir were both reported to be effective in treating patients during the 2010 influenza pandemic, but neither is currently licensed for routine use in this way.

Novel anti-influenza drugs

Baloxavir inhibits the cap-dependent endonuclease activity of the influenza polymerase. Clinical trials have shown efficacy similar to that of oseltamivir, and this drug achieved Food and Drug Administration approval in October 2018.

Anti-hepatitis B drugs

A number of nucleoside and nucleotide analogues have been shown to inhibit the reverse transcriptase function of hepatitis B virus and thereby suppress viral replication (see p. 1281). The first such agents, lamivudine and adefovir, have largely been superseded by the more potent drugs entecavir and tenofovir, both of which also have a considerably higher barrier to resistance.

Telbivudine is also a nucleoside analogue inhibitor of HBV DNA polymerase activity.

Other drugs

Ribavirin. This synthetic purine nucleoside derivative, which interferes with 5′-capping of messenger RNA, is active against several RNA and DNA viruses, at least in vitro. Its major use is in the treatment of chronic hepatitis C infection in combination with other agents, although it has no effect when given alone. It is administered orally. Haemolytic anaemia is the most frequent adverse reaction. It is also administered by a small-particle aerosol generator (SPAG) to infants with acute respiratory syncytial virus (RSV) infection. Another indication is in the treatment of Lassa fever virus infection.

Palivizumab. This monoclonal antibody is specifically indicated to prevent seasonal RSV infection in infants at high risk of this infection. It is administered by intramuscular injection.

Interferons

These are naturally occurring proteins with a multiplicity of actions, including antiviral, immunomodulatory and antiproliferative effects. Interferons are produced by virus-infected cells, macrophages and lymphocytes. They induce an antiviral state in uninfected cells, through
activation of a complex set of biochemical pathways. They have been synthesized commercially and are licensed for therapeutic use. The potency of INF-α has been enhanced by coupling the protein with polyethylene glycol. The resulting pegylated (PEG) interferon, given once weekly, has been shown to improve the response to, and reduce the side-effects from, treatment for hepatitis B and C (see p. 1281).

TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES (PRION DISEASES)

Transmissible spongiform encephalopathies (TSEs) are caused by the accumulation in the nervous system of a protein, termed a ‘prion’, which is an abnormal isoform (PrPSc) of a normal host protein (PrP).

Although familial forms of prion disease are known to exist, these conditions can be transmissible, particularly if brain tissue enters another host. There is no convincing evidence for the presence of nucleic acid in association with prions, and it is the abnormal prion protein itself that is infectious and can trigger a conversion of the normal protein into the atypical isoform. After infection, a long incubation period is followed by CNS degeneration associated with dementia or ataxia, which invariably leads to death. Histology of the brain reveals spongiform change with an accumulation of the abnormal prion protein in the form of amyloid plaques.

The human prion diseases are Creutzfeldt–Jakob disease, including the sporadic, familial, iatrogenic and variant forms of the disease, Gerstmann–Straussler–Scheinker syndrome, fatal familial insomnia and kuru.

• Creutzfeldt–Jakob disease (CJD). CJD occurs sporadically worldwide with an annual incidence of 1 per million of the population. Although, in most cases, the epidemiology remains obscure, iatrogenic transmission to others has occurred as a result of administration of human cadaveric growth hormone or gonadotrophin, from dura mater and corneal grafting and in neurosurgery from reuse of contaminated instruments and electrodes (iatrogenic CJD).

• Variant CJD (vCJD). In the UK, knowledge that large numbers of cattle with the prion disease, bovine spongiform encephalopathy (BSE), had gone into the human food chain, led to enhanced surveillance for emergence of the disease in humans. Based on transmission studies in mice and on glycosylation patterns of prion proteins, the evidence is convincing that this has occurred and, to date, there have been approximately 180 confirmed and suspected cases of vCJD (human BSE) in the UK and 50 in the rest of the world. In contrast to sporadic CJD, which presents with dementia at a mean age of onset of 60 years, vCJD presents with ataxia, dementia, myoclonus and chorea at a mean age of onset of 29 years.

• Gerstmann–Straussler–Scheinker syndrome and fatal familial insomnia. These are rare prion diseases, usually occurring in families with a positive history. The pattern of inheritance is autosomal dominant with some degree of variable penetrance. The gene encoding PrPSc in these families often contains mutations.

• Kuru. This disease was described and characterized in the Fore highlanders in north-east New Guinea. Transmission was associated with ritualistic cannibalism of deceased relatives. With the cessation of cannibalism by 1960, the disease has gradually diminished and recent cases had all been exposed to the agent before 1960.

The infectious agents of prion disease have remarkable characteristics. In the infected host there is no evidence of inflammatory, cytokine or immune reactions. The agent is highly resistant to decontamination, and infectivity is not reliably destroyed by autoclaving or by treatment with formaldehyde and most other gas or liquid disinfectants. It is very resistant to γ-irradiation. Autoclaving at a high temperature (134–137°C for 18 min) is used for decontamination of instruments and hypochlorite (20 000 p.p.m. available chlorine) or 1 molar sodium hydroxide is used for liquid disinfection. Uncertainty about the reliability of any methods for safe decontamination of surgical instruments has necessitated the introduction of guidelines for patient management.

BACTERIAL INFECTIONS

UBIQUITOUS BACTERIAL INFECTIONS

Bacteria are ubiquitous single-celled organisms that form the major part of the normal human microbiome. Bacterial infection is caused by commensal bacteria invading normally sterile parts of the body, or by pathogenic bacteria that are not normal commensal organisms. Infection can be the result of translocation of bacteria from non-sterile to sterile areas (e.g. from the gut to the urinary tract), acquisition from other people or animals, or transmission on fomites or in the environment.

In some cases, bacterial infection may be localized to a specific site, with few or no systemic symptoms. In other circumstances a localized infection may be accompanied by systemic illness or sepsis syndrome (see Ch. 8). Sometimes there is no obvious localized infection and the presentation is undifferentiated sepsis. In a few cases, bacteria cause illness through release of a specific toxin, which produces symptoms distant from the actual site of infection (Box 20.39).

Some bacterial infections are found worldwide, while others are particularly common in tropical/subtropical countries or in areas that have poorer access to fresh water, good hygiene and medical care. These factors are often interdependent, and many of the conditions that are traditionally labelled as ‘tropical’ are, in fact, related to socioeconomic conditions rather than climate.

Many of the common organ-specific bacterial conditions are covered in the relevant system chapters and the sepsis syndrome is described in Chapter 8. This section deals with those bacterial infections that do not fit readily into an organ-specific model, and those that are more defined by geographical and economic constraints than by body site.

BACTERIAL INFECTIONS OF THE SKIN AND SOFT TISSUES

Most common bacterial infections of skin and soft tissue are covered in Chapter 22, although some of the more unusual causes are described here and listed in Box 20.40. The majority of soft tissue
Infections are caused by *Staphylococcus aureus*, and while most *Staph. aureus* infections remain superficial, this organism can spread from the skin to cause a variety of more serious infections (see Box 20.23). Staphylococci are part of the normal microflora of the human skin and nasopharynx; up to 25% of people are carriers of *Staph. aureus*, the species responsible for the majority of staphylococcal infections. Other species of staphylococci are only rarely pathogenic.

### Invasive staphylococcal infection

Invasive staphylococcal infection is often associated with breaches in the skin: for example, those due to injecting drug use, iatrogenic cannulation, surgery or trauma. Other predisposing factors are listed in Box 20.24. In clinical situations, scrupulous attention to disinfection and hygiene when performing invasive procedures can minimize the risk of infection. Although *Staph. aureus* is the most common species of staphylococcus implicated in intravenous catheter-related infections, other normally non-pathogenic species, such as *Staph. epidermidis* (which is often intrinsically resistant to flucloxacillin), may be found. Flucloxacillin remains the first-choice antibiotic in staphylococcal infection when the organism is known to be sensitive (see p. 163 and Box 8.8), but with the increasing prevalence of meticillin-resistant *Staph. aureus* (MRSA), alternative anti-staphylococcal agents are being used more widely.

### Staphylococcal virulence factors

*Staph. aureus* can produce a variety of toxins and virulence factors that affect the type and severity of infection. These include staphylococcal enterotoxin A, superantigenic staphylococcal exotoxins, toxic shock toxin 1 and Panton Valentine-leukocidin (PVL). The last of these has been found mainly in community-associated strains of *Staph. aureus* (both MRSA and meticillin-sensitive *Staph. aureus*, MSSA), rather than in hospital-acquired or epidemic strains. PVL-producing MRSA and MSSA are becoming an increasingly common cause of invasive soft tissue and lung infections in some countries (notably the USA), although it is unclear whether PVL itself is directly responsible for the increased virulence.

### Meticillin-resistant *Staphylococcus aureus*

*Staph. aureus* is commonly resistant to penicillin, and isolated resistance to other β-lactam antibiotics, such as meticillin (now rarely used) and flucloxacillin, has been recognized since the development of the first semi-synthetic penicillins in the early 1960s. However, in the last 40 years, strains of meticillin-resistant *Staphylococcus aureus* (MRSA) with resistance to a much wider range of antibiotics have emerged.

MRSA is usually found as a skin commensal, especially in hospitalized patients or nursing home residents. However, it can cause a variety of infections in soft tissues and elsewhere, and can lead to death. It is particularly associated with surgical wound infections. Eradication of the organism is difficult and people who are known to have been in contact with it should be kept isolated from others until they are known to be sensitive (see p. 163 and Box 8.8).
to be colonized should be isolated from those at risk of significant infection. Topical decolonization is often used to decrease bacterial load prior to invasive procedures but is of limited efficacy in clearing carriage completely. Careful attention to hand-washing and hygiene is the main method of controlling spread (see p. 292).

Although MRSA is generally regarded as a hospital-associated organism, it is commonly seen in people away from this setting, both as a colonizer and as a cause of disease. Often the organisms are the typical ‘hospital’ strains of MRSA and have been acquired directly or indirectly from a healthcare setting (e.g. in workers in care homes). However, there is an increasing prevalence in some countries of true community-associated MRSA (CA-MRSA), with no discernible links to hospital or residential care. These CA-MRSA strains have different resistance profiles to those of typical hospital strains (often retaining sensitivity to tetracyclines, clindamycin and co-trimoxazole) and are more likely to produce PVL.

**Pasturellosis**

*Pasturella multocida* is found in the oropharynx of up to 90% of cats and 70% of dogs. It can cause soft tissue infections following animal bites. Although the infection initially resembles other forms of cellulitis, there is a greater tendency to spread to deeper tissues, resulting in osteomyelitis, tenosynovitis or septic arthritis. It can also spread haematogenously to other organs, including the lungs and heart. The organism is sensitive to penicillin, but as infections following animal bites are often polymicrobial, co-amoxiclav is a better choice.

**Cat-scratch disease**

Cat-scratch disease is a zoonosis caused by *Bartonella henselae*. Asymptomatic bacteraemia is relatively common in domestic and especially feral cats, and human infection is probably due to direct inoculation from the claws or via cat flea bites. Regional lymphadenopathy appears 1–2 weeks after infection; the nodes become tender and may suppurate. Histology of the nodes shows granuloma formation and the illness may be mistaken for mycobacterial infection or lymphoma. There are usually few systemic symptoms in immunocompetent patients, although more severe disease may be seen in the immunocompromised. In these patients, tender cutaneous or subcutaneous nodules are seen (*bacillary angiomatosis*), which may ulcerate. The lymphadenopathy resolves spontaneously over weeks or months, although surgical drainage of very large suppurating nodes may be necessary. *B. henselae* is sensitive to azithromycin, doxycycline and ciprofloxacin, but drug selection and clinical benefit of treatment vary according to the primary site of the infection and the immune status of the patient.

**Toxin-mediated skin disease**

A number of skin conditions, although caused by bacteria, are mediated by exotoxins rather than direct local tissue damage.

**Staphylococcal scalded skin syndrome**

The scalded skin syndrome is caused by a toxin-secreting strain of *Staph. aureus* (see p. 669). It principally affects children under the age of 5. The toxin, exfoliatin, causes intra-epidermal cleavage at the level of the stratum corneum, leading to the formation of large, flaccid blisters that shear readily. It is a relatively benign condition and responds to treatment with flucloxacillin.

**Toxic shock syndrome**

Toxic shock syndrome (TSS) is usually due to toxin-secreting staphylococci but toxin-secreting streptococci have also been implicated. Although historically associated with vaginal colonization and tampon use in women, this is not always the case. The exotoxin (normally toxic shock syndrome toxin 1, TSST-1) induces cytokine release, causing abrupt onset of fever and shock, with a diffuse macular rash and desquamation of the palms and soles. Many patients are severely ill and mortality is about 5%. Management is mainly supportive, although the organism should be eradicated.

**Bacterial infections of the respiratory tract**

Infections of the respiratory tract are divided into those affecting the upper respiratory tract and those affecting the lower respiratory tract, which are separated by the larynx. The majority of common respiratory infections are covered elsewhere.

**Upper respiratory tract infections**

**Scarlet fever**

Scarlet fever occurs when the infectious organism (usually *Streptococcus* group A but occasionally group C or G) produces erythrogenic toxin in an individual who does not possess neutralizing antitoxin antibodies. Infections may be sporadic or epidemic, occurring in residential institutions such as schools, prisons and military establishments.

**Clinical features**

The onset of this relatively mild disease, which mainly affects children, is 2–4 days following a streptococcal infection (usually in the pharynx). Common features include regional lymphadenopathy, fever, rigors, headache and vomiting. The rash, which blanches on pressure, usually appears on the second day of illness. It is generalized but typically absent from the face, palms and soles. It usually lasts about 5 days and is followed by extensive desquamation of the skin (Fig. 20.18). The face is flushed, with characteristic circumoral pallor. Early in the disease the tongue has a white coating, through which
prominent bright red papillae can be seen ("strawberry tongue"). Later the white coating disappears, leaving a raw-looking, bright red colour ("raspberry tongue"). The patient is infective for 10–21 days after the onset of the rash, unless treated with antibiotics.

Scarlet fever may be complicated by peritonsillar or retropharyngeal abscesses and otitis media.

The diagnosis is established by the typical clinical features, and culture of a throat swab. Scarlet fever should be treated with penicillin, to which group A streptococcus is invariably sensitive.

**Diphtheria**

Diphtheria (caused by *Corynebacterium diphtheriae* or *C. ulcerans*) occurs worldwide. Its incidence in the West has fallen dramatically following widespread active immunization, but the disease has re-emerged in Eastern Europe. Transmission is mainly through airborne droplet infection. *C. diphtheriae* is a Gram-positive bacillus; only strains that carry the tox+ gene are capable of toxin production.

**Clinical features**

Diphtheria was formerly a disease of childhood but may affect adults in countries where childhood immunization has been interrupted or uptake is poor. The incubation period is 2–7 days. The manifestations are local (due to the membrane) or systemic (due to exotoxin). The presence of a membrane, however, is not essential to the diagnosis.

**Nasal diphtheria** is characterized by the presence of a unilateral, serosanguineous nasal discharge that crusts around the external nares.

**Pharyngeal diphtheria** is associated with the greatest toxicity and is characterized by marked tonsillar and pharyngeal inflammation and, usually, the presence of a membrane. The tough, greyish-yellow membrane is formed by fibrin, bacteria, epithelial cells, mononuclear cells and polymorphs, and is firmly adherent to the underlying tissue. Regional lymphadenopathy, often tender, is prominent and produces the so-called ‘bull-neck’.

**Laryngeal diphtheria** is usually a result of extension of the membrane from the pharynx. A husky voice, a brassy cough and, later, dyspnoea and cyanosis due to respiratory obstruction are common features.

Diphtheria toxin principally affects the heart and the nervous system. Clinically evident myocarditis occurs, sometimes weeks after initial infection, in a proportion of patients with pharyngeal or laryngeal diphtheria. Acute circulatory failure due to myocarditis may occur in convalescent individuals around the tenth day of illness and can often be fatal. Neurological manifestations occur either early in the disease (palatal and pharyngeal wall paralysis) or several weeks after its onset (cranial nerve palsies, paraesthesiae, polyneuropathy or, rarely, encephalitis).

**Cutaneous diphtheria** (caused by *C. ulcerans*) is uncommon but seen in association with burns and in individuals with poor personal hygiene. Typically, the ulcer is punched-out with undermined edges and is covered with a greyish-white to brownish adherent membrane. Constitutional symptoms are uncommon.

**Diagnosis**

This must be made on clinical grounds since therapy is usually urgent; the mortality rate is about 10%. It is confirmed by bacterial culture and toxin studies.

**Management**

Antitoxin therapy is the only specific treatment. It must be given promptly to prevent further fixation of toxin to tissue receptors, since fixed toxin is not neutralized by antitoxin. Depending on the severity, 20 000–100 000 units of horse-serum antitoxin should be administered intramuscularly, after an initial test dose to exclude any allergic reaction. Intravenous therapy may be required in a very severe case. There is a risk of acute anaphylaxis after antitoxin administration, and of serum sickness 2–3 weeks later (Box 20.41). However, the risk of death outweighs the problems of anaphylaxis. Antibiotics (penicillin, amoxicillin or a macrolide) should be administered concurrently to eliminate the organisms and thereby remove the source of toxin production.

The cardiac and neurological complications need intensive supportive therapy. Recovery and rehabilitation can take many weeks.

**Prevention**

Patients with suspected diphtheria must be isolated and the local public health authorities should be informed. Staff caring for the patient should have documented immunization status. All contacts of the patient should have throat swabs sent for culture; those with a positive result should be treated with antibiotic, and be given active immunization or a booster dose of diphtheria toxoid. Diphtheria is prevented by active immunization in childhood (see p. 508). Travelers to high-risk countries may require a booster dose, even if they have had childhood immunization (although monovalent diphtheria vaccine is no longer available).

**Acute epiglottitis**

Acute epiglottitis has been virtually eliminated among children in countries that have introduced *Haemophilus influenzae* vaccine, as in the UK. Occasionally, infections are seen in adults. The clinical features are described on page 947.

**Lower respiratory tract infections**

**Pneumonia, lung abscess and tuberculosis**

For community-acquired pneumonia, see page 963; hospital-acquired pneumonia, page 965; and pneumonia in immunocompromised persons, page 967.

**Lung abscess** is described on page 965.

**Tuberculosis** is described on page 967.

BACTERIAL INFECTIONS OF THE GASTROINTESTINAL TRACT

Gastroenteritis
The most common form of acute gastrointestinal infection is gastroenteritis, causing diarrhoea with or without vomiting. Children in the developing world can expect, on average, 3–6 bouts of severe diarrhoea annually. Although oral rehydration programmes have cut the death toll significantly, more than half a million children die every year as a direct result of diarrhoeal disease. In the Western world, diarrhoea is both less common and less likely to cause death, but remains a major cause of morbidity, especially in the elderly. Other groups at increased risk of infectious diarrhoea include travellers to developing countries, people in residential care and infants in daycare facilities.

Viral gastroenteritis (see p. 529) is a common cause of diarrhoea and vomiting in young children but is less commonly seen in adults, other than in the context of common source outbreaks (usually due to norovirus). It is a major cause of morbidity and mortality among infants in low-income countries. Protozoal and helminthic gut infections (see pp. 563 and 573) are rare in the West but relatively common in developing countries. However, the most common cause of significant adult gastroenteritis worldwide is bacterial infection.

Bacteria can cause diarrhoea in three different ways (Box 20.42). Some species may employ more than one of these methods. In addition to these direct mechanisms, a proportion of people develop post-infectious irritable bowel syndrome, a functional bowel disorder triggered by infection but persisting after resolution of the inflammation (see p. 1187).

Mucosal adherence
Most bacteria causing diarrhoea must first adhere to specific receptors on the gut mucosa: a number of different molecular adherence mechanisms have been elaborated. For some pathogens this is merely the prelude to invasion or toxin production but others, such as enteropathogenic Escherichia coli (EPEC), cause mucosal lesions and produce a secretory diarrhoea as a direct result of adherence. Enteraggregative E. coli (EAggEC) adhere in an aggregative pattern, with the bacteria clumping on the cell surface, and their toxin causes persistent diarrhoea. Diffusely adhering E. coli (DAEC) adheres in a uniform manner and may also cause diarrhoea. Both are seen mainly in low-income countries with poor hygiene and inadequate clean water supply.

E. coli O104:H4, which has caused huge outbreaks of gastroenteritis in Germany and other developed countries, has two different diarrhoea-causing E. coli pathotypes: typical enteraggregative E. coli and Shiga-toxin-producing E. coli.

Mucosal invasion
Invasive pathogens, such as Shigella spp., enteroinvasive E. coli (EIEC) and Campylobacter spp., penetrate the intestinal mucosa. Initial entry into the mucosal cells is facilitated by the production of ‘invasins’, which disrupt the host-cell cytoskeleton. Subsequent destruction of the epithelial cells allows further bacterial entry, which also causes the typical symptoms of dysentery: low-volume bloody diarrhoea with abdominal pain.

Toxin production
Gastroenteritis can be caused by different types of bacterial toxin. Enterotoxins produced by bacteria adhering to the intestinal epithelium induce excessive fluid secretion into the bowel lumen, leading to watery diarrhoea without physically damaging the mucosa (e.g. cholera, enterotoxigenic E. coli, ETEC). Some enterotoxins that are pre-formed in food primarily cause vomiting (e.g. entero-toxigenic Staph. aureus and Bacillus cereus). Cytotoxins damage the intestinal mucosa and, in some cases, vascular endothelium as well (e.g. E. coli O157).

Clinical syndromes
Bacterial gastroenteritis can be divided on clinical grounds into two broad syndromes: watery diarrhoea (usually due to enterotoxins or adherence) and dysentery (usually due to mucosal invasion and damage) (Box 20.43). With some pathogens, such as Campylobacter jejuni, there may be overlap between the two syndromes. A third clinical type of infective gastroenteritis, chronic diarrhoea, is rarely bacterial in origin.

The most common form of acute gastrointestinal infection is gastroenteritis, causing diarrhoea with or without vomiting. Children in the developing world can expect, on average, 3-6 bouts of severe diarrhoea annually. Although oral rehydration programmes have cut the death toll significantly, more than half a million children die every year as a direct result of diarrhoeal disease. In the Western world, diarrhoea is both less common and less likely to cause death, but remains a major cause of morbidity, especially in the elderly. Other groups at increased risk of infectious diarrhoea include travellers to developing countries, people in residential care and infants in daycare facilities.

Viral gastroenteritis (see p. 529) is a common cause of diarrhoea and vomiting in young children but is less commonly seen in adults, other than in the context of common source outbreaks (usually due to norovirus). It is a major cause of morbidity and mortality among infants in low-income countries. Protozoal and helminthic gut infections (see pp. 563 and 573) are rare in the West but relatively common in developing countries. However, the most common cause of significant adult gastroenteritis worldwide is bacterial infection.

Bacteria can cause diarrhoea in three different ways (Box 20.42). Some species may employ more than one of these methods. In addition to these direct mechanisms, a proportion of people develop post-infectious irritable bowel syndrome, a functional bowel disorder triggered by infection but persisting after resolution of the inflammation (see p. 1187).

Mucosal adherence
Most bacteria causing diarrhoea must first adhere to specific receptors on the gut mucosa: a number of different molecular adherence mechanisms have been elaborated. For some pathogens this is merely the prelude to invasion or toxin production but others, such as enteropathogenic Escherichia coli (EPEC), cause mucosal lesions and produce a secretory diarrhoea as a direct result of adherence. Enteraggregative E. coli (EAggEC) adhere in an aggregative pattern, with the bacteria clumping on the cell surface, and their toxin causes persistent diarrhoea. Diffusely adhering E. coli (DAEC) adheres in a uniform manner and may also cause diarrhoea. Both are seen mainly in low-income countries with poor hygiene and inadequate clean water supply.

E. coli O104:H4, which has caused huge outbreaks of gastroenteritis in Germany and other developed countries, has two different diarrhoea-causing E. coli pathotypes: typical enteraggregative E. coli and Shiga-toxin-producing E. coli.

Mucosal invasion
Invasive pathogens, such as Shigella spp., enteroinvasive E. coli (EIEC) and Campylobacter spp., penetrate the intestinal mucosa. Initial entry into the mucosal cells is facilitated by the production of ‘invasins’, which disrupt the host-cell cytoskeleton. Subsequent destruction of the epithelial cells allows further bacterial entry, which also causes the typical symptoms of dysentery: low-volume bloody diarrhoea with abdominal pain.

Toxin production
Gastroenteritis can be caused by different types of bacterial toxin. Enterotoxins produced by bacteria adhering to the intestinal epithelium induce excessive fluid secretion into the bowel lumen, leading to watery diarrhoea without physically damaging the mucosa (e.g. cholera, enterotoxigenic E. coli, ETEC). Some enterotoxins that are pre-formed in food primarily cause vomiting (e.g. entero-toxigenic Staph. aureus and Bacillus cereus). Cytotoxins damage the intestinal mucosa and, in some cases, vascular endothelium as well (e.g. E. coli O157).

Clinical syndromes
Bacterial gastroenteritis can be divided on clinical grounds into two broad syndromes: watery diarrhoea (usually due to enterotoxins or adherence) and dysentery (usually due to mucosal invasion and damage) (Box 20.43). With some pathogens, such as Campylobacter jejuni, there may be overlap between the two syndromes. A third clinical type of infective gastroenteritis, chronic diarrhoea, is rarely bacterial in origin.
Management of infective diarrhoea is usually syndromic (see later), as, except during outbreaks, the causative organism is rarely known at presentation. Bacterial gastroenteritis is usually self-limiting and in otherwise healthy individuals does not require antibiotics, unless the infection is particularly severe or prolonged. An exception is dysentery in children, where antibiotic therapy is proven to reduce mortality (Box 20.44).

**Salmonella**

Gastroenteritis can be caused by many of the numerous serotypes of non-typhoidal Salmonella (all of which are members of a single species of Gram-negative bacillus, *S. choleraeus*), but the most commonly implicated are *S. enteritidis* and *S. typhimurium* (*S. typhi* and *S. paratyphi*, the causes of enteric fever, which are covered on p. 554). These organisms, which are found all over the world, are commensals in the bowels of livestock (especially poultry) and oviducts of chicken (where the eggs can become infected). They are usually transmitted to humans in contaminated foodstuffs and water.

Salmonellae can affect both the large and the small bowel, and induce diarrhoea both by production of enterotoxins and by invasion. The typical symptoms commence abruptly, 12–48 hours after infection, and consist of nausea, cramping abdominal pain, diarrhoea and sometimes fever. The diarrhoea can vary from profuse and watery to a bloody dysentery syndrome. Spontaneous resolution usually occurs in 3–6 days, although the organism may persist in the faeces for several weeks. Bloodstream infection occurs in 1–4% of cases and is more common in the elderly and the immunosuppressed; some serotypes are more prone to cause bacteraemia than others. Occasionally, this is complicated by metastatic infection, especially of atheroma on vascular endothelium, with potentially devastating consequences. In healthy adults, *Salmonella* gastroenteritis is usually a relatively minor illness, but young children and the elderly are at risk of significant dehydration.

Specific diagnosis is made by culturing the organism from blood or faeces, but management is usually empirical and includes oral rehydration. Antibiotic resistance in salmonellae is increasing, with 13% of European human isolates now resistant to ciprofloxacin. Resistance to azithromycin or third-generation cephalosporins remains rare.

**Campylobacter jejuni**

The Gram-negative bacillus *C. jejuni* is a zoonotic organism, existing as a bowel commensal in many species of livestock, including poultry and cattle. It is found worldwide and is an important cause of childhood gastroenteritis in developing countries. Adults in these countries may be tolerant of the organism, excreting it asymptotically. In the West, it is a common cause of sporadic food-borne outbreaks of gastroenteritis. About 50000 cases are confirmed annually in England and Wales, but the actual incidence is much higher. The most common sources are undercooked meat.

</table>

*aAntibiotics are not needed for the majority of adult cases in developed countries.*
Shigella

Shigellae are enteroinvasive Gram-negative bacteria, which cause classical bacillary dysentery. The principal species causing gastroenteritis are *S. dysenteriae*, *S. flexneri* and *S. sonnei*, which are found with varying prevalence in different parts of the world. All cause a similar syndrome, as a result of damage to the intestinal mucosa. Some strains of *S. dysenteriae* also secrete a cytotoxin affecting vascular endothelial cells in the gut and in the kidney. After an incubation period of 12–48 hours, a toxin (Shiga-like toxin 1) that affects vascular endothelial cells in nearly 50,000 children under 5 years old every year.

The organism is spread from person to person (either directly, or via contaminated food or water) and only a small number of bacteria need to be ingested to cause illness (<200, compared with 10⁴ for *Campylobacter* and >10⁵ for *Salmonella*). Symptoms start 24–48 hours after ingestion and typically consist of frequent, small-volume stools containing blood and mucus. Dehydration is not as significant as in the secretory diarrhoeas but systemic symptoms and intestinal complications are worse. The illness is usually self-limiting in 7–10 days, but in children in developing countries it can carry a significant mortality.

Antibiotic treatment decreases the severity and duration of diarrhoea, reduces mortality in children, and possibly lowers the risk of further transmission. Resistance to antibiotics is widespread and, wherever possible, treatment should be based on known local sensitivity patterns. Antibiotics such as nalidixic acid and co-trimoxazole, which were widely used in the past, are no longer recommended by the WHO, due to extensive resistance. Most guidelines recommend ciprofloxacin as the first-choice antibiotic but resistance to this antibiotic is also increasing rapidly in some parts of the world. Other options include azithromycin, ceftriaxone, but these all have disadvantages compared to the cheap and safe ciprofloxacin.

Enteroinvasive *Escherichia coli*

Enteroinvasive *E. coli* (EIEC) causes an illness that is indistinguishable from shigellosis. Definitive diagnosis is made by stool culture but most cases are probably treated empirically as shigellosis.

Enterohaemorrhagic *Escherichia coli*

Enterohaemorrhagic *E. coli* (EHEC; usually serotype O157:H7 and also known as verotoxin-producing *E. coli*, VTEC) is a well-recognized cause of gastroenteritis in humans. It is a zoonosis that is usually associated with cattle, and there have been a number of major outbreaks (notably in Scotland, Japan and the USA) linked to contaminated food. A variety of modes of transmission have been reported and the epidemiology of EHEC infection is a paradigm for all enteric livestock-associated zoonoses (*Fig. 20.19*). EHEC secretes a toxin (Shiga-like toxin 1) that affects vascular endothelial cells in the gut and in the kidney. After an incubation period of 12–48 hours, it causes diarrhoea (frequently bloody), associated with abdominal pain and nausea. Some days after the onset of symptoms the patient may develop thrombotic thrombocytopenic purpura (see p. 374) or haemolytic uraemic syndrome (see p. 1368). These are more
common in children and may lead to permanent renal damage or death. Non-O157 serotypes are of increasing concern.

Between May and June 2011, the largest ever recorded outbreak of Shiga toxin-producing \textit{E. coli} (STEC) causing HUS was recorded in Germany. The outbreak was caused by the O104 serotype and over 2000 people were affected. High rates of HUS were observed in adults not in the typical ‘at-risk’ age range. The increased virulence of this strain is possibly due to it having two different pathotypes (see p. 539).

Treatment is mainly supportive; there is evidence that antibiotic therapy might precipitate HUS by causing increased toxin release, although this remains controversial.

\textbf{Enterotoxigenic \textit{Escherichia coli}}

Enterotoxigenic \textit{E. coli} (ETEC) produce both heat-labile and heat-stable enterotoxins, which stimulate secretion of fluid into the intestinal lumen. The result is watery diarrhoea of varying intensity, which usually resolves within a few days. Transmission is normally from person to person via contaminated food and water. The organism is common in developing countries and is a major cause of travellers’ diarrhoea (see later).

\textit{Vibrio}

Cholera, due to \textit{Vibrio cholerae}, is the prototypic pure enterotoxigenic diarrhoeal disease; it is described on page 553.

\textit{V. parahaemolyticus} can cause acute watery diarrhoea after consumption of contaminated raw fish or shellfish. Explosive diarrhoea, abdominal cramps and vomiting occur, with fever in 50\%. The infection is self-limiting but can last for up to 10 days.

\textbf{Yersiniosis}

\textit{Yersinia enterocolitica} infection is a zoonosis of a variety of domestic and wild mammals. Human disease can arise via either contaminated food products, such as pork, or direct animal contact. \textit{Y. enterocolitica} can cause a range of gastrointestinal symptoms, including watery diarrhoea, dysentery and mesenteric adenitis. The illness is usually self-limiting but ciprofloxacin may shorten the duration. \textit{Y. pseudotuberculosis} is a much less common human pathogen; it causes mesenteric adenitis and terminal ileitis.

\textbf{Enterotoxin-producing \textit{Staphylococcus aureus}}

Some strains of \textit{Staph. aureus} can produce a heat-stable toxin (enterotoxin B), which causes massive secretion of fluid into the intestinal lumen. It is a common cause of food-borne gastroenteritis in Europe and the USA, outbreaks usually occurring as a result of poor food hygiene. Because the toxin is pre-formed in the contaminated food, onset of symptoms is rapid, often within 2–4 hours of consumption. There is violent vomiting, followed within hours by profuse watery diarrhoea. Symptoms usually settle within 24 hours.

\textbf{Bacillus cereus}

\textit{B. cereus} produces two toxins. The first causes vomiting 2–4 hours after ingesting pre-formed heat-stable exotoxins. The second causes watery diarrhoea up to 12 hours after ingestion of uncooked food that contains spores or viable bacteria that multiply and produce a toxin within the bowel.

\textbf{Clostridial infections}

\textbf{Clostridium difficile}

\textit{C. difficile} can cause watery diarrhoea, colitis and pseudomembranous colitis. It is a Gram-positive, anaerobic, spore-forming bacillus that is found in the bowel flora of 3–5\% of the asymptomatic population (increasing to up to 20\% in hospitalized people).

\textbf{Pathogenesis}

\textit{C. difficile} produces two toxins: toxin A is an enterotoxin, while toxin B is cytotoxic and causes bloody diarrhoea. It usually causes illness either in patients who have been given antibiotic therapy that has eliminated other bowel commensals, or in those who are debilitated for other reasons. Almost all antibiotics have been implicated but an increase in cases has been attributed in part to greater use of quinolones. Hospital-acquired infections remain common, partly due to increased spread from person to person and via fomites, and partly to high rates of antibiotic use in hospitalized people. Strains of \textit{C. difficile} with greater capacity for toxin production have been reported (e.g. ribotype 027) in a number of hospital outbreaks, with a high mortality.

\textbf{Clinical features}

\textit{C. difficile}-associated diarrhoea (CDAD) can begin anything from 2 days to some months after taking antibiotics. Elderly hospitalized patients are most frequently affected. It is unclear why some carriers remain asymptomatic. Symptoms can range from mild diarrhoea to profuse, watery, haemorrhagic colitis, along with lower abdominal pain. The colonic mucosa is inflamed and ulcerated, and can be covered by an adherent membrane-like material (pseudomembranous colitis). The disease is usually more severe in the elderly and can cause intractable diarrhoea; occasionally, it can cause toxic megacolon. Markers of severity include:

\begin{itemize}
  \item temperature $>38.5\, ^\circ\mathrm{C}$
  \item white cell count $>15 \times 10^9$
  \item serum creatinine $>50\%$ above baseline
  \item raised serum lactate
  \item severe abdominal pain.
\end{itemize}

\textbf{Diagnosis}

Diagnosis is made by detecting A or B toxins in the stools using ELISA, or PCR for \textit{C. difficile} nucleic acid.

\textbf{Management}

Treatment is with metronidazole 400mg three times daily (in mild disease) or oral vancomycin 125–500mg four times daily (in more severe or relapsing cases). Fidaxomicin may be effective in cases that have relapsed following other treatments. Other antibiotics should be discontinued if possible. In refractory or relapsing cases, instilling faeces from the bowel of a healthy donor (faecal transplant) can restore normal bowel flora and eradicate the \textit{C. difficile} infection. This therapy may become the standard for refractory \textit{C. difficile} infections.

\textbf{Prevention}

Infection control relies on:

\begin{itemize}
  \item Responsible use of antibiotics (see p. 159).
  \item Hygiene, which should involve all health workers, as well as patients and relatives. Washing hands thoroughly using soap and water is essential, as alcohol disinfectants do not kill spores (see p. 292).
  \item Isolation of patients with symptomatic \textit{C. difficile} in hospitals or residential care.
\end{itemize}

\textbf{Clostridium perfringens}

\textit{C. perfringens} infection is due to inadequately cooked food, usually meat or poultry allowed to cool for a long time, during which period the spores germinate. The ingested organism produces an
enterotoxin that causes watery diarrhoea with severe abdominal pain, usually without vomiting.

**Travellers’ diarrhoea**

Travellers’ diarrhoea is defined as the passage of three or more unformed stools per day in a resident of an industrialized country travelling in a developing nation. Infection is usually food- or water-borne and younger travellers are most often affected (probably reflecting behaviour patterns). Reported attack rates vary from country to country but approach 50% for a 2-week stay in some nations. The disease is usually benign and self-limiting; treatment with quinolone antibiotics may hasten recovery but is not normally necessary. Prophylactic antibiotic therapy may also be effective for short stays but should not be used routinely. The common causative organisms are listed in Box 20.45.

**Management of acute gastroenteritis**

In children in low-income countries, untreated diarrhoea has a high mortality due to dehydration, often on a background of malnutrition and other chronic infection. Death and serious morbidity are less common in adults but still occur, particularly in developing countries and in the elderly.

The mainstay of treatment for all types of gastroenteritis is oral rehydration solutions (ORS) (Fig. 20.20; see Box 20.36). The use and formulation of ORS are discussed on page 553. Antibiotics may sometimes have a role, especially in children in developing countries. It is also important to remember that other diseases, notably UTIs and chest infections in the elderly, and malaria at any age, can present with acute diarrhoea. Most cases of acute gastroenteritis (especially in developed countries) resolve within 10 days; if symptoms persist, other causes, such as colitis, are more likely.

**Food poisoning**

Food poisoning is a legally notifiable condition in England and Wales. There is some overlap between food poisoning (defined as ‘any disease of an infective or toxic nature caused by or thought to be caused by the consumption of food and water’) and gastroenteritis. However, not all cases of gastroenteritis are due to food poisoning, as the pathogens are not always food- or water-borne. Conversely, some types of food poisoning (e.g. botulism) do not primarily cause gastroenteritis. Common bacterial causes of food poisoning are listed in Box 20.46. Food poisoning may also be caused by a number of non-infectious organic and inorganic toxins (Box 20.47).

The increase in reported food poisoning in developed countries is due, at least in part, to changes in the production and distribution of food. Livestock raised and slaughtered under modern intensive farming conditions is frequently contaminated with Salmonella or Campylobacter. However, the main problem is not at this stage. Only 0.02–0.1% of the eggs from a flock of chickens infected with *S. enteritidis* will be affected and then only at a level of less than 20 cells per egg – harmless to most healthy individuals. It is flaws in the processing, storage and distribution of food products that allow massive amplification of the infection, resulting in extensive contamination. The internationalization of the food supply encourages widespread and distant transmission of the resulting infections.

**Enteric fever, *Helicobacter pylori*, Whipple’s disease and bacterial peritonitis**

*Enteric fever*: see page 554.

*H. pylori*: see page 1173.

*Whipple’s disease*: see page 1194.

*Bacterial peritonitis*: see page 1222.
Infective endocarditis is discussed on page 1103.

Rheumatic fever

Rheumatic fever is a multisystem disorder but is included here as the cardiac effects are usually the most significant (about 35 million people worldwide have rheumatic heart disease). It is an immune-mediated inflammatory disease that occurs in children and young adults as a result of infection with group A streptococci (GAS). It affects the heart, skin, joints and CNS. It is relatively common in the Middle and Far East, Eastern Europe and South America, but is now rare in Western Europe and North America. This decline in the incidence of rheumatic fever in the developed world (from 10% of children in the 1920s to 0.01% today) parallels the reduction in all streptococcal infections and is largely due to improved hygiene and the use of antibiotics.

Pharyngeal infection with GAS is followed, in a small proportion of cases, by the clinical syndrome of rheumatic fever. This is thought to develop because of an autoimmune reaction triggered by molecular mimicry between the cell-wall M proteins of the infecting Streptococcus pyogenes and cardiac myosin and laminin. The condition is not due to direct infection of the heart or the production of a toxin.

**Clinical features**

The disease presents 2–3 weeks after the initial GAS infection with fever, joint pains and malaise. Diagnosis relies on the presence of
two or more major clinical manifestations, or one major manifestation plus two or more minor features, in addition to evidence of current or recent streptococcal infection. These are known as the modified Jones criteria (Box 20.48).

Carditis manifests as new or changed heart murmurs, development of cardiac enlargement or cardiac failure, appearance of a pericardial effusion, or electrocardiographic (ECG) changes of pericarditis, myocardiitis or cardiac arrhythmias.

Non-cardiac features include fever, arthritis, Sydenham’s chorea (see p. 862) and skin lesions. The arthritis is typically a fleeting migratory polyarthritis affecting large joints such as the knees, elbows, ankles and wrists. Once the acute inflammation disappears, the rheumatic process leaves the joints normal. Skin manifestations include erythema marginatum, a transient pink rash with slightly raised edges, which occurs in 20% of cases, and small painless subcutaneous nodules.

Management
The streptococcal infection should be eradicated with penicillin. If the diagnosis is suspected clinically, antibiotics should be administered, even if nasal or pharyngeal swabs do not culture the streptococci.

The arthritis of rheumatic fever usually responds to non-steroidal anti-inflammatory drugs (NSAIDs), although these have no impact on long-term cardiac sequelae. There is no good evidence that steroids are of benefit, although some experts give high-dose prednisolone if there is severe carditis. In areas of high prevalence, recurrence is common and persistent cardiac damage more likely. Further infection can largely be prevented by prophylaxis with daily oral or monthly intramuscular benzathine penicillin until the age of 20 years or for 10 years after the latest attack. Erythromycin or clarithromycin is used if the patient is allergic to penicillin. Any streptococcal infection that does develop should be treated promptly.

Prognosis
More than 50% of those who suffer acute rheumatic fever with carditis will later (after 10–20 years) develop chronic rheumatic valvular disease, predominantly affecting the mitral and aortic valves.

Bacterial meningitis
The most common bacterial disease affecting the CNS is acute meningitis (see p. 869), which causes about 175,000 deaths per year, predominantly in the developing world. The most common causes are Neisseria meningitidis (or meningococcus) and Streptococcus pneumoniae, while tuberculous meningitis (see p. 870) is common in sub-Saharan Africa and parts of Asia.

Haemophilus influenzae type b (Hib) was once a common cause of meningitis in children, but since an effective vaccine has been available serious H. influenzae infections have become rare in countries that have also instituted immunization programmes; however, invasive H. influenzae infection remains common in some parts of the world.

Other less common causes of meningitis in adults include group B streptococci, Listeria monocytogenes (see p. 548), Staph. aureus and Gram-negative bacilli. These organisms are usually associated with an underlying illness or immunocompromising condition, or with a CSF leak.

N. meningitidis is also an important cause of bloodstream infection and sepsis. There is a spectrum of presentation ranging from pure meningitis with few systemic features to a typical sepsis syndrome without clinical evidence of meningitis.

Meningococcal sepsis
Neisseria meningitidis is found worldwide. Twelve serogroups have been identified, of which six (A, B, C, W, X and Y) cause significant outbreaks of infection. In sub-Saharan Africa and parts of Asia, where group A meningococcus is prevalent, it usually causes epidemic disease. The main burden falls on the so-called “meningitis belt”, which includes 25 countries across Africa stretching from Senegal in the west to Ethiopia in the east. Groups X, Y and W can also cause epidemic infection, while groups B and C (the predominant strains in Europe and North America) tend to be sporadic.

Humans are the only known reservoir for the organism, which is carried asymptomatically in the nasopharynx of 5–20% of the general population. Meningococcal disease occurs when the bacteria invade the nasal mucosa and enter the bloodstream; this happens only in a small percentage of those colonized. Invasion depends on both host and bacterial factors. It is more likely to take place soon after colonization has occurred, and following viral upper respiratory infections.

Clinical features
Invasive meningococcal infection may cause meningitis, the meningococcal sepsis syndrome or both. Meningitic disease (see p. 868) usually presents with the classical triad of headache, fever and neck stiffness. Vomiting, diminished consciousness and focal neurological signs sometimes occur, although many patients, especially in

### Box 20.48 Modified Jones criteria for the diagnosis of rheumatic fever

**Evidence of antecedent streptococcal infection**
- Positive throat culture for group A streptococcus
- Good clinical history (e.g. of scarlet fever)
- Elevated antistreptolysin O titre (or other serological assay for streptococci)

**Major criteria**
- Carditis
- Polyarthritis
- Chorea
- Erythema marginatum
- Subcutaneous nodules

**Minor criteria**
- Fever
- Arthralgia (unless arthritis counted as major criterion)
- Previous rheumatic fever
- Raised erythrocyte sedimentation rate/C-reactive protein
- Leucocytosis
- Prolonged PR interval on electrocardiogram (unless carditis counted as major criterion)
the early stages, have only mild symptoms. Meningococcal blood stream infection causes the typical features of septic shock, such as fever, myalgia and hypotension (see p. 218), and may be accompanied by a petechial or haemorrhagic rash (Fig. 20.21). In some cases the patient can deteriorate rapidly, with shock, DIC and multiorgan failure.

**Diagnosis**

The presence of meningitis and sepsis syndrome with a typical rash is strongly suggestive of meningococcal disease. The rash is not always present, however, and its absence does not rule out the diagnosis. Gram-negative diplococci may be seen on Gram stain of CSF or of aspirate from petechiae; meningococci can also be cultured from CSF or blood, or detected by PCR. PCR can also be used to identify the serogroup, which may be important for public health management.

**Management**

*N. meningitidis* is sensitive to benzylpenicillin (in most cases), third-generation cephalosporins, and chloramphenicol; cefotaxime or ceftriaxone is the recommended treatment in the UK (see Box 26.57). Meningococcal sepsis should be managed in the same way as any other form of bacterial sepsis (see p. 157). The mortality from meningococcal sepsis in developed countries is currently approximately 10%, while that from meningococcal meningitis alone is less than 5% (see later). Mild neurological sequelae (especially vestibular nerve damage) are common but serious brain damage is relatively unusual.

The meningococcal C conjugate vaccine has contributed to an overall reduction of invasive meningococcal disease in the UK: only 755 cases were reported in England and Wales in 2017, compared with 2784 in 1999 (when the group C meningococcal immunization programme began). Group B vaccines were licensed and approved for use in the UK in 2014, and were introduced into the routine childhood/young adult immunization programme in 2017. A combined A/C/W135/Y vaccine is available for control of outbreaks caused by these strains and for travellers to endemic areas: it gives relatively short-term protection. A cheap and effective conjugate meningococcal A vaccine, giving long-term immunity, has been distributed widely in the African meningitis belt, with more than 280 million people in 21 countries receiving the vaccine so far.

In an outbreak, close contacts of a case of meningococcal disease should be given prophylaxis with oral rifampicin or ciprofloxacin to eradicate the bacteria from the nasopharynx and reduce the risk of onward spread (this has little impact in epidemic areas). In some outbreak situations, contacts should be offered immunization.

**Cerebral abscess**

This is covered on page 873.

**Toxin-mediated infections**

**Botulism**

*Clostridium botulinum* is a common environmental organism that produces spores that can survive heating to 100°C. It can cause illness through a number of routes:

- contamination of canned or bottled foodstuffs, in which the anaerobic organism can multiply and elaborate a neurotoxin
- infection of wounds
- contamination of injectable drugs (especially heroin).

In botulism (food poisoning), the toxin is ingested and causes profound neuromuscular blockade, leading to autonomic and motor paralysis. The first symptoms, occurring 18–24 hours after ingestion, are nausea and diarrhoea. These are followed by cranial nerve palsies and then progressive symmetrical paralysis, leading to respiratory failure.

The diagnosis is usually clinical and is confirmed by detection of toxin in faeces or in contaminated food. Management is mainly supportive, with mechanical ventilation if necessary. Antitoxin is available in some countries (including the UK); the risk of anaphylaxis is relatively high and antitoxin should be used only in severe cases. A subcutaneous test dose should be given before intravenous or intramuscular injection. Antibiotics have no proven role. The overall mortality from botulism is high, but patients who survive the acute paralysis can make a full recovery.

A similar clinical picture can follow the contamination of wounds, or injection of street heroin contaminated with *C. botulinum*; in infants, botulism may be related to bowel colonization by the organism.

**Tetanus**

Tetanus is also due to a toxin-secreting clostridium: *C. tetani*. The organism is found in soil, and illness usually results from a contaminated wound. The injury itself may be trivial and disregarded by the individual. Tetanus can also complicate injecting drug use, if the drug (usually heroin) is contaminated with *C. tetani*. In developing countries, neonatal tetanus follows contamination of the umbilical stump, often after the area is dressed with dung. The overall incidence of tetanus across the world has fallen significantly in the past 20 years, due mainly to active immunization.

The organism is not invasive and clinical manifestations of the disease are due to the potent neurotoxin, tetanospasmin. Tetanospasmin causes disinhibition at synapses, neuromuscular blockade and skeletal muscle spasm, and acts on the sympathetic nervous system. The end result is marked flexor muscle spasm and autonomic dysfunction.

**Clinical features**

The incubation period varies from a few days to several weeks. The most common form of the disease is generalized tetanus. General malaise is rapidly followed by trismus (lockjaw) due to masseter muscle spasm. Spasm of the facial muscles produces the characteristic grinning expression known as *risus sardonicus*. If the disease is severe, painful reflex spasms develop, usually within 24–72 hours of the initial symptoms. The interval between the first
symptom and the first spasm is referred to as the ‘onset time’. The spasms may occur spontaneously but are easily precipitated by noise, handling of the patient or light. Respiration may be impaired because of laryngeal spasm; oesophageal and urethral spasm lead to dysphagia and urinary retention, respectively, and there is arching of the neck and back muscles (opisthotonus). Autonomic dysfunction produces tachycardia, a labile blood pressure, sweating and cardiac arrhythmias. Patients with tetanus are mentally alert.

Death results from aspiration, hypoxia, respiratory failure, cardiac arrest or exhaustion. Mild cases with rigidity usually recover. Poor prognostic indicators include a short incubation period, short onset time and extremes of age.

Localized tetanus is a milder form of the disease. Pain and stiffness are confined to the site of the wound, with increased tone in the surrounding muscles. Recovery is usual.

Cephalic tetanus is uncommon but invariably fatal. It usually occurs when the portal of entry of C. tetani is the middle ear. Cranial nerve abnormalities, particularly of the VIIth nerve, are usual. Generalized tetanus may or may not develop.

Neonatal tetanus is characterized by failure to thrive, poor sucking, grimacing and irritability, followed by the rapid development of intense rigidity and spasms. Mortality approaches 100%. One aim of the WHO’s EPI is to eliminate this condition by immunizing all women of child-bearing age, providing clean delivery facilities, and strengthening surveillance in high-risk areas.

Diagnosis
Few diseases resemble tetanus in its fully developed form and the diagnosis is therefore usually clinical. Rarely, C. tetani is isolated from wounds. Phenothiazine overdosage, strychnine poisoning, meningitis and tetany can occasionally mimic tetanus.

Management
If tetanus is suspected, any wound must be cleaned and debrided to remove the source of toxin. Human tetanus immunoglobulin 250 units should be given, along with an intramuscular injection of tetanus toxoid. If the patient is already protected, a single booster dose of the toxoid is given; otherwise, the full three-dose course of adsorbed vaccine is required (see later).

In established disease, management consists of supportive medical and nursing care. Improvement in this area has contributed, more than any other single measure, to the decrease in the mortality rate from 60% to nearer 20%. Patients are nursed in a quiet, isolated, well-ventilated, darkened room. Benzodiazepines are used to control spasms and sedate the patient; if the airway is compromised, intubation and mechanical ventilation may be necessary. Magnesium sulphate infusion may decrease the need for antispasmodics.

Antibiotics and antitoxin should be administered, even in the absence of an obvious wound. Intravenous metronidazole for 7–10 days is the drug of choice, although penicillin is also effective. Human tetanus immunoglobulin (HTIG) should be given as soon as possible, by either intravenous infusion or intramuscular injection, to neutralize any circulating toxin. If HTIG is not available, human normal immunoglobulin (HNIG) can be used. If the patient recovers, active immunization should be instituted, as immunity following tetanus is incomplete.

Prevention
An effective, safe and relatively cheap vaccine means that tetanus is an eminently preventable disease. After initial active immunization, boosters are recommended at 10-year intervals for all adults. Infant immunization schedules in all countries include tetanus. Protection by passive immunization with HTIG or HNIG is short-lived, lasting only about 2 weeks.

BACTERIAL INFECTIONS OF THE URINARY TRACT
See page 1381.

SYSTEMIC/MULTISYSTEM BACTERIAL INFECTIONS
Many infections are confined to a particular body organ or system, owing to the metabolic requirements of the organism, the route of infection or the response of host defences. Other infections can potentially affect several systems or the entire body. Under unusual circumstances, such as altered host immunity, infections that are normally circumscribed may become systemic. The general principles of systemic infections, bacteraemia and the sepsis syndrome are described in Chapter 8, as are the common causes of sepsis. This section describes some specific and less common bacterial infections that cause multisystem disease in an immunocompetent host.

Leptospirosis
Leptospirosis is a zoonosis caused by the spirochaete Leptospira interrogans. There are over 200 serotypes. The main types affecting humans are:

• L. i. icterohaemorrhagiae (normal host: rodents)
• L. i. canicola (dogs and pigs)
• L. i. hardjo (cattle)
• L. i. pomona (pigs and cattle).

Leptospires are excreted in the animals’ urine and enter the host through a skin abrasion or intact mucous membranes. Leptospirosis can also be caught by ingestion of contaminated water. The organism can survive for many days in warm freshwater and for up to 24 hours in seawater.

In England and Wales, between 50 and 100 cases of leptospirosis are reported every year, although many mild infections probably go undiagnosed. It is traditionally an occupational disease of farmers, vets and others who work with animals, but is increasingly associated with recreational activities that bring people into closer contact with rodents or contaminated water. Outbreaks of leptospirosis have also been associated with flooding.

Clinical features
In 1896, Weil described a severe illness consisting of jaundice, haemorrhage and renal impairment caused by L. i. icterohaemorrhagiae, but fortunately 90–95% of infections are subclinical
or cause only a mild fever. The incubation period of leptospirosis is usually 7–14 days and the illness typically has two phases. A leptospiraemic phase, which lasts for up to a week, is followed after a couple of days' interval by an immunological phase. The first phase is characterized by severe headache, malaise, fever, anorexia and myalgia. Most patients have conjunctival suffusion. Hepatosplenomegaly, lymphadenopathy and various skin rashes are sometimes seen. The second phase is usually mild. Meningism is common; if lumbar puncture is performed, there is often CSF lymphocytosis. The majority of patients recover uneventfully at this stage.

In severe disease, there may not be a clear distinction between phases. Following the initial symptoms, patients progressively develop hepatic and kidney injury, haemolytic anaemia and circulatory collapse. Cardiac failure and pulmonary haemorrhage may also occur. Even with full supportive care, the mortality is around 10%, rising to 15–20% in the elderly.

**Diagnosis**

The diagnosis is usually a clinical one. Leptospires can be cultured from blood or CSF during the first week of illness, but culture requires special media and may take several weeks. Leptospiral DNA can be detected by PCR in the blood and urine. A minority of patients may also excrete the organism in their urine from the second week onwards. Confirmation is usually serological. Specific IgM antibodies start to appear from the end of the first week and the diagnosis is often made retrospectively with a microscopic agglutination test (MAT) showing a fourfold rise. There is typically a leucocytosis and, in severe infection, thrombocytopenia and an elevated creatine phosphokinase.

**Management**

Early antibiotic therapy may limit progress of the disease, and penicillin or ceftriaxone should be given in severe cases. The efficacy of antibiotics in mild disease is debated; if they are used, oral doxycycline is the best choice. Intensive supportive care is needed for those patients who develop hepatorenal failure.

**Brucellosis**

Brucellosis (Malta fever, undulant fever) is caused by various species of *Brucella*, a Gram-negative intracellular coccobacillus. It is a zoonosis, especially of goats, sheep and cattle, and has a worldwide distribution (although the UK is officially ‘brucellosis-free’). A handful of imported human cases are diagnosed in England each year. The highest incidence is in the Mediterranean countries, the Middle East and the tropics; there are about 500 000 new cases diagnosed per year worldwide.

The organisms usually gain entry into the human body via the mouth; less frequently, they may enter via the respiratory tract, genital tract or abraded skin. The bacilli travel in the lymphatics and infect lymph nodes. This is followed by haematogenous spread with ultimate localization in the reticulo-endothelial system. Acquisition is usually by the ingestion of raw milk from infected cattle or goats, although occupational exposure is also common. Person-to-person transmission is rare.

**Clinical features**

The incubation period of acute brucellosis is 1–3 weeks. The onset is insidious, with malaise, headache, weakness, generalized myalgia and night sweats. The fever pattern is classically undulant, although continuous and intermittent patterns are also seen. Lymphadenopathy and hepatosplenomegaly are common; sarcoiditis, arthritis, osteomyelitis, epididymo-orchitis, meningoencephalitis and endocarditis have all been described.

Untreated brucellosis can give rise to chronic infection, lasting a year or more. This is characterized by easy fatigability, myalgia and occasional bouts of fever and depression. Splenomegaly is usually present. Occasionally, infection can lead to localized brucellosis, which may not be associated with systemic symptoms. Bones and joints, spleen, endocardium, lungs, urinary tract and nervous system may be involved.

**Diagnosis**

Blood (or bone marrow) cultures are positive during the acute phase of illness in 50% of patients (higher in *B. melitensis*) but prolonged culture is needed. In chronic disease, serological tests are of greater value. The *Brucella* agglutination test, which demonstrates a fourfold or greater rise in titre (>1 in 160) over a 4-week period, is highly suggestive of brucellosis. An elevated serum IgG level is evidence of current or recent infection; a negative test excludes chronic (non-localized) brucellosis. In localized brucellosis, antibody titres are low and the diagnosis is usually established by culturing the organisms from the involved site. Species-specific PCR tests are also available.

**Management and prevention**

Brucellosis should be treated with a combination of doxycycline, rifampicin and an aminoglycoside (usually gentamicin). Prevention and control involve careful attention to hygiene when handling infected animals, eradication of infection in animals through vaccination, and the pasteurization of milk. No vaccine is available for use in humans.

**Listeriosis**

*Listeria monocytogenes* is an environmental organism that is widely disseminated in soil and decayed matter. It affects both animals and humans; the most common route of human infection is in contaminated foodstuffs. The organism can grow at temperatures as low as 4°C and the most commonly implicated foods are unpasteurized soft cheeses, raw vegetables and chicken pâtés. Listeriosis is a rare but serious infection affecting mainly neonates, pregnant women, the elderly and the immunocompromised. *L. monocytogenes* has also been recognized as a cause of self-limiting, food-borne gastroenteritis in healthy adults, but the incidence of this is unknown.

In pregnant women, *Listeria* causes an influenza-like illness, but infection of the fetus can lead to septic abortion, premature labour and stillbirth. Early treatment of *Listeria* in pregnancy may prevent this but the overall fetal loss rate is about 50%. In the elderly and the immunocompromised, *Listeria* can cause bacteraemia, meningoencephalitis and a variety of focal infections.

The diagnosis is established by culture of blood, CSF or other body fluids. The treatment of choice for adult listeriosis is ampicillin plus gentamicin. Co-trimoxazole and meropenem are also effective but the organism is resistant to cephalosporins.

**Q fever**

Q fever is a zoonosis caused by *Coxiella burnetii*, a Gram-negative intracellular bacterium. Infection is widespread in domestic, farm and other animals, birds and arthropods; spread is mainly by ticks. Modes of transmission to humans are by dust, aerosol and unpasteurized milk from infected cows. The formation of spores means that *C. burnetii* can survive in extreme environmental conditions for long periods. The infective dose is very small, so that minimal animal contact is required. One reported outbreak occurred among inhabitants of a village through which infected sheep had passed.
A large outbreak in the Netherlands (with 4000 human cases) was linked to goat farming, with the main risk factor being residence within 5 km of an affected farm. Infection in the UK is rare and usually associated with farm and abattoir workers.

Clinical features
Symptoms begin insidiously 2–4 weeks after infection. Fever is accompanied by influenza-like symptoms with myalgia and headache. The acute illness usually resolves spontaneously but pneumonia or hepatitis may develop. In pregnant women, Q fever can cause severe fetal damage. Occasionally, infection can become chronic, with endocarditis, myocarditis, uveitis, osteomyelitis or other focal infections.

C. burnetii is an obligate intracellular organism and does not grow on standard culture media. Diagnosis is made serologically using an immunofluorescent assay. Antibody tests for two different bacterial antigens allow distinction between acute and chronic infection. A PCR assay is available but the sensitivity is low.

Management
Treatment with doxycycline or azithromycin shortens the duration of the acute illness and there is emerging evidence that it may reduce the incidence of chronic sequelae. For chronic Q fever, including endocarditis, doxycycline is often combined with rifampicin or hydroxychloroquine. Even prolonged courses of treatment may not clear the infection. A vaccine is available for those at high risk.

Lyme disease
Lyme disease is caused by spirochaetes of the genus Borrelia. B. burgdorferi is the sole cause of Lyme disease in the USA. In Europe, B. afzelii and B. garinii are also implicated. Lyme disease is a zoonosis of deer and other wild mammals. It has increased in both incidence and detection; it is now known to be widespread in the USA, Europe, Russia and the Far East. About 1000 autochthonous laboratory-confirmed infections are reported in England and Wales each year, but many other cases may be diagnosed clinically or are subclinical. Infection is transmitted from animal to human by ixodid ticks and is most likely to occur in rural wooded areas in spring and early summer. In places where other tick-borne infections such as ehrlichia are endemic, simultaneous co-infection may occur.

Clinical features
Early localized disease presents about a week after the tick bite with erythema migrans (a macular rash; Fig. 20.22), lymphadenopathy, and associated fever and headache. Most people recover spontaneously at this stage, with no further symptoms or signs. A small number may develop early disseminated disease, which occurs days to weeks after the appearance of erythema migrans. There can be a more widespread rash, and a small proportion of untreated cases may develop neurological complications such as meningitis, encephalitis, cranial or peripheral neuritis, or radiculopathies. Cardiac involvement is seen in the USA but is rare elsewhere. Myalgia and arthritis may also occur at this stage. Late Lyme disease, which is rare, can cause chronic arthritis, encephalomyelitis and other neurological disorders, and acrodermatitis chronica atrophicans. Much of the damage in late Lyme disease is likely to be immune-mediated, and although antibiotics should be given to eradicate any persistent infection, there is no evidence to support a role for prolonged antibiotic treatment.

Diagnosis
The clinical features and epidemiological considerations are usually strongly suggestive. The presence of a typical rash after potential risk exposure requires antibiotic treatment without further diagnostic tests (which may well be negative at this stage anyway). The diagnosis can be confirmed only rarely by isolation of the organisms from blood, skin lesions or CSF. IgM antibodies are detectable in the first month and IgG antibodies are invariably present late in the disease. Sensitive antibody detection tests are available but false-positive results occur and an initial positive test should always be followed by a confirmatory immunoblot assay. Even a genuine positive IgG result may be a marker of previous exposure rather than of ongoing infection.

Management
Amoxicillin or doxycycline given early in the course of the disease shortens the duration of the illness in approximately 50% of patients. Disseminated or late disease should be treated with 2–4 weeks of intravenous ceftriaxone. However, treatment is unsatisfactory and preventative measures are recommended. In tick-infested areas, repellents and protective clothing should be worn. Prompt removal of any tick is essential, as infection is unlikely to take place unless the tick has been attached for more than 48 hours. Ticks should be grasped with forceps near to the point of attachment to the skin and then withdrawn by gentle traction. Antibiotic prophylaxis following a tick bite is not usually justified, even in areas where Lyme disease is common. There is currently no effective vaccine.

Tularaemia
Tularaemia is due to infection with Francisella tularensis, a Gram-negative coccobacillus. It is primarily a zoonosis, usually acquired from rodents. Infection can be transmitted by arthropod vectors or by the handling of infected animals, when the microorganisms enter through minor abrasions or mucous membranes. Occasionally, infection occurs from contaminated water or from uncooked meat. The disease is widely distributed in North America, Northern Europe and Asia, but the particularly virulent type A subspecies is seen only in the USA. It is relatively rare, occurring mainly in hunters, trappers and others in close contact with animals; about 800 cases per year are recorded in Europe, mainly in Scandinavia.

The incubation period of 2–7 days is followed by a generalized illness. The most common presentation is ulceroglandular tularaemia. A papule occurs at the site of inoculation. This ulcerates and is followed by tender, suppurative lymphadenopathy. Rarely, this can be followed by bacteraemia, leading to septicemia, pneumonia or meningitis. These forms of the disease carry a high mortality if untreated.
Infectious disease

Routine cultures are often negative, and diagnosis has traditionally been made serologically. PCR is now becoming the standard diagnostic test.

Doxycycline can be used in mild disease but the most effective antibiotics are aminoglycosides and quinolones.

BACTERIAL INFECTIONS SEEN IN DEVELOPING AND TROPICAL COUNTRIES

Skin, soft tissue and eye disease

Leprosy (Hansen’s disease)

Leprosy is caused by the acid-fast bacillus *Mycobacterium leprae*. Unlike other mycobacteria, this does not grow in artificial media or even in tissue culture. Apart from the nine-banded armadillo, humans are the only natural host of *M. leprae*, although it can be grown in the footpads of mice.

The WHO has provided free drug treatment for leprosy since 1995. The campaign to control the disease has been hugely successful, with more than 16 million people having been cured of the disease since the year 2000. The number of people with active leprosy has fallen from 5.4 million in 1985 to about 175,000 at the end of 2015, largely as the result of supervised multidrug treatment regimens. The majority of the remaining cases are in India and Brazil; despite the successes, many new infections are occurring in these countries. The WHO has published a Global Leprosy Strategy, with the aim of eradicating the disease completely.

The precise mode of transmission of leprosy is still uncertain but it is likely that nasal secretions play a role. Infection is related to poverty and overcrowding. Once an individual has been infected, subsequent progression to clinical disease appears to be dependent on several factors. Males appear to be more susceptible than females and there is evidence from twin studies of a genetic susceptibility. The main factor, however, is the response of the host's cell-mediated immune system.

Two polar types of leprosy are recognized, with most patients falling on a spectrum between (Fig. 20.23):

- **Tuberculoid leprosy** is a localized disease that occurs in individuals with a high degree of cell-mediated immunity (CMI). The T-cell response to the antigen releases interferon, which activates macrophages to destroy the bacilli (Th1 response), but with associated destruction of the tissue.
- **Lepromatous leprosy** is a generalized disease that occurs in individuals with impaired CMI. Here the tissue macrophages fail to be activated and the bacilli multiply intracellularly. Th2 cytokines are produced.

In the 1960s the spectrum was divided into five clinico-pathological groups (Fig. 20.24). This remains the ‘gold standard’ classification, but for the purposes of treatment the WHO has defined two main patterns of disease:

- **Paucibacillary leprosy** has five or fewer skin lesions with no bacilli
- **Multibacillary leprosy** has six or more lesions that may have bacilli.

Skin smears are not always available in practice and the distinction must be made on clinical grounds alone. Concern has been raised that this may lead to undertreatment of some people incorrectly identified as having paucibacillary leprosy, but overall the WHO regimen has been remarkably successful.

Clinical features

The incubation period is typically from 2 to 6 years, although it may be as short as a few months or as long as 20 years. The onset of leprosy is generally insidious (although acute onset is known to occur). Patients may present with a transient rash, features of an acute febrile illness, evidence of nerve involvement, or with any combination of these.

Diagnosis

The diagnosis of leprosy is essentially clinical, with hypopigmented/reddish patches with loss of sensation, and thickening of peripheral nerves. Acid-fast bacilli (AFB) may be seen on skin-slit smears. Occasionally, nerve biopsies are helpful. Detection of *M. leprae* DNA is possible in all forms of leprosy using PCR and can be employed to assess the efficacy of treatment.

Management

Multidrug therapy (MDT) is essential because of developing drug resistance (up to 40% of bacilli in some areas are resistant to dapsone). Much shorter courses of treatment are now being used; the current WHO-recommended drug regimens for leprosy are shown in Box 20.49 but longer therapy is required in severe cases. Follow-up, including skin smears where possible, is obligatory. Immunological reactions (‘lepra reactions’) can occasionally occur after treatment is started, especially in borderline and lepromatous disease (Box 20.50).

Patients should be taught self-care of their anaesthetic hands and feet to prevent ulcers. Cheap canvas shoes with cushioned insoles are protective.

Leprosy should be treated in specialist centres with adequate physiotherapy and occupational therapy support. Surgery and physiotherapy also play a role in the management of trophic ulcers and deformities of the hands, feet and face.

Bacterial infections seen in developing and tropical countries

Prognosis in tuberculoid leprosy is good, even if untreated; lepromatous leprosy is progressive if untreated.

Prevention
The prevention and control of leprosy depend on rapid treatment of infected patients, particularly those with lepromatous and borderline lepromatous types, to decrease the bacterial reservoir.

Anthrax
Anthrax is caused by *Bacillus anthracis*. The spores of these Gram-positive bacilli are extremely hardy and withstand extremes of temperature and humidity. The organism is capable of toxin production and this property correlates most closely with its virulence. The disease occurs worldwide but is most common in Africa and Southern Asia. Surveillance data are limited but the likely global annual incidence is in the tens of thousands. In Europe and the USA there are only very occasional cases. Transmission is through direct contact with an infected animal; infection is most frequently seen in farmers, butchers, and dealers in wool and animal hides. Spores can also be ingested or inhaled. Cases in the USA have been caused by the deliberate release of anthrax spores as a bioterrorist weapon.

Clinical features
The incubation period is 1–10 days.

**Cutaneous anthrax** is the most common form. The small, erythematous, maculopapular lesion is initially painless. It may subsequently vesiculate and ulcerate, with formation of a central black eschar. The illness is self-limiting in the majority of patients, but occasionally perivascular oedema and regional lymphadenopathy may be marked and toxaemia can occur.

**Inhalational anthrax** (wool-sorter’s disease) follows inhalation of spores. A febrile illness is accompanied by a non-productive cough and retrosternal discomfort; pleural effusions are common. If the disease is untreated, mortality is about 90%; in the bioterrorism cases in the USA, it was 45%, despite treatment.

Gastrointestinal anthrax is due to consumption of undercooked, contaminated meat. It presents as severe gastroenteritis, sometimes with haematemesis and bloody diarrhoea. In some cases, systemic toxin spread may lead to shock and death.

Diagnosis
The diagnosis is established by demonstration of the organism in smears from cutaneous lesions or by culture of blood and other body fluids. Serological confirmation can be obtained using ELISAs that detect antibodies to both the organism and a toxin. PCR tests are available.

Management
Ciprofloxacin is considered the best treatment. In mild cutaneous infections, oral therapy for 2 weeks is adequate. In more severe infections, high doses of intravenous antibiotics are needed, along with appropriate supportive care. The monoclonal antibody raxibacumab has been shown in animal studies to improve survival in

inhalational anthrax. Any suspected case should be reported to the relevant authority.

Control
Any infected animal that dies should be burned and the area in which it was housed disinfected. Where animal husbandry is poor, mass vaccination of animals may prevent widespread contamination but needs to be repeated annually. A human vaccine is available for those at high risk and prophylactic ciprofloxacin is used following exposure. Some countries are establishing public health policies to deal with the deliberate release of anthrax spores.

Mycobacterial ulcer (buruli ulcer)
Buruli ulcer, caused by Mycobacterium ulcerans, is seen in humid rural areas of the tropics, especially in Africa. About 2000 cases per year are reported to the WHO but this does not reflect the true prevalence (which is much higher). The mode of transmission remains unknown. A small subcutaneous nodule at the site of infection gradually ulcerates, involving subcutaneous tissue, muscle and fascial planes, and occasionally bone. The ulcers are usually large with undermined edges and markedly necrotic bases due to mycolactone (a toxin produced by the mycobacterium). Smears taken from necrotic tissue generally reveal numerous acid-fast bacilli; a PCR assay is widely available. Combination therapy with rifampicin plus one of streptomycin, clarithromycin or moxifloxacin, given for 8 weeks, will heal ulcers in many cases. However, in more severe cases, surgical debridement and, where possible, skin grafting may be needed as well.

Tropical ulcer
Tropical ulcer is a non-specific infection, usually polymicrobial, seen in damp, hot climates. A wide variety of organisms have been implicated but there is no characteristic bacterium associated with the condition. Good wound hygiene is the mainstay of management, with antibiotic therapy used (either empirically or based on culture) as needed.

Endemic treponematoses
Yaws
Yaws (caused by Treponema pallidum subspecies pertenue) is the most widespread and common of the endemic treponemal diseases, although it has been eradicated from a number of areas. Most cases are now reported from West Africa and the South Pacific. After an incubation period of weeks or months, a primary inflammatory reaction occurs at the inoculation site, from which organisms can be isolated. Dissemination of the organism leads to multiple popular lesions containing treponemes; these skin lesions usually involve the palms and soles. There may also be bone involvement, particularly affecting the long bones and those of the hand.

Approximately 10% of those infected go on to develop late yaws. Bony gummatous lesions may progress to cause gross destruction and disfigurement, particularly of the skull and facial bones, interphalangeal joints and long bones. Planter hyperkeratosis is characteristic. As in syphilis, there may be a latent period between the early and late phases of the disease but visceral, neurological and cardiovascular problems do not occur.

In endemic areas the diagnosis is usually clinical. The causative organism can be identified from the exudative lesions under dark-ground microscopy. Serological tests for syphilis are positive and do not differentiate between the conditions. Rapid point-of-care, species-specific tests are used but do not distinguish between past and current infection. PCR diagnosis is not widely available but may become important in the yaws eradication campaign, as it is necessary to distinguish active from treated infection.

Single-dose oral azithromycin has now replaced intramuscular benzathine penicillin as the treatment of choice. This drug has now been placed on the WHO list of essential medicines, as part of the international strategy to eradicate yaws through mass treatment.

Bejel (endemic syphilis)
Bejel is seen in Africa, the Middle East and Central Asia. The causative organism (Treponema endemicum) enters through abrasions in the skin directly or by mouth-to-mouth contact. Bejel differs from venereal syphilis in that the primary lesion is small and often in the mouth; it is easily missed. The late stages resemble syphilis but cardiological and neurological manifestations are rare.

Pinta
Pinta (caused by Treponema carateum) is restricted mainly to Central and South America. There is no effective surveillance and the current prevalence is unknown. It is milder than the other treponematoses and confined to the skin. The primary lesion is a pruritic red papule, usually on the hand or foot. It may become scaly but never ulcerates, and is generally associated with regional lymphadenopathy. In the later stages, similar lesions can continue to occur for up to 1 year, associated with generalized lymphadenopathy. Eventually, the lesions heal, leaving hyperpigmented or depigmented patches.
The diagnosis of bejel and pinta is largely clinical. Treatment is still with benzathine penicillin usually, although it is likely that azithromycin will prove to be effective. Surveillance, diagnosis and treatment are much less well coordinated than for yaws.

**Trachoma**

Trachoma is caused by the intracellular bacterium *Chlamydia trachomatis* (which can also cause a number of sexually transmitted infections, see p. 1416). It is the most common infectious cause of blindness in the world. It is estimated that there are 21 million active infections and 2 million people who have been blinded by trachoma. It is a disease of poverty, found mainly in the tropics and the Middle East, and is entirely preventable. Trachoma commonly occurs in children and is spread by direct transmission or by flies. Isolated infection is probably self-limiting and it is repeated infection that leads to chronic eye disease.

**Clinical features**

Infection is bilateral and begins in the conjunctiva, with marked follicular inflammation and subsequent scarring. Damage to the upper eyelid causes entropion, leaving the cornea exposed to further abrasion from the eyelashes rubbing against it (trichiasis). The corneal scarring that eventually occurs leads to blindness.

Trachoma may also occur as an acute ophthalmic infection in the neonate.

**Diagnosis and management**

The diagnosis is generally made clinically.

Systemic therapy with a single dose of azithromycin is the treatment of choice, but re-infection is common and repeated treatments are often needed. In some endemic areas, routine mass drug administration is used in children. Once infection has been controlled, surgery may be required for eyelid reconstruction and for treatment of corneal opacities.

**Prevention**

Community health education, improvements in water supply and sanitation (pit latrines), and earlier case reporting could have a substantial impact on disease prevalence. This is reflected in the ‘SAFE’ approach to trachoma:

- surgery
- antibiotics
- facial cleanliness
- environmental improvement.

The WHO Global Partnership for Trachoma Eradication is working with numerous countries throughout the world: Iran, Nepal and Ghana are the latest previously endemic countries to be declared trachoma-free.

**Further reading**

**Gastrointestinal infections**

**Cholera**

Cholera is caused by the curved, flagellated, Gram-negative bacillus *Vibrio cholerae*. The organism is killed by temperatures of 100°C in a few seconds but can survive in ice for up to 6 weeks.

The fertile, humid plains of the River Ganges in West Bengal have traditionally been regarded as the home of cholera. However, a series of pandemics have spread the disease across the world, usually following trade routes. The seventh pandemic currently affects large areas of Asia, sub-Saharan Africa and the Americas. Until recently, all outbreaks of cholera were caused by *V. cholerae* O1, which is responsible for the current pandemic. In the 1990s a new serogroup (O139 Bengal) caused outbreaks of an illness indistinguishable from O1 cholera, but it has not been reported outside Bangladesh, India and South-east Asia. Outbreaks of cholera are common when there is disruption of water supplies and sanitation: for example, that due to natural disasters or to conflict. More than a million cases of cholera have been reported in Yemen during the last 2 years of the civil war in that country.

Transmission is by the faeco-oral route. Contaminated water plays a major role in the dissemination of cholera, although contaminated foodstuffs and contact carriers may contribute in epidemics. Achlorhydria or hypochlorhydria facilitates passage of the cholera bacilli into the small intestine. Here they proliferate, elaborating an exotoxin that produces massive secretion of isotonic fluid into the intestinal lumen. Cholera toxin also releases serotonin (5-hydroxytryptamine, 5-HT) from enterochromaffin cells in the gut, which activates a neural secretory reflex in the enteric nervous system. This may account for at least 50% of cholera toxin’s secretory activity. *V. cholerae* also produces other toxins (zona occludens toxin (ZOT) and accessory cholera toxin (ACT)), which contribute to its pathogenic effect.

**Clinical features**

The incubation period varies from a few hours to 6 days. The majority of patients with cholera have a mild illness that cannot be distinguished clinically from diarrhoea due to other infective causes. In severe cases, there is abrupt onset of profuse painless diarrhoea, followed by vomiting. As the illness progresses, the typical ‘rice water’ stool, flecked with mucus, may be seen. There is massive fluid loss, and if this is not replaced, the features of hypovolaemic shock (cold clammy skin, tachycardia, hypotension and peripheral cyanosis) and dehydration (sunken eyes, hollow cheeks and a diminished urine output) can develop within hours. Muscle cramps may be severe. Children may present with convulsions owing to hypoglycaemia.

As long as the patient can be adequately rehydrated the prognosis is good, with a gradual return to normal clinical and biochemical parameters in 1–3 days.

**Diagnosis**

This is largely clinical. Examination of freshly passed stools may demonstrate rapidly motile organisms (although this is not diagnostic, as *Campylobacter jejuni* may give a similar appearance). A rapid dipstick test is also available. Stool and rectal swabs should be taken for culture to confirm the diagnosis and establish antibiotic sensitivity. Cholera should always be reported to the appropriate public health authority.

**Management**

The mainstay of treatment is rehydration, and with appropriate and effective rehydration therapy, mortality has decreased to less than 1%. Oral rehydration is usually adequate, but intravenous therapy is sometimes required (Fig. 20.25). Antibiotics may shorten the duration and severity of diarrhoea but should be given only to patients with severe dehydration.

**Oral rehydration solutions (ORS)** are based on the observation that glucose (and other carbohydrates) enhance sodium and water absorption in the small intestine, even in the presence of secretory...
Enteric fever, caused by *Salmonella typhi*. A similar but generally less severe illness known as *paratyphoid* is due to infection with *S. paratyphi* A, B or C. Humans are the only natural host for *S. typhi*, which is transmitted in contaminated food or water. The incubation period is 10–14 days.

**Clinical features**

After ingestion, the bacteria invade the small bowel wall via Peyer’s patches, from where they spread to the regional lymph nodes and then to the blood. The onset of illness is insidious and non-specific, with intermittent fever, headache and abdominal pain. Physical findings in the early stages include abdominal tenderness, hepatosplenomegaly, lymphadenopathy and a scaly maculopapular rash (‘rose spots’). Without treatment (and occasionally even after treatment), serious complications can arise, usually in the third week of illness. These include meningitis, lobar pneumonia, osteomyelitis, intestinal perforation and intestinal haemorrhage. The fourth week is characterized by gradual improvement but in areas with limited healthcare up to 30% of those infected will die and 10% of untreated survivors will relapse. This compares with a mortality rate of 1–2% in the USA.

After clinical recovery, up to 10% of patients will continue to excrete *S. typhi* for several months: these are termed *convalescent carriers*. Between 1% and 4% will continue to carry the organism for more than a year: this is *chronic carriage*. The usual site of carriage is the gall bladder, and chronic carriage is associated with the presence of gallstones. However, in parts of the Middle East and Africa where urinary schistosomiasis is prevalent, chronic carriage of *S. typhi* in the urinary bladder is also common.

*Paratyphoid fever* is associated with a milder and shorter illness, and complications are uncommon.

**Diagnosis**

The definitive diagnosis of enteric fever requires the culture of *S. typhi* or *S. paratyphi* from the patient. Blood culture is positive in most cases in the first 2 weeks. Culture of intestinal secretions, faeces and urine is also used, although care must be taken to distinguish acute infection from chronic carriage. Bone marrow culture is more sensitive than blood culture but is rarely required, except in patients who have already received antibiotics. Leucopenia is common but non-specific. Serological investigations, such as the Widal antigen test, are of little practical value, are easily misinterpreted and should not be used.

**Management**

Increasing antibiotic resistance is seen in isolates of *S. typhi*, especially in the Indian subcontinent. Chloramphenicol, cotrimoxazole and amoxicillin may still be effective in some cases, but resistance to all of these drugs (known as multidrug-resistant (MDR) *typhi*) is spreading rapidly. For example, the proportion of *S. typhi* isolates with MDR *typhi* in Malawi rose from 7% in 2010 to 97% in 2014. In most areas the treatment of choice is now a quinolone (e.g. ciprofloxacin 500 mg twice daily), but resistance is starting to appear to these agents as well, and ideally treatment should be based on known local resistance patterns. In a few countries (notably Pakistan), so-called extensively drug-resistant (XDR) *typhi* is becoming common; this is resistant to quinolones and to third-generation cephalosporins, and only azithromycin and carbapenems are still effective.

The patient’s temperature may remain elevated for several days after antibiotics are started and this alone is not a sign of treatment failure. Prolonged antibiotic therapy may eliminate the carrier...
state, but in the presence of gall bladder disease it is rarely effective. Cholecystectomy is not usually justified on clinical or public health grounds.

**Prevention**
This is mainly through improved sanitation and clean water. Travelers should avoid drinking untreated water, taking ice in drinks or eating ice creams. Vaccination with either injectable inactivated or oral live attenuated vaccines gives partial protection and should be used for travellers to high-risk areas. A new conjugate vaccine that provides more effective and longer-lasting immunity has recently become available; with funding from the Global Alliance for Vaccines and Immunization (GAVI), this new vaccine is to be rolled out to children in endemic countries from 2019.

**Further reading**

### Systemic infections

#### Tuberculosis
See page 967.

#### Non-tuberculous mycobacterial infections
Environmental mycobacteria can cause a wide variety of infections in susceptible hosts (Box 20.51). These are discussed in more detail on page 972.

#### Plague
Plague is caused by *Yersinia pestis*, a Gram-negative bacillus. Sporadic cases of plague (as well as occasional epidemics) occur worldwide but it is relatively uncommon: about 1000 cases per year are reported to the WHO, with a 10% mortality. The majority are in Madagascar and Central Africa, although the disease is occasionally seen in developed countries (usually associated with hunting). The main reservoirs are woodland rodents, which transmit infection to domestic rats (*Rattus rattus*). The usual vector is the rat flea, *Xenopsylla cheopis*. These fleas bite humans when there is a sudden decline in the rat population. Occasionally, spread of the organisms may be through infected faeces being rubbed into skin wounds, or through inhalation of droplets.

#### Clinical features
Four clinical forms are recognized: bubonic, pneumonic, septicaemic and cutaneous.
- **Bubonic plague** is the most common form, accounting for about 90% of cases. The incubation period is 2–7 days. The onset of illness is acute, with high fever, chills, headache, myalgia, nausea, vomiting and, when severe, prostration. This is rapidly followed by the development of lymphadenopathy (buboes), most commonly involving the inguinal region. Characteristically, these are matted and tender, and suppurate in 1–2 weeks.
- **Pneumonic plague** is characterized by the abrupt onset of features of a fulminant pneumonia with bloody sputum, marked respiratory distress, cyanosis, and death in almost all affected patients.
- **Septicaemic plague** presents as an acute fulminant infection with evidence of shock and DIC. If it is left untreated, death usually occurs in 2–5 days.
- **Cutaneous plague** can present as a pustule, eschar or papule, or as extensive purpura, which can become necrotic and gangrenous.

#### Diagnosis
This is based on clinical, epidemiological and laboratory findings. Microscopy (on blood or lymph node aspirate) or a rapid dipstick antigen detection test can provide a presumptive diagnosis in an appropriate clinical setting. Confirmation is by blood or lymph node culture, or paired serological tests.

#### Management
Treatment is urgent and should be instituted before the results of culture studies are available. *Y. pestis* remains sensitive to most antibiotics for Gram-negative bacteria. Gentamicin is the most widely used agent: doxycycline, ciprofloxacin and chloramphenicol are also effective.

#### Prevention
Prevention of plague is largely dependent on control of the flea population. Outhouses or huts should be sprayed with insecticides that are effective against the local flea. During epidemics, rodents should not be killed until the fleas are under control, as the fleas will leave dead rodents to bite humans. Tetracycline is an effective chemoprophylactic agent for those at risk during an outbreak. Both killed and attenuated vaccines have been available for many years but have limited efficacy and are not widely used.

#### Relapsing fevers
These conditions are so named because, after apparent recovery from the initial infection, recurrences may occur after a week or more without fever. They are caused by spirochaetes of the genus *Borrelia*.

#### Louse-borne relapsing fever
This condition (caused by *B. recurrentis*) is spread by body lice and only humans are affected. Classically, it is an epidemic disease of armies and refugees, although it is also endemic in the highlands of Ethiopia and Yemen, and in the Andes. Lice are spread from person to person when humans live in close contact in impoverished conditions. The spirochaete penetrates through the skin or mucosa when infected lice are crushed by scratching or by biting (a traditional
means of killing the insect, hence the adage ‘man bites louse is more
dangerous than louse bites man’). Symptoms begin 3–10 days after
infection and consist of abrupt high fever, generalized myalgia and
headache. A petechial or ecchymotic rash may be seen. In severe
cases the condition then deteriorates, with delirium, hepatosplenome-
galy, jaundice, bleeding and circulatory collapse. A proportion of
those who recover have no further symptoms but the majority
experience one or more relapses of diminishing intensity over the
weeks following the initial illness. Severity varies enormously, with
many people experiencing only mild symptoms, and some develop-
ing antibodies with no history of clinical illness. In some epidemics,
however, mortality in untreated people has exceeded 50%.

**Tick-borne relapsing fever**

This is caused by *B. duttoni* and other *Borrelia* species, spread by
soft (argasid) ticks of the genus *Ornithodoros*. Rodents are the main
reservoir of infection and humans are incidental hosts, acquiring the
spirochaete from the saliva of the infected tick. The disease is found
worldwide and is endemic in parts of North America and Europe,
but the clinical burden falls mainly in Africa. It is particularly com-
mon where traditional mud huts are the principal form of human
shelter, as the ticks live in the walls and feed on inhabitants at night.
The illness is generally similar to the louse-borne disease, with the
same variability in presentation and severity.

**Diagnosis and management**

Spirochaetes can be demonstrated microscopically in the blood
during febrile episodes; organisms are more numerous in louse-
borne relapsing fever. Treatment is usually with tetracycline or doxy-
cycline. A severe Jarisch–Herxheimer reaction (see p. 1424) occurs
in many patients, especially those who have the louse-borne form.

**Prevention**

Control of infection relies on elimination of the vector. Ticks live
for years and remain infected, passing the infection to their prog-
eny. These reservoirs of infection should be controlled by spraying
houses with insecticides and reducing the number of rodents. Post-
exposure prophylaxis has been shown to be effective in areas where
tick-borne disease is highly endemic. Infested patients should be
deloused by washing with a suitable insecticide. All clothes must be
thoroughly disinfected.

**Rickettsiae and rickettsia-like infections**

Rickettsiae (and the closely related orientiae) are small, intracellular
bacteria that are spread to humans by arthropod vectors, including
body lice, fleas, hard ticks and larval mites. Rickettsiae inhabit the
alimentary tract of these arthropods and infection is spread to the
human host by inoculation of their faeces through broken human
skin, generally produced by scratching. Rickettsiae multiply intra-
cellularly and can enter most mammalian cells, although the main
lesion produced is a vasculitis caused by invasion of endothelial
cells of small blood vessels. Multisystem involvement is usual.

Typhus is the collective name given to a group of diseases
caused by *Rickettsia* species. Box 20.52 provides a list of some of
the more important rickettsial diseases; with the advent of molecu-
lar techniques, many new species of *Rickettsia* causing human dis-
ease have been identified and more than 30 pathogenic species
are now recognized. Various ways of classifying rickettsial disease
have been proposed, based on genetic typing, clinical presentation
and geography. None of these is ideal, as species that are geneti-
cally very similar can occur in different parts of the world and there
is considerable overlap between the various rickettsial syndromes.

A useful clinical approach is to divide rickettsial infections into
three groups: typhus, spotted fever and scrub typhus (although the
organisms causing the last of these are now strictly classified as
orientiae and not rickettsiae).

**Typhus group**

**Epidemic typhus**

The vector of epidemic typhus is the human body louse and, as
with louse-borne relapsing fever, epidemics are associated with war
and refugees.

The incubation period of 1–3 weeks is followed by an abrupt
febrile illness associated with profound malaise and generalized
myalgia. Headache is severe and there may be conjunctivitis with
orbital pain. A measles-like eruption appears around the fifth day. At
the end of the first week, signs of meningoencephalitis appear and
CNS involvement may progress to coma. At the height of the illness,
splenomegaly, pneumonia, myocarditis and gangrene at the peripher-
ies may be evident. Oliguric acute kidney injury occurs in fulminating
disease, which is usually fatal. Recovery begins in the third week but
is generally slow. If untreated, the disease may recur many years after
the initial attack, owing to rickettsiae that lie dormant in lymph nodes.
The recrudescence, which is now rarely seen due to appropriate use
of antibiotics in the primary phase, is known as Brill–Zinsser disease.

**Endemic (murine) typhus**

This is an infection of rodents that is inadvertently spread to humans
by rat fleas. The disease closely resembles epidemic typhus but is
much milder and rarely fatal.

**Spotted fever group**

A variety of *Rickettsia* species, collectively known as the spot-
ted fever group rickettsiae, cause the illnesses known as spotted
fevers. In most cases the vector is a hard tick. Although the caus-
ative organism and the name of the illness vary from place to place,
the clinical course is common to all.
The typical feature of the spotted fevers is a widespread petechial rash (Fig. 20.26), although a variety of other types of skin lesion are seen, especially in Rocky Mountain spotted fever. An exception is the form of African tick typhus caused by *R. africae*, which often presents without a rash.

After an incubation period of 4–10 days, an eschar (a black, crusted, necrotic papule) may develop at the site of the bite in association with regional lymphadenopathy (Fig. 20.27). There is abrupt onset of fever, myalgia and headache, accompanied by a maculopapular rash that may become petechial. Neurological, haematological and cardiovascular complications can occur, as in epidemic typhus, although these are uncommon.

**Scrub typhus**

Found throughout Asia and the Western Pacific (and also reported occasionally from Africa), this disease is spread by larval trombiculid mites (chiggers). An eschar can often be found at the site of the bite. The clinical illness is very variable, ranging from a mild illness to fulminating and potentially fatal disease. The more severe cases resemble epidemic typhus. Unlike in other types of typhus, the organism is passed on to subsequent generations of mites, which consequently act as both reservoir and vector.

**Diagnosis**

The diagnosis of all types of rickettsial infection is generally made on the basis of the history and clinical course. It can be confirmed serologically or by PCR.

**Management and prevention**

Doxycycline or tetracycline given for 5–7 days is the treatment of choice. Ciprofloxacin is also effective. Prophylactic doxycycline 200 mg weekly protects against scrub typhus; it is reserved for highly endemic areas. Rifampicin is also used when resistance to tetracycline is present. Seriously ill patients need intensive care. Control of typhus is achieved by eradication of the arthropod vectors: lice and fleas can be eradicated from clothing with insecticides (0.5% malathion or DDT). Control of rodents is necessary in endemic typhus and some of the spotted fevers. Areas of vegetation infested with trombiculid mites can be cleared by chemical spraying from the air. Bites from ticks and mites should be avoided by wearing protective clothing on exposed areas of the body. The likelihood of infection from ticks is related to the duration of feeding; in high-risk areas the body should be inspected twice a day, as the bites are painless, and any ticks should be removed.

**Bartonellosis**

*Bartonella* spp. are intracellular bacteria closely related to the rickettsiae. A number of human diseases can be caused by these organisms; as in rickettsial disease, infection is usually spread from animals via an arthropod vector (Box 20.53).

**Carrion’s disease** (*Bartonella bacilliformis*)

This disease is largely restricted to the habitat of its main vector, the sandfly, in the river valleys of the Andes mountains at an altitude of 500–3000 m. Two clinical presentations are seen, which may occur alone or consecutively. *Oroya fever* is an acute febrile illness causing myalgia, arthralgia, severe headache and confusion, followed by a haemolytic anaemia. *Verruga peruana* consists of eruptions of reddish-purple haemangiomatous nodules, resembling bacillary angiomatosis. It may follow 4–6 weeks after *Oroya fever* or be the presenting feature of infection. Spontaneous resolution may occur over a period of months or years. Carrion’s disease is frequently complicated by superinfection, especially with *Salmonella* spp.

**Box 20.53 Human infections caused by *Bartonella* spp. and *Ehrlichia* spp.**

a Also known as human granulocytic anaplasmosis. b Formerly known as *Ehrlichia phagocytophilum*.
The diagnosis is made by culturing bacilli from blood or peripheral lesions. Serological tests have been developed but are not widely available.

Treatment with chloramphenicol or tetracycline is effective in acute disease but less so in verruga peruana. Carrion’s disease is a paradigm for eradicable but neglected diseases of poverty. It is readily treatable, geographically constrained and has no known hosts other than humans. However, because of the areas in which it is found, there is almost no surveillance or organized treatment programme.

Cat-scratch disease and bacillary angiomatosis
(Bartonella henselae)

These are described on page 537.

Trench fever

Trench fever is caused by Bartonella quintana and transmitted by human body lice. It is mainly seen in refugees and the homeless. It is characterized by cyclical fever, chills and headaches, accompanied by myalgia and pretilial pain. The disease is usually self-limiting but it can be treated with erythromycin or doxycycline if symptoms are severe.

Ehrlichiosis

Ehrlichiosis and anaplasmosis are infections caused by tick-borne, rickettsia-like bacteria. At least three species have been implicated: Ehrlichia chaffeensis, which causes human monocytic ehrlichiosis (HME), and E. ewingii and Anaplasma phagocytophilum (formerly known as E. phagocytophilum), which cause human granulocytic ehrlichiosis (HGE), also known as human granulocytic anaplasmosis. All cause a rather non-specific febrile illness with fever, myalgia and headache. Treatment is with doxycycline. The vectors are hard ticks and the main reservoir hosts are deer. As with most tick-borne zoonoses, the avoidance of tick bites and the prompt removal of feeding ticks are the best forms of prevention.

Actinomycosis

Actinomyces spp. are branching, Gram-positive higher bacteria, which are normal mouth and intestine commensals; they are particularly associated with poor mouth hygiene. Actinomyces have a worldwide distribution but are a rare cause of disease in the West.

Cervicofacial actinomycosis, the most common form, usually occurs following dental infection or extraction. It is often indolent and slowly progressive, is associated with little pain, and results in induration and localized swelling of the lower part of the mandible. Sinuses and tracts develop, with discharge of ‘sulphur’ granules. Thoracic actinomycosis follows inhalation of organisms, usually into a previously damaged lung. The clinical picture is not distinctive and is often mistaken for malignancy or tuberculosis. Symptoms such as fever, malaise, chest pain and haemoptysis are present. Empyema occurs in 25% of patients and local extension produces chest-wall sinuses with discharge of ‘sulphur’ granules.

Abdominal and pelvic actinomycosis most frequently affects the caecum. Characteristically, an indurated mass is felt in the right iliac fossa. Later, sinuses develop. The differential diagnosis includes malignancy, tuberculosis, Crohn’s disease and amoeboma. The incidence of pelvic actinomycosis appears to be increasing with wider use of intrauterine contraceptive devices. Occasionally, actinomycosis becomes disseminated to involve any site.

Diagnosis is by microscopy and culture of the organism. Treatment often involves surgery, as well as antibiotics. Penicillin is the drug of choice and should usually be given for 4–6 weeks, followed by oral amoxicillin for at least 3–4 months after clinical resolution (longer courses may be required if source control is not feasible). Tetracyclines are also effective.

Nocardia infections

Nocardia spp. are Gram-positive branching bacteria, found in soil and decomposing organic matter. N. asteroides and, less often, N. brasiliensis are the main human pathogens.

Mycetoma is the most common illness. It is a result of local invasion by Nocardia spp. and presents as a painless swelling, usually on the sole of the foot (Madura foot). The swelling of the affected part of the body continues inexorably. Nodules gradually appear, which eventually rupture and discharge characteristic ‘grains’, which are colonies of organisms. Systemic symptoms and regional lymphadenopathy are rare. Sinuses may occur several years after the onset of the first symptom. A similar syndrome may be produced by other branching bacteria and also by species of eumycete fungi, such as Madurella mycetomi (see p. 561).

Pulmonary disease, which follows inhalation of the organism, presents with cough, fever and haemoptysis; it is usually seen in the immunocompromised. Pleural involvement and empyema occur. In severely immunosuppressed patients, initial pulmonary infection may be followed by disseminated disease.

The diagnosis is often delayed, partly because of inadequate specimens and partly because Nocardia requires prolonged culture on standard media. Severe pulmonary or disseminated infection may require parenteral treatment. Co-trimoxazole, linezolid, ceftriaxone and amikacin have all been used successfully, but in vitro sensitivities are variable and there is no consensus on the best treatment.

Other bacterial infections

Meliodosis

This term refers to infections caused by the Gram-negative bacterium Burkholderia pseudomallei. This environmental organism, which is found in soil and surface water, is distributed widely in the tropics and subtropics. The majority of clinical cases of melioidosis occur in South-east Asia. Infection follows inhalation or direct inoculation. More than half of all patients with melioidosis have pre-disposing underlying disease; it is particularly common in people with diabetes.

B. pseudomallei causes a wide spectrum of disease and the majority of infections are probably subclinical. Illness may be acute or chronic, and localized or disseminated, but one form may progress to another and individual patients may be difficult to categorize. The most serious form is septicaemic melioidosis, which is often complicated by multiple metastatic abscesses; it is frequently fatal. Serological tests are available but definitive diagnosis depends on isolating the organism from blood or appropriate tissue. B. pseudomallei has extensive intrinsic antibiotic resistance. The most effective agent is ceftazidime, given intravenously for 2–4 weeks; this should be followed by several months of co-amoxiclav or cotrimoxazole to prevent relapses.
ANTIBiotic THERAPIES

Drugs used to combat bacterial infections are described on page 161.

FUNgAL INFECTIONS

Morphologically, fungi can be grouped into three major categories:

• yeasts and yeast-like fungi, which reproduce by budding
• moulds, which grow by branching and longitudinal extension of hyphae
• dimorphic fungi, which behave as yeasts in the host but as moulds in vitro.

Despite the fact that fungi are ubiquitous, systemic fungal infections are relatively rare (in contrast to superficial fungal infections of the skin, nails and orogenital mucosae). Systemic mycoses are usually seen in immunocompromised patients and in critical care settings, and are becoming more prevalent as this population increases.

Fungal infections are transmitted by inhalation of spores, contact with the skin or direct inoculation. This last can occur through penetrating injuries, injecting drug use or iatrogenic procedures. Fungi may also produce allergic pulmonary disease. Some fungi, such as Candida albicans, are human commensals. Fungal infections are usually divided into systemic, subcutaneous or superficial (Box 20.54). However, these divisions can be misleading, as many fungi that cause superficial infection in the healthy host can cause invasive or disseminated infection in immunocompromised patients, while ‘deep’ subcutaneous infections can invade other organs to cause systemic disease.

SYSTEMIC FUNgAL INFECTIONS

Candidiasis

Candidiasis is the most common fungal infection in humans and is predominantly caused by Candida albicans, although other species of Candida are increasingly seen. Candida are small asexual yeasts. They are found worldwide, and most species that cause serious invasive disease are also normal oropharyngeal and gastrointestinal commensals.

Clinical features

Most human candidiasis is superficial. Vaginal thrush and oral thrush are the most common forms, typically seen in the very young, the elderly, patients on antibiotic therapy and those who are immunosuppressed. Candidal oesophagitis presents with painful dysphagia. Cutaneous candidiasis typically occurs in intertriginous areas. It is also a cause of paronychia.

Invasive candidiasis is usually associated with intravascular devices (especially in intensive care units) and with profound immunosuppression (e.g. due to treatment of haematological malignancy). Dissemination can lead to meningitis, visceral and pulmonary abscesses, endophthalmitis and osteomyelitis.

Diagnosis and management

The fungi can be demonstrated in scrapings from infected lesions, tissue secretions or, in invasive disease, from blood cultures. Serological tests for beta D glucan, a fungal cell wall component, can be used to look for systemic fungal infection, but are common to many pathogenic fungi and the test does not distinguish different infections.

Treatment varies, depending on the site and severity of infection, and on the sensitivity of the organism. Superficial lesions may respond to topical nystatin or amphotericin B, although systemic agents may be needed for more extensive infection. For invasive infection, parenteral therapy with amphotericin B, fluconazole, voriconazole or echinocandins is necessary. Many non-albicans species are intrinsically resistant to many antifungals and even C. albicans can develop extensive resistance (especially to azoles).

Candida auris

Since 2010 there has been an increase in human colonization and infection with C. auris, a species first identified in Japan in 2009 and which has no known environmental niche. C. auris is particularly worrying as it is intrinsically resistant to many antifungals, and sometimes to all three major classes of drug. It is also spread readily from person to person (especially in healthcare settings), and can survive for extended periods on hard surfaces despite normal cleaning and disinfection processes. Laboratory diagnosis is difficult and it can easily be mistaken for other species. Healthcare-associated outbreaks have been reported from a number of countries across all continents.

Histoplasmosis

Histoplasmosis is caused by Histoplasma capsulatum. Spores can survive in moist soil for several years, particularly when the soil is...
enriched by bird and bat droppings. Histoplasmosis occurs world-
wide but is most commonly seen in the Ohio and Mississippi river
valleys, where over 80% of the population have been subclinically
exposed. An increasing number of cases are being reported from
parts of Asia (especially China). Transmission is mainly by inhalation
of the spores, particularly when clearing out attics, barns and bird
roosts, or exploring caves.

Clinical features
Primary pulmonary histoplasmosis is usually asymptomatic.
Calcification in the lungs, spleen and liver occurs in patients from
areas of high endemicity. When symptomatic, primary pulmonary
histoplasmosis generally presents as a mild influenza-like illness,
although symptoms can be more severe. Occasionally, there can
be complications such as secondary bacterial pneumonia, pleural
effusions, erythema nodosum and erythema multiforme.

Chronic pulmonary histoplasmosis is clinically similar to pul-
monary tuberculosis (see p. 967). It is usually seen in white Ameri-
can males over the age of 50 years. Disseminated histoplasmosis
resembles disseminated tuberculosis, with fever, lymphadenopathy,
hepatosplenomegaly, weight loss, leucopenia and thrombocytopenia.
Rarely, features of meningitis, hepatitis, hypoadrenalism, endo-
carditis and peritonitis may dominate the clinical picture.

Diagnosis
Definitive diagnosis is possible by culturing the fungi (e.g. from spu-
tum) or by demonstrating them on histological sections. H. cap-
sulatum glycoprotein can be detected in the urine and serum of
those with acute pulmonary and disseminated infection. Antibodies
usually develop within 3 weeks of the onset of illness and are best
detected by complement fixation or immunodiffusion (sensitivity of
95% and 90%, respectively). Although molecular detection tests are
available, they are not in widespread use.

Management
Only symptomatic acute pulmonary histoplasmosis, chronic histo-
plasmosis and acute disseminated histoplasmosis require therapy.
Itraconazole is effective in mild to moderate disease. Severe infection
is treated with intravenous amphotericin B for 1–2 weeks, followed
by itraconazole for a total of 12 weeks, or with voriconazole. Surgi-
cal excision of histoplasmonas (granulomatous pulmonary nodules
cased by H. capsulatum) or chronic cavitatory lung lesions, and
release of adhesions following mediastinitis may be required.

African histoplasmosis
This is caused by a specific subspecies: Histoplasma capsulatum
var. duboisii, the spores of which are larger than those of H. capsula-
tum. Skin lesions (e.g. abscesses and nodules), lymph node involve-
ment and lytic bone lesions are prominent. Pulmonary lesions do
not occur. Treatment is similar to that for H. capsulatum infection.

Aspergillosis
Aspergillosis is caused by one of several species of dimorphic fungi
of the genus Aspergillus. Of these, A. fumigatus is the most com-
mon, although A. flavus and A. niger are also recognized. These
fungi are ubiquitous in the environment and are commonly found on
decaying leaves and trees. Humans are infected by inhalation of the
spores. Disease manifestation depends on the dose of the spores
inhaled, as well as the immune response of the host. Three major
forms of the disease are recognized: bronchopulmonary allergic
aspergillosis, aspergilloma and invasive aspergillosis.

Diagnosis and treatment are described on page 993.

Cryptococcosis
Cryptococcosis is caused by the yeast-like fungus Cryptococcus
neofor mans. It has a worldwide distribution, with bird droppings
being an important mode of spread. The spores gain entry into
the body through the respiratory tract, where they elicit a granu-
Iomatous reaction. Pulmonary symptoms are, however, uncom-
mon. Meningitis, which usually occurs in those with HIV infection or
lymphoma, is a common mode of presentation and often develops
subacutely. Less commonly, lung cavitation, hilar lymphadeno-
pathy, pleural effusions and pulmonary fibrosis occur. Skin and
bone involvement are rare.

Diagnosis and management
Diagnosis is established by demonstrating the organisms in appro-
priately stained tissue sections. A positive latex cryptococcal agglu-
tinin test performed on the CSF is diagnostic of cryptococcosis.

Liposomal amphotericin B alone or in combination with flucy-
tosine for 2 weeks is followed by oral fluconazole. Therapy should
be continued for 8 weeks if meningitis is present. Fluconazole has
greater CSF penetration and is used when toxicity is encountered
with amphotericin B and flucytosine, and as maintenance therapy in
immunocompromised patients, especially those with HIV infection
(see p. 1443).

Coccidioidomycosis
Coccidioidomycosis is caused by the non-budding spherical form
(spherule) of Coccidioides immitis. This is a soil saprophyte and
is found in the southern USA, Central America and parts of South
America. Humans are infected by inhalation of the thick-walled,
barrel-shaped spores called arthrospores. Occasionally, epidemics of
coccidioidomycosis have been documented following dust storms.

Clinical features
The majority of patients are asymptomatic and the infection is
detected only by the conversion of a skin test using coccidioidin
(extract from a culture of mycelial growth of C. immitis) from nega-
tive to positive. Acute pulmonary coccidioidomycosis presents
after an incubation period of about 10 days with fever, malaise and
cough. Erythema nodosum, erythema multiforme, phlyctenular con-
junctivitis and, less commonly, pleural effusions may occur. Com-
plete recovery is usual.

Pulmonary cavitation with haemoptysis, pulmonary fibrosis,
meningitis, lytic bone lesions, hepatosplenomegaly, skin ulcers and
abscesses may occur in severe disease.

Diagnosis
The organism can be identified in respiratory secretions and cul-
tured in specialist laboratories. Serological tests are also widely
used for diagnosis. These include the highly specific latex aggluti-
nation and precipitin tests (IgM), which are positive within 2 weeks
of infection and decline thereafter. Other tests include complement
fixation, ELISA and radioimmunoassay.

A complement fixation test (IgG) performed on the CSF is diag-
nostic of coccidioidomycosis meningitis; it becomes positive within
4–6 weeks and remains so for many years.

Management
Mild pulmonary infections are self-limiting and require no treatment,
but progressive and disseminated disease mandates urgent therapy.
Itraconazole or fluconazole for 6 months is the treatment of choice for
primary pulmonary disease, with more prolonged courses for cavitat-
ing or fibronodular disease. Fluconazole in high dose (600–1000 mg
daily) is given for meningitis. Voriconazole or posaconazole is used for poor responders. Surgical excision of cavitory pulmonary lesions or localized bone lesions may be necessary.

Blastomycosis
Blastomycosis is a systemic infection caused by the biphasic fungus *Blastomyces dermatitidis*. Although previously believed to be confined to certain parts of North America, it has now been reported from South America, India and the Middle East.

Clinical features
Blastomycosis primarily involves the skin, causing non-itchy papular lesions that later develop into ulcers with red verrucous margins. The ulcers are initially confined to the exposed parts of the body but later involve the unexposed parts as well. Atrophy and scarring may occur. Pulmonary involvement presents as a solitary lesion resembling a malignancy or gives rise to radiological features similar to the primary complex of tuberculosis. Systemic symptoms, such as fever, malaise, cough and weight loss, are usually present. Bone lesions are common and present as painful swellings.

Diagnosis and management
The diagnosis is confirmed by demonstrating the organism in histological sections or by culture, although results can be negative in 30–50% of cases. Enzyme immunoassay may be helpful, although there is some cross-reactivity of antibodies to *Blastomyces* with *Histoplasma*.

Itraconazole is preferred for treating mild to moderate disease in the immunocompetent for periods of up to 6 months. In severe or unresponsive disease and in the immunocompromised, amphotericin B is usually used.

Paracoccidioidomycosis
Sometimes known as ‘South American blastomycosis’, paracoccidioidomycosis is caused by dimorphic fungi of the genus *Paracoccidioides*. It is confined to localized areas of Brazil and neighbouring countries. Like the other pathogenic dimorphic fungi it is usually acquired by inhalation. It can cause a wide variety of systemic and local manifestations, although skin lesions are particularly common. Itraconazole is generally the best treatment, although amphotericin B can be used in severe cases.

Mucormycosis
The terminology relating to mucormycosis and zygomycosis is confusing. *Invasive zygomycosis* (also known as *mucormycosis*) is rare and is caused by several fungi, including *Mucor* spp., *Rhizopus* spp. and *Absidia* spp. It usually occurs in immunocompromised or severely ill patients and has a high mortality. The hallmark of the disease is vascular invasion with marked haemorrhagic necrosis.

*Rhinocerebral mucormycosis* is a specific, locally invasive form of the condition. Nasal stuffiness, facial pain and oedema, and necrotic, black nasal turbinates are characteristic. It is rare and is mainly seen in people with diabetes.

Other forms of invasive zygomycosis include pulmonary and disseminated infection (in immunosuppressed patients) and gastrointestinal infection (in malnutrition).

*Subcutaneous zygomycosis* is described later.

Management of locally invasive and systemic disease is with amphotericin B and surgical debridement, but even with the best care mortality exceeds 50%. The newer triazoles, posaconazole and isavuconazole, have been shown to be effective in mucormycosis but their role in therapy remains unclear.

Further reading

SUBCUTANEOUS FUNGAL INFECTIONS

Sporotrichosis
Sporotrichosis is caused by the saprophytic fungus *Sporothrix schenckii*, which is found worldwide. It is common in soil and on plants, and infection classically follows cutaneous inoculation from thorns (‘rose handler’s disease). A reddish, non-tender, maculo-papular lesion develops at the site of inoculation; this is referred to as ‘plaque sporotrichosis’. Satellite lesions may develop over time. Pulmonary involvement and disseminated disease occur very rarely.

Treatment with itraconazole 100–200mg/day for 3–6 months is usually curative.

Subcutaneous zygomycosis
Subcutaneous zygomycosis can be a form of mucormycosis in immunocompromised patients, as described earlier. However, the term is also used to describe a largely tropical condition caused by filamentous fungi of the *Basidiobolus* genus, and typically associated with inoculation injuries and trauma. The disease usually remains confined to the subcutaneous tissues and muscle fascia. It presents as a brawny, woody infiltration involving the limbs, neck and trunk. Amphotericin B is the drug of choice, usually in combination with surgical debridement. Even the cutaneous/subcutaneous form of the infection carries a significant mortality.

Chromoblastomycosis
Chromoblastomycosis (chromomycoisis) is caused by fungi of various genera, including *Phialophora*, *Wangella* and *Fonsecaea*. These are found mainly in tropical and subtropical countries. Chromoblastomycosis presents initially as a small papule, usually at the site of a previous injury, which persists for several months before ulcerating. The lesion later becomes warty and encrusted, and gradually spreads. Satellite lesions may be present. Itching is common. The drug of choice is amphotericin B in combination with itraconazole or voriconazole. Cryosurgery is used to remove local lesions.

Mycetoma (Madura foot)
Mycetoma may be due to subcutaneous infection with fungi (*Eumycetes* spp.) or bacteria (see p. 558). It is largely confined to the tropics. Infection results in local swelling, which may discharge through sinuses. Bone involvement may follow.

Management consists of surgical debridement, combined with antimicrobials chosen according to the aetiological agent.

Pneumocystis jirovecii infection
Genetic analysis has shown *Pneumocystis jirovecii* to be homologous with fungi. *P. jirovecii* disease is almost invariably associated with immunodeficiency states, particularly AIDS (see p. 1443).
SUPERFICIAL FUNGAL INFECTIONS

Dermatophytosis
Dermatophyte infections are chronic fungal infections of keratinous structures, such as the skin, hair or nails. The main causative organisms are species of the genera Trichophyton, Microsporum and Epidermophyton.

Malassezia infection
Malassezia spp. are found on the scalp and greasy skin, and are responsible for seborrhoeic dermatitis, pityriasis versicolor (hypo- or hyperpigmented rash on the trunk) and Malassezia folliculitis (itchy rash on the back) (see p. 674).

Treatment of any superficial fungal infection is with topical antifungals, or oral triazole drugs if infection is refractory or more extensive.

ANTIFUNGAL DRUGS

Fungal infections range from trivial superficial skin and nail infections to life-threatening systemic conditions. The antifungal armoury is relatively limited, and because fungal cells share more enzymes and other pathways with human cells than do bacteria, targeting the pathogen without harming host metabolism is more difficult. There are three main groups of parenteral drugs for treating severe fungal infections: amphotericin, triazoles and echinocandins (Box 20.55). Although each has specific licence indications, antifungal drugs often have to be given empirically in severely ill patients. The best choice from among the available agents depends on a number of factors, including local resistance patterns and availability, potential for toxicity, and cost, and many countries have specific national guidelines.

Polenes
Polenes react with the sterols in fungal membranes, increasing permeability and thus damaging the organism. The most potent is amphotericin, which is used intravenously in severe systemic fungal infections. Nephrotoxicity is a major problem and dosage levels must take background renal function into account. Liposomal formulations of amphotericin are less toxic and are used in preference where cost is not prohibitive. Nystatin is not absorbed through mucous membranes and is therefore useful for the treatment of oral and enteric candidiasis and for vaginal infection. It can only be given orally or as pessaries.

Azoles

Imidazoles
Imidazoles are broad-spectrum antifungal drugs. They act by inhibiting fungal sterol synthesis, resulting in damage to the cell wall.

Ketoconazole is active orally but can produce liver damage, and is now rarely used systemically. It continues to be used topically, along with clotrimazole and miconazole, for the treatment of ringworm, and cutaneous and genital candidiasis. Econazole is used for the topical treatment of cutaneous and vaginal candidiasis and dermatophyte infections, while tioconazole is indicated for fungal nail infections.

Triazoles
These drugs also act by interfering with fungal sterol synthesis. Itraconazole was the first triazole to be used widely in clinical practice, but its relatively poor absorption and failure to penetrate CSF mean that it has largely been superseded (except for a few specific conditions such as histoplasmosis and blastomycosis). Fluconazole is well absorbed and has excellent CNS penetration; it is used for mucosal and invasive candidiasis and for the treatment of CNS infection with Cryptococcus neoformans. Some non-albicans Candida species are intrinsically resistant to fluconazole, and resistance can develop in C. albicans. Voriconazole has broad-spectrum activity that includes most Candida, Cryptococcus and Aspergillus species and other filamentous fungi. It is available for oral and intravenous use. Adverse effects include visual disturbance, abnormalities of liver enzymes and a variety of dermatological problems (including a possible link with squamous cell carcinoma). It also has significant drug–drug interactions with drugs metabolized by the CYP450 enzymes and, like all the triazoles, can cause QTc prolongation. It is indicated for invasive aspergillosis and severe Candida infections unresponsive to amphotericin and fluconazole, respectively, and also for empirical treatment of suspected or confirmed severe fungal infection. Posaconazole has a similar range of activity and is also associated with hepatotoxicity and CYP450 interactions. Isavuconazole is the newest triazole: it is licensed for use in invasive mould disease and mucormycosis but (largely due to cost) is generally a second- or third-line agent.

Echinocandins
These act by inhibiting the cell-wall polysaccharide glucan. Caspofungin, which is administered intravenously, is active against Candida spp. and Aspergillus spp., and is indicated for invasive candidiasis and invasive aspergillosis unresponsive to other drugs, as well as for empirical therapy in seriously ill patients. Other echinocandins include micafungin and anidulafungin, approved for the treatment of disseminated candidiasis. Severe hepatotoxicity has been reported with micafungin and liver biochemistry must be monitored.

Flucytosine
The fluorinated pyidine derivative flucytosine is used in combination with amphotericin B for cryptococcal meningitis. Side-effects

Box 20.55 Antifungal agents

- Polenes
  - Amphotericin, nystatin
- Echinocandins
  - Caspofungin
  - Anidulafungin
  - Micafungin
- Azoles
  - Miconazole, ketoconazole, fluconazole,itraconazole, voriconazole, posaconazole, isavuconazole

- Topical clotrimazole, sulconazole, tolnaftate, econazole, tioconazole
- Allylamines
  - Terbinafine
- Other antifungals
  - Amorolfine (topical only)
  - 5-Flucytosine
  - Griseofulvin
are uncommon, although it may cause bone marrow suppression. It is active when given orally or parenterally, but there is very limited availability in resource-poor settings.

### Allylamines

*Terbinafine* has broad-spectrum antifungal and also anti-inflammatory activity. It is well absorbed orally and accumulates in keratin. It is useful for the treatment of superficial mycoses, such as dermatophyte infections, onychomycosis and cutaneous candidiasis. A topical formulation is also available to treat fungal skin infections.

### PROTOZOAL INFECTIONS

Protozoa are unicellular eukaryotic organisms. They are more complex than bacteria and belong to the animal kingdom. Although many protozoa are free-living in the environment, some have become parasites of vertebrates, including humans, often developing complex life cycles involving more than one host species. In order to be transmitted to a new host, some protozoa transform into hardy cyst forms, which can survive harsh external conditions. Others are transmitted by an arthropod vector, in which a further replication cycle takes place before infection of a new vertebrate host.

#### BLOOD AND TISSUE PROTOZOA

### Malaria

Human malaria is usually caused by one of four species of the genus *Plasmodium*: *P. falciparum*, *P. vivax*, *P. ovale* or *P. malariae*. Occasionally, other species of malaria more commonly found in primates (e.g. *P. knowlesi*) can affect humans. Human malaria probably originated from animal malarias in Central Africa but was spread around the globe by human migration. Public health measures and changes in land use have eradicated malaria in most developed countries, although the potential for malaria transmission still exists in many areas. Some 220 million people were infected in 2017, with 415,000 deaths (mainly in African children). Over 25,000 infections per year occur in travellers from non-malarious countries.

#### Epidemiology

Malaria is transmitted by the bite of female anopheline mosquitoes. The parasite undergoes a temperature-dependent cycle of development in the gut of the insect, and its geographical range therefore depends on the presence of the appropriate mosquito species and an adequate temperature. The disease occurs in endemic or epidemic form throughout the tropics and subtropics, except for some areas above 2000 m (Fig. 20.28).

In areas of so-called stable transmission (including much of sub-Saharan Africa), transmission occurs consistently year round. The bulk of the mortality is seen in children, while those who survive

---

**Fig. 20.28** *Plasmodium falciparum* malaria transmission: geographical distribution. Grey areas are likely to be risk-free, either because health surveillance reports 0 cases for 3 years, because low temperatures or high aridity are likely to preclude transmission, or because specific medical intelligence exists defining the area as risk-free. Pink areas are where local transmission cannot be ruled out but levels of risk are extremely low, with annual case incidence reported at less than 1 per 10,000. Red areas are at risk of stable malaria transmission. This is a very broad classification of risk, including any regions where the annual case incidence is likely to exceed 1 per 1000. (From Malaria Atlas Project, with permission; [http://www.map.ox.ac.uk/browse-resources/transmission-limits/Pf_limits/world/](http://www.map.ox.ac.uk/browse-resources/transmission-limits/Pf_limits/world/).)
to adulthood acquire significant immunity; low-grade parasitaemia is still present but causes few symptoms. **Unstable transmission** occurs when there is erratic, seasonal or low-level transmission (e.g. in the Sahel belt, where mosquitoes feed only in the rainy season). In these circumstances, little protective immunity develops and symptomatic malaria occurs at all ages. Changes in environmental or social conditions in such areas can lead to epidemics with substantial mortality in all age groups.

Malaria can also be transmitted in contaminated blood transfusions. It has occasionally been seen in injecting drug users who share needles, and in patients with a hospital-acquired infection related to contaminated equipment. Rare cases are acquired outside the tropics when mosquitoes are transported from endemic areas (‘airport malaria’), or when the local mosquito population becomes infected by a returning traveller.

**Parasitology**

The female mosquito becomes infected after taking a blood meal containing gametocytes, the sexual form of the malarial parasite (Fig. 20.29). The developmental cycle in the mosquito usually takes 7–20 days (depending on temperature), culminating in the migration of infective sporozoites to the insect’s salivary glands. The sporozoites are inoculated into a new human host and those not destroyed by the immune response are rapidly taken up by the liver. Here they multiply inside hepatocytes as merozoites: this is pre-erythrocytic (or hepatic) sporogony. After a few days the infected hepatocytes rupture, releasing merozoites into the blood, from where they are rapidly taken up by erythrocytes. In the case of *P. vivax* and *P. ovale*, a few parasites remain dormant in the liver as hypnozoites. These may reactivate at any time subsequently, causing relapsing infection.

Inside the red cell the parasites again multiply, changing from merozoite to trophozoite to schizont, and finally appearing as 8–24 new merozoites. The erythrocyte ruptures, releasing the merozoites to infect further cells. Each cycle of this process, which is called erythrocytic schizogony, takes about 48 hours in *P. falciparum*, *P. vivax* and *P. ovale* disease, and about 72 hours in *P. malariae* disease. *P. vivax* and *P. ovale* mainly attack reticulocytes and young erythrocytes, while *P. malariae* tends to attack older cells; *P. falciparum* will parasitize any stage of erythrocyte.

A few merozoites develop not into trophozoites but into gametocytes. These are not released from the red cells until taken up by a feeding mosquito to complete the life cycle.

**Pathogenesis**

The pathology of malaria is related to anaemia, cytokine release and, in the case of *P. falciparum*, widespread organ damage due to impaired microcirculation. The anaemia seen in malaria is multifactorial (Box 20.56). In *P. falciparum* malaria, red cells containing schizonts adhere to the lining of capillaries in the brain, kidneys, gut, liver and other organs. As well as causing mechanical obstruction, these schizonts rupture, releasing toxins and stimulating further cytokine release.

After repeated infections, partial immunity develops, allowing the host to tolerate parasitaemia with minimal ill effects. This immunity is largely lost if there is no further infection for a few years. Certain genetic traits also confer some immunity to malaria. People who lack the Duffy antigen on the red cell membrane (a common finding in West Africa) are not susceptible to infection with *P. vivax*. Certain haemoglobinopathies (including sickle cell trait) also give some protection against the severe effects of malaria; this may account for the persistence of these otherwise harmful mutations in tropical countries. Iron deficiency may also have some protective effect. The spleen appears to play a role in controlling infection and splenectomized people are at risk of overwhelming malaria. Some individuals appear to have a genetic predisposition for developing cerebral malaria following infection with *P. falciparum*. Pregnant women are especially susceptible to severe disease.

### Clinical features

Typical malaria is seen in non-immune individuals. This includes children in any area, adults in areas of unstable transmission, and any visitors from a non-malarious region.

The normal incubation period is 10–21 days but can be longer. The most common symptom is fever, although malaria may present initially with general malaise, headache, vomiting or diarrhoea. At first the fever may be continual or erratic; the classical tertian or quartan fever appears only after some days. The temperature often reaches 41°C and is accompanied by rigors and drenching sweats.

The illness caused by *P. vivax* or *P. ovale* infection is usually relatively mild (although *P. vivax* can occasionally cause severe
disease). Anaemia develops slowly and there may be tender hepatosplenomegaly. Spontaneous recovery usually occurs within 2–6 weeks but hypnozoites in the liver can cause relapses for many years after infection. Repeated infections often cause chronic ill health due to anaemia and hyper-reactive splenomegaly.

*P. malariae* infection also causes a relatively mild illness but tends to run a more chronic course. Parasitaemia may persist for years, with or without symptoms. In children, *P. malariae* infection is associated with glomerulonephritis and nephrotic syndrome.

*P. knowlesi* is primarily a parasite of macaque monkeys but causes human malaria in certain areas of South-east Asia. The clinical picture is very variable, ranging from a chronic relatively mild illness similar to *P. malariae*, through to fulminant and fatal disease.

*P. falciparum* infection causes, in many cases, a self-limiting illness similar to the other types of malaria, although the paroxysms of fever are usually less marked. However, it may also cause serious complications (Fig. 20.30) and the vast majority of malaria deaths are due to *P. falciparum*. Patients can deteriorate rapidly, and children in particular progress from reasonable health to coma and death within hours. A high parasitaemia (>1% of red cells infected) is an indicator of severe disease, although patients with apparently low parasite levels may also develop complications (peripheral parasite counts can be misleading, as many parasitized cells are sequestered in the microcirculation). Cerebral malaria is marked by diminished consciousness, confusion and convulsions, often progressing to coma and death. Untreated, it is universally fatal. Blackwater fever is due to widespread intravascular haemolysis, affecting both parasitized and unparasitized red cells, giving rise to dark urine.

Hyper-reactive malarial splenomegaly (tropical splenomegaly syndrome) is seen in older children and adults in areas where malaria is hyperendemic. It is associated with an exaggerated immune response to repeated malaria infections and is characterized by anaemia, massive splenomegaly and elevated IgM levels. Malaria parasites are scanty or absent. Tropical splenomegaly syndrome usually responds to prolonged treatment with prophylactic antimalarial drugs.

**Diagnosis**

Malaria should be in the differential diagnosis of anyone who presents with a febrile illness in, or having recently left, a malarious area. *Falciparum* malaria is unlikely to present more than 3 months after exposure, even if the patient has been taking prophylaxis, but *vivax* malaria may cause symptoms for the first time up to a year after leaving a malarious area.

Diagnosis is usually made by identifying parasites on a Giemsa-stained thick or thin blood film (thick films are more difficult to interpret and it may be difficult to speciate the parasite, but they have a higher yield). At least three films should be examined before malaria is declared unlikely. Rapid antigen detection tests are available for near-patient use. In many endemic areas, malaria is over-diagnosed on clinical grounds and a definite diagnosis should be made wherever possible. Serological tests are of no diagnostic value.

Parasitaemia is common in endemic areas and the presence of parasites does not necessarily mean that malaria is the cause of the patient’s symptoms. Further investigation, including a lumbar puncture, may be needed to exclude bacterial infection.

**Management**

**Uncomplicated malaria**

Chloroquine is still widely used to treat non-*falciparum* malaria (Box 20.57) and in many areas it remains effective. However, there
is increasing resistance to chloroquine in some strains of *P. vivax*, and co-infection with *P. falciparum* is common in some parts of the world. It is therefore sensible to use oral artemisinin combination therapy, where available, for all cases of malaria. Following successful treatment of *P. vivax* or *P. ovale* malaria, it is necessary to give a 2- to 3-week course of primaquine (0.25–0.5 mg daily) to eradicate the hepatic hypnozoites and prevent relapse. This drug can precipitate haemolysis in patients with glucose-6-phosphate dehydrogenase deficiency (see p. 346).

The artemisinin-based drugs are the most effective treatment for both uncomplicated and severe infections with *P. falciparum*, in adults and in children. Artemisinin-based combination therapy (ACT) is the recommended oral treatment for uncomplicated *falciparum* malaria worldwide. These drugs are now widely available, partly through the efforts of the Global Fund. Five different fixed-dose combinations are recommended by the WHO (Box 20.58); the choice should be based on local resistance to the ‘partner’. A sixth combination, artemunate–pyronaridine, has recently been approved by the European Medicines Agency, and may be useful in areas where there is resistance to current partner drugs. In order to limit the development of resistance, artemisinin derivatives should never be given as monotherapy. Partial resistance to artemether has already been reported in parts of South-east Asia, and also in South and Central America. As long as combination therapy is used and the parasite is sensitive to the partner drug, ACT will still be effective. Longer courses of artemether may also overcome the partial resistance. However, malaria partially resistant to artemether, and resistant to all partner drugs, is emerging along the Mekong river.

In addition to treating the acute infection, the WHO recommends that a single dose of primaquine should be given as a gametocide, to decrease onward transmission.

**Severe falciparum malaria**

Severe malaria, indicated by the presence of any of the complications discussed earlier or a parasite count of more than 1% in a non-immune patient, is a medical emergency (Box 20.59). Anyone involved in managing patients with malaria should be familiar with the latest WHO guidelines.

- Intravenous artesunate is more effective than intravenous quinine and should be used where available. Absorption from intramuscular injection is less reliable than that from intravenous injection.
- Intensive care facilities may be needed, including mechanical ventilation and dialysis.
- Severe anaemia may require transfusion.
- Careful monitoring of fluid balance is essential; both pulmonary oedema and pre-renal failure are common.
- Hypoglycaemia can be induced both by the infection itself and by quinine treatment.
- Superadded bacterial infection is common.

</tbody>
</table>

Continue parenteral treatment for at least 24 h, regardless of improvement in condition. After this, if the patient is improving, switch to oral therapy to complete 7 days with:

- ACT
- Or
- Quinine + doxycycline

\(^a\)10 mg/kg if patient has already received oral quinine or mefloquine.

ACT, artemisinin-based combination therapy.

Box 20.60 Strategy for controlling malaria

1. Aggressive control in highly endemic countries, to reduce mortality and decrease transmission
2. Progressive eradication at the endemic margins, to shrink the ‘malaria map’
3. Research into new vaccines, new drugs, new diagnostics and better ways of delivering malaria care

Prevention and control

Malaria is a priority for the WHO, which announced its ‘Roll Back Malaria’ campaign in 1998. This has had considerable success, and global malaria-specific mortality decreased by 25% between 2000 and 2010. However, the latest WHO Global Malaria Report (2018) shows that, following an unprecedented period of success in reducing malaria incidence and mortality, progress has stalled, with no significant improvement between 2015 and 2017. Although some countries either have eradicated malaria or plan to do so soon, for much of Africa the aim remains control rather than eradication. A three-part strategy is now widely endorsed and supported by governments and non-governmental organizations (Box 20.60).

As with many vector-borne diseases, control of malaria relies on a combination of case treatment, vector eradication and personal protection from vector bites, such as that provided by insecticide (permethrin)-treated nets. Mosquito eradication is usually achieved by a combination of insecticide use (e.g. house spraying with DDT) and manipulation of the habitat (e.g. marsh drainage). Alongside these elements, there has been renewed interest in chemoprevention, in which children in endemic areas are given monthly doses of antimalarials during the rainy season. This has been shown to reduce the incidence of malaria but may lead to an increased risk of drug resistance. Pregnant women, who are at greater risk of complications from malaria, may also be offered chemoprevention (although drug options are limited). Enormous effort (and resource) has been devoted to the search for a malaria vaccine, and some progress has been made. The first vaccine to go through large-scale phase 3 clinical trials, RTS,S/AS01, prevented approximately 39% of predicted cases of malaria, with an associated reduction in mortality and need for transfusion. Pilot implementation programmes are now being developed, although there are currently no plans for widespread use of the vaccine.

Non-immune travellers to malarious areas should take measures to avoid insect bites, such as using a repellent (diethyltoluamide (DEET) 20–50% in lotions and sprays) and sleeping under a mosquito net. Antimalarial prophylaxis should also be taken in most cases, although this is never 100% effective (Box 20.61). The precise choice of prophylactic regimen depends both on the individual traveller and on the specific itinerary; further details can be found in national formularies or travel advice centres.

Trypanosomiasis

African trypanosomiasis (sleeping sickness)

Sleeping sickness is caused by trypanosomes transmitted to humans by the bite of the tsetse fly (genus Glossina) (although mother to child transmission has also occasionally been reported). It is endemic in a belt across sub-Saharan Africa, extending to about 14 degrees north and 20 degrees south: this marks the natural range of the tsetse fly. Two subspecies of trypanosome cause human sleeping sickness: Trypanosoma brucei gambiense (‘Gambian sleeping sickness’) and T. b. rhodesiense (‘Rhodesian sleeping sickness’).

Epidemiology

Sleeping sickness due to T. b. gambiense accounts for 97% of reported new cases. It is currently found in 24 countries in an area stretching from Uganda in Central Africa, west to Cameroon and south as far as Angola, but Democratic Republic of Congo (DRC) and Central African Republic are the only countries still reporting significant numbers. Humans are the major reservoir and infection is transmitted by riverine Glossina species (e.g. G. palpalis).

Sleeping sickness due to T. b. rhodesiense occurs in 13 countries in East and Central Africa but cases are rare and sporadic. It is a zoonosis of both wild and domestic animals. In endemic situations, it is maintained in game animals and transmitted by savannah...
flies such as *G. morsitans*. Previous epidemics have been related to cattle and the vectors were riverine flies.

Political upheavals during the 1990s disrupted established treatment and control programmes, resulting in major epidemics in Angola, DR Congo, and Uganda. By 1997, as many as 500,000 people were affected by sleeping sickness. A concerted control programme has gradually brought this number under control: by 2009 there were fewer than 10,000 cases reported, and in 2017 fewer than 1,500. The WHO believes that it is on course to eliminate African trypanosomiasis as a public health problem by 2020.

Parasitology

Tsetse flies bite during the day and, unlike most arthropod vectors, both males and females take blood meals. An infected insect may deposit metacyclic trypanastigotes (the infective form of the parasite) into the subcutaneous tissue. These cause local inflammation ("trypanosomal chancre") and regional lymphadenopathy. Within 2–3 weeks the organisms invade the bloodstream, subsequently spreading to all parts of the body, including the brain.

Clinical features

*T. b. gambiense* causes a chronic, slowly progressive illness. Episodes of fever and lymphadenopathy occur over months or years and hepatosplenomegaly may develop. Eventually, infection reaches the CNS, causing headache, behavioural changes, confusion and daytime somnolence. As the disease progresses, patients may develop tremors, ataxia, convulsions and hemiplegias; eventually, coma and death supervene. Histologically, there is a lymphocytic meningoencephalitis, with scattered trypanosomes visible in the brain substance.

*T. b. rhodesiense* sleeping sickness is a much more acute disease. Early systemic features may include myocarditis, hepatitis and serous effusions, and patients can die before the onset of CNS disease. If they survive, cerebral involvement occurs within weeks of infection and is rapidly progressive.

Diagnosis

Diagnosis involves three stages:

- screening using serological tests (only available for *T. b. gambiense*) and clinical signs
- confirmation of the presence of parasites in body fluids
- assessment of stage of disease.

The card agglutination test for trypanosomiasis (CATT) is a robust and easy-to-use field assay for screening. If this is positive (or there are clinical signs of disease), Giemsa-stained smears of thick or thin blood films, or of lymph node aspirate, should be examined for parasites. Blood films are usually positive in *T. b. rhodesiense* infection but may be negative in *T. b. gambiense* disease; concentration techniques may increase the yield. The main investigation for staging disease is lumbar puncture: examination of CSF is essential in patients with evidence of trypanosomal infection. CNS involvement causes lymphocytosis and elevated protein in the CSF, and parasites may be seen in concentrated specimens. A single dose of suramin should be given to patients with parasitaemia prior to lumbar puncture, to avoid inoculation into the CSF.

Management

The treatment of sleeping sickness remained largely unchanged for more than 40 years but better drugs are now available for *T. b. gambiense* infection and further new agents are undergoing clinical trials. In both forms of disease, treatment is usually effective if given in the first stage (i.e. before the onset of CNS involvement) (Box 20.62). The treatment of choice for second-stage (CNS) disease in *T. b. gambiense* is a combination of eflornithine and nifurtimox, a therapy introduced in 2009 and provided free of charge via the WHO. Melarsoprol remains the only treatment for CNS infection with *T. b. rhodesiense*. It is extremely toxic: 2–10% of patients develop an acute encephalopathy, with a 50–75% mortality; peripheral neuropathy and hepatorenal toxicity are also common. Between 3% and 6% of patients relapse following melarsoprol treatment.

Control

Control programmes coordinated by the WHO have been effective in many areas. As in many vector-borne diseases, prevention depends largely on elimination, control or avoidance of the vector.

South American trypanosomiasis (Chagas’ disease)

Chagas’ disease is widely distributed in rural areas of South and Central America, where up to 7 million people are infected. Since 2009, more cases have been detected in other parts of the world, due to increased migration from Latin America. The disease is caused by *Trypanosoma cruzi*, which is transmitted to humans in the faeces of blood-sucking reduvid bugs (also called cone-nose or assassin bugs). Faeces infected with *T. cruzi* trypanastigotes are rubbed in through skin abrasions, mucosa or conjunctiva. The bugs, which live in mud or thatch buildings, feed on a variety of vertebrate hosts (e.g. rats, opossums) at night, defecating as they do so.

The parasites spread in the bloodstream before entering host cells and multiplying. Cell rupture releases them back into the circulation, where they can be taken up by a feeding bug. Further multiplication takes place in the insect gut, completing the trypanosome life cycle. Human infection can also occur via contaminated blood transfusion or, occasionally, by transplacental spread.

Clinical features

Acute infection usually occurs in children and often passes unnoticed. A firm, reddish papule is sometimes seen at the site of entry, associated with regional lymphadenopathy. In the case of conjunctival infection, there is swelling of the eyelid, which may close the eye (Romana’s sign). There may be fever, lymphadenopathy, hepatosplenomegaly and, rarely, meningoencephalitis. Acute Chagas’ disease is occasionally fatal in infants but normally there is full recovery within a few weeks or months.

Some 10–30% of people go on to develop chronic Chagas’ disease after a latent period of many years. The pathogenesis remains controversial, although the most likely explanation is an autoimmune response to persistent parasite DNA integrated into

*Severe allergic reactions common: give test dose.
the host genome. The heart is commonly affected, with conduction abnormalities, arrhythmias, aneurysm formation and cardiac dilatation. Gastrointestinal involvement leads to progressive dilation of parts of the gastrointestinal tract; this commonly results in megaoesophagus (causing dysphagia and aspiration pneumonia) and megacolon (causing severe constipation).

**Diagnosis**

Trypanosomes may be seen on a stained blood film during the acute illness. PCR is also sensitive in the acute phase. In chronic disease, serological tests are the most useful method, although they need to be interpreted in the clinical context.

**Management and control**

Nifurtimox and benznidazole are the main drugs used. Both are highly effective in acute infection, with a cure rate of over 90%, but much less so in chronic disease. They are relatively toxic, with adverse reactions in up to 40% of patients, and new drugs are urgently needed. Anti-arrhythmic drugs and pacemakers may be needed in cardiac disease and surgical treatment is sometimes required for gastrointestinal complications.

In the long term, prevention of Chagas’ disease relies on improved housing and living conditions, and eradication of vectors. Several coordinated multinational vector control programmes have been implemented, with some success in reducing transmission. Screening of blood donors and pregnant women in high-risk areas can reduce transmission through non-vector routes.

**Leishmaniasis**

This group of diseases is caused by protozoa of the genus *Leishmania*, which are transmitted by the bite of the female phlebotome sandfly (Box 20.63). Leishmaniasis is seen in localized areas of Africa, Asia (particularly India and Bangladesh), Europe, the Middle East and South and Central America. It is strongly linked to poverty and poor hygiene. Certain parasite species are specific to each geographical area. The clinical picture is dependent on the species of parasite and on the host’s cell-mediated immune response. Asymptomatic infection, in which the parasite is suppressed or eradicated by a strong immune response, is common in endemic areas, as demonstrated by a high incidence of positive leishmanin skin tests. Symptomatic infection may be confined to the skin (sometimes with spread to the mucous membranes) or widely disseminated throughout the body (visceral leishmaniasis). Relapse of previously asymptomatic infection is seen in patients who become immunocompromised, especially those with HIV infection.

In some areas, leishmania is primarily zoonotic, whereas in others humans are the main reservoir of infection. In the vertebrate host the parasites are found as oval amastigotes (Leishman–Donovan bodies). These multiply inside the macrophages and cells of the reticuloendothelial system and are then released into the circulation as the cells rupture. Parasites are taken into the gut of a feeding sandfly (genus *Phlebotomus* in the Old World, genus *Lutzomyia* in the New World), where they develop into the flagellate promastigote form. These migrate to the salivary glands of the insect, where they can be inoculated into a new host.

**Visceral leishmaniasis**

**Clinical features**

Visceral leishmaniasis (kala azar) is caused by *L. donovani*, *L. infantum* or *L. chagasi*, and is prevalent in localized areas of Asia, Africa, the Mediterranean littoral and South America. In parts of India, where humans are the main host, the disease occurs in epidemics. In most other areas, it is endemic, and it is mainly children and visitors to the area who are at risk. The main animal reservoirs in Europe and Asia are dogs and foxes, while in Africa it is carried by various rodents. Between 50 000 and 100 000 new cases occur each year, the vast majority in Brazil, East Africa and the Indian subcontinent. Mortality rates have fallen in Asia due to improved treatment programmes, but not in Africa, where conflicts have disrupted management initiatives.

The incubation period is usually 1–2 months but may be several years. The onset of symptoms is insidious and the patient may feel quite well, despite markedly abnormal physical findings. Fever is common and may be high and intermittent, although usually low-grade. The liver and especially the spleen become enlarged; lymphadenopathy is common in African kala azar. The skin becomes rough and pigmented. If the disease is not treated, profound pancytopenia develops and the patient becomes wasted and immunosuppressed. Death usually occurs within a year and is normally due to bacterial infection or uncontrolled bleeding.

**Diagnosis**

Specific diagnosis is made by demonstrating the parasite in stained smears of aspirates of bone marrow, lymph node, spleen or liver. The organism can also be cultured from these specimens. Specific serological tests are positive in 95% of cases. Pancytopenia, hypoalbuminaemia and hypergammaglobulinaemia are common. The leishmanin skin test is usually negative, indicating a poor cell-mediated immune response.

**Management**

The most widely used drugs for visceral leishmaniasis remain the pentavalent antimony salts (e.g. sodium stibogluconate and meglumine antimoniate), despite toxicity and increasing resistance. Intravenous amphotericin B (preferably liposomal, which may be curative as a single-dose treatment) is effective but expensive; intramuscular
paromomycin is cheaper and also has a good cure rate. The oral drug miltefosine has been shown in India to be highly effective, especially in combination with liposomal amphotericin; this and other combination therapies are increasingly being used to shorten treatment courses and limit resistance. The recommended treatment regimens vary from region to region and are available from the WHO (see Further reading).

Successful treatment may be followed in a small proportion of patients by a skin eruption called post-kala azar dermal leishmaniasis (PKDL). It starts as a macular or maculopapular nodular rash, which spreads over the body. It is most often seen in Sudan and India, and is difficult to treat, although it may improve with miltefosine.

**HIV co-infection**

Visceral leishmaniasis is strongly associated with HIV-related immunosuppression (see p. 1444), and the two infections may be passed on together through injecting drug use. In Southern Europe, anti-retroviral therapy has largely controlled the problem, but increasing numbers of cases are being seen in Brazil and India.

**Cutaneous leishmaniasis**

Cutaneous leishmaniasis is caused by a number of geographically localized species, which may be zoonotic or anthropotonic. It is by far the most common form of the disease, with up to a million new cases worldwide every year. Some 95% of these occur in just seven countries: Iran, Iraq, Syria, Algeria, Afghanistan, Brazil and Colombia. Following a sandfly bite, Leishmania amastigotes multiply in dermal macrophages. The local response depends on the species of Leishmania, the size of the inoculum, and the host immune response. Single or multiple painless nodules appear 1 week to 3 months after the bite (Fig. 20.31). These enlarge and ulcerate with a characteristic erythematous raised border. An overlying crust may develop. The lesions heal slowly over months or years, sometimes leaving a disfiguring scar.

*L. major* and *L. tropica* are found in Russia and Eastern Europe, the Middle East, Central Asia, the Mediterranean littoral and sub-Saharan Africa. The reservoir for *L. major* is desert rodents, while *L. tropica* has a mainly urban distribution with dogs and humans as reservoirs. *L. aethiopica* is found in the highlands of Ethiopia and Kenya, where the animal reservoir is the hyrax. The skin lesions caused by these species usually heal spontaneously with scarring; this may take a year or more in the case of *L. tropica*. Leishmaniasis recidivans is a rare chronic relapsing form caused by *L. tropica*. *L. mexicana* is found predominantly in Mexico, Guatemala, Brazil, Venezuela and Panama; infection usually runs a benign course with spontaneous healing within 6 months. *L. braziliensis* infections (which are seen throughout tropical South America) also usually heal spontaneously but may take longer.

*L. mexicana amazonsensis* and *L. aethiopica* may occasionally cause diffuse cutaneous leishmaniasis. This is rare and is characterized by diffuse infiltration of the skin by Leishman–Donovan bodies. Visceral lesions are absent.

**Diagnosis and management**

The diagnosis can often be made clinically in a patient who has been in an endemic area. Giemsa stain on a split-skin smear will demonstrate Leishmania parasites in 80% of cases. Biopsy tissue from the edge of the lesion can be examined histologically and parasites identified by PCR; culture is less often successful. The leishmanin skin test is positive in over 90% of cases but does not distinguish between active and resolved infection. Serology is unhelpful.

**Mucocutaneous leishmaniasis**

Mucocutaneous leishmaniasis occurs in 3–10% of infections with *L. b. braziliensis* and is most common in Bolivia and Peru. It can also follow infection with *L. aethiopica*. The cutaneous sores are followed months or years later by indurated or ulcerating lesions affecting mucosa or cartilage, typically on the lips or nose (‘espundia’). The condition can remain static, or there may be progression over months or years affecting the nasopharynx, uvula, palate and upper airways.

**Diagnosis and management**

Biopsies usually show only very scanty organisms, although parasites can be detected by PCR; serological tests are frequently positive.

Amphotericin B is the treatment of choice, if available, although systemic antimonial compounds are widely used; miltefosine may also be effective. Relapses are common following treatment. Patients may die because of secondary bacterial infection or, occasionally, laryngeal obstruction.

Prevention of leishmaniasis relies on control of vectors and/or reservoirs of infection. Insecticide spraying, control of host animals and treatment of infected humans may all be helpful. Personal protection against sandfly bites is also important, especially in travellers visiting endemic areas. Sandflies are poor fliers and sleeping off the ground helps prevent bites.

**Other protozoal diseases of the blood and tissues**

**Toxoplasmosis**

Toxoplasmosis is caused by the intracellular protozoan parasite *Toxoplasma gondii*. The sexual form of the parasite lives in the gut of the definitive host, the cat, where it produces oocysts. After a period of maturing in the environment, these oocysts become the source...
of infection for secondary hosts, which may ingest them. In the secondary hosts (which include humans, cattle, sheep, pigs, rodents and birds) there is disseminated infection. Following a successful immune response, the infection is controlled but dormant parasites remain encysted in host tissue for many years. The life cycle is completed when carnivorous felines eat infected animal tissue. Humans are infected either from contaminated cat faeces or undercooked infected meat; transplantal infection may also occur.

Clinical features
Toxoplasmosis is common: seroprevalence in adults in the UK is about 25%, rising to 90% in some parts of Europe. Most infections are asymptomatic or trivial. Symptomatic patients usually present with lymphadenopathy, mainly in the head and neck. There may be fever, myalgia and general malaise; occasionally, there are more severe manifestations, including hepatitis, pneumonia, myocarditis, and choroidoretinitis. Lymphadenopathy and fatigue can sometimes persist for months after the initial infection.

Congenital toxoplasmosis may also be asymptomatic but can produce serious disease. Clinical manifestations include microcephaly, hydrocephalus, encephalitis, convulsions and mental retardation. Choroidoretinitis is common; occasionally, this may be the only feature.

Immunocompromised patients, especially those with HIV infection, are at risk of serious infections with *T. gondii*. In acquired immunodeficiency states, this is usually due to reactivation of latent disease (see p. 1444).

Diagnosis
Diagnosis is usually made serologically. IgG antibodies detectable by the Sabin–Feldman dye test remain positive for years; acute infection can be confirmed by demonstrating a rising titre of specific IgM.

Management
Acquired toxoplasmosis in an immunocompetent host rarely requires treatment. In those with severe disease (especially eye involvement), sulfadiazine and pyrimethamine are given for 4 weeks, along with folic acid. The management of pregnant women with toxoplasmosis aims to decrease the risk of fetal complications. However, there is only weak evidence that giving spiramycin, either alone or in combination with sulfadiazine (which is the recommended treatment), has any significant effect on the frequency or severity of fetal damage. Infected infants should be treated from birth. The treatment of toxoplasmosis in HIV-positive patients is covered on page 1444.

Babesiosis
Babesiosis is a tick-borne parasitic disease, diagnosed most commonly in North America and Europe. It is a zoonosis of rodents and cattle, and is occasionally transmitted to humans; infection is more common and more severe in those who are immunocompromised following splenectomy. The causative organisms are the *Plasmodium*-like *Babesia microti* (rodents) and *B. divergens* (cattle).

The incubation period averages 10 days. In patients with normal splenic function the illness is usually mild. In splenectomized individuals, systemic symptoms are more pronounced and haemolytic anaemia is associated with haemoglobinuria, jaundice and acute kidney injury. Examination of a peripheral blood smear may reveal the characteristic *Plasmodium*-like organisms.

The standard treatment of severe babesiosis is a combination of quinine 650 mg and clindamycin 600 mg orally three times daily for 7 days. Atovaquone and azithromycin is an alternative combination therapy.

GASTROINTESTINAL PROTOZOA

The major gastrointestinal protozoal parasites of humans are shown in Box 20.64.

**Amoebiasis**
Amoebiasis is caused by *Entamoeba histolytica*. There are three morphologically identical species of amoeba, which can be distinguished by molecular techniques after culture of the trophozoite:

- **E. histolytica**, which is pathogenic
- **E. dispar**, which is non-pathogenic
- **E. moshkovskii**, which is of uncertain significance.

Amoebiasis occurs worldwide, although much higher incidence rates are found in the tropics and subtropics. The organism exists both as a motile trophozoite and as a cyst that can survive outside the body. Cysts are transmitted by ingestion of contaminated food or water, or they can be spread directly
Infectious disease

572

by person-to-person contact. Trophozoites emerge from the cysts in the small intestine and then pass on to the colon, where they multiply.

**Clinical features**

It is believed that many individuals can carry the pathogen without obvious evidence of clinical disease (asymptomatic cyst passers). However, this may be due, in some cases, to the misidentification of non-pathogenic *E. dispar* as *E. histolytica*, and it is not clear how often true *E. histolytica* infection is symptomless. In affected people, *E. histolytica* trophozoites invade the colonic epithelium, probably with the aid of their own cytotoxins and proteolytic enzymes. The parasites continue to multiply and eventually cause frank ulceration of the mucosa. If penetration continues, trophozoites may enter the portal vein, via which they reach the liver and cause intrahepatic abscesses. This invasive form is serious and may even be fatal.

The incubation period of intestinal amoebiasis is highly variable and may be as short as a few days or as long as several months. The usual course is chronic, with mild intermittent diarrhoea and abdominal discomfort. This may progress to bloody diarrhoea with mucus, sometimes accompanied by systemic symptoms such as headache, nausea and anorexia. Less commonly, infection presents as acute amoebic dysentery, resembling bacillary dysentery or acute ulcerative colitis.

Complications are unusual but include toxic dilation of the colon, chronic infection with stricture formation, severe haemorrhage, amoeboma and amoebic liver abscess. Amoebic liver abscesses often develop in the absence of a recent episode of colitis. Tender hepatomegaly, a high swinging fever and profound malaise are characteristic, although early in the course of the disease both symptoms and signs may be minimal. The clinical features are described in more detail on page 1306.

**Diagnosis**

Microscopic examination of fresh stool or colonic exudate obtained at sigmoidoscopy has been the standard means of diagnosing colonic amoebic infection. To confirm the diagnosis, motile trophozoites containing red blood cells must be identified; the presence of amoebic cysts alone does not imply disease. However, it is impossible to distinguish with certainty between the pathogenic and non-pathogenic species of *Entamoeba* using microscopy, and it is recommended that, wherever possible, species-specific molecular methods should be used. Sigmoidoscopy and barium enema examination may show colonic ulceration but are rarely diagnostic.

The amoebic fluorescent antibody test is positive in at least 90% of patients with liver abscess and in 60–70% with active colitis. Seropositivity is low in asymptomatic cyst passers.

**Management**

Metronidazole 800mg three times daily for 5 days is given in amoebic colitis; a lower dose (400mg three times daily for 5 days) is usually adequate in liver abscess. Tinidazole is also effective. After treatment of the invasive disease, the bowel should be cleared of parasites with a luminal amoebicide such as diloxanide furoate.

**Prevention**

Amoebiasis is difficult to eradicate because of the substantial human reservoir of infection. Progress will only be through improved standards of hygiene and sanitation, and better access to clean water. Cysts are destroyed by boiling but chlorine and iodine sterilizing tablets are not always effective.

**Giardiasis**

*Giardia intestinalis* is a flagellate (Fig. 20.32) that is found worldwide. It causes small intestinal disease, with diarrhoea and malabsorption. Prevalence is high in many developing countries and it is the most common parasitic infection in travellers returning to the UK. In certain parts of Europe and in some rural areas of North America, large water-borne epidemics have been reported. Person-to-person spread may occur in day nurseries and residential institutions. The organism exists as both a trophozoite and a cyst, the latter being the form in which it is transmitted.

The organism sometimes colonizes the small intestine and may remain there without causing detriment to the host. In other cases, severe malabsorption may occur, which is thought to be related to morphological damage to the small intestine. The changes in architecture are usually mild partial villous atrophy; subtotal villous atrophy is rare. The mechanism by which the parasite causes alteration in mucosal architecture and produces diarrhoea and intestinal malabsorption is unknown, though there is evidence that the morphological damage is immune-mediated. Bacterial overgrowth has also been found in association with giardiasis and may contribute to fat malabsorption.

**Clinical features**

Many individuals excreting *Giardia* cysts have no symptoms. Others become ill within 1–3 weeks of ingesting cysts; symptoms include diarrhoea, often watery in the early stage of the illness, nausea, anorexia, and abdominal discomfort and bloating. In most these symptoms resolve after a few days, but in some they persist. Stools may then become paler, with the characteristic features of steatorrhoea. If the illness is prolonged, weight loss occurs and can be marked. Chronic giardiasis, frequently seen in developing countries, can result in growth retardation in children.

![Giardia intestinalis on small intestinal mucosa.]( Courtesy of Dr A Phillips)
Diagnosis
Both cysts and trophozoites can be found in the stool, but negative stool examination does not exclude the diagnosis since the parasite may be excreted at irregular intervals. The parasite can also be seen in duodenal aspirates (obtained with either an endoscope or a luminal capsule) and in histological sections of jejunal mucosa.

Management
Metronidazole 2g as a single dose on three successive days will cure the majority of infections, although sometimes a second or third course is necessary. Alternative drugs include tinidazole, nitazoxanide and albendazole. Preventative measures are similar to those outlined earlier for E. histolytica.

Cryptosporidiosis
This organism is found worldwide, cattle being the major natural reservoir. It has also been demonstrated in supplies of drinking water in the UK. The parasite is able to reproduce both sexually and asexually; it is transmitted by oocysts excreted in the faeces.

In healthy individuals, cryptosporidiosis is a self-limiting illness. Acute watery diarrhoea is associated with fever and general malaise lasting for 7–10 days. In immunocompromised patients, especially those with HIV, diarrhoea is severe and intractable (see p. 1444). Cryptosporidium may also be an important cause of childhood diarrhoea in resource-poor countries, contributing to overall morbidity and mortality.

Diagnosis is usually made by faecal microscopy, although the parasite can also be detected in intestinal biopsies. There is no reliable treatment but nitazoxanide may be of benefit.

Balantidiasis
Balantidium coli is the only ciliate that produces clinically significant infection in humans. It is found throughout the tropics, particularly in Central and South America, Iran, Papua New Guinea and the Philippines. It is usually carried by pigs, and infection is most common in those communities that live in close association with swine. Its life cycle is identical to that of E. histolytica. B. coli causes diarrhoea and sometimes a dysenteric illness, with invasion of the distal ileal and colonic mucosa. Trophozoites rather than cysts are found in the stool. Treatment is with tetracycline or metronidazole.

Blastocystis hominis infection
B. hominis is a strictly anaerobic protozoal pathogen that inhabits the colon. The pathogenicity for humans remains controversial. Many people appear to excrete the organism with no symptoms at all, but there are numerous reports of people with diarrhoea whose symptoms improve after eradication of the parasite. Whether this is due to pathogenic and non-pathogenic subspecies or individual host variation is unclear.

 Cyclospora cayetanensis infection
C. cayetanensis, a coccidian protozoal parasite, was originally recognized as a cause of diarrhoea in travellers to Nepal. It has been detected in stool specimens from immunocompetent and immunodeficient people worldwide. Infection is usually self-limiting but can be treated with co-trimoxazole.

Microsporidiosis
Protozoa of the phylum Microsporea can cause diarrhoea in patients with HIV/AIDS (see p. 1444).

Further reading

**Helminthic Infections**

Worm infections are very common in developing countries, causing much disease in both humans and domestic animals. Worms are frequently imported into industrialized countries. The most common human helminth infections are listed in Box 20.65. Eight of the 17 ‘neglected tropical diseases’ identified by the WHO as causing major morbidity in the poorest areas are caused by helminths. Even those parasites that, in developed countries, are regarded as little more than an inconvenience (e.g. roundworm or whipworm) cause huge morbidity in resource-poor settings due to the very high worm burden in children.
Helminths are the largest internal human parasite. They reproduce sexually, generating millions of eggs or larvae. Nematodes and trematodes have a mouth and intestinal tract, while cestodes absorb nutrients directly through the outer tegument. All worms are motile, although once the adults are established in their definitive site, they rarely migrate further. Adult helminths may be very long-lived: up to 30 years in the case of the schistosomes.

Many helminths have developed complex life cycles, involving more than one host. Both primary and intermediate hosts are often highly specific to a particular species of worm. In some cases of human infection, humans are the primary host, while in others, humans are a non-specific intermediary or are coincidentally infected. Multiple infections with different helminths are common in endemic areas. Mass treatment programmes, in which one or more antihelminthic drugs are given on a regular (usually annual) basis, are used to keep the total worm load down, and the WHO recommends treating all schoolchildren at regular intervals in areas where helminth infections are common (Box 20.66).

**NEMATODES**

**Tissue-dwelling worms**

**Filariasis**

Several nematodes belonging to the superfamily Filarioidea can infect humans (Box 20.67). The adult worms are long and thread-like, ranging from 2 cm to 50 cm in length; females are generally much larger than males. Larval stages are inoculated into humans by various species of biting flies (each specific to a particular parasite). The adult worms that develop from these larvae mate, producing millions of offspring (microfilariae), which migrate in the blood or skin. These are ingested by feeding flies, in which the remainder of the life cycle takes place. Disease, which may be caused either by the adult worms or by microfilariae, stems from the host immune response to the parasite and is characterized by massive eosinophilia. Adult worms are long-lived (10–15 years) and re-infection is common, so that disease tends to be chronic and progressive.

**Lymphatic filariasis**

Lymphatic filariasis, which may be caused by different species of filarial worm, has a scattered distribution in the tropics and sub-tropics. Almost 1 billion people in developing countries are at risk. *Wuchereria bancrofti* is transmitted to humans by a number of mosquito species, mainly *Culex fatigans*. Adult female worms (5–10 cm long) live in the lymphatics, releasing large numbers of microfilariae into the blood. Generally, this occurs at night, coinciding with the nocturnal feeding pattern of *C. fatigans*. Non-periodic forms of *W. bancrofti*, transmitted by day-biting species of mosquito, are found in the South Pacific. *Brugia malayi* (and the closely related *B. timori*) is very similar to *W. bancrofti*, exhibiting the same nocturnal periodicity. The usual vectors are mosquitoes of the genus *Manson*ia, although other mosquitoes have been implicated.

Many filarial worms coexist with symbiotic *Wolbachia* bacteria, which are, in themselves, a cause of inflammation in the human host.

**Clinical features**

Following the bite of an infected mosquito, the larvae enter the lymphatics and are carried to regional lymph nodes. Here, they grow and mature for 6–18 months.

Adult worms produce allergic lymphangitis. The clinical picture depends on the individual immune response, which in turn may depend on factors such as age at first exposure. In endemic areas, many people have asymptomatic infection. Sometimes early infection is marked by bouts of fever accompanied by pain, tenderness and erythema along the course of affected lymphatics. Involvement of the spermatic cord and epididymis is common in Bancroftian filariasis. These acute attacks subside spontaneously in a few days but usually recur. Recurrent episodes cause intermittent lymphatic obstruction, which in time can become fibrotic and irreversible. Obstructed lymphatics may rupture, causing cellulitis and further fibrosis; there may also be chylous pleural effusions and ascites. Over time, there is progressive enlargement, coarsening...
and fissuring of the skin, leading to the classical appearances of elephantiasis. The limbs or scrotum may become hugely swollen. Eventually, the adult worms will die, but the lymphatic obstruction remains and tissue damage continues. Elephantiasis takes many years to develop and is seen only in association with recurrent infection in endemic areas.

Occasionally, the predominant features of filarial infection are pulmonary. Microfilariae become trapped in the pulmonary capillaries, generating an intense local allergic response. The resulting pneumonitis causes cough, fever, weight loss and shifting radiological changes, associated with a high peripheral eosinophil count. This is known as tropical pulmonary eosinophilia.

Diagnosis
The clinical picture in established disease is usually diagnostic, although similar lymphatic damage may occasionally be caused by silicates absorbed through the feet from volcanic soil (podoconiosis). Parasitological diagnosis has traditionally relied on detecting microfilariae in blood films or skin snips, but rapid and sensitive near-patient antigen detection tests are now available.

Management
Diethylcarbamazine (DEC) kills both adult worms and microfilariae. Serious allergic responses may occur as the parasites are killed, and particular care is needed when using DEC in areas endemic for loiasis. Mass treatment programmes, using combinations of DEC, ivermectin and albendazole to target various helminthic infections, are deployed in many parts of the world; the exact regimens depend on local situations. The WHO reported in 2017 that over 7 billion courses of treatment had been given to 850 million people since 2000, and several countries have eliminated filariasis as a significant public health problem. There is currently much interest in using new agents to kill the symbiotic Wolbachia bacteria, without which the adult worm will eventually die. However, the best way of incorporating this tactic into the overall management strategy remains unclear. Vector control with insecticide bed nets is helpful in certain areas.

Loiasis
Loiasis is found in the humid forests of West and Central Africa. The causative parasite, *Loa loa*, is a small (3–7 cm) filarial worm, found in the subcutaneous tissues. The microfilariae circulate in the blood during the day but cause no direct symptoms. The vectors are day-biting flies of the genus *Chrysops*.

Adult worms migrate around the body in subcutaneous tissue planes. Worms may be present for years, frequently without causing symptoms. From time to time, localized, tender, hot, soft tissue swellings (Calabar swellings) occur due to hypersensitivity, often near a joint. These are produced in response to the passage of a worm and usually subside over a few days or weeks. There may also be more generalized urticaria and pruritus. Occasionally, a worm may be seen crossing the eye under the conjunctiva; it may also enter retro-orbital tissue, causing severe pain. Short-term residents of endemic areas often have more severe manifestations of the disease.

Microfilariae may be seen on stained blood films, although these are often negative. Serological tests are relatively insensitive and cross-react with other microfilariae. There is usually massive eosinophilia. DEC, which was used in early treatment campaigns, can cause severe allergic reactions associated with parasite killing and is being replaced by newer agents. Ivermectin in single doses of 200–400 μg/kg is effective but may also cause severe reactions occasionally. Albendazole, which brings about a more gradual reduction in microfilarial load, may be preferable in heavily infected patients. Mass treatment with either DEC or ivermectin can decrease the transmission of infection but the mainstay of prevention is vector avoidance and control.

Onchocerciasis
Onchocerciasis (river blindness) affects 37 million people worldwide, of whom 250,000 are blind and 500,000 visually impaired; most of these are in West and Central Africa, with small foci in Yemen and in Central and South America. It is the result of infection with *Onchocerca volvulus*. Infection is transmitted by day-biting flies of the genus *Simulium*.

Pathogenesis
Infection occurs when larvae are inoculated into humans by the bite of an infected fly. The worms mature in 2–4 months and can live for more than 15 years. Adult worms, which can reach lengths of 50 cm (although they are <0.5 mm in diameter), live in the subcutaneous tissues. They may form fibrotic nodules, especially over bony prominences and sites of trauma. Huge numbers of microfilariae are distributed in the skin and may invade the eyes. Live microfilariae cause relatively little harm but dead parasites may cause severe allergic reactions, with hyaline necrosis and loss of tissue collagen and elastin. In the eye a similar process causes conjunctivitis, sclerosing keratitis, uveitis and secondary glaucoma. Choroidoretinitis is also seen occasionally.

Clinical features
Symptoms usually start about a year after infection. Initially, there is generalized pruritus, with urticaria and fleeting oedema. Subcutaneous nodules (which can be detected by ultrasound) start to appear, and in dark-skinned individuals there is hypo- and hyperpigmentation from excoriation and inflammatory changes. Over time, more chronic inflammatory changes appear, with roughened, inelastic skin. Superficial lymph nodes become enlarged and, in the groin, may hang down in loose folds of skin (‘hanging groin’). Eye disease, which is associated with chronic heavy infection, usually first manifests as itching and conjunctival irritation. This gradually progresses to more extensive eye disease and eventually to blindness.

Diagnosis
In endemic areas the diagnosis can often be made clinically, especially if supported by finding eosinophilia on a blood film. In order to identify parasites, skin snips taken from the iliac crest or shoulder are placed in saline under a cover slip. After 4 hours, microscopy will show microfilariae wriggling free on the slide. If this is negative, DEC can be applied topically under an occlusive dressing and will provoke an allergic rash in the majority of infected people (modified Mazzotti reaction). Slit-lamp examination of the eyes may reveal the microfilariae. However, skin snip tests are less reliable in lower worm loads and are therefore of limited value in assessing success of treatment. Rapid near-patient serological card tests are under evaluation, and PCR tests are being developed.

Management and prevention
A single dose of ivermectin kills microfilariae and prevents their return for 6–12 months. There is little effect on adult worms and so annual (or more frequent) retreatment is needed. In patients co-infected with *Loa loa*, ivermectin may occasionally induce severe allergic reactions, including a toxic encephalopathy. An alternative agent, moxidectin, is currently under investigation.
Infectious disease

The WHO Onchocerciasis Control Programme (OCP), which started in 1974, had a considerable impact on the disease in West Africa. A combination of vector control measures and, more recently, mass treatment with ivermectin led to a decrease in both infection rates and progression to serious disease. The control programme has been handed over to local governments by the WHO, and local mass treatment programmes are still running in most endemic countries. Eradication may eventually be possible, as humans are the only host, but measures are required over a long period because of the longevity of the worm (10–15 years).

Mansonellosis

*Mansonella perstans* is a filarial worm transmitted by biting midges of the genus *Culicoides*. Small numbers of microfilariae are found in the blood, and although they do not cause serious disease, there may be minor allergic reactions and an eosinophilia.

Dracunculiasis

Infection with the Guinea worm, *Dracunculus medinensis*, occurs when water fleas (copepods) containing the parasite larvae are swallowed in contaminated drinking water. Ingested larvae mature and the female worm, which can reach over 1 metre in length, migrates through connective and subcutaneous tissue for 9–18 months before surfacing on the skin. The uterus of the worm ruptures, releasing larvae that are ingested by the small crustacean water fleas, and the cycle is completed.

The diagnosis is clinical. The traditional management, extracting the worm over several days by winding it round a stick, is probably still the most effective. The worm should not be damaged. Antibiotics may be needed to control secondary infection.

Prevention and control of dracunculiasis has been one of the success stories in tropical medicine. Large-scale eradication programmes (involving removal of water fleas, and thus infective larvae, by chemical treatment or simple filtration) have been in place for several years. In 1989, active surveillance in Africa identified nearly a million cases of dracunculiasis; similar (though probably more robust) surveillance in 2018 found only 28 cases. The disease is now confined to a handful of small areas of Africa, notably in South Sudan, Chad and Angola.

Human intestinal nematodes

Adult intestinal nematodes (also referred to sometimes as soil-transmitted helminths, or geohelminths) live in the human gut. There are two main types of life cycle, both usually including a soil-based stage. In some species, infection is spread by ingestion of eggs (which often require a period of maturation in the environment); in others, the eggs hatch in the soil and larvae penetrate directly through the skin of a new host. *Strongyloides* (see p. 577) is unusual in that it is the only nematode that is able to complete its life cycle entirely within the human host without requiring a stage in the environment or an insect vector. Larvae may hatch before leaving the colon and so are able to re-infect the host by penetrating the intestinal wall and entering the venous system.

Although light infestations with intestinal worms cause few symptoms, heavy worm loads cause significant morbidity, especially in children. Cheap, effective and safe treatments are available and the WHO promotes mass treatment programmes for those at risk (without individual diagnosis): 600 million children in endemic areas received albendazole or mebendazole in 2017 (Box 20.68).

### Ascariasis (roundworm infection)

*Ascaris lumbricoides* is a pale yellow worm, 20–35 cm in length (Fig. 20.33). It is found worldwide but is particularly common in poor rural communities, where there is heavy faecal contamination of the immediate environment. Larvae hatch and penetrate the duodenum, migrating through the tissues to the lungs before being expectorated and swallowed. The adult worms live in the small intestine. Ova are deposited in faeces and require a 2–4-month maturation in the soil before they are infective.

Infection is usually asymptomatic, although heavy infections are associated with nausea, vomiting, abdominal discomfort and anorexia. Worms can sometimes obstruct the small intestine, the most common site being the ileocaecal valve. They may also occlusively invade the appendix, causing acute appendicitis, or the bile

++: highly effective; +: moderately effective; –: ineffective; n/a, drug not used for this indication/no data available. <sup>a</sup>Single dose unless otherwise stated. <sup>b</sup>Twice daily for 3 days in strongyloidiasis. <sup>c</sup>WHO-recommended dose for developing countries; in the UK, commonly given as 100 mg single dose for threadworm or 100 mg twice daily for 3 days for whipworm. <sup>d</sup>Once daily for 2 days.

**Fig. 20.33** *Ascaris lumbricoides*. The worm is approximately 20 cm long.
duct, resulting in biliary obstruction and suppurative cholangitis. Larvae in the lung may produce pulmonary eosinophilia. Heavy infection in children, especially those who are already malnourished, may have significant effects on nutrition and development. Serious morbidity and mortality are relatively rare in ascariasis, but the huge number of people infected means that on a global basis roundworm infection causes a significant burden of disease, especially in children.

Ascaris eggs can be identified in the stool and, occasionally, adult worms emerge from the mouth or the anus. They may also be seen on barium enema studies. Appropriate drug treatments are shown in Box 20.68. Very rarely, surgical or endoscopic intervention may be required for intestinal or biliary obstruction.

**Threadworm (Enterobius vermicularis)**

E. vermicularis is a small (2–12 mm) worm, which is common throughout the world. Larval development takes place mainly in the small intestine and adult worms are normally found in the colon. The gravid female deposits eggs around the anus, causing intense itching, especially at night. Unlike those of A. lumbricoides, the eggs do not require a maturation period in soil, and infection is often directly transmitted from anus to mouth via the hands. Eggs may also be deposited on clothing and bed linen, and are subsequently either ingested or inhaled. Apart from discomfort and local excoriations, infection is usually harmless.

Ova can be collected either by using a moistened perianal swab or by applying adhesive cellophane tape to the perianal skin. They can then be identified by microscopy.

The most commonly used drugs are mebendazole and piperaquine (see Box 20.68). However, isolated treatment of an affected person is often ineffective. Other family members (especially small children) may also need to be treated and the whole family should be given advice about personal hygiene. Two courses of treatment 2 weeks apart may break the cycle of autoinfection.

**Whipworm (Trichuris trichiura)**

Infections with whipworm are common worldwide, especially in poor communities with inadequate sanitation. Adult worms, which are 3–5 cm long, inhabit the terminal ileum and caecum, although in heavy infection they are found throughout the large bowel. The head of the worm is embedded in the intestinal mucosa. Ova are deposited in the faeces and require a maturation period of 3–4 weeks in the soil before becoming infective.

Infection is usually asymptomatic, but mucosal damage can occasionally be so severe that there is colonic ulceration, dysentery, or rectal prolapse.

Diagnosis is made by finding ova on stool microscopy, or occasionally by seeing adult worms on sigmoidoscopy. Drug treatment is shown in Box 20.68.

**Hookworm**

Hookworm infections, caused by the human hookworms *Ancylostoma duodenale* and *Necator americanus*, are found worldwide. They are relatively rare in developed countries but very common in areas with poor sanitation and hygiene; overall, about 25% of the world’s population is affected. Hookworm infection is a major contributing factor to anaemia in the tropics. *A. duodenale* is found mainly in East Asia, North Africa and the Mediterranean, while *N. americanus* is the predominant species in South and Central America, South-east Asia and sub-Saharan Africa.

Adult worms (which are about 1 cm long) live in the duodenum and upper jejunum, where they are often found in large numbers. They attach firmly to the mucosa using the buccal plate, feeding on blood. Eggs passed in the faeces develop in warm, moist soil, producing infective filariform larvae. These penetrate directly through the skin of a new host and are carried in the bloodstream to the lungs. Having crossed into the alveoli, the parasites are expectorated and then swallowed, thus arriving at their definitive home.

**Clinical features**

Local irritation as the larvae penetrate the skin (‘ground itch’) may be followed by transient pulmonary signs and symptoms, often accompanied by eosinophilia. Light infections, especially in a well-nourished person, are often asymptomatic. Heavier worm loads may be associated with epigastric pain and nausea, resembling peptic ulcer disease. Chronic heavy infection, particularly on a background of malnutrition, may cause iron deficiency anaemia and hypoproteinaemia. Heavy infection in children is associated with delays in physical and mental development.

**Diagnosis and management**

The diagnosis is made by finding eggs on faecal microscopy. In infections heavy enough to cause anaemia, these will be present in large numbers. The aim of treatment in endemic areas is reduction of worm burden rather than complete eradication; albendazole given as a single dose is the best drug (see Box 20.68).

**Strongyloidiasis**

*Strongyloides stercoralis* is a small (2 mm long) worm that lives in the small intestine. It is found in many parts of the tropics and sub-tropics, and is especially common in Asia. Eggs hatch in the bowel, and larvae are found in the stool. Usually, these are non-infective rhabditiform larvae, which require a further period of maturation in the soil before they can infect a new host, but sometimes this maturation can occur in the large bowel. Infective filariform larvae can therefore penetrate directly through the perianal skin, re-infecting the host. In this way, autoinfection may continue for years or even decades. Some war veterans who were imprisoned in the Far East during the Second World War were found to have active strongyloidiasis over 50 years later. After skin penetration, the life cycle is similar to that of the hookworm, except that the adult worms may burrow into the intestinal mucosa, causing a local inflammatory response.

**Clinical features**

Following skin penetration, *S. stercoralis* causes a similar local dermatitis to hookworm. In autoinfection, this manifests as a migratory linear weal around the buttocks and lower abdomen (*cutaneous larva currens*). In heavy infections, damage to the small intestinal mucosa can cause malabsorption, diarrhoea and even perforation. There is usually a persistent eosinophilia.

In patients who are immunosuppressed (e.g. by corticosteroid therapy or intercurrent illness), filariform larvae may penetrate directly through the bowel wall in huge numbers, causing an overwhelming and usually fatal generalized infection (the strongyloidiasis hyperinfection syndrome). This condition is often complicated by Gram-negative bacteraemia due to bowel organisms.

**Diagnosis and management**

Motile larvae may be seen on stool microscopy, especially after a period of incubation. Serological tests are also useful. The best drug for treating strongyloidiasis is ivermectin (200 μg/kg daily for 2 days); albendazole and thiabendazole are also effective. In hyperinfection, antibiotics against Gram-negative organisms should be given.
Zoonotic nematodes

A number of nematodes that are principally parasites of animals may also affect humans. The most common are described here.

Trichinosis

The normal hosts of *Trichinella spiralis*, the cause of trichinosis, include pigs, bears and warthogs. Humans are infected by eating undercooked meat from these animals. Ingested larvae mature in the small intestine, where adults release new larvae that penetrate the bowel wall and migrate through the tissues. Eventually, these larvae encyst in striated muscle.

Light infections are usually asymptomatic. Heavier loads of worms produce gastrointestinal symptoms as the adults establish themselves in the small intestine, followed by systemic symptoms as the larvae invade. The latter include fever, oedema and myalgia. Massive infection may occasionally be fatal but usually the symptoms subside once the larvae encyst.

The diagnosis can usually be made from the clinical picture, associated eosinophilia and serological tests. If necessary, it can be confirmed by muscle biopsy a few weeks after infection. Longstanding infection may be revealed by the presence of numerous calcified cysts on X-ray. Albendazole (20 mg/kg for 7 days), given early in the course of the illness, will kill the adult worms and decrease the load of larvae reaching the tissues. Analgesia and steroids may be needed for symptomatic relief.

Toxocariasis (visceral larva migrans)

Eggs of the dog roundworm, *Toxocara canis*, are occasionally ingested by humans, especially children. The eggs hatch and the larvae penetrate the small intestinal wall and enter the mesenteric circulation, but are then unable to complete their life cycle in a ‘foreign’ host. Many are held up in the capillaries of the liver, where they generate a granulomatous response, but some may migrate into other tissues, including lungs, striated muscle, heart, brain and eye. In most cases, infection is asymptomatic and the larvae die without causing serious problems. In heavy infections, there may be generalized symptoms (fever and urticaria) and eosinophilia, as well as focal signs related to the migration of the parasites. Pulmonary involvement may cause bronchospasm and chest X-ray changes. Ocular infection may produce a granulomatous swelling mimicking a retinoblastoma, while cardiac or neurological involvement is occasionally fatal. Rarely, larvae survive in the tissues for many years, causing symptoms long after infection.

Isolation of the larvae is difficult and the diagnosis is usually made serologically. Albendazole 400 mg daily (5–10 mg/kg in children) for a week is the most effective treatment.

Cutaneous larva migrans

Cutaneous larva migrans is caused by the larvae of the non-human hookworms, *Ancylostoma braziliense* and *A. caninum*. Like human hookworms, these hatch in warm, moist soil and then penetrate the skin. In humans, they are unable to complete a normal life cycle and instead migrate under the skin for days or weeks until they eventually die. The wandering of the larva is accompanied by a clearly defined, serpiginous, itchy rash, which progresses at the rate of about 1 cm per day. There are usually no systemic symptoms. The diagnosis is purely clinical. Single larvae may be treated with a 15% solution of topical tiabendazole; multiple lesions require systemic therapy with a single dose of albendazole 400 mg or ivermectin 150–200 μg/kg.

Trematodes (flukes) are flat, leaf-shaped worms. They have complex life cycles, often involving freshwater snails and intermediate mammalian hosts. Disease is caused by the inflammatory response to eggs or to the adult worms.

Water-borne flukes

Schistosomiasis

Schistosomiasis affects over 200 million people in the tropics and subtropics, mostly in sub-Saharan Africa. Chronic infection causes significant morbidity and, after malaria, it has the greatest socioeconomic impact of any parasitic disease. Schistosomiasis is largely a disease of the rural poor but has also been associated with major development projects, such as dams and irrigation schemes.

Parasitology and pathogenesis

There are three species of schistosome that commonly cause disease in humans: *Schistosoma mansoni*, *S. haematobium* and *S. japonicum*. *S. mekongi* and *S. intercalatum* also affect humans but have a very restricted distribution (Fig. 20.34). Eggs are passed in the urine or faeces of an infected person and hatch in freshwater to release the miracidia. These ciliated organisms penetrate the tissue of the intermediate host, a species of water snail specific to each species of schistosome. After multiplying in the snail, large numbers of fork-tailed cercariae are released back into the water, where they can survive for 2–3 days. During this time the cercariae can penetrate the skin or mucous membranes of the definitive host, humans. Transforming into schistosomulae, they pass through the lungs before reaching the portal vein, where they mature into adult worms (the male is about 20 mm long and the female a little larger). Worms pair in the portal vein before migrating to their final destination: mesenteric veins in the case of *S. mansoni* and *S. japonicum*, and the vesicular plexus for *S. haematobium*. Here they may remain for many years, producing vast numbers of eggs. The majority of these are released in urine or faeces, but a small number become embedded in the bladder or bowel wall and a few are carried in the circulation to the liver or other distant sites.

The pathology of schistosome infection varies with species and stage of infection. In the early stages, there may be local and systemic allergic reactions to the migrating parasites. As eggs start to be deposited, there is a local inflammatory response in the bowel or bladder, while ectopic eggs may produce granulomatous lesions anywhere in the body. Chronic heavy infection, in which large numbers of eggs accumulate in the tissues, leads to fibrosis, calcification and, in some cases, dysplasia and malignant change. Morbidity and mortality are related to duration of infection and worm load, as well as to the species of parasite. Children in endemic areas tend to have the heaviest worm load because of both increased exposure to infection and differences in the immune response between adults and children.

Clinical features

Cercarial penetration of the skin may cause local dermatitis (‘swimmer’s itch’). After a symptom-free period of 3–4 weeks, systemic allergic features may develop, including fever, rash, myalgia and pneumonitis (Katayama fever). These allergic phenomena are common in non-immune travellers but are rarely seen in local populations, who are usually exposed to infection from early childhood
onwards. If infection is sufficiently heavy, symptoms from egg deposition may start to appear 2–3 months after infection.

**S. haematobium infection (bilharzia)**

The earliest symptom is usually painless terminal haematuria. As bladder inflammation progresses, there is increased urinary frequency and groin pain. Obstructive uropathy develops, leading to hydrenephrosis, chronic kidney disease and recurrent urinary infection. There is a strong association between chronic urinary schistosomiasis and squamous cell bladder carcinoma. The genitalia may also be affected and ectopic eggs may cause pulmonary or neurological disease.

**S. mansoni**

This usually affects the large bowel. Early disease produces superficial mucosal changes, accompanied by blood-stained diarrhoea. Later, the mucosal damage becomes more marked, with the formation of rectal polyps, deeper ulceration and, eventually, fibrosis and stricture formation. Ectopic eggs are carried to the liver, where they cause an intense granulomatous response. Hepatitis is followed by progressive periportal fibrosis, leading to portal hypertension, oesophageal varices and splenomegaly (see p. 1306). Hepatocellular function is usually well preserved.

**S. japonicum**

Unlike the other species, *S. japonicum* infects numerous other mammals apart from humans. It is similar to *S. mansoni* but infects both large and small bowel and produces a greater number of eggs. Disease therefore tends to be more severe and rapidly progressive. Hepatic involvement is more common and neurological involvement is seen in about 5% of cases.

**Diagnosis**

Schistosomiasis is suggested by relevant symptoms following freshwater exposure in an endemic area. In the early allergic stages the diagnosis can only be made clinically. When egg deposition has started, the characteristic eggs (with a terminal spine in the case of *S. haematobium* and a lateral spine in the other species) can be detected on microscopy. In *S. haematobium* infection the best specimen for examination is a filtered midday urine sample; parasites may also be found in semen. *S. mansoni* and *S. japonicum* eggs can usually be found in faeces or in a rectal snip. Serological tests are available and may be useful in the diagnosis of travellers returning from endemic areas, although the test may not become positive for 12 weeks after infection; a direct parasitological diagnosis should always be made if possible. In chronic disease X-rays, ultrasound examinations and endoscopy may show abnormalities of the bowel or urinary tract, although these are non-specific. Liver biopsy may show the characteristic periportal fibrosis.

**Management**

The aim of treatment in endemic areas is to decrease the worm load and therefore minimize the chronic effects of egg deposition. It may not always be possible (or even desirable) to eradicate adult worms completely, and re-infection is common. However, a 90% reduction in egg output has been achieved in mass treatment programmes, and in light infections, where there is no risk of re-exposure, the drugs are usually curative. The most widely used is praziquantel (*Box 20.69*), which is effective against all species of schistosome, well tolerated and reasonably cheap. Nearly 90 million people in sub-Saharan Africa received praziquantel through coordinated treatment programmes in 2016.
Prevention of schistosomiasis is difficult and relies on a combination of approaches. Mass treatment of the population (especially children) will decrease the egg load in the community. Health education programmes, the provision of latrines and access to a safe water supply should decrease contact with infected water. Attempts to eradicate the snail host have generally been unsuccessful, although man-made bodies of water can often be made less ‘snail-friendly’. Travellers should be advised to avoid potentially infected water.

### Food-borne flukes

Many flukes infect humans via ingestion of an intermediate host, often freshwater fish or crustaceans.

#### Paragonimiasis

Over 20 million people are infected with lung flukes of the genus *Paragonimus*. It is common throughout South and East Asia, and is also found in parts of Africa and Latin America. *Paragonimus* spp. are principally parasites of a variety of mammals that feed on crustacea, and humans can become infected through eating uncooked or poorly prepared shellfish. The adult worms (of which the major species is *P. westermani*) live in the lungs, producing eggs that are either expectorated, or swallowed and passed in the faeces. Miracidia emerging from the eggs penetrate the first intermediate host, a freshwater snail. Larvae released from the snail seek out the second intermediate host, freshwater crustacea, in which they encyst as metacercariae. After consumption by mammalian hosts, cercariae penetrate the small intestinal wall and migrate directly from the peritoneum to the lungs across the diaphragm. Having established themselves in the lung, the adult worms may survive for 20 years.

The common clinical features are fever, cough and mild haemoptysis. In heavy infections the disease may progress, sometimes mimicking pneumonia or pulmonary tuberculosis. Ectopic worms may cause signs in the abdomen or the brain.

The diagnosis is made by detection of ova on sputum or stool microscopy. Radiological appearances are variable and non-specific. Treatment is with praziquantel or triclabendazole: the latter, which has a simpler regimen and is supplied free through the WHO, is generally preferred. Prevention involves avoidance of inadequately cooked shellfish.

#### Liver flukes

Humans can become infected with a variety of liver flukes. Terminology is confused; three parasite species, *Clonorchis sinensis*, *Opisthorchis felineus* and *O. viverrini*, are commonly referred to as the human liver flukes, although feline and other mammals are the principal hosts. *C. sinensis* and *O. viverrini* are almost entirely confined to East and South-east Asia, while the distribution of *O. felineus* extends across Central Asia as far as Eastern Europe. Adult worms live in the bile ducts, releasing eggs into the faeces. The parasite requires two intermediate hosts, a freshwater snail and a fish, and humans are infected by consumption of raw fish. The cycle is completed when excysted worms migrate from the small intestine into the bile ducts.

Infestation is often asymptomatic but may be associated with cholangitis and biliary carcinoma. The diagnosis is made by identifying eggs on stool microscopy. Treatment is with praziquantel, and infection can be avoided by preparing and cooking fish adequately.

#### Other food-borne flukes

Humans can also be infected with a variety of other animal flukes: notably, the liver fluke, *Fasciola hepatica*, and the intestinal fluke, *Fasciolopsis buski*. Both require a water snail as an intermediate host; cercariae encyst on aquatic vegetation and then are consumed by animals or humans. After ingestion, *F. hepatica* penetrates the intestinal wall before migrating to the liver: during this stage, it causes systemic allergic symptoms. After reaching the bile ducts, it gives rise to similar problems to those caused by the other liver flukes. *F. buski* does not migrate after it excysts and causes mainly bowel symptoms.

#### Management of trematode infections

For drug treatment, see Box 20.69.

### CESTODES

Cestodes (tapeworms) are ribbon-shaped worms, which vary from a few millimetres to several metres in length. Adult worms live in the human intestine, where they attach to the epithelium using suckers on the anterior portion (scolex). From the scolex arises a series of progressively developing segments, called proglottids. The mature distal segments contain eggs, which either may be released directly into the faeces, or are carried out with an intact detached proglottid. The eggs are consumed by intermediate hosts, after which they hatch into larvae (oncospheres). These penetrate the intestinal wall of the host (pigs, cattle or other animals) and encyst in the tissues. Humans ingest the cysts in undercooked meat and the cycle is completed when the parasites excyst in the stomach and develop into adult worms in the small intestine. Infections are usually solitary but several adult tapeworms may coexist. The exceptions to this life cycle are the dwarf tapeworm, *Hymenolepis nana*, which has no intermediate host and is transmitted from person to person by the faeco-oral route; and *Taenia solium*, which can cause either normal tapeworm infection (when humans are the definitive host) or cysticercosis (when humans are the intermediate host).

#### Taenia saginata

*T. saginata*, the beef tapeworm, may reach a length of several metres. It is found in all countries where undercooked beef is eaten, although human infection can largely be eradicated by good abattoir hygiene and inspection regimes, and the main burden of disease falls on economically less developed countries. The adult worm causes few,
if any, symptoms, and is not a significant cause of chronic health problems. Infection is usually discovered when proglottids are found in faeces or on underclothing, often causing considerable anxiety. Ova may also be seen on stool microscopy. Infection can be cleared with a single dose of praziquantel (10 mg/kg).

**Taenia solium** and cysticercosis

*T. solium*, the pork tapeworm, is generally smaller than *T. saginata*, although it can still reach 6 metres in length. It is particularly common in South America, South Africa, China and parts of South-east Asia. As with *T. saginata*, infection is usually asymptomatic. The ova of the two species are identical but the proglottids can be distinguished on inspection.

Pork tapeworm infection is acquired by eating uncooked pork. Treatment is with praziquantel or niclosamide. Drug treatment should not be accompanied by a purgative, as was previously believed.

Cysticercosis occurs when humans become the intermediate host of the parasite, and is caused by cysts rather than the adult worm. It follows the ingestion of eggs from contaminated food and water. Faeco-oral autoinfection can occur but is rare. Patients with tapeworms do not usually develop cysticercosis, and individuals with cysticercosis do not usually harbour tapeworms. Following the ingestion of eggs the larvae are liberated, penetrate the intestinal wall and are carried to various parts of the body, where they develop into cysticerci. These are cysts, 0.5–1 cm in diameter, containing the scolex of a new adult worm. Common sites for cysticerci include subcutaneous tissue, skeletal muscle and brain.

Superficial cysts may be felt under the skin but usually cause no significant symptoms. Cysts in the brain can give rise to a variety of problems, including epilepsy, personality change, hydrocephalus and focal neurological signs (see p. 872). These may only appear many years after infection.

Muscle cysts tend to calcify and are often visible on X-rays. Cutaneous cysts can be excised and examined. Brain cysts are less prone to calcification and are often seen only on CT or MRI scan. Serological tests may support the diagnosis.

**Management of cysticercosis**

Following years of controversy, recent studies suggest that anthelminthic drugs are of benefit in most cases of neurocysticercosis, although their role in other forms of cysticercosis remains unproven. Albendazole 15 mg/kg daily for 8–20 days is the drug of choice; the alternative is praziquantel 50 mg/kg daily (in divided doses) for 15 days.

Successful treatment is accompanied by increased local inflammation, and corticosteroids should be given during and after the course of anthelminthic. Prevention of cysticercosis depends mainly on good hygiene.

**Cerebral cysticercosis**

Anticonvulsants should be given for epilepsy, and surgery may be indicated if there is hydrocephalus (see p. 876).

**Diphyllobothrium latum**

Infection with the fish tapeworm, *D. latum*, is common in Northern Europe and Japan, owing to the consumption of raw fish. The adult worm reaches a length of several metres but, like the other tapeworms, usually causes no symptoms. A megaloblastic anaemia (due to competitive utilization of vitamin B₁₂ by the parasite) may occur. Diagnosis and treatment are the same as for *Taenia* species.

**Hydatid disease**

Hydatid disease occurs when humans become an intermediate host of the dog tapeworm, *Echinococcus granulosus*. The adult worm lives in the gut of domestic and wild canines and the larval stages are usually found in sheep, cattle and camels. Humans may become infected either from direct contact with dogs, or from food or water contaminated with dog faeces. After ingestion, the parasites excyst, penetrate the small intestine wall, and are carried to the liver and other organs in the bloodstream. A slow-growing, thick-walled cyst is formed, inside which further larval stages of the parasite develop. The life cycle cannot be completed unless the cyst is eaten by a dog. Hydatid disease is prevalent in areas where dogs are used in the control of livestock, especially sheep. It is common in Argentina, Peru, Central Asia, China and parts of East Africa, and about 1 million people are infected worldwide.

Symptoms depend mainly on the site of the cyst. The liver is the most common organ affected (60%), followed by the lung (20%), kidneys (3%), brain (1%) and bone (1%). The symptoms are those of a slowly growing benign tumour. Pressure on the bile ducts may cause jaundice. Rupture into the abdominal cavity, pleural cavity or biliary tree may occur. A cyst rupturing into a bronchus may result in its expectoration and spontaneous cure, but if secondary infection supervenes, a chronic pulmonary abscess will form. Focal seizures can occur if cysts are present in the brain. Renal involvement produces lumbar pain and haematuria. Calcification of the cyst occurs in about 40% of cases. The diagnosis and treatment of hydatid liver disease are described on page 1307.

A related parasite of foxes, *E. multilocularis*, causes a similar but more severe infection, alveolar hydatid disease. These cysts are invasive and metastases may occur; if untreated, the disease is usually fatal. Treatment requires radical surgery as well as anthelmintic treatment.

**Further reading**

**ARTHROPOD ECTOPARASITES**

Arthropods, which include the arachnid ticks and mites as well as insects, may be responsible for human disease in several ways.

**LOCAL HYPERSENSITIVITY REACTIONS**

Local lesions may be caused by hypersensitivity to allergens in arthropod saliva. This common reaction, known as papular urticaria, is non-specific and is seen in the majority of people in response to the bite of a variety of blood-sucking arthropods, including mosquitoes, bugs, ticks, lice and mites (Fig. 20.35). Occasionally, tick bites may cause a more severe systemic allergic response, especially in previously sensitized individuals. The saliva of some tick species contains a neurotoxin, which causes flaccid paralysis in the victim following a bite; this condition is rare but occurs worldwide, most commonly in children.
RESIDENT ECTOPARASITE INFECTIONS

Most ectoparasites alight on humans only to feed (although some species of lice live in very close proximity to the skin: body lice in clothing, and head and pubic lice on human hairs, see p. 675). However some types of parasite are actually resident within the skin, causing more specific local lesions.

**Scabies**  
See page 674.

**Jiggers**  
Jiggers is due to infection with the jigger flea, *Tunga penetrans*, and is common throughout South America and Africa. The pregnant female flea burrows into the sole of the foot, often between the toes. The egg sac grows to about 0.5 cm in size, before the eggs are discharged onto the ground. The main danger is bacterial infection or tetanus. The flea should be removed with a needle or scalpel and the area kept clean until it heals.

**Myiasis**  
Myiasis is caused by invasion of human tissue by the larva of certain flies, principally the Tumbu fly, *Cordylobia anthropophaga* (found in sub-Saharan Africa) and the human botfly, *Dermatobia hominis* (Central and South America). The larvae, which hatch from eggs laid on laundry and linen, burrow into the skin to form boil-like lesions; a central breathing orifice may be visible. Again, the main risk is secondary infection. It is not always easy to extract the larva; covering it with petroleum jelly may bring it up in search of air.

SYSTEMIC ENVENOMING

Many arthropods can cause local or systemic illness through envenoming: that is, injection of venom. A detailed discussion of spider, scorpion and other bites is beyond the scope of this chapter (see Further reading and online topics).

VECTORS OF INFECTION

By far the most important role of arthropods in causing human disease is as vectors of parasitic and viral infections. Some of these infections are shown in Box 20.17 and discussed in detail elsewhere.

CORE SKILLS AND KNOWLEDGE

Many endocrine conditions are common and seen outside the hospital setting. They often affect young people and can usually be cured or completely controlled with appropriate therapy. For example, the UK prevalence of hypothyroidism is 2%, and it is usually managed in primary care. Excluding obesity (Ch. 33) and diabetes mellitus (Ch. 23), the commonest endocrine disorders are thyroid disorders; menstrual disorders; disorders affecting reproduction; hyperparathyroidism; and increasingly incidental findings in endocrine organs found on scans being done for other reasons – termed ‘incidentalomas’.

Most endocrinologists specialize in both diabetes and endocrinology, seeing patients in outpatient clinics and often looking after general medical inpatients. Joint clinics that include specialist endocrine surgeons, endocrine oncologists, obstetricians, gynaecologists and paediatricians combine the expertise patients require in one clinical environment. Specialist nurses oversee dynamic testing of endocrine function, and coordinate education and management of patients with endocrine conditions.

Key skills required in endocrinology include:

- Mastering key principles of hormone action (such as negative feedback) in order to distinguish primary from secondary gland failure.
- Understanding the concept of dynamic endocrine tests and interpreting their results.
- Becoming familiar with the hormones most commonly used in endocrine replacement including levothyroxine, hydrocortisone and testosterone (in men) and oestrogen/progesterone (in women).

The best way to learn about endocrinology is to attend specialist and general outpatient clinics, where patients presenting with endocrine syndromes are evaluated and complex dynamic tests are planned and interpreted. Attend specialist multidisciplinary team meetings (MDTs) to learn about the radiology, histology and different management approaches to endocrine disease.
Specific features of the history relevant in endocrine disease are described in Box 21.1. On examination, weight, height, body mass index (BMI), blood pressure and general habitus should be documented, together with the presence or absence of specific signs of deficiency or excess of individual hormone axes indicated in the diagram opposite. Emergency presentations are listed in Box 21.2. In addition:

- In people with suspected pituitary disease, visual fields and adjacent cranial nerves should be assessed.
- In thyroid disease, the presence of goitre or orbitopathy should be documented.
- In hypogonadism both sexes require assessment of other secondary sexual characteristics, and testicular volumes in males should be documented as well as presence or absence of gynaecomastia.

### Dynamic endocrine tests

Because of intra-individual and diurnal variations in the levels of many clinically relevant hormones, a single blood test often does not provide the information necessary to make a diagnosis (see p. 590). Dynamic endocrine tests assess the response of an endocrine axis to a specific challenge and are performed according to detailed protocols, which must be followed precisely. There are two types of dynamic tests – stimulation and suppression tests (Box 21.3).
Clinical skills for endocrinology

**Facial features**
- Hypothyroid
  - coarse features
  - 'peaches and cream' complexion
  - puffy eyes
  - dry skin
- Hyperthyroid
  - eye problems

**Eyes**
- Signs of Graves’ orbitopathy - proptosis, erythema, swelling
- Diplopia
- Visual fields defects
- Ophthalmoscopy
  - Papilloedema
  - Pale optic discs

**Breasts**
- Gynaecomastia
- Galactorrhoea

**Pulse**
- Atrial fibrillation

**Hands**
- Sweating, tremor, palmar erythema
- Carpal tunnel
- Large, spade-like hands (acromegaly)
- Pigmentation of creases (Addison’s)

**Blood pressure**
- ↑ Cushing’s
  - Conn’s
  - Phaeochromocytoma
  - Hypertension
  - Acromegaly
  - Thyroid disease
- ↓ Adrenal insufficiency

**Central**
- Obesity
- Striae (Cushing’s)

**Genitalia**
- Testicular volume
- Pubertal development
- Virilization

**Hair**
- Alopecia
- Coarse hair
- Frontal balding

**General**
- Look for features of:
  - Hypothyroidism
  - Hyperthyroid
  - Acromegaly
  - Mood
    - depressed/lethargic
    - restlessness
    - memory
- Voice – hoarse
- Weight – loss or gain
- Sweating
- Hirsutism

**Exophthalmos**

**Breasts**
- Gynaecomastia
- Galactorrhoea

**Pulse**
- Atrial fibrillation

**Hands**
- Sweating, tremor, palmar erythema
- Carpal tunnel
- Large, spade-like hands (acromegaly)
- Pigmentation of creases (Addison’s)

**Acromegaly**
- Proximal myopathy
- Pretibial myxoedema

(From Rojanametin K, Masaru T. J Am Coll Dermatol 2015; 73:e195-e196, with permission)
INTRODUCTION

The endocrine system consists of glands that exert their actions at distant parts of the body via the production of biologically active hormones secreted into the bloodstream. Unlike the neurological system, which produces an immediate response, the endocrine system typically has a slower and longer-lasting effect on the body. The main endocrine glands are the pituitary, thyroid, adrenals, gonads, parathyroids and pancreas, and the common endocrine problems seen in clinical practice are shown in Fig. 21.1. The pituitary gland, a pea-sized structure situated at the base of the brain, plays a key role in the control and feedback mechanisms of the endocrine system and has been termed the ‘conductor of the endocrine orchestra’.

Hormonal activity

Synthesis, storage and release of hormones

Hormones have several chemical structures: polypeptide, glycoprotein, steroid or amine. Hormone release is the end-product of a cascade of intracellular events. In the case of polypeptide hormones, neural or endocrine stimulation of the cell causes increased transcription from DNA to a specific messenger RNA (mRNA), which is, in turn, translated to the peptide product. This is often a precursor molecule that may itself be biologically inactive. This ‘prohormone’ is further processed before being packaged into granules, in the Golgi apparatus. These granules are transported to the plasma membrane before release, which is itself regulated by a complex combination of intracellular regulators. Hormone release may be in a brief spurt caused by the sudden stimulation of granules, often induced by an intracellular Ca\(^{2+}\)-dependent process, or ‘constitutive’ (immediate and continuous secretion).

Plasma transport

Most classical hormones are secreted into the systemic circulation. In contrast, hypothalamic releasing hormones are released into the pituitary portal system so that higher concentrations of the releasing hormones reach the pituitary than occur in the systemic circulation.

Many hormones are bound to proteins within the circulation. In most cases, only the free (unbound) hormone is available and thus biologically active. This binding serves to buffer against rapid changes in plasma levels of the hormone, and some binding protein interactions are also involved in the active regulation of hormone action. Many tests of endocrine function measure total rather than free hormone, which can give rise to difficulties in interpretation when binding proteins are altered in disease states or by drugs.

Binding proteins comprise both specific, high-affinity proteins of limited capacity, such as thyroxine-binding globulin (TBG), cortisol-binding globulin (CBG), sex-hormone-binding globulin (SHBG) and insulin-like growth factor (IGF)-binding proteins (e.g. IGF-BP3), and other less specific, low-affinity ones, such as prealbumin and albumin.

Hormone action and receptors

Hormones act by binding to specific receptors in the target cell. Most hormone receptors are proteins with complex tertiary structures. The structure of the hormone-binding domain of the receptor complements the tertiary structure of the hormone, while changes in other parts of the receptor in response to hormone binding are responsible for the effects of the activated receptor within the cell. The structure of common hormones and their receptors is described under individual hormone axes.

Fig. 21.1 The major endocrine organs and common endocrine problems.
Hormone receptors are broadly divided into:

- **cell surface or membrane receptors**: transmembrane receptors that contain hydrophobic sections spanning the lipid-rich plasma membrane and trigger internal cellular messengers
- **nuclear receptors**: bind hormones and translocate them to the nucleus, where they bind hormone response elements of nuclear DNA via characteristic amino-acid sequences (e.g. so-called ‘zinc fingers’). Abnormal receptors are an occasional cause of endocrine disease.

**Mechanisms of hormone–receptor action**

Common structural mechanisms of hormone–receptor action include:

- **G-protein coupled receptors (7-transmembrane or serpentine receptors)**. These bind hormones on their extracellular domain and activate the membrane G-protein complex with their intracellular domain. The activated complex may then:
  - stimulate cyclic AMP (cAMP) generation by adenylate cyclase – activating further intracellular kinases and leading to phosphorylation
  - activate phospholipase C (PLC), leading to generation of inositol 1,4,5-triphosphate (IP₃) and release of intracellular calcium – in turn, leading to calmodulin-dependent kinase activity and phosphorylation
  - lead to diacylglycerol (DAG) activation of C-kinase and subsequent protein phosphorylation.

Most peptide hormones act via G-protein coupled receptors.

- **Dimeric transmembrane receptors**. These receptors, from several receptor superfamilies, bind hormone in their extracellular components (sometimes causing dimerization of the receptor monomer) and directly phosphorylate intracellular messengers via intracellular components, leading to a variety of intracellular activation cascades. Growth hormone, prolactin and IGF-1 act via this type of receptor.

- **Lipid-soluble molecules.** These pass through the cell membrane and bind with their **nuclear receptors** in the cell cytoplasm before translocation of the activated hormone–receptor complex to the nucleus; here, it binds to nuclear DNA, often in combination with a multi-component complex of promoters, inhibitors and transcription factors. This interaction leads to increased transcription of the relevant gene product. Steroid and thyroid hormones act via this type of receptor.

**Hormone release and binding to receptors**

The activation of intracellular kinases, phosphorylation, release of intracellular calcium and other ’second messenger’ pathways, and the direct stimulation of DNA transcription may result in the following:

- stimulation/release of pre-formed hormone from storage granules
- stimulation/synthesis of hormone and other cellular components
- opening/closing of ion or water channels in the cell membrane (e.g. calcium channels or aquaporin water channels)
- activation/deactivation of other DNA binding proteins, leading to stimulation or inhibition of DNA transcription.

In each case, binding of the hormone to its receptor is the first step in a cascade of intracellular events, which eventually lead to the overall effects of that hormone on cellular function.

**The sensitivity and/or number of receptors** for a hormone are often decreased after prolonged exposure to a high hormone concentration, the receptors thus becoming less sensitive (‘down-regulation’, e.g. angiotensin II receptors, β-adrenoceptors). The reverse is true when stimulation is absent or minimal, the receptors showing increased numbers or sensitivity (‘upregulation’).

**Control and feedback**

Most hormone systems are under tight regulatory control (typically by the hypothalamic–pituitary (HP) axis) by a system known as negative feedback. An example of the negative feedback system in the hypothalamic–pituitary–thyroid axis is demonstrated in **Fig. 21.2** and described here:

- Thyrotrophin-releasing hormone (TRH) is secreted in response to hypothalamic thyrotrophin-releasing hormone (TRH) and stimulates secretion of T₃ and T₄ from the thyroid. T₃ and T₄ have actions in peripheral tissues and exert negative feedback on the pituitary and hypothalamus.

**Fig. 21.2** The hypothalamic–pituitary–thyroid axis. Pituitary thyroid-stimulating hormone (TSH) is secreted in response to hypothalamic thyrotrophin-releasing hormone (TRH) and stimulates secretion of T₃ and T₄ from the thyroid. T₃ and T₄ have actions in peripheral tissues and exert negative feedback on the pituitary and hypothalamus.
Endocrinology

- If $T_3$ and $T_4$ levels are low – for example, after thyroidectomy, increased amounts of TRH and TSH are secreted, stimulating the remaining thyroid to produce more $T_3$ and $T_4$; blood levels of $T_3$ and $T_4$ may be restored to normal, at the expense of increased TSH drive, reflected by a high TSH level: ‘compensated euthyroidism’.
- Conversely, in thyrotoxicosis, when factors other than TSH itself are maintaining high $T_3$ and $T_4$ levels, the same mechanisms lead to suppression of TSH secretion.

Primary and secondary gland failure

It is useful in clinical endocrinology to distinguish between ‘primary’ disease of the end-organ gland (e.g. that due to autoimmune destruction, atrophic change, infiltration or surgical removal of the gland) and ‘secondary’ disorders of the same axis, caused by disease of the pituitary gland. An understanding of the negative feedback system is key to interpreting endocrine blood results and diagnosing the site of the disease process in clinical practice. In general terms:
- ‘Primary’ gland failure due to a disease process in the endocrine end-organ (thyroid, adrenal or gonad) will lead to deficiency of the hormone produced by that gland and a loss of negative feedback and subsequent elevation in the corresponding anterior pituitary hormone.
- In ‘secondary gland failure’, there are low or ‘inappropriately normal’ levels of the pituitary trophic hormone in the face of a low end-organ hormone level. For example, if a patient has low circulating free $T_3$ ($fT_3$) and $T_4$ levels in the context of a low TSH, pituitary disease should be suspected.

Hormone excess

Abnormal hormone excess due to a disease process in the primary endocrine gland, or excess amount of exogenous hormone, will lead to increased negative feedback and suppression of the corresponding pituitary hormones. For example, in autoimmune hyperthyroidism, free $T_3$ and $T_4$ levels are elevated in the context of a suppressed TSH. Equally, the presence of a non-suppressed plasma pituitary hormone in the context of excess primary hormone implies that the pituitary, rather than the primary gland itself, is the cause. For example, in pituitary-driven Cushing’s disease, cortisol levels are elevated but ACTH is not suppressed.

Hormone resistance

In certain situations, receptor abnormalities can give rise to abnormal negative feedback due to hormone resistance, which can lead to an unusual pattern of blood results. For example, thyroid hormone resistance, due to mutations in the thyroid hormone receptor, is characterized by an elevation in thyroid hormones with a non-suppressed TSH. With this pattern of thyroid results, the clinician should also consider the rare diagnosis of a TSH-secreting pituitary tumour, as well as the possibility of assay issues.

Measurement of hormones

Hormones are routinely measured by biochemical assays in the laboratory. It is possible to measure pituitary trophic hormones and the hormones produced by the end-organ glands, but hypothalamic hormones are not measured in practice because of their low concentration and local action within the HP axis. Circulating levels of most hormones are very low ($10^{-6}$–$10^{-12}$ mol/L) and cannot be measured by simple chemical techniques. Hormones are therefore usually measured by immunoassays, which rely on highly specific polyclonal or monoclonal antibodies, which bind to the hormone being measured. This hormone–antibody interaction is measured by use of labelled hormone after separation of bound and free fractions (Fig. 21.3).

Immunoassays are sensitive but have limitations. In particular, the immunological activity of a hormone, as used in developing the antibody, may not necessarily correspond to biological activity and there may be false-positive and negative results. The patient’s blood may also contain heterophile antibodies, which interact with the animal antibodies used in the assay and produce falsely low or high values. When there is a discrepancy between endocrine blood results and the clinical presentation, the clinician must question the validity of an endocrine result, and liaise with chemical pathology. It may be necessary for the sample to be measured in a different laboratory using an alternative antibody, or to measure hormones in ways other than immunoassay. Examples of alternative techniques include equilibrium dialysis, high-pressure liquid chromatography (HPLC) and mass spectroscopy.

Hormone-binding proteins

Many hormones are transported in the bloodstream by a specific binding protein (see p. 586). It is more helpful to measure the free hormone rather than total bound hormone level, as this is the part that is biologically active. Some modern assays attempt to measure the free hormone level directly (e.g. free $T_3$) and are a more accurate reflection of biological activity, although many assays still measure total hormone level.

Cortisol, which is bound to cortisol-binding globulin (CBG), and testosterone, which is bound to sex-hormone-binding globulin (SHBG), are still usually measured in their total form and can be affected by alterations in binding protein levels. In women who are pregnant or on the combined oral contraceptive pill, high oestrogen levels may lead to an elevation in CBG, which can overestimate cortisol and give the false impression of
Clinical syndrome

Testis

Gastric parietal is the normal pattern for the gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), with major pulses released every 1–2 hours, depending on the phase of the menstrual cycle. Growth hormone (GH) is also secreted in a pulsatile fashion, with undetectable levels in between pulses. A single measurement is therefore not helpful to diagnose GH deficiency or excess.

Patterns of hormonal secretion

Hormone secretion can be continuous or intermittent, for example:

- **Continuous secretion** is shown by the thyroid hormones, with a half-life of 7–10 days for T₄ and 6–10 hours for T₃, and with little variation in levels over the day, month and year.
- **Pulsatile secretion** is the normal pattern for the gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), with major pulses released every 1–2 hours, depending on the phase of the menstrual cycle. Growth hormone (GH) is also secreted in a pulsatile fashion, with undetectable levels in between pulses. A single measurement is therefore not helpful to diagnose GH deficiency or excess.

Biological rhythms

*Circadian* means changes over the 24 hours of the day–night cycle and is best shown for the pituitary–adrenal axis. Fig. 21.4 shows plasma cortisol measured over 24 hours; levels are highest in the early morning and lowest overnight. Additionally, cortisol release is pulsatile, following the pulsatility of pituitary ACTH. Thus, ‘normal’ cortisol levels vary during the day and great variations can be seen in samples taken only 30 minutes apart.

The menstrual cycle is an example of a longer and more complex (28-day) biological rhythm (see p. 1467).

Other regulatory factors

- **Stress.** Physiological ‘stress’ and acute illness produce rapid increases in ACTH and cortisol, GH, prolactin, adrenaline (epinephrine) and noradrenaline (norepinephrine). These can occur within seconds or minutes.
- **Sleep.** Secretion of GH and prolactin is increased during sleep, especially the rapid eye movement (REM) phase.
- **Feeding and fasting.** Many hormones regulate the body’s control of energy intake and expenditure, and are therefore influenced by feeding and fasting. Secretion of insulin increases, while testosterone and GH decrease after ingestion of food, and secretion of a number of hormones is altered during prolonged food deprivation.

### Aetiology and pathology

Aetiological mechanisms common to many endocrine disorders are described as follows.

#### Autoimmune disease

Organ-specific autoimmune diseases can affect every major endocrine organ (Box 21.4). They are characterized by the presence of

![Box 21.4 Types of autoimmune disease affecting endocrine organs](image-url)
specific antibodies in the serum, often present years before clinical symptoms are evident, usually more common in women and have a strong genetic component, often with an identical-twin concordance rate of 50% and with human leucocyte antigen (HLA) associations (see individual diseases).

**Endocrine tumours**

Most endocrine tumours are benign, although a cytological or histological diagnosis may be needed if there is suspicion of malignancy. Clinical presentation depends on whether the tumour is functional or non-functional, the latter presenting only as a mass clinically or on imaging. Palpable thyroid nodules are common, and mass effects are a frequent presentation of pituitary adenomas, but the increased use of high-resolution ultrasound and detailed cross-sectional imaging has revealed a very high prevalence of asymptomatic, incidentally discovered thyroid, adrenal and pituitary lesions, commonly termed ‘ incidentalomas’.

Functional tumours cause their effects via excess secretion of the relevant hormone. While often considered to be ‘autonomous’ – that is, independent of the physiological control mechanisms – many functional tumours do show evidence of feedback occurring at a higher ‘ set-point ’ than normal (e.g. adrenocorticotropic hormone (ACTH) secretion from a corticotroph adenoma). This is relevant in the dynamic assessment of endocrine diseases, such as in the differential diagnosis of Cushing’s syndrome.

Endocrine adenomas typically present in a single gland, although rarer multiple endocrine neoplasia (MEN) syndromes exist that are due to very specific mutations of a single gene, such as the mutations of the RET proto-oncogene in MEN 2 or the MEN1 gene mutation in MEN 1 (see p. 649). The diagnosis of some endocrine tumours, particularly at a young age, or the identification of a family history should prompt genetic screening.

**Enzyme defects**

The biosynthesis of most hormones involves many stages. Deficient or abnormal enzymes can lead to absent or reduced production of the secreted hormone. In general, severe deficiencies present early in life with obvious signs; partial deficiencies usually present later with mild signs or are only evident under stress. An example of an enzyme deficiency is congenital adrenal hyperplasia (CAH), whose molecular basis has also been identified as mutations or deletions of the gene encoding the relevant enzymes (see p. 604).

**Receptor abnormalities**

There are rare conditions in which hormone secretion and control are normal but the receptors are defective; thus, if androgen receptors are defective, normal levels of androgen will not produce masculinization (e.g. androgen insensitivity syndrome). There are also a number of rare syndromes of diabetes and insulin resistance from receptor abnormalities (see Box 23.4); other examples include nephrogenic diabetes insipidus, pseudohypoparathyroidism and thyroid hormone resistance.

**Endocrine investigations**

Endocrine function is assessed by measurement of hormone levels in blood (or, more precisely, in plasma or serum) and sometimes in other body fluids on samples obtained basally and in response to stimulation and suppression tests.

**Basal blood levels**

Assays for all clinically relevant pituitary and end-organ hormones are available.

The time, day and conditions of measurement make great differences to hormone levels, and the method and timing of samples therefore depend upon the characteristics of the endocrine system involved. There are also gender, pubertal and age differences.

Basal levels are especially useful for systems with long half-lives (e.g. T4 and T3, IGF-1, androstenedione, SHBG). These vary little over the short term and random samples are therefore satisfactory.

Basal samples for many hormones need to be interpreted with respect to normal ranges for the time of day/month, diet or posture concerned. Hormones with a marked circadian rhythm (e.g. testosterone and cortisol) must be measured at an appropriate time of day. Testosterone should be measured before 11am in the fasting state; cortisol should be checked between 8am and 10am to exclude hypoadrenalism, but at midnight to demonstrate normal low levels (to exclude Cushing’s). LH/FSH, oestrogen and progesterone vary with time of menstrual cycle, and renin/aldosterone may vary with sodium intake, posture and age. For these hormones, all relevant details must be recorded or the results may prove uninterpretable.

**Stress-related hormones**

Measurement of stress-related hormones may be problematic either because the patient is stressed by hospital attendance or venepuncture, leading to falsely high levels (e.g. catecholamines, prolactin; sampling via an indwelling needle may be required, some time after initial venepuncture), or because low levels in a non-stressed individual are unable to confirm an adequate reserve required for normal physiological stress (cortisol and GH).

**Urine collections**

Collections over 24 hours have the advantage of providing an ‘ integrated mean ’ of a day’s secretion but, in practice, are often incomplete or wrongly timed. They also vary with sex and body size or age. Written instructions should be provided for the patient to ensure accurate collection. Examples of hormones measured in this way are catecholamines and urinary free cortisol levels.

**Saliva**

Saliva is sometimes used for steroid estimations, especially in children or for samples taken at home. Midnight salivary cortisol levels are increasingly used for the diagnosis of Cushing’s syndrome due to the practical difficulties in obtaining a midnight blood sample.

**Stimulation and suppression tests**

These tests are used when basal levels give equivocal information. In general, stimulation tests are used to confirm suspected deficiency of hormone secretion, and suppression tests to confirm suspected excess (see Box 21.3). These tests are valuable in many instances. For example, where the secretory capacity of a gland is damaged, maximal stimulation by the trophic hormone will give a diminished output. Thus, in the short ACTH stimulation test for adrenal reserve (Box 21.5; Fig. 21.5A), the healthy subject shows a normal response while the subject with primary hypoadrenalism (Addison’s disease) demonstrates an impaired cortisol response to tetracosactide (an ACTH analogue).

A patient with a hormone-producing tumour usually fails to show normal negative feedback. A patient with Cushing’s disease (excess pituitary ACTH) will thus fail to suppress ACTH and cortisol production when given a dose of synthetic steroid, in contrast to normal subjects. Fig. 21.5B shows the response of a normal subject given dexamethasone 1 mg at midnight; cortisol is suppressed the following morning. The subject with Cushing’s disease shows inadequate suppression.
The detailed protocol for each test must be followed exactly, since differences in technique will produce variations in results.

**Box 21.5 Short ACTH (tetracosactide) stimulation test**

**Indications**
- Diagnosis of Addison's disease
- Screening test for ACTH deficiency

**Procedure**
- I.v. cannula for sampling
- Any time of day, but best at 09:00 hours; non-fasting and may indicate deficiency)

**Normal response**
- Tetracosactide 250 μg, i.v. or i.m. at time 0
- Measure serum cortisol at time 0 and time +30 min

30 min cortisol >600 nmol/L; (400–600 nmol/L borderline accuracy)

Precise cortisol normal ranges are variable between laboratories and assays; appropriate local reference ranges must be used.

**Fig. 21.5** Short ACTH stimulation and dexamethasone suppression tests. (A) The short ACTH stimulation test shows a normal response in a healthy subject and a decreased response in a patient with Addison's disease. (B) Dexamethasone suppression tests in a normal subject and in a patient with Cushing's disease, showing inadequate suppression.

endocrine tumours are common ('incidentalomas') and may have no clinical significance. Conversely, functional endocrine tumours may be too small to visualize on routine imaging. There is an increasing role for functional imaging e.g. positron emission tomography (PET) to detect endocrine tumours. Selective venous sampling is a useful interventional technique to localize hormone excess and is discussed in the relevant section.

**THE PITUITARY GLAND AND HYPOTHALAMUS**

**Anatomy**
Most peripheral hormone systems are controlled by the hypothalamus and pituitary. The hypothalamus is sited at the base of the brain around the third ventricle and above the pituitary stalk, which leads down to the pituitary itself, carrying the hypophyseal–pituitary portal blood supply.

The anatomical relations of the hypothalamus and pituitary (Fig. 21.6) include the optic chiasm above the pituitary fossa; any expanding lesion from the pituitary or hypothalamus can thus produce visual field defects by pressure on the chiasm. Such upward expansion of the gland through the diaphragma sellae is termed 'suprasellar extension'. Lateral extension of pituitary lesions may involve the vascular and nervous structures in the cavernous sinus and may rarely reach the temporal lobe of the brain. The pituitary is itself encased in a bony box; therefore, any lateral, anterior or posterior expansion must cause bony erosion.

Embryologically, the anterior pituitary is formed from an upgrowth of Rathke's pouch (ectoderm); this meets an outpouching of the third ventricular floor, which becomes the posterior pituitary. This combination of primitive gut and neural tissue provides an essential link between the rapidly responsive central nervous system and the longer-acting endocrine system. Several transcription factors – LHX3, HESX1, PROP1, POU1F1 – are responsible for the
Physiology

Hypothalamus

This contains many vital centres for such functions as appetite, thirst, thermal regulation and sleeping/waking. It acts as an integrator of many neural and endocrine inputs to control the release of pituitary hormone-releasing factors. It plays a role in circadian rhythm, menstrual cyclicity, and responses to stress, exercise and mood.

Hypothalamic neurones secrete pituitary hormone-releasing and inhibiting factors and hormones into the portal system; these run down the stalk to the pituitary. As well as the classical hormones (Fig. 21.7), the hypothalamus also contains large amounts of other neuropeptides and neurotransmitters such as neuropeptide Y, vasoactive intestinal peptide (VIP) and nitric oxide, which can also alter pituitary hormone secretion.

Synthetic hypothalamic hormones and their antagonists are available for the testing of many aspects of endocrine function and for treatment.

Anterior pituitary

The majority of anterior pituitary hormones are under predominantly positive control by the hypothalamic releasing hormones; the exception is prolactin, which is under tonic inhibition by dopamine. Pathological conditions interrupt the flow of hormones between the hypothalamus and pituitary gland, and therefore cause deficiency of most hormones but oversecretion of prolactin. There are five major anterior pituitary axes: the gonadotrophin axis, the growth axis, prolactin, the thyroid axis and the adrenal axis.

Posterior pituitary

The posterior pituitary is neuroanatomically connected to specific hypothalamic nuclei and acts merely as a storage organ. Antidiuretic hormone (ADH, also called vasopressin) and oxytocin, both nonapeptides, are synthesized in the supraoptic and paraventricular nuclei in the anterior hypothalamus. They are then transported along the axon and stored in the posterior pituitary (see Fig. 21.7). This means that damage to the stalk or pituitary alone does not prevent synthesis and release of ADH and oxytocin. ADH is discussed on pages 641–643; oxytocin produces milk ejection and uterine myometrial contraction.

Presentation of pituitary and hypothalamic disease

Diseases of the pituitary can cause under- or overactivity of each hypothalamic–pituitary–end-organ axis. The clinical features of the syndromes associated with such altered pituitary function, such as Cushing’s syndrome, can be the presenting symptom of pituitary disease or of end-organ disease and are discussed later. First, however, we look at the clinical features of pituitary disease that are common to all hormonal axes.

Pituitary space-occupying lesions and tumours

Pituitary tumours (Box 21.6) are the most common cause of pituitary disease, and the great majority are benign pituitary adenomas, usually monoclonal in origin. Problems are caused by:
- local effects of a tumour
- excess hormone secretion
- inadequate production of hormone by the remaining normal pituitary, i.e. hypopituitarism.
Approach for a possible or proven mass

**Is there a tumour?**

If there is, how big is it and what *local anatomical effects* is it exerting? Pituitary and hypothalamic space-occupying lesions, hormonally active or not, can cause symptoms by pressure on, or infiltration of:

- the visual pathways, with field defects and visual loss (most common)
- the cavernous sinus, with III, IV and VI cranial nerve lesions
- bony structures and the meninges surrounding the fossa, causing headache
- hypothalamic centres: altered appetite, obesity, thirst, somnolence/wakefulness or precocious puberty

- the ventricles, causing interruption of cerebrospinal fluid (CSF) flow and hydrocephalus
- the sphenoid sinus, causing CSF rhinorrhoea.

**Investigations**

- **MRI of the pituitary.** MRI is superior to CT (Fig. 21.8) and readily shows any significant pituitary mass. Small lesions within the pituitary fossa, ‘microadenomas’, are very common on MRI (10% of normal individuals in some studies). Such small lesions are sometimes detected during MRI of the head for other reasons – so-called ‘pituitary incidentalomas’.
- **Visual fields.** These should be plotted formally by automated computer perimeter or Goldmann perimetry, but clinical assessment by confrontation using a small red pin as the target is also sensitive and valuable. Common defects are upper temporal quadrantanopia and bitemporal hemianopia (see p. 810).

**Is there a hormonal excess?**

There are three major conditions that are usually caused by excess secretion from pituitary adenomas and which will show positive immunostaining for the relevant hormone:

- prolactin excess (*prolactinoma or hyperprolactinaemia*): histologically, prolactinomas are ‘chromophobe’ adenomas (a description of their appearance on classical histological staining)
- GH excess (*acromegaly or gigantism*): somatotroph adenomas, usually ‘acidophil’, and sometimes due to specific G-protein mutations (see p. 633)
- excess ACTH secretion (Cushing’s disease and Nelson’s syndrome): corticotroph adenomas, usually ‘basophil’.

Many tumours are able to synthesize several pituitary hormones, and occasionally more than one hormone is secreted in clinically significant excess (e.g. both GH and prolactin).

The clinical features of acromegaly, Cushing’s disease or hyperprolactinaemia are usually (but not always) obvious (see pp. 602 and 639). Tumours producing LH, FSH or TSH are well described but very rare.

Some common pituitary tumours cause no clinically apparent hormone excess and are referred to as ‘non-functioning’ tumours. Laboratory studies such as immunocytochemistry or *in situ* hybridization show that these tumours may often produce small amounts of LH and FSH or the α-subunit of LH, FSH and TSH, and occasionally ACTH.

**Fig. 21.8 Investigation of the pituitary gland.** (A) Left-sided lucent intrasellar microadenoma (arrowed) (coronal MRI). The pituitary stalk is deviated slightly to the right. (B) Macroadenoma with moderate suprasellar extension, and lateral extension compressing the left cavernous sinus (coronal MRI). The top of the adenoma is compressing the optic chiasm (arrowed). (C) Pituitary macroadenoma with massive suprasellar extension (arrowed) (sagittal MRI).
All hormone levels are measured in plasma unless otherwise stated. Tests shown in bold are those normally measured on a single basal 09:00 hours sample in the initial assessment of pituitary function.

*Releasing hormone tests were a traditional part of pituitary function testing but have been largely replaced by the advent of more reliable assays for basal hormones. They test only the ‘readily releasable pool’ of pituitary hormones, and normal responses may be seen in hypopituitarism. Bold text indicates commonly performed investigations.

ACTH, adrenocorticotrophic hormone; CRH, corticotrophin-releasing hormone; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone-releasing hormone; IGF, insulin-like growth factor; LH, luteinizing hormone; LHRH, luteinizing hormone-releasing hormone; TRH, thyroid-releasing hormone; TSH, thyroid-stimulating hormone.

**Is there a deficiency of any hormone?**

Clinical examination may give clues; thus, short stature in a child with a hypothalamic pituitary mass is likely to be due to GH deficiency. An adult complaining of lethargy with pale skin is likely to be deficient in TSH and/or ACTH. Milder deficiencies may not be obvious and require specific testing (Box 21.7).

**Management**

Management depends on the type and size of tumour (Box 21.8). Decisions about pituitary tumour management are made in an MDT setting, which typically comprises an endocrinologist, pituitary surgeon and radiologist. In general, therapy has three aims: removal/control of the tumour, reduction of excess hormone secretion and replacement of hormone deficiencies.

**Removal/control of tumour**

This is only required if the tumour is large enough to cause, or is likely to cause, anatomical effects or if it is secreting excess hormones. Small tumours producing no significant symptoms, pressure or endocrine effects may be observed with appropriate clinical, visual field, imaging and endocrine assessments.

- **Surgery** via the trans-sphenoidal route is usually the treatment of choice. Very large tumours are occasionally removed via the open transcranial (usually transfrontal) route.
- **Radiotherapy** – by conventional linear accelerator or newer stereotactic techniques – is usually employed when surgery is impracticable or incomplete, as it controls but rarely abolishes tumour mass. The conventional regimen involves a dose of 45 Gy, given as 20–25 fractions via three fields. Stereotactic techniques use either a linear accelerator or multiple cobalt sources (‘gamma-knife’).
- **Medical therapy** with somatostatin analogues and/or dopamine agonists sometimes causes shrinkage of specific tumour types (see p. 638) and, if successful, can be used as primary therapy, particularly in the case of prolactinomas.
Reduction of excess hormone secretion

Reduction is usually obtained by surgical removal but sometimes by medical treatment. Useful control can be achieved with dopamine agonists for prolactinomas or somatostatin analogues for acromegaly, but ACTH secretion usually cannot be controlled by medical means. GH antagonists are also available for acromegaly (see p. 638).

Replacement of hormone deficiencies

See Box 21.9. Replacement of hormone deficiencies, i.e. hypopituitarism, is discussed further on page 597.

Differential diagnosis of pituitary or hypothalamic masses

Although pituitary adenomas are the most common mass lesion of the pituitary (90%), a variety of other conditions may also present as a pituitary or hypothalamic mass and form part of the differential diagnosis.

Other tumours

- **Craniopharyngioma** (1–2%), a usually cystic hypothalamic tumour that is often calcified and arises from Rathke’s pouch. It is the most common pituitary tumour in children but may present at any age (Fig. 21.9).
- **Uncommon tumours** include meningiomas (Fig. 21.10), gliomas, chondromas, germinomas and pinealomas. Primary pituitary carcinomas are very rare, but occasionally prolactin- and ACTH-secreting tumours present in an aggressive manner, which may require chemotherapy in addition to conventional treatment. Metastases occasionally present as apparent pituitary tumours, typically accompanied by headache and diabetes insipidus.

**Hypophysitis and other inflammatory masses**

A variety of inflammatory masses occur in the pituitary or hypothalamus. These include rare pituitary-specific conditions (e.g. autoimmune (lymphocytic) hypophysitis, giant cell hypophysitis, postpartum hypophysitis), or pituitary manifestations of more generalized disease processes (sarcoidosis, Langerhans’ cell histiocytosis, granulomatosis with polyangiitis). These lesions may be associated with diabetes insipidus and/or an unusual pattern of hypopituitarism.

**Other lesions**

**Carotid artery aneurysms** may masquerade as pituitary tumours and must be diagnosed before surgery. Cystic lesions may also present as a pituitary mass, including arachnoid and Rathke cleft cysts.

**Hypopituitarism**

**Pathophysiology**

Deficiency of hypothalamic releasing hormones or of pituitary trophic hormones can be selective or multiple. Thus isolated deficiencies of GH, LH/FSH, ACTH, TSH and vasopressin (ADH) are all seen, some cases of which are genetic and congenital, and others sporadic and autoimmune or idiopathic in nature.

Multiple deficiencies usually result from tumour growth or other destructive lesions. There is generally a progressive loss of anterior pituitary function. GH and gonadotrophins are usually first affected. Hyperprolactinaemia, rather than prolactin deficiency, occurs relatively early because of loss of tonic inhibitory control by dopamine. TSH and ACTH are usually last to be affected.

**Panhypopituitarism** refers to deficiency of all anterior pituitary hormones; it is most commonly caused by pituitary tumours, surgery or radiotherapy. Vasopressin (ADH) will only be significantly
affected if the hypothalamus is involved by a hypothalamic tumour or major suprasellar extension of a pituitary lesion, or if there is an infiltrative/inflammatory process. Posterior pituitary deficiency with diabetes insipidus is rare in an uncomplicated pituitary adenoma.

Genetics
Specific genes are responsible for the development of the anterior pituitary, involving interaction between signalling molecules and transcription factors. For example, mutations in PRO1 and POU1F1 (previously PIT-1) prevent the differentiation of anterior pituitary cells (precursors to somatotroph, lactotroph, thyrotroph and gonadotroph cells), leading to deficiencies of GH, prolactin, TSH and gonadotrophin-releasing hormone (GnRH). In addition, novel mutations within GH and growth hormone-releasing hormone (GHRH) receptor genes have been identified, which explain the pathogenesis of isolated GH deficiency in some children. Despite these advances, most cases of hypopituitarism do not have specific identifiable genetic causes.

Aetiology
Disorders that cause hypopituitarism are listed in Box 21.10. Pituitary and hypothalamic tumours, and surgical or radiotherapy treatment, are the most common.

Clinical features
Symptoms and signs depend upon the extent of hypothalamic and/or pituitary deficiencies, and mild deficiencies may not lead to any complaint. In general, symptoms of deficiency of a pituitary-stimulating hormone are the same as those of primary deficiency of the peripheral endocrine gland (e.g. TSH deficiency and primary hypothyroidism cause similar symptoms due to lack of thyroid hormone secretion).

- **Secondary hypothyroidism, hypoadrenalism, hypogonadism** and GH deficiency lead to tiredness and general malaise and reduced quality of life.
- **Hypothyroidism** causes weight gain, slowness of thought and action, dry skin, cold intolerance, constipation and potentially bradycardia and hypothermia.
- **Hypoadrenalism** causes mild hypotension, hyponatraemia and, ultimately, cardiovascular collapse during severe intercurrent stressful illness.
- **Hypogonadism** leads to loss of libido, loss of secondary sexual hair, amenorrhoea and erectile dysfunction and, eventually, osteoporosis.
- **Hyperprolactinaemia** may cause galactorrhoea and hypogonadism, including amenorrhoea.
- **GH deficiency** causes growth failure in children, and impaired wellbeing in some adults.
- **Weight gain** (due to hypothyroidism; see above), or **weight loss** in severe combined deficiency.
- **Longstanding panhypopituitarism** gives the classic picture of pallor with hairlessness (‘alabaster skin’).

Particular syndromes related to hypopituitarism are described below.

**Kallmann’s syndrome**
This is isolated gonadotrophin (GnRH) deficiency (see p. 626) caused by mutations in the KAL1 gene, which is located on the short (p) arm of the X chromosome. Kallmann’s classically causes anosmia because the KAL1 gene provides instructions to make anosmin, which has a role both in development of the olfactory system and in migration of GnRH-secreting neurones.

**Septo-optic dysplasia**
This rare congenital syndrome (rarely associated with mutations in the HESX1 gene), presents in childhood with two out of the clinical triad of midline forebrain abnormalities, optic nerve hypoplasia and hypopituitarism.

**Sheehan’s syndrome**
This is due to pituitary infarction following postpartum haemorrhage and is rare in developed countries but not uncommon in countries where there are not established obstetric services.

**Pituitary apoplexy**
A pituitary tumour occasionally enlarges rapidly owing to infarction or haemorrhage. This may produce severe headache, double vision and sudden severe visual loss, sometimes followed by acute life-threatening hypopituitarism. Often, pituitary apoplexy can be managed conservatively with replacement of hormones and close monitoring of vision, although if there is a rapid deterioration in visual acuity and fields, surgical decompression of the optic chiasm may be necessary (Fig. 21.11).

‘Empty sella’ syndrome
An ‘empty sella’ is sometimes reported on pituitary imaging. This is sometimes due to a defect in the diaphragma and extension of the subarachnoid space (cisternal herniation), or may follow
spontaneous infarction or regression of a pituitary tumour. All or most of the sella turcica is devoid of apparent pituitary tissue but, despite this, pituitary function is usually normal, the pituitary being eccentrically placed and flattened against the floor or roof of the fossa.

Investigations

Each axis of the hypothalamic–pituitary system requires separate investigation. However, the presence of normal gonadal function in women as evidenced by the menstrual cycle obviates the need for investigation.

Investigations range from measurement of simple basal levels (e.g. TSH and free T₄ for the thyroid axis) to stimulatory tests for the pituitary and tests of feedback for the hypothalamus (see Box 21.7). Assessment of the hypothalamic–pituitary–adrenal (HPA) axis is complex: depending on the assay basal 9am cortisol levels above 400 nmol/L usually indicate adequate reserve, while levels below 100 nmol/L predict an inadequate stress response. In many cases, basal levels are equivocal and a dynamic test is essential. The insulin tolerance test (Box 21.11) is widely regarded as the ‘gold standard’ but the short ACTH stimulation test (see Box 21.5), though an indirect measure, is used by many as a routine test of HPA status as long as it is performed 6 weeks after any pituitary insult. Occasionally, the difference between ACTH deficiency and normal HPA axis can be subtle, and interpretation requires experience.

Management

- Glucocorticoid and thyroid hormones are essential for life. Both are given as oral replacement drugs, hydrocortisone and levothyroxine respectively, as in primary thyroid and adrenal failure, with the aim of restoring the patient to clinical and biochemical normality (see Box 21.9); for levothyroxine replacement, levels are monitored by routine hormone assays, whereas for hydrocortisone replacement monitoring is more limited to symptoms. **Note:** Thyroid replacement therapy should not commence until normal adrenal axis function has been demonstrated or glucocorticoid replacement therapy initiated, as an adrenal ‘crisis’ may otherwise be precipitated.

- Sex hormone replacement is with testosterone in males and a combination of oestrogen and progestogen in females, both for symptomatic control and for prevention of long-term problems related to deficiency (e.g. osteoporosis).

- When fertility is desired, gonadal function is stimulated directly by human chorionic gonadotrophin (HCG, mainly acting as LH) or by purified or biosynthetic gonadotrophins, or indirectly by pulsatile gonadotrophin-releasing hormone (GnRH – also known as luteinizing hormone-releasing hormone, LHRH) if gonadotrophs are undamaged; their use should be restricted to specialist units.

- GH replacement therapy is given for growth in a child, under the care of a paediatric endocrinologist. If the adolescent remains deficient at the achievement of adult height, GH replacement therapy can be offered until patients reach their mid-twenties to maximize muscle and bone mass. In adult GH deficiency, GH replacement therapy also produces improvements in body composition, work capacity and psychological wellbeing, together with reversal of lipid abnormalities associated with high cardiovascular risk, and often results in significant symptomatic benefit. The National Institute for Health and Care Excellence (NICE) recommends GH replacement for children and adolescents with GH deficiency, and in adults with severe GH deficiency and significant quality-of-life impairment. It is expensive and in the UK costs £2500–6000 per annum.

- Glucocorticoid deficiency may mask impaired urine concentrating ability, with diabetes insipidus only becoming apparent after glucocorticoid replacement therapy because glucocorticoids are required for excretion of free water.

Further reading

Hypothalmo–Pituitary–Adrenal Axis
Anatomy and physiology

The human adrenals (Box 21.12) together weigh 8–10 g and comprise an outer cortex and inner medulla. The cortex has three zones: the zona glomerulosa, which secretes aldosterone under the control of the renin–angiotensin system, and the zona fasciculata and zona reticularis, which produce glucocorticoids, cortisol, and sex steroids and androgens under feedback control of the hypothalamic–pituitary–adrenal (HPA) axis. The inner medulla synthesizes, stores and secretes catecholamines (see later and Fig. 21.12).

The adrenal cortex

The steroids produced by the adrenal cortex are grouped into three classes, based on their predominant physiological effects: glucocorticoids, mineralocorticoids and androgens.

Glucocorticoids

These are named after their effects on carbohydrate metabolism. Major actions are listed in Box 21.13. They act on intracellular corticosteroid receptors and combine with coactivating proteins to bind the ‘glucocorticoid response element’ (GRE) in specific regions of DNA to cause gene transcription. Glucocorticoid action is modified locally by the action of 11β-hydroxysteroid dehydrogenase (11βHSD). 11βHSD type 1 converts inactive cortisone into active cortisol, hence amplifying the hormone signal, while 11βHSD type 2 does the opposite.

The relative potency of common steroids is shown in Box 21.14.

Mineralocorticoids

The predominant effect of mineralocorticoids is on the extracellular balance of sodium and potassium in the distal tubule of the kidney. Aldosterone, produced solely in the zona glomerulosa, is the predominant mineralocorticoid in humans (about 50%); corticosterone makes a small contribution to overall mineralocorticoid activity. Mineralocorticoids act on type 1 corticosteroid receptors, while glucocorticoids act on type 2 receptors, both having a very similar structure. The mineralocorticoid activity of cortisol is weak but cortisol is present in considerable excess. The mineralocorticoid receptor in the kidney is protected from this excess by the intrarenal conversion (‘shuttle’) of cortisol to cortisone by 11βHSD type 2.

Androgens

Although secreted in considerable quantities, most androgens have relatively weak intrinsic androgenic activity until metabolized peripherally to testosterone or dihydrotestosterone. Dihydrotestosterone is metabolized from testosterone by 5α-reductase and is a potent androgen receptor agonist. The androgen receptor has been well characterized and mutations within this gene may cause androgen insensitivity syndromes.
Biochemistry
All steroids have the same basic skeleton (Fig. 21.13B) and the chemical differences between them are slight. The major biosynthetic pathways are shown in Fig. 21.13A.

Physiology
Glucocorticoid production by the adrenal is under hypothalamic–pituitary control (Fig. 21.14). Corticotrophin-releasing hormone (CRH) is secreted in the hypothalamus in response to circadian rhythm, stress and other stimuli. CRH travels down the portal system to stimulate adrenocorticotropic hormone (ACTH) release from the anterior pituitary. Hypothalamic vasopressin (antidiuretic hormone, ADH) also stimulates ACTH secretion and acts synergistically. ACTH is derived from the prohormone pro-opiomelanocortin (POMC), which undergoes processing within the pituitary to produce ACTH and a number of other peptides, including beta-lipotrophin and beta-endorphin. Many of these peptides, including ACTH, contain melanocyte-stimulating hormone (MSH)-like sequences, which cause pigmentation when levels of ACTH are markedly raised as in Addison’s disease.

Circulating ACTH stimulates cortisol production in the adrenal. The secreted cortisol (or any other synthetic corticosteroid administered to the patient) causes negative feedback on the hypothalamus and pituitary to inhibit further CRH/ACTH release. The set-point of this system varies through the day according to the circadian rhythm, and is usually overridden by severe stress. Unlike cortisol, mineralocorticoids and sex steroids do not cause negative feedback on the CRH/ACTH axis.

Following adrenalectomy or other adrenal damage (e.g. Addison’s disease), cortisol secretion is absent or reduced; ACTH levels will therefore rise.

Mineralocorticoid secretion is mainly controlled by the renin–angiotensin system (see p. 1346).

Investigation of glucocorticoid abnormalities
Basal levels
Cortisol has a circadian rhythm and increases in response to stress. When taking a blood sample, remember:
• Sampling time should be recorded.
• Basal cortisol levels should be taken between 8am and 10am, near the peak of the circadian variation, if investigating for deficiency.
• Stress should be minimized.
• Appropriate reference ranges (for time and assay method) should be used.

The measurement of ACTH levels are only really required once an abnormality in cortisol levels has been identified. A plasma sample is required and has to be transported on ice to the lab immediately.

Suppression tests are used if excess cortisol is suspected, and stimulation tests are used if cortisol deficiency is suspected.
Dexamethasone suppression tests
Administration of a synthetic glucocorticoid (dexamethasone) to a normal subject produces suppression of CRH and ACTH levels, and thus of endogenous cortisol secretion (dexamethasone is not measured by most cortisol assays). Three forms of the test, used in the diagnosis and differential diagnosis of Cushing’s syndrome, are available (Box 21.15).

ACTH stimulation tests
Synthetic ACTH (tetracosactide, which consists of the first 24 amino acids of human ACTH) is given to stimulate adrenal cortisol production (see Box 21.5 and Fig. 21.5).

Cushing’s syndrome
Cushing’s syndrome describes the clinical state of increased free circulating glucocorticoid. It is most often iatrogenic following the therapeutic administration of synthetic steroids. The next most common cause is excess endogenous secretion of ACTH from a pituitary adenoma, when it is called Cushing’s disease (see below).

Pathophysiology and aetiology
Spontaneous Cushing’s syndrome is rare, with an incidence of fewer than 5/million per year.
Causes of Cushing’s syndrome are usually subdivided into two groups (Box 21.16):
• Increased circulating ACTH from the pituitary (65% of cases), known as Cushing’s disease, or from an ‘ectopic’, non-pituitary, ACTH-producing tumour elsewhere in the body (10%) with consequent glucocorticoid excess (‘ACTH-dependent’ Cushing’s).
• A primary excess of endogenous cortisol secretion (25%) by an adrenal tumour or, more rarely, by bilateral primary pigmented nodular hyperplasia (PPNH) with suppression of ACTH (‘non-ACTH-dependent’ Cushing’s). Rare cases are due to aberrant expression of receptors for other hormones (e.g. glucose-dependent insulinotrophic peptide (GIP), LH or catecholamines) in adrenal cortical cells. Germline changes in protein kinase A (PKA) can also result in adrenal hyperplasia and adenomas.

History and examination
The clinical features of Cushing’s syndrome are illustrated in Fig. 21.15.
• Pigmentation occurs only with ACTH-dependent causes (most frequently in ectopic ACTH syndrome).
• A cushingoid appearance can also be caused by excess alcohol consumption (pseudo-Cushing’s syndrome); the pathophysiology is poorly understood.
• **Impaired glucose tolerance** or frank diabetes is common, especially with ectopic ACTH.
• **Hypokalaemia** due to the mineralocorticoid activity of cortisol is common with ectopic ACTH secretion.
• **Hypertension** is common in all causes of Cushing’s syndrome.

**Investigations**
There are two phases to investigation.

**Confirmation**
Most patients with obesity and hypertension or women with obesity and hirsutism do not have Cushing’s syndrome, but some cases of genuine Cushing’s can also relatively subtle clinical signs. Confirmation rests on demonstrating inappropriate cortisol secretion that is not suppressed by exogenous glucocorticoids; difficulties occur with obesity and depression, where cortisol dynamics are often abnormal. Random cortisol measurements are of no value. Occasional patients are seen with ‘cyclical Cushing’s’, in which the abnormalities come and go. Investigations to confirm the diagnosis include:

• **48-h low-dose dexamethasone test** (see Box 21.15). Normal individuals suppress plasma cortisol to less than 50 nmol/L. People with Cushing’s syndrome fail to show complete suppression of plasma cortisol levels (although levels may fall substantially in a few cases). This test is highly sensitive (>97%). The overnight dexamethasone test is simpler but has a higher false-positive rate so often used as an initial screening test, before progressing to the longer test.

• **24-hour urinary free cortisol measurements**. This is another screening test. It is simple but less reliable; repeatedly normal values render the diagnosis unlikely, but some people with Cushing’s syndrome have normal values on some collections (approximately 10%).

• **Circadian rhythm**. After 48 h in hospital, cortisol samples are taken at 09:00 hours and 24:00 hours (without warning the patient and ideally when they are asleep). Normal subjects show a pronounced circadian variation (see Fig. 21.4); those with Cushing’s syndrome have high midnight cortisol levels (>100 nmol/L), though the 09:00 hours value may be normal. Increasingly, loss of circadian rhythm recorded using midnight or late-night salivary cortisol collected at home can be used for the diagnosis and surveillance of Cushing’s, removing the need for a hospital stay.

• **Other tests**. There are frequent exceptions to the classic responses to diagnostic tests in Cushing’s syndrome. If any clinical suspicion of Cushing’s remains after preliminary tests, then specialist investigations are still indicated. These may include the **insulin stress test**, **desmopressin stimulation test** (see Box 21.53) and **corticotrophin releasing hormone (CRH)** tests.

**Differential diagnosis of the cause**
This can be extremely difficult on symptoms and signs alone since all causes can result in clinically identical Cushing’s syndrome. The classical ectopic ACTH syndrome is distinguished by a short history, pigmention, weight loss, hypokalaemia, diabetes and plasma ACTH levels above 200 ng/L, but many ectopic tumours are benign and mimic pituitary disease closely, both clinically and biochemically. Severe hirsutism/virilization suggests an adrenal tumour.

Biochemical and radiological procedures for diagnosis include:

• If **plasma ACTH levels** are low or undetectable (<10 ng/L) on two or more occasions, this is a reliable indicator of non-ACTH-dependent disease and adrenal imaging should be planned, using **adrenal CT or MRI scan**. Adrenal adenomas and carcinoma causing Cushing’s syndrome are relatively large and always detectable by CT. Carcinomas are distinguished by their large

---

**Fig. 21.15 Cushing’s syndrome: symptoms and signs.** Bold italic type indicates signs of most value in discriminating Cushing’s syndrome from simple obesity and hirsutism.
size and irregular outline, and signs of infiltration or metastases. Bilateral adrenal hyperplasia may be seen in ACTH-dependent causes or in ACTH-independent nodular hyperplasia.

- If plasma ACTH levels are normal or high on two or more occasions, this is a reliable indicator of ACTH-dependent disease and pituitary imaging should be planned in the first instance and biochemical tests to distinguish between pituitary and ectopic sources of ACTH.

- Pituitary MRI. A pituitary adenoma may be seen but the adenoma is often small and not visible in a significant proportion of cases.

- High-dose dexamethasone suppression test (see Box 21.15). Failure of significant plasma cortisol suppression suggests an ectopic source of ACTH (or an adrenal tumour).

- CRH test. An exaggerated ACTH and cortisol response to exogenous CRH suggests pituitary-dependent Cushing’s disease, as ectopic sources rarely respond.

- Chest X-ray. A carcinoma of the bronchus or a bronchial carcinoma is sought. Carcinoid lesions may be very small; if ectopic ACTH is suspected, whole-lung, mediastinal and abdominal CT scanning should be performed. Further investigations may involve:

  - Selective catheterization of the inferior petrosal sinus to measure ACTH for pituitary lesions, or blood samples taken throughout the body to look for ectopic sources.

  - Radiolabelled octreotide ($^{11}$In octreotide) is occasionally helpful in locating ectopic ACTH sites.

### Management

#### Cushing’s syndrome

Successful treatment with a normal biochemical profile should lead to reversal of clinical features. However, untreated Cushing’s syndrome has a very poor prognosis, with death from venous thromboembolism, hypertension, myocardial infarction, infection and heart failure. Whatever the underlying cause, cortisol hypersecretion should be controlled prior to surgery or radiotherapy. Considerable morbidity and mortality are otherwise associated with operating on unprepared patients, especially when abdominal surgery is required.

The usual drug is metyrapone, an 11β-hydroxylase blocker, which is given in doses of 750 mg to 4 g daily in 3–4 divided doses. Ketoconazole (200 mg three times daily) is also used and is synergistic with metyrapone. Plasma cortisol should be monitored, aiming to reduce the mean level during the day to 150–300 nmol/L, equivalent to normal production rates. Aminogluthimide, trilostane (which reversibly inhibits 3-hydroxysteroid dehydrogenase/5–4 isomers) and etomidae infusion (in severe cases) are occasionally used.

Choice of further treatment depends upon the cause.

#### Cushing’s disease (pituitary-dependent hypercortisolism)

- **Trans-sphenoidal removal of the tumour** is the treatment of choice. Selective adenomectomy nearly always leaves the patient ACTH-deficient immediately postoperatively, and this is a good prognostic sign. Overall, pituitary surgery results in remission in 75–80% of cases, but results vary considerably and an experienced surgeon is essential.

- **External pituitary irradiation** alone is slow-acting, only effective in 50–60% even after prolonged follow-up, and mainly used after failed pituitary surgery. Children respond much better to radiotherapy, 80% being cured. Stereotactic radiotherapy can be useful in selected cases.

- **Medical therapy** to reduce ACTH (e.g. bromocriptine, cabergoline and cyproheptadine) is rarely effective. The somatostatin analogue pasireotide may provide medical control of Cushing’s in some patients, but is associated with hyperglycaemia as a common side-effect. Aggressive corticotroph adenomas may respond to temozolomide chemotherapy.

- **Bilateral adrenalectomy** is an effective last resort if other measures fail to control the disease (see ‘Nelson’s syndrome’ later). This can be performed laparoscopically.

### Cushing’s syndrome due to other causes

#### Adrenal adenomas

Should be resected laparoscopically. Contralateral adrenal suppression may last for a year or more.

#### Adrenal carcinomas

Are highly aggressive and the prognosis is poor. In general, if there are no widespread metastases, tumour bulk should be reduced surgically. The adrenolytic drug mitotane may inhibit growth of the tumour and prolong survival, though it can cause nausea and ataxia. Some would also give radiotherapy to the tumour bed after surgery.

**Tumours secreting ACTH ectopically** should be removed if possible. Otherwise chemotherapy/radiotherapy may be used, depending on the tumour. Control of the Cushing’s syndrome with metyrapone or ketoconazole is beneficial for symptoms, and bilateral adrenalectomy may be appropriate to give complete control of Cushing’s syndrome if prognosis from the tumour itself is reasonable.

If the source of ACTH is not clear, cortisol hypersecretion should be controlled with medical therapy until a diagnosis can be made.

#### Nelson’s syndrome

Nelson’s syndrome occurs in about 20% of cases after bilateral adrenalectomy for Cushing’s disease and is characterized by increased pigmentation (because of high levels of ACTH), associated with an enlarging pituitary tumour. The syndrome is rare now that adrenalectomy is an uncommon primary treatment, and its incidence may be reduced by pituitary radiotherapy soon after adrenalectomy. The Nelson’s adenoma may be treated by pituitary surgery and/or radiotherapy (unless given previously).

### Further reading

### Addison’s disease

#### Pathophysiology and aetiology

In this condition, there is destruction of the entire adrenal cortex. Glucocorticoid, mineralocorticoid and sex steroid production are therefore all reduced. This differs from hypothalamic–pituitary disease, in which mineralocorticoid secretion remains largely intact, being predominantly stimulated by angiotensin II. Adrenal sex steroid production is also largely independent of pituitary action. In Addison’s disease, reduced cortisol levels lead, through feedback, to increased CRH and ACTH production, the latter being directly responsible for the hyperpigmentation.
Addison’s disease is rare, with an incidence of 3–4/million per year and prevalence of 40–60/million. Primary adrenal insufficiency shows a marked female preponderance and is usually caused by autoimmune disease (>90% in the UK), but in countries with a high prevalence of HIV/AIDS, tuberculosis is an increasing cause. Autoimmune adrenalitis results from the destruction of the adrenal cortex by organ-specific autoantibodies, with 21-hydroxylase as the common antigen. There are associations with other autoimmune conditions in polyglandular autoimmune syndromes types I and II (e.g. type 1 diabetes mellitus, pernicious anaemia, thyroiditis, hypoparathyroidism, premature ovarian insufficiency; see p. 648).

All other causes are rare (Box 21.17). In patients with degenerative neurological symptoms, a diagnosis of adrenoleukodystrophy should be excluded. In childhood the most common cause of primary adrenal insufficiency is congenital adrenal hyperplasia (CAH).

### History and examination

See Fig. 21.16. The symptomatology of Addison’s disease is often non-specific. These symptoms may be the prelude to an addisonian crisis with severe hypotension and dehydration precipitated by intercurrent illness, accident or operation.

Pigmentation (dull, slaty, grey-brown) is the predominant sign in over 90% of cases.

Postural systolic hypotension, due to hypovolaemia and sodium loss, is present in 80–90% of cases, even if supine blood pressure is normal. Mineralocorticoid deficiency is the cause of the hypotension.

#### Box 21.17 Causes of primary hypoadrenalism

- Tuberculosis (<10% in UK)
- Surgical removal
- Haemorrhage/infarction:
  - Meningococcal septicaemia
  - Venography
- Infusion:
  - Malignant destruction
  - Amyloid
- Schilder’s disease (adrenal leukodystrophy)

### Investigations

Once Addison’s disease is suspected, investigation is urgent. If the patient is seriously ill or hypotensive, hydrocortisone 100 mg should be given intravenously or intramuscularly, together with intravenous 0.9% saline. Ideally, this should be done immediately after a blood sample is taken for later measurement of plasma cortisol. Full investigation should be delayed until emergency treatment (see below) has improved the patient’s condition. Otherwise, tests are as follows:

- **Single cortisol measurements** are of little value, although a random cortisol below 100 nmol/L during the day is highly suggestive, and a random cortisol higher than 550 nmol/L makes the diagnosis unlikely.
- **The short ACTH stimulation test** should be performed (see Box 21.5 and Fig. 21.5). Note that an absent or impaired cortisol response confirms the presence of hypoadrenalism but does not differentiate Addison’s disease from ACTH deficiency or iatrogenic suppression by steroid medication. The long ACTH test is no longer used because of the availability of accurate ACTH assays.
- **A 08:00-hours plasma ACTH level** is measured, a high level (>80 ng/L) with low cortisol confirming primary adrenal insufficiency.
- **Adrenal antibodies** are present in approximately 90% of cases of autoimmune adenalinosis.
- **Chest and abdominal X-rays** or cross-sectional imaging of the abdomen (CT or MRI) may show evidence of tuberculosis and/or calcified adrenals (Fig. 21.17).
- **Plasma renin activity** is high due to low serum aldosterone.
- **Serum creatinine and electrolytes** classically show hyponaatraemia, hyperkalaemia and a high urea, but they can be normal.
- **Blood glucose** may be low, with hypoglycaemia.
- **Hypercalcaemia and anaemia** (after rehydration) are sometimes seen.

### Management

Acute hypoadrenalism needs urgent treatment (Box 21.18).

---

**Symptoms**

- Weight loss
- Malaise
- Weakness
- Fever
- Anorexia
- Nausea/vomiting
- Diarrhoea
- Abdominal pain
- Constipation
- Depression
- Confusion
- Myalgia
- Joint or back pain
- Impotence/amenorrhoea
- Syncope from postural hypotension

**Signs**

- General
  - Loss of weight
  - General wasting
- **Pigmentation, especially of new scars and palmar creases**
- Buccal pigmentation
- **Postural hypotension**
- Loss of body hair (vitiligo)
- Dehydration

---

**Fig. 21.16** Primary hypoadrenalism (Addison’s disease): symptoms and signs. **Bold italic** type indicates signs of greater discriminant value.
Dual-release, oral, once-daily hydrocortisone preparations are expected. Replacement dosage details are shown in Box 21.19.

Long-term treatment is with replacement glucocorticoid and mineralocorticoid; tuberculosis must be treated if present or suspected. Replacement dosage details are shown in Box 21.19. Dual-release, oral, once-daily hydrocortisone preparations are becoming increasingly available. Dehydroepiandrosterone (DHEA) replacement has also been advocated by some for quality of life; some studies suggest that this may cause symptomatic improvements, although others show no clear benefit and acne and hirsutism occur.

Adequacy of glucocorticoid dose is judged by:
- clinical wellbeing and restoration of normal, but not excessive, weight; ideally aiming for a low dose, for example, total dose of hydrocortisone between 15 and 25 mg split in two or three divided doses throughout the day
- measuring cortisol levels during the day while on replacement hydrocortisone (cortisol levels cannot be used for synthetic steroids) is not recommended as an assessment of dose adequacy.

Adequacy of fludrocortisone replacement is assessed by:
- restoration of serum electrolytes to normal
- no evidence of hypertension or postural hypotension (it should not fall >10 mmHg systolic after 2 minutes’ standing)
- suppression of plasma renin activity to high normal.

### Patient advice

All patients requiring replacement steroids should:
- know how to increase steroid replacement by doubling the dose for intercurrent illness
- carry a ‘steroid card’
- wear a MedicAlert bracelet (or similar), which gives details of their condition so that emergency replacement therapy can be given if found unconscious
- keep an (up-to-date) ampoule of hydrocortisone at home in case oral therapy is impossible, for administration by self, family, ambulance or doctor.

### Secondary hypoadrenalism

This may arise from:
- hypothalamic–pituitary disease (inadequate ACTH production) or
- long-term steroid therapy leading to ACTH suppression.

Most people with hypothalamic–pituitary disease have panhypopituitarism (see p. 595) and need T4 replacement, as well as cortisol; in this case, hydrocortisone must be started before T4.

Long-term corticosteroid medication for non-endocrine disease is the most common cause of secondary hypoadrenalism. The hypothalamic–pituitary axis and the adrenal may both be suppressed and the patient may have vague symptoms of feeling unwell. ACTH levels are low in secondary hypoadrenalism. Weaning off steroids is often a long and difficult process.

### Congenital adrenal hyperplasia

#### Pathophysiology

Congenital adrenal hyperplasia (CAH) is an autosomal recessive disorder resulting in deficiency of an enzyme in the cortisol synthetic pathways. There are six major types; most common is 21-hydroxylase deficiency (CYP21A2), which occurs in about 1 in 15 000 births and is due to defects on chromosome 6 near the HLA region, affecting one of the cytochrome p450 enzymes (p450C21).

As a result, cortisol secretion is reduced and feedback leads to increased ACTH secretion, causing adrenal hyperplasia. Diversion of the steroid precursors into the androgenic steroid pathways occurs (see Fig. 21.13A). Thus, 17-hydroxyprogesterone, androstenedione and testosterone levels are increased, leading to virilization. Aldosterone synthesis may be impaired with resultant salt wasting.

The other forms affect 11β-hydroxylase, 17α-hydroxylase, 3β-hydroxysteroid dehydrogenase and a cholesterol side-chain cleavage enzyme (p450ccc) (see Fig. 21.13A).
History and examination
Classical CAH presents at birth with:
- Ambiguous genitalia in females (clitoral hypertrophy, urogenital abnormalities and labioscrotal fusion are common) or
- Adrenal failure (collapse, hypotension, hypoglycaemia), sometimes with a salt-losing state (hypotension, hyponatraemia). The syndrome may be unrecognized in the male until a salt-losing crisis occurs, usually within 10 days of birth.
Non-classical disease presents later as precocious puberty with hirsutism; rare, milder cases present in adult life, usually accompanied by primary amenorrhoea. Hirsutism developing before puberty is suggestive of CAH.

Investigations
In many developed countries neonatal screening for CAH takes place by assessing 17OHP in dried blood spots soon after birth. This approach would prevent undiagnosed children presenting with adrenal failure and identify those that may present later with precocious puberty.

Expert advice is essential in the confirmation and differential diagnosis of 21-hydroxylase deficiency; with ambiguous genitalia, advice must be sought urgently before any assignment of gender is made.

Unless 17 OHP levels are very elevated (>30 nmol/L) a synacthen test should be performed with measurement of 17OHP and cortisol at 0 and 60 minutes. If 17OHP levels at baseline or after synacthen are above 30 nmol/L 21 hydroxylase deficiency is confirmed.

Assessment of mineralocorticoid activity is also required.

Management
Glucocorticoid activity must be replaced, as must mineralocorticoid activity if deficient. The practice in CAH of giving the larger dose of glucocorticoid at night to suppress the morning ACTH peak, with a smaller dose in the morning, is largely outdated. Correct dosage is often difficult to establish in the child but should ensure normal androstenedione and mildly elevated 17OHP levels while allowing normal growth; excessive replacement leads to stunting of growth. In adults, clinical features and biochemistry (plasma renin, androstenedione and 17-hydroprogesterone) are used to modify treatment. The use of modified-release hydrocortisone may have a role in the management of CAH.

Prenatal diagnosis
Prenatal genetic counselling is essential (see Ch. 2). There is a 1 : 4 chance of an affected child if one child in the family is already affected. In a parent with CAH, genetic testing of the partner provides important information about the risk of having an affected child. Dexamethasone can be offered to the mother as it may prevent virilization of an affected female fetus by suppressing ACTH levels. There are, however, concerns about the potential adverse consequences of this practice.

Problems of therapeutic steroid therapy
Apart from their use as therapeutic replacement for endocrine deficiency states, synthetic glucocorticoids are widely used for many non-endocrine conditions. Short-term use (e.g. for acute asthma) carries only small risks of significant side-effects, except for the simultaneous suppression of immune responses. The danger lies in their continuance, often through medical oversight or patient default. In general, therapy for 3 weeks or less, or a dose of prednisolone of less than 5 mg per day, will not result in significant long-term suppression of the normal adrenal axis.

Long-term therapy with synthetic or natural steroids will, in most respects, mimic endogenous Cushing’s syndrome. Exceptions are the relative absence of hirsutism, acne, hypertension and severe sodium retention, as the common synthetic steroids have low androgenic and mineralocorticoid activity. Excessive doses of steroids may also be absorbed from skin when strong dermatological preparations are used, and along with inhaled steroids may rarely cause Cushing’s syndrome; they may, however, quite commonly cause adrenal suppression.

The major hazards are detailed in Box 21.20. In the long term, many are of such severity that the clinical need for high-dose steroids should be continually and critically assessed. Steroid-sparing agents should always be considered, and screening and prophylactic therapy for osteoporosis introduced (see p. 477). New targeted biological therapies for inflammatory conditions may reduce the incidence of steroid-induced adrenal suppression.

Supervision of steroid therapy
All patients receiving steroids should carry a ‘steroid card’. They should be made aware of the following points:
- Long-term steroid therapy must never be stopped suddenly.
- Doses should be reduced very gradually, with most being given in the morning at the time of withdrawal; this minimizes adrenal suppression. Many believe that ‘alternate-day therapy’ produces less suppression.
- Depending on current dose, doses need to be increased at times of serious intercurrent illness, accident and stress. Double doses should be taken during these periods.
- Other physicians, anaesthetists and dentists must be told about steroid therapy.

Patients should also be informed of potential side-effects, and all this information should be documented in the clinical record. If prophylactic use of bisphosphonate therapy is required to prevent...

* A useful summary of surgical steroid guidelines can be found at: [http://www.addisons.org.uk/](http://www.addisons.org.uk/).

Even in the absence of symptoms, biochemical tests to exclude secretory activity should be performed, as adrenal adenomas often secrete cortisol at a low level – “autonomous cortisol secretion”, which may confer increased cardiovascular risk. If no endocrine activity is found, then most authorities recommend removal only of large adrenal tumours (>4–5 cm) because of the risk of malignancy. Smaller, hormonally inactive lesions are usually left alone.

Phaeochromocytoma must be excluded before surgery due to the risk of perioperative hypertensive or hypotensive crises (see p. 608).

**Primary hyperaldosteronism**

Increased mineralocorticoid secretion from the adrenal cortex, termed primary hyperaldosteronism, accounts for 5–10% of all hypertension. Other endocrine causes of hypertension should also be considered if there is clinical suspicion (Box 21.22). It is impracticable to screen all hypertensive patients for secondary endocrine causes. The highest chances of detecting such causes are in patients:

- under 35 years, especially those without a family history of hypertension
- with accelerated (malignant) hypertension
- with hypokalaemia
- resistant to conventional antihypertensive therapy (e.g. more than three drugs) or
- with unusual symptoms (e.g. sweating attacks or weakness).

**Pathophysiology**

Primary hyperaldosteronism is characterized by excess aldosterone production leading to sodium retention, potassium loss and the combination of hypokalaemia and hypertension. This must be distinguished from secondary hyperaldosteronism, which arises when there is excess renin (and hence angiotensin II) stimulation of the zona glomerulosa. Common causes of secondary hyperaldosteronism are accelerated hypertension and renal artery stenosis, when the patient will also be hypertensive. Causes associated with normotension include congestive cardiac failure and cirrhosis, where excess aldosterone production contributes to sodium retention.
Aetiology
Adrenal adenomas (Conn’s syndrome; see Box 21.22) originally accounted for 60% of cases of primary hyperaldosteronism but represented a rare cause of hypertension. The use of the aldosterone:renin ratio in the routine investigation of hypertension now suggests that hyperaldosteronism due to bilateral adrenal hyperplasia (idiopathic hyperaldosteronism) is much more common than the classical Conn’s adenoma.

History and examination
The usual presentation is simply hypertension; hypokalaemia (<3.5 mmol/L) is frequently not present. The few symptoms are non-specific; rarely, muscle weakness, nocturia and tetany are seen. Hypertension may be severe and associated with renal, cardiac and retinal damage.

Adenomas, often very small, are more common in young females, while bilateral hyperplasia rarely occurs before the age of 40 years and is more common in males.

Investigations
Beta-blockers and other drugs may interfere with renin activity, and spironolactone, angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor antagonists will all affect results; all should be discontinued, if possible. The characteristic features of investigation are as follows:

- Plasma aldosterone:renin ratio (ARR) is now most frequently used as a screening test for the condition, but raised ARR alone does not confirm the diagnosis (if the renin is low enough, ARR will always be high). Note that normal ranges are highly assay-dependent.
- Elevated plasma aldosterone levels are not suppressed with 0.9% saline infusion (2 L over 4 h) or fludrocortisone administration. Between 30% and 50% of people with a raised ARR on screening will suppress normally, excluding the diagnosis.
- Suppressed plasma renin activity or immunoreactivity is seen.
- Hypokalaemia is often present but a normal potassium does not exclude the diagnosis.
- Urinary potassium loss greater than 30 mmol daily during hypokalaemia is inappropriate.

Once a diagnosis of hyperaldosteronism is established, differentiation of adenoma from hyperplasia involves adrenal CT or MRI, but small adenomas may be missed and non-functioning incidentalomas also occur. Further information is obtained from diurnal/postural changes in plasma aldosterone levels (which tend to rise with adenomas between 09:00 hours supine and 13:00 hours erect samples; in contrast, they fall with hyperplasia), measurement of 18-OH cortisol levels (raised in adenoma), and venous catheterization for aldosterone levels. All of these tests have pitfalls and exceptions.

Management
An adenoma can be removed surgically, usually laparoscopically; blood pressure falls in 70% of patients. Those with hyperplasia should be treated with the aldosterone antagonist, spironolactone (100–400 mg daily); frequent side-effects include nausea, rashes and gynaecomastia. The pure aldosterone receptor antagonist, eplerenone, is a useful alternative if side-effects preclude the use of spironolactone (see p. 179) Spironolactone metabolites have been linked with tumour development in animals but not in humans. Amiloride and calcium-channel blockers are moderately effective in controlling hypertension but do not correct the hyperaldosteronism.

Hypothalamo-pituitary-adrenal axis

Glucocorticoid (or dexamethasone)-suppressible hyperaldosteronism
This rare condition is caused by a chimeric gene on chromosome 8. A fusion gene resulting from an unusual crossover at meiosis between the genes encoding aldosterone synthase and adrenal 11β-hydroxylase produces aldosterone, which is under ACTH control. Treatment with glucocorticoid resolves the problem.

Syndrome of apparent mineralocorticoid excess
This causes the clinical syndrome of primary hyperaldosteronism but with low renin and aldosterone levels. Reduced activity of the enzyme 11β-hydroxysteroid dehydrogenase type 2 (11βHSD2) prevents the normal conversion in the kidney of cortisol (which is active at the mineralocorticoid receptor) to cortisone (which is not), and therefore ‘exposes’ the mineralocorticoid receptor in the kidney to the usual molar excess of cortisol over aldosterone in the blood. While the inherited syndrome is rare, the same clinical syndrome can occur with excessive ingestion of liquorice, which inhibits the 11βHSD2 enzyme.

The adrenal medulla
The adrenal medulla is the innermost part of the adrenal gland, consisting of cells that secrete the major catecholamines, noradrenaline (norepinephrine) and adrenaline (epinephrine), which produce the sympathetic nervous response. The catecholamines are interconverted in the adrenal medulla, and an increase in levels of their metabolites in the urine is a marker of abnormal hypersecretion (Fig. 21.18).

Fig. 21.18 The synthesis and metabolism of catecholamines. COMT, catechol-O-methyl transferase; MAO, monoamine oxidase.
Phaeochromocytoma and paraganglioma

These are very rare tumours of the sympathetic nervous system (less than 1 in 1000 cases of hypertension) that secrete catecholamines, noradrenaline (norepinephrine), adrenaline (epinephrine) and their metabolites (see Fig. 21.18):

- 90% arise in the adrenal medulla (phaeochromocytomas)
- 10% occur elsewhere in the sympathetic chain (paragangliomas).

Some are associated with MEN 2 (see below), von Hippel–Lindau’s (VHL) syndrome (see p. 887) and neurofibromatosis. Most tumours release both noradrenaline (norepinephrine) and adrenaline (epinephrine), but large tumours and extra-adrenal tumours produce almost entirely noradrenaline.

Paragangliomas typically occur in the head and neck but are also found in the thorax, pelvis and bladder. They are more closely associated with other genetic associations than phaeochromocytoma. The association of paraganglioma, bilateral adrenal phaeochromocytomas, positive family history or young age at presentation is seen in multiple endocrine neoplasms (see p. 650). Mutations in the succinate dehydrogenase (SDHD) gene have been shown to be strongly associated with the development of paraganglioma.

Pathology

Oval groups of cells occur in clusters and stain for chromogranin A; 25% are multiple and 10% malignant, the latter being more frequent in extra-adrenal tumours. Malignancy cannot be determined on simple histological examination alone.

History and examination

The clinical features are those of catecholamine excess and are frequently, but not necessarily, intermittent (Box 21.23). All people with suspected phaeochromocytomas must be investigated because phaeochromocytomas may cause acute cardiovascular compromise during routine medical procedures and can also present with sudden death if the diagnosis is missed.

Investigations

Specific tests are:

- **Measurement of urinary catecholamines and metabolites** (metanephrines are most sensitive and specific; see Fig. 21.18) is a useful screening test; normal levels on three 24-hour collections of metanephrines virtually exclude the diagnosis. Many drugs, e.g. tricyclics, and dietary vanilla interfere with these tests.

- **Resting plasma metanephrines** are raised.

- **Plasma chromogranin A** (a storage vesicle protein) is raised.

- **Clonidine suppression test** may be appropriate but should only be performed in specialist centres.

- **CT/MRI scans**, initially of the abdomen, are helpful to localize the tumours, which are often large (Fig. 21.19).

- **Scanning with \[^{123}I\]meta-iodobenzylguanidine (MIBG)** produces specific uptake in sites of sympathetic activity with about 90% success. It is particularly useful with extra-adrenal tumours. \[^{18}F\]-deoxyglucose positron emission tomography (PET) is also used by some centres (Fig. 21.20).

- **Genetic testing** for MEN2, VHL, SDHB and SDHD mutations should be performed in all people with confirmed phaeochromocytoma or paraganglioma.

Management

Tumours should be removed if possible; 5-year survival is about 95% for non-malignant tumours. Medical preoperative and perioperative treatment is vital and includes complete alpha- and beta-blockade with phenoxybenzamine (20–80 mg daily in divided doses), then propranolol (120–240 mg daily), plus intravenous hydration to re-expand the contracted plasma volume. Alpha-blockade must precede the beta-blockade, as worsened hypertension may otherwise result. Labetalol is not recommended. Surgery in the unprepared patient is fraught with dangers of both hypertension and hypotension; expert anaesthesia and an experienced surgeon are vital, and sodium nitroprusside, phentolamine (a rapid-acting \(\alpha\)-blocker) and magnesium should be available in case sudden severe hypertension develops.

When operation is not possible, combined alpha- and beta-blockade can be used long term. Radionucleotide treatment with MIBG has been employed but has had limited success in malignant phaeochromocytoma.
The thyroid gland consists of follicles lined by cuboidal epithelial cells. Inside is the colloid (the iodinated glycoprotein thyroglobulin), which is synthesized by the follicular cells. Each follicle is surrounded by basement membrane, and between them are parafollicular cells containing calcitonin-secreting C cells.

**Physiology**

**Synthesis**

The thyroid synthesizes two hormones:

- triiodothyronine (T₃), which acts at the cellular level
- L-thyroxine (T₄), which is the prohormone.

Inorganic iodide is trapped by the gland via an enzyme-dependent system, oxidized and incorporated into the glycoprotein thyroglobulin to form mono- and diiodotyrosine, and then T₄ and T₃ (Fig. 21.21).

More T₄ than T₃ is produced, but T₄ is converted in some peripheral tissues (liver, kidney and muscle) to the more active T₃ by 5'-monodeiodination; an alternative 3'-monodeiodination yields the inactive reverse T₃ (rT₃). The latter step occurs particularly in severe non-thyroidal illness (see later).

In plasma, more than 99% of all T₄ and T₃ is bound to hormone-binding proteins (thyroxine-binding globulin, TBG; thyroid-binding prealbumin, TBPA; and albumin). Only free hormone is available for action in the target tissues, where T₃ binds to specific nuclear receptors within target cells. Many drugs and other factors affect TBG; all may result in confusing total T₄ levels in blood, and most laboratories therefore now measure free T₄ levels.

**Control of the hypothalamic–pituitary–thyroid axis**

Thyrotrophin-releasing hormone (TRH), a peptide produced in the hypothalamus, stimulates the pituitary to secrete thyroid-stimulating hormone (TSH) (see Fig. 21.2). TSH, in turn, stimulates growth and activity of the thyroid follicular cells via the G-protein-coupled TSH membrane receptor (Box 21.24). The T₃ and T₄ subsequently secreted into the circulation by follicular cells exert negative feedback on the hypothalamus, as described on page 587.

Circulating T₄ is peripherally deiodinated to T₃, which binds to the thyroid hormone nuclear receptor (TR) on target organ cells to cause modified gene transcription. There are two TR receptors (TR-α and TR-β) and the tissue-specific effects of T₃ are dependent upon the local expression of these TR receptors. TR-α knockout mice show poor growth, bradycardia and hypothermia, while TR-β knockout mice show thyroid hyperplasia and high T₄ levels in the presence of inappropriately normal circulating TSH, suggesting a role for the latter receptors in thyroid hormone resistance (see p. 618).

**Dietary iodine requirement**

Globally, dietary iodine deficiency is a major cause of thyroid disease, as iodine is an essential requirement for thyroid hormone synthesis. The recommended daily intake of iodine should be at least 140 μg, and dietary supplementation of salt and bread has reduced the number of areas where ‘endemic goitre’ still occurs (see later).
Investigations: thyroid function tests

Immunoassays for free $T_4$, free $T_3$ and TSH are widely available. There are only minor circadian rhythms and measurements may be made at any time. Particular uses of the tests are summarized in Box 21.26, with typical findings in common disorders.

TSH measurement

In most circumstances, TSH levels can discriminate between hyperthyroidism, hypothyroidism and euthyroidism (normal thyroid gland function). Exceptions are hypopituitarism, and the ‘sick euthyroid’ syndrome where low levels (which normally imply hyperthyroidism) occur in the presence of low or normal $T_4$ and $T_3$ levels. As a single test of thyroid function, TSH measurement is the most sensitive in most circumstances, but accurate diagnosis requires at least two tests: for example, TSH plus free $T_4$ or free $T_3$ where hyperthyroidism is suspected; TSH plus serum free $T_4$ where hypothyroidism is likely.

TRH test

This has been rendered almost obsolete by modern sensitive TSH assays, except for investigation of hypothalamic–pituitary dysfunction. TRH (prolactin) is occasionally used to differentiate between thyroid hormone resistance and TSHoma in the context of raised $T_4$ and TSH levels. Typically, after TRH administration, there is a rise in TSH in thyroid hormone resistance, while in TSHoma there is a flat response due to continued autonomous TSH secretion, which does not respond to TRH.
Normal or low basal TSH (the ‘sick euthyroid’ syndrome). Levels are usually only mildly below normal and are thought to be mediated by interleukins IL-1 and IL-6; the tests should be repeated after resolution of the underlying illness.

**Pregnancy and oral contraceptives**

These lead to greatly increased TBG levels and thus to high or high-normal total T₄. Free T₄ is usually normal. Normal ranges for free T₃ and TSH alter with the normal physiological changes during pregnancy and TSH is often slightly suppressed in the first trimester, but this rarely causes clinical problems.

**Drugs**

Amiodarone decreases T₄ to T₃ conversion and free T₄ levels may therefore be above normal in a euthyroid patient; conversely, amiodarone may induce both hyper- and hypothyroidism – the TSH level is usually reliable. Many drugs affect thyroid function tests by interfering with protein binding but this now rarely causes a problem with free T₄ assays.

**Anti-thyroid antibodies**

Serum antibodies to the thyroid are common.

- **Destructive antibodies** are directed against the microsomes or against thyroglobulin; the antigen for thyroid microsomal antibodies is the thyroid peroxidase (TPO) enzyme. TPO antibodies are found in up to 20% of the normal population, especially older women, but only 10–20% of these develop overt hypothyroidism.

- **TSH receptor IgG antibodies (TRAb) typically stimulate, but occasionally block, the receptor. They are specific for Graves’ disease (see p. 614).**

**Hypothyroidism**

**Pathophysiology**

Underactivity of the thyroid is usually primary, caused by disease of the thyroid, but may be secondary to hypothalamic–pituitary disease (reduced TSH drive) **(Box 21.27).** Primary hypothyroidism is one of the most common endocrine conditions, with an overall UK prevalence of over 2% in women but under 0.1% in men; lifetime prevalence for an individual is higher – perhaps as high as 9% for women and 1% for men, with mean age at diagnosis around 60 years. The worldwide prevalence of subclinical hypothyroidism varies from 1% to 10%.

---

**Problems in interpretation of thyroid function tests**

There are three major areas of difficulty: serious acute or chronic illness, pregnancy and use of oral contraceptives, and certain drugs.

**Serious acute or chronic illness**

Thyroid function is affected in several ways:

- reduced concentration and affinity of binding proteins
- decreased peripheral conversion of T₄ to T₃ with more rT₃
- reduced hypothalamic–pituitary TSH production.

Systemically ill patients can therefore have an apparently low total and free T₄ and T₃ with a normal or low basal TSH (the ‘sick euthyroid’ syndrome). Levels are usually only mildly below normal and are thought to be mediated by interleukins IL-1 and IL-6; the tests should be repeated after resolution of the underlying illness.
**Aetiology of primary hypothyroidism**

See Box 21.27.

**Autoimmune**

Atrophic (autoimmune) hypothyroidism

This is the most common cause of hypothyroidism and is associated with anti-thyroid autoantibodies, leading to lymphoid infiltration of the gland and eventual atrophy and fibrosis. It is six times more common in females and the incidence increases with age. The condition is associated with other autoimmune diseases, such as pernicious anaemia, vitiligo and other endocrine deficiencies. Occasionally, intermittent hypothyroidism occurs with subsequent recovery; antibodies that block the TSH receptor may sometimes be involved in the aetiology.

Hashimoto’s thyroiditis

This form of autoimmune thyroiditis, again more common in women and most common in late middle age, produces atrophic changes with regeneration, leading to goitre formation. The gland is usually firm and rubbery but may range from soft to hard. TPO antibodies are present, often in very high titres (>1000 IU/L). Patients may be hypothyroid or euthyroid, though they may go through an initial toxic phase, ‘Hashi-toxicity’. Levothyroxine therapy may shrink the goitre, even when the patient is not hypothyroid.

Postpartum thyroiditis

This is usually a transient phenomenon observed following pregnancy. It may cause hyperthyroidism, hypothyroidism or the two sequentially. It is believed to result from the modifications to the immune system necessary in pregnancy, and histologically is a lymphocytic thyroiditis. The process is normally self-limiting, but when conventional antibodies are found there is a high chance of this proceeding to permanent hypothyroidism. Postpartum thyroiditis may be misdiagnosed as postnatal depression, emphasizing the need for thyroid function tests in this situation.

**Defects of hormone synthesis**

**Iodine deficiency**

Dietary iodine deficiency still exists (see p. 1245) as ‘endemic goitre’ in some areas where goitre, occasionally massive, is common. The patients may be euthyroid or hypothyroid, depending on the severity of iodine deficiency. The mechanism is thought to be borderline hypothyroidism leading to TSH stimulation and thyroid enlargement in the face of continuing iodine deficiency. Iodine deficiency is still a problem in the Netherlands, Western Pacific, India, South-east Asia, Russia and parts of Africa. Efforts to prevent deficiency by providing iodine in salt continue worldwide but often with incomplete success. Even in the late 20th century, of the 500 million with iodine deficiency in India, about 2 million had cretinism (see later).

**Dyshormonogenesis**

This rare condition is due to genetic defects in the synthesis of thyroid hormones; patients develop hypothyroidism with goitre. One particular familial form is associated with sensorineural deafness due to a deletion mutation in chromosome 7, causing a defect of the transporter pendrin (Pendred’s syndrome) (see Fig. 21.21).

**History and examination**

Hypothyroidism produces many symptoms (Fig. 21.22). The alternative term ‘myxoedema’ refers to the accumulation of mucopolysaccharide in subcutaneous tissues. The classic picture of the slow, dry-haired, thick-skinned, deep-voiced patient with weight gain,
cold intolerance, bradycardia and constipation makes the diagnosis easy. Milder symptoms are, however, more common and hard to distinguish from other causes of non-specific tiredness. Many cases are detected on biochemical screening.

Special difficulties in diagnosis may arise in certain circumstances:

- **Children with hypothyroidism** may not show classic features but often have a slow growth velocity, poor school performance and sometimes arrest of pubertal development.
- **Young women with hypothyroidism** may not show obvious signs. Hypothyroidism should be excluded in all people with oligomenorrhea/amenorrhoea, menorrhagia, infertility or hyperprolactinaemia.
- **The elderly** show many clinical features that are difficult to differentiate from normal ageing. Hypothyroidism should be excluded in elderly patients with cognitive impairment.

**Investigation of primary hypothyroidism**

**Serum TSH** is the investigation of choice; a high TSH level confirms primary hypothyroidism. A low free $T_4$ level confirms the hypothyroid state (and is also essential to exclude TSH deficiency if clinical hypothyroidism is strongly suspected and TSH is normal or low).

Thyroid and other organ-specific antibodies may be present. Other abnormalities include the following:

- **anaemia**, which is usually normochromic and normocytic in type but may be macrocytic (sometimes this is due to associated pernicious anaemia) or microcytic (in women, due to menorrhagia or undiagnosed coeliac disease)
- **increased serum aspartate transferase levels**, from muscle and/or liver
- **increased serum creatine kinase levels**, with associated myopathy
- **hypercholesterolaemia** and hypertriglyceridaemia
- **hyponatraemia** due to an increase in ADH and impaired free water clearance.

**Management**

**Replacement therapy**

Replacement therapy with levothyroxine (thyroxine, i.e. $T_4$) is given for life. The starting dose will depend upon the severity of the deficiency and on the age and fitness of the patient, especially their cardiac performance: 100 μg daily for the young and fit, 50 μg (increasing to 100 μg after 2–4 weeks) for the small, old or frail. People with ischaemic heart disease require even lower initial doses, especially if the hypothyroidism is severe and longstanding. Most physicians would then begin with 25 μg daily and perform serial electrocardiograms (ECGs), increasing the dose at 3- to 4-week intervals if angina does not occur or worsen, and the ECG does not deteriorate. Occasional patients develop “thyrotoxic” (hyperthyroid) symptoms despite normal $T_4$ levels if the dose is increased too rapidly.

**Monitoring**

The aim is to restore $T_4$ and TSH to well within the normal range. Adequacy of replacement is assessed clinically and by thyroid function tests after at least 6 weeks on a steady dose. If serum $T_4$ remains high, the dose of $T_4$ should be increased in increments of 25–50 μg, and the tests repeated at 6–8-week intervals until TSH becomes normal, ideally in the lower third of the normal range. Complete suppression of TSH should be avoided because of the risk of atrial fibrillation and osteoporosis. The usual maintenance dose is 100–150 μg given as a single daily dose. An annual thyroid function test is recommended – this is usually performed in the primary care setting, often assisted and prompted by district ‘thyroid registers’.

Clinical improvement on $T_4$ may not begin for 2 weeks or more, and full resolution of symptoms may take 6 months. The necessity for lifelong therapy must be emphasized and the possibility of other autoimmune endocrine disease developing, especially Addison’s disease or pernicious anaemia, should be considered. During pregnancy, an increase in $T_4$ dosage of about 25–50 μg is often needed to maintain relatively stricter TSH range of 0.3–2.5 mU/L, and the necessity for optimal replacement during pregnancy is emphasized by the finding of reductions in cognitive function in children of mothers with elevated TSH during pregnancy.

In cases where there is difficulty normalizing the TSH, compliance issues, concurrent medication that can interfere with thyroxine absorption (such as iron, calcium compounds and proton pump inhibitors) and undiagnosed coeliac disease should be considered.

A few people with primary hypothyroidism complain of incomplete symptomatic response to $T_4$ replacement. Combination $T_3$ and $T_4$ replacement has been advocated in this context, but randomized clinical trials show no consistent benefit in quality-of-life symptoms.

**Borderline hypothyroidism or ‘compensated euthyroidism’**

Patients are frequently seen with low-normal serum $T_4$ levels and slightly raised TSH levels. Treatment with levothyroxine is normally recommended where the TSH is consistently above 10 mU/L, or when possible symptoms, high-titre thyroid antibodies, or lipid abnormalities are present. Where the TSH is only marginally raised, the tests should be repeated 3–6 months later, as a significant proportion will be normal on repeat testing. Conversion to overt hypothyroidism is more common in men or when TPO antibodies are present. In practice, vague symptoms in people with marginally elevated TSH (below 10 mU/L) rarely respond to treatment, but a ‘therapeutic trial’ of replacement may be needed to confirm that symptoms are unrelated to the thyroid. It is also considered best to normalize TSH during (and ideally before) pregnancy to avoid potential fetal adverse effects.

**Myxoedema coma**

Severe hypothyroidism, especially in the elderly, may present with confusion or even coma. Myxoedema coma is very rare; hypothermia is often present and the patient may have severe cardiac failure, pericardial effusions, hypoventilation, hypoglycaemia and hyponatraemia. The mortality was previously at least 50% and patients require full intensive care. Optimal treatment is controversial and data are lacking; most physicians would advise $T_3$ orally or intravenously in doses of 2.5–5 μg every 8 hours, then increasing as above. Large intravenous doses should not be used. Additional measures, though unproven, should include:

- oxygen (by ventilation if necessary)
- monitoring of cardiac output and pressures
- gradual rewarming
- hydrocortisone 100 mg i.v. 8-hourly
- glucose infusion to prevent hypoglycaemia.

**Myxoedema madness**

Depression is common in hypothyroidism. Rarely, with severe hypothyroidism in the elderly, the patient may become frankly demented or psychotic, sometimes with striking delusions. This may occur shortly after starting $T_4$ replacement.
Screening for hypothyroidism
The incidence of congenital hypothyroidism is approximately 1 in 3500 births. Untreated, severe hypothyroidism produces permanent neurological and intellectual damage (‘cretinism’). Routine screening of the newborn using a blood spot, as in the Guthrie test, to detect a high TSH level as an indicator of primary hypothyroidism is efficient and cost-effective; cretinism is prevented if T₄ is started within the first few months of life.

Screening of elderly patients for thyroid dysfunction has a low pick-up rate, is controversial and is not currently recommended unless as part of a confusion screen. However, patients who have undergone thyroid surgery or received radio-iodine should have regular thyroid function tests, as should those receiving lithium or amiodarone therapy.

Hyperthyroidism
Hyperthyroidism (thyroid overactivity, thyrotoxicosis) is common, affecting perhaps 2–5% of all females at some time and having a sex ratio of 5:1; it most often occurs between the ages of 20 and 40 years. Nearly all cases (>99%) are caused by intrinsic thyroid disease; a pituitary cause is extremely rare (Box 21.28). Most common patterns of hyperthyroidism and their distinctive features are outlined in Box 21.29.

Graves’ disease
This is the most common cause of hyperthyroidism and is due to an autoimmune process. Serum IgG antibodies bind to TSH receptors in the thyroid, stimulating thyroid hormone production; that is, they behave like TSH. These TSH receptor antibodies (TSHR-Ab) are specific for Graves’ disease. Persistent high levels predict a relapse when drug treatment is stopped. There is an association with HLA-B8, DR3 and DR2; the concordance rate amongst monozygotic twins is 50% and that in dizygotic twins is 5%. There is an association with cytotoxic T lymphocyte-associated antigen 4 (CTLA-4), HLA-DRB¹*08 and DRB³*0202 on chromosome 6. The mechanism of immune damage is illustrated in Fig. 3.16.

Yersinia enterocolitica, Escherichia coli and other Gram-negative organisms contain TSH-binding sites. This raises the possibility that the initiating event in the pathogenesis may be an infection with possible ‘molecular mimicry’ in a genetically susceptible individual, but the precise initiating mechanisms remain unproven in most cases.

Thyroid eye disease is a feature of Graves’ disease. It may accompany the hyperthyroidism in many cases but patients may also be euthyroid or hypothyroid. Other components of Graves’ disease, such as Graves’ dermopathy, are very uncommon. Rarely, lymphadenopathy and splenomegaly may occur. Graves’ disease is also associated with other autoimmune disorders such as pernicious anaemia, vitiligo and myasthenia gravis.

The natural history is one of fluctuation, many patients showing a pattern of alternating relapse and remission; perhaps only 40% of subjects have a single episode. Many patients eventually become hypothyroid.

Other causes of hyperthyroidism/thyrotoxicosis
Solitary toxic adenoma/nodule
This is the cause of about 5% of cases of hyperthyroidism. While the hyperthyroidism will be controlled by the anti-thyroid drugs, it does not usually remit after a course of anti-thyroid drugs.
Toxic multinodular goitre
This commonly occurs in older women. Again, anti-thyroid drugs are rarely successful in inducing a remission, although they can control the hyperthyroidism.

De Quervain’s thyroiditis
This is transient hyperthyroidism from an acute inflammatory process, probably viral in origin. Apart from the toxicosis, there is usually fever, malaise and pain in the neck with tachycardia and local thyroid tenderness. Thyroid function tests show initial hyperthyroidism, the erythrocyte sedimentation rate (ESR) and plasma viscosity are raised, and thyroid uptake scans show suppression of uptake in the acute phase. Hypothyroidism, usually transient, may then follow after a few weeks. Treatment of the acute phase is with aspirin, using short-term prednisolone in severely symptomatic cases.

Postpartum thyroiditis
This is described on page 612.

Amiodarone-induced thyrotoxicosis
Amiodarone, a class III antiarrhythmic drug (see p. 1067), causes two types of hyperthyroidism.

- **Type I amiodarone-induced thyrotoxicosis (AIT)** is associated with pre-existing Graves’ disease or multinodular goitre. In this situation, hyperthyroidism is probably triggered by the high iodine content of amiodarone.

- **Type II AIT** is not associated with previous thyroid disease and is thought to be due to a direct effect of the drug on thyroid follicular cells, leading to a destructive thyroiditis with release of T₄ and T₃. Type II AIT may be associated with a hypothyroid phase several months after presentation. Because amiodarone inhibits the deiodination of T₄ to T₃, biochemical presentation of both types of AIT may be associated with higher T₄:T₃ ratios than usual.

Immunotherapy-induced thyrotoxicosis
Cancer immunotherapy drugs that block negative regulators on T cell, called immune checkpoint inhibitors (ipilimumab, pembrolizumab, nivolumab) have been found to be effective in wide range cancers. These drugs cause immune-related adverse events (irAEs) in various organs, including in endocrine glands, resulting in thyroiditis (15%), hypophysitis (9%), adrenalitis (1%) and type 1 diabetes mellitus (<1%). Thyroiditis is the most common of endocrine irAEs and occurs between 3 and 12 weeks after initiation of the drug. Treatment is with beta-blockers, analgesia and, rarely, with anti-thyroid medication if thyrotoxicosis persists, especially with symptoms.

History and examination
The symptoms and signs of hyperthyroidism affect many systems (Fig. 21.23). Symptomatology and signs vary with age and with the underlying aetiology.

- **The eye signs – lid lag and ‘stare’** – may occur with hyperthyroidism of any cause but other features of thyroid eye disease (see below) occur only in Graves’ disease.
hyperthyroidism. The hyperdynamic circulation with warm peripheries seen with hyperthyroidism can be contrasted with the clammy hands of anxiety.

Investigations
• Serum TSH is suppressed in hyperthyroidism (<0.05 mU/L), except for the very rare instances of TSH hypersecretion.
• A raised free T₄ or T₃ confirms the diagnosis; T₄ is almost always raised but T₃ is more sensitive, as there are occasional cases of isolated ‘T₃ toxicosis’.
• TSH receptor stimulating antibodies (TSHR-Ab) are now measured routinely and the third-generation tests are 97–99% specific for Graves’ disease.
• Thyroid peroxidase (TPO) and thyroglobulin antibodies are present in 80% of cases of Graves’ disease, but are also found in normal individuals.
• Scintiscan ⁹⁹Tm is used in patients who are antibody negative to look for toxic nodular disease.

Management
Three possibilities are available: anti-thyroid drugs, radio-iodine and surgery. Practices and beliefs differ widely within and between countries.

Anti-thyroid drugs
Carbimazole is most often used in the UK, and propylthiouracil (PTU) is also an option. Thiamazole (methimazole), the active metabolite of carbimazole, is used in the USA. These drugs inhibit the formation of thyroid hormones and also have other minor actions; carbimazole/thiamazole is also an immunosuppressive agent. Initial doses and side-effects are detailed in Box 21.30.

Although thyroid hormone synthesis is reduced very quickly, the long half-life of T₄ (7 days) means that clinical benefit is not apparent for 10–20 days. As many of the manifestations of hyperthyroidism are mediated via the sympathetic system, beta-blockers are used to provide rapid partial symptomatic control; they also decrease peripheral conversion of T₄ to T₃. Preferred drugs are those without intrinsic sympathomimetic activity, e.g. propranolol (see Box 21.30).

Differential diagnosis
Hyperthyroidism is often clinically obvious but treatment should never be instituted without biochemical confirmation.

Differentiation of the mild case from anxiety states may be difficult; useful positive clinical markers are eye signs, a diffuse goitre, proximal myopathy and wasting. Weight loss, despite a normal or increased appetite, is a very useful clinical symptom of hyperthyroidism. They may also show weight gain rather than loss.

So-called ‘apathetic thyrotoxicosis’ in some elderly patients presents with a clinical picture more like that of hypothyroidism. There may be very few signs and a high degree of clinical suspicion is essential.

They should not be used alone for hyperthyroidism except when the condition is self-limiting, as in subacute thyroiditis.

Subsequent management is either by gradual dose titration or by a ‘block and replace’ regimen. Neither regimen has been shown to be unequivocally superior. TSH often remains suppressed for many months after clinical improvement and normalization of T₄ and T₃.

Dosage regimen
Gradual dose titration
1. Start carbimazole 20–40 mg daily.
2. Review after 4–6 weeks and reduce the dose of carbimazole, depending on clinical state and fT₄/fT₃ levels. TSH levels may remain suppressed for several months and are unhelpful at this stage.
3. When the patient is clinically and biochemically euthyroid, stop beta-blockers.
4. Review thyroid function regularly during the planned course of treatment (typically 18 months – but some use courses between 6 and 24 months).
5. Reduce carbimazole if fT₄ is above normal, and when approaching the end of the planned course.
6. Increase carbimazole if TSH remains suppressed after several months with a normal fT₄.
7. Stop treatment at the end of the course if the patient is euthyroid on 5 mg daily carbimazole. PTU is used in similar fashion (see Box 21.30).

‘Block and replace’ regimen
With this policy, full doses of anti-thyroid drugs, usually carbimazole 40 mg daily, are given to suppress the thyroid completely while replacing thyroid activity with 100 µg of levothyroxine daily once euthyroidism has been achieved. This is continued usually for 18 months, the claimed advantages being the avoidance of overtreatment and the better use of the immunosuppressive action of carbimazole. This regimen is contraindicated in pregnancy, as T₄ crosses the placenta less well than carbimazole.
Relapse
About 50% of patients will relapse after a course of carbimazole or PTU, mostly within the following 2 years but occasionally much later. Long-term anti-thyroid therapy is then used, or surgery or radiotherapy is considered (see below). Most patients (90%) with hyperthyroidism have a diffuse goitre but those with large single or multinodular goitres are unlikely to remit after a course of anti-thyroid drugs and will usually require definitive treatment. Severe biochemical hyperthyroidism is also less likely to remain in remission.

Toxicity
The major side-effect of drug therapy is agranulocytosis, which occurs in approximately 1 in 1000 patients, usually within 3 months of treatment. All patients must be warned to seek immediate medical attention and to have a check of their white blood cell count if they develop unexplained fever or sore throat; written information is essential. Rash is more frequent and usually require a change of drug. If toxicity occurs on carbimazole, PTU may be used, and vice versa; side-effects are only occasionally repeated on the other drug.

Radioactive iodine
Radioactive iodine (RAI) is given to patients of all ages, although it is contraindicated in pregnancy and while breast-feeding. RAI is the most common treatment modality in the USA, whereas anti-thyroid drugs tend to be favoured in Europe.

\[^{131}\text{I} \text{iodine} \] is given in an empirical dose (usually 400–550 MBq) because of variable uptake and radiosensitivity of the gland. It accumulates in the thyroid and destroys the gland by local radiation, although it takes several months to be fully effective.

Patients must be rendered euthyroid before treatment. They should stop anti-thyroid drugs at least 4 days before radio-iodine, and not recommence until 3 days after radio-iodine. Patients on PTU should stop anti-thyroid medication before RAI earlier than those on carbimazole because it has a radioprotective action. Many patients do not need to restart anti-thyroid medication after treatment.

Early discomfort in the neck and immediate worsening of hyperthyroidism are sometimes seen. If worsening occurs, the patient should receive propranolol (see Box 21.30); if necessary, carbimazole can be restarted. Euthyroidism normally returns in 2–3 months. People with dysthyroid eye disease are more likely to show worsening of eye problems after radio-iodine than after anti-thyroid drugs; this represents a partial contraindication to RAI, although worsening can usually be prevented by steroid administration.

Long-term surveillance
Hyperthyroidism affects the majority of subjects over the following 20 years. Some 75% of patients are rendered euthyroid in the short term, but a small proportion remain hyperthyroid and may require a second dose of radio-iodine. Long-term surveillance of thyroid function is necessary, with frequent tests in the first year after therapy and at least annually thereafter.

There is no increased risk of malignancy after RAI.

Surgery
Thyroidectomy should be performed only in patients who have previously been rendered euthyroid. Conventional practice is to stop the anti-thyroid drug 10–14 days before operation and to give potassium iodide (60 mg three times daily), which reduces the vascularity of the gland and reduces thyroid hormone synthesis by inhibiting organification of iodine (Wolff–Chaikoff effect).

The operation should be performed only by experienced surgeons to reduce the chance of complications:

- Early postoperative bleeding causing tracheal compression and asphyxia is a rare emergency that mandates immediate removal of all clips/sutures to allow escape of the blood/haematoma.
- Laryngeal nerve palsy occurs in 1%. Vocal cord movement should be checked preoperatively. Mild hoarseness is more common and thyroidectomy is best avoided in professional singers!
- Transient hypocalcaemia occurs in up to 10% but with permanent hypoparathyroidism in fewer than 1%.
- Ongoing thyroid function depends on the operation performed. With a single toxic nodule, excision of the lesion is curative. With Graves’ disease or multinodular goitre, the traditional ‘subtotal’ thyroidectomy, aiming for euthyroidism on no treatment, results in recurrent hyperthyroidism in 1–3% within 1 year, then 1% per year and hypothyroidism in about 10% of patients within 1 year, and then increasing with time. ‘Near-total’ thyroidectomy is therefore now preferred, with inevitable hypothyroidism but a much-reduced risk of recurrence. Indications for either surgery or radio-iodine are given in Box 21.31.

Special situations in hyperthyroidism

Thyroid crisis or ‘thyroid storm’
This rare condition, with a mortality of 10%, is a rapid deterioration of hyperthyroidism with hyperpyrexia, severe tachycardia, extreme restlessness, cardiac failure and liver dysfunction. It is usually precipitated by stress, infection or surgery in an unprepared patient, or by radio-iodine therapy. With careful management, it should no longer occur and most cases referred to as a ‘crisis’ are simply severe but uncomplicated thyrotoxicosis.

Treatment is urgent. Propranolol in full doses is started immediately together with potassium iodide, anti-thyroid drugs, corticosteroids (which suppress many of the manifestations of hyperthyroidism) and full supportive measures. Control of cardiac failure and tachycardia is also necessary.

Occasionally, hyperthyroidism can lead to a thyrotoxic myopathy, which causes ischaemic changes on a 12-lead ECG; these reverse after euthyroidism is achieved (Fig. 21.24).

Hyperthyroidism in pregnancy and neonatal life
Since hyperthyroidism typically affects young women, pregnancies, both planned and unplanned, inevitably occur during anti-thyroid treatment. PTU is usually the preferred anti-thyroid drug at conception and in the first trimester of pregnancy or in any woman planning pregnancy, due to rare reports of congenital abnormalities with carbimazole, which have not been described with PTU (p. 1459). However, carbimazole is recommended in the second and third trimesters, as liver problems are more frequently described on PTU.

The high level of HCG found in normal pregnancy is a weak stimulator of the TSH receptor, commonly causing suppressed TSH with slightly elevated \( \text{fT}_4/\text{fT}_3 \) in the first trimester, which may be
Thyroid hormone resistance is an inherited condition, caused by an abnormality of the thyroid hormone receptor. Mutations to the receptor (TR β) result in the need for higher levels of thyroid hormones to achieve the same intracellular effect. As a result, the normal feedback control mechanisms (see Fig. 21.2) result in high blood levels of T₄ with a normal TSH in order to maintain a euthyroid state. This has two consequences:

- Thyroid function tests appear abnormal, even when the patient is euthyroid and requires no treatment. Specialist review is needed to differentiate this condition from hyperthyroidism due to inappropriate TSH secretion.
- Different tissues contain different thyroid hormone receptors and, in some families, receptors in certain tissues may have normal activity. In this case, the level of thyroid hormones to maintain euthyroidism at pituitary and hypothalamic levels (which controls secretion of TSH) may be higher than that required in other tissues such as heart and bone, so that these tissues may exhibit ‘thyrotoxic’ effects in spite of a normal serum TSH. This ‘partial thyroid hormone resistance’ can be very difficult to manage effectively.

Thyroid hormone resistance is diagnosed on the basis of a raised T₄/T₃ in the context of a non-elevated TSH. The differential diagnosis of this pattern of blood results includes TSHoma and laboratory assay interference.

Long-term consequences of hyperthyroidism

Long-term follow-up studies of hyperthyroidism show a slight increase in overall mortality, which affects all age groups, is not fully explained and tends to occur in the first year after diagnosis. Thereafter, the only long-term risk of adequately treated hyperthyroidism appears to be an increased risk of osteoporosis. People with persistently suppressed TSH levels have an increased likelihood of developing atrial fibrillation, which may predispose to thromboembolic disease.

Graves’ orbitopathy (ophthalmopathy)

Pathophysiology

Graves’ orbitopathy is due to a specific immune response that causes retro-orbital inflammation (Fig. 21.25). Swelling and oedema of the extraocular muscles lead to limitation of movement and to proptosis, which is usually bilateral but can sometimes be unilateral. Ultimately, increased pressure on the optic nerve may cause optic atrophy. Histology of the extraocular muscles shows focal oedema and glycosaminoglycan deposition followed by fibrosis. The precise autoantigen that leads to the immune response remains to be identified, but it appears to be an antigen in retro-orbital tissue with similar immunoreactivity to the TSH receptor.

Eye disease is a manifestation of Graves’ disease and can occur in patients who may be hyperthyroid, euthyroid or hypothyroid. Thyroid dysfunction and orbitopathy usually occur within 2 years of each other, although sometimes a gap of many years is seen. TSH receptor antibodies are almost invariably found in the serum; their role in the pathogenesis is becoming clearer (see Fig. 21.25). Orbitopathy is more common and more severe in smokers.

Clinical features

The clinical appearances are characteristic (see Fig. 21.23) but thyroid eye disease demonstrates a wide range of severity. A high proportion of people with Graves’ disease notice some soreness, painful watering or prominence of the eyes, and the ‘stare’ of lid retraction is relatively common. More severe proptosis occurs in a minority of cases, and limitation and discomfort of eye movement
The thyroid axis 619

...and visual impairment due to optic nerve compression are relatively uncommon. Proptosis and lid retraction may limit the ability to close the eyes completely so that corneal damage may occur. There is periorbital oedema, and conjunctival oedema and inflammation.

Eye manifestations do not parallel the degree of biochemical thyrotoxicosis or the need for anti-thyroid therapy, but exacerbation of eye disease is more common after radio-iodine treatment (15% versus 3% on anti-thyroid drugs). Sight is threatened in only 5–10% of cases, but the discomfort and cosmetic problems cause great patient anxiety.

Investigations
If the appearance is characteristic, consideration is needed as to whether the patient requires review by an ophthalmologist. Investigation would include:

- TSH, fT3 and fT4 measurement.
- MRI or CT of the orbits to exclude retro-orbital space-occupying lesions. In Graves’ orbitopathy, there may be enlarged muscles and oedema, with a taut optic nerve due to raised intra-orbital pressure.
- Assessment of vision, particularly optic nerve function.

Management
If the patient is thyrotoxic, this should be treated, but treatment will not directly result in an improvement of the orbitopathy; hypothyroidism must be avoided, as it may exacerbate the eye problem. Smoking should be stopped. Treatment of the eyes may be either local or systemic, and always requires close liaison between specialist endocrinologist and ophthalmologist:

- Methylcellulose or hypromellose eyedrops or ointment are given to aid lubrication and improve comfort.
- Sleeping upright affords some patients relief.
- Taping the eyelids ensures closure at night.

- Systemic steroids (prednisolone 30–120 mg daily) usually reduce inflammation if more severe symptoms are present. Pulse intravenous methylprednisolone may be used initially and is more rapidly effective in severe cases.
- Surgical decompression of the orbit(s) may be required, particularly if pressure of orbital contents on the optic nerve threatens vision (often called a ‘hot’ decompression), and at a later, stable stage for cosmetic reasons (‘cold’ decompression).
- Lid surgery will protect the cornea if lids cannot be closed, and can be useful later for cosmetic reasons.
- Corrective eye muscle surgery may improve diplopia due to muscle changes; it should be deferred until the situation has been stable for 6 months and should follow any orbital decompression.
- Irradiation of the orbits (20 Gy in divided doses) is used in some centres. This reduces inflammation and ocular motility but has little effect on proptosis; its precise role is debated.
- Immunomodulatory agents may produce a response in some patients when conventional treatments fail, although clinical trial evidence is inconsistent.
- Selenium may have a beneficial effect on mild orbitopathy in some patients.

Goitre (thyroid enlargement)
Goitre is more common in women than in men and may be either physiological or pathological.

Clinical features
Goitres are present on examination in up to 9% of the population. Most commonly, a goitre is noticed as a cosmetic defect by the patient or by friends or relatives. The majority are painless, but pain or discomfort can occur in acute varieties. Large goitres can...
produce dysphagia and difficulty in breathing, implying oesophageal or tracheal compression.

A small goitre may be more easily visible (on swallowing) than palpable. Clinical examination should record the size, shape, consistency and mobility of the gland, as well as whether its lower margin can be demarcated (thus implying the absence of retrosternal extension). A bruit may be present. Associated lymph nodes should be sought and the tracheal position determined if possible. Examination should never omit an assessment of the patient’s clinical thyroid status.

Specific enquiry should be made about any medication, especially iodine-containing preparations, and possible exposure to radiation.

Particular points of note are as follows:
- Puberty and pregnancy may produce a diffuse increase in size of the thyroid.
- Pain in a goitre may be caused by thyroiditis, bleeding into a cyst or (rarely) a thyroid tumour.
- Excessive doses of carbimazole or PTU will induce goitre.
- Iodine deficiency and dyshormonogenesis (see earlier) can also cause goitre.

**Diagnosis**

There are four major aspects to any goitre: its pathological nature, whether it is causing any compressive symptoms, the patient’s thyroid status and whether it is of cosmetic concern. The nature can often be judged clinically. Goitres (Box 21.32) are usually separable into diffuse and nodular types, the causes of which differ.

**Diffuse goitre**

**Simple goitre**
In this instance, no clear cause is found for enlargement of the thyroid, which is usually smooth and soft. It may be associated with thyroid growth-stimulating antibodies.

**Autoimmune thyroid disease**
Hashimoto’s thyroiditis and Grave’s disease thyrotoxicosis are both associated with firm diffuse goitre of variable size. A bruit is often present in thyrotoxicosis.

**Thyroiditis**
Acute tenderness in a diffuse swelling, sometimes with severe pain, is suggestive of an acute viral thyroiditis (de Quervain’s). It may produce transient clinical hyperthyroidism with an increase in serum T4 (see p. 615).

**Nodular goitres**

**Multinodular goitre**
Most common is the multinodular goitre, especially in older patients. The patient is usually euthyroid but may have clinical hyperthyroidism or subclinical hyperthyroidism (suppressed or low TSH levels but normal free T4 and T3). Multinodular goitre is the most common cause of tracheal and/or oesophageal compression and can lead to laryngeal nerve palsy. It may also extend retrosternally (Fig. 21.26).

The classical ‘multinodular goitre’ is usually readily apparent clinically, but it should be noted that modern, high-resolution ultrasound frequently reports multiple small nodules in glands, which are clinically diffusely enlarged and associated with autoimmune thyroid disease. These nodules are also found in up to 40% of the normal population.

**Fig. 21.26 Imaging of goitre.** (A) Tc scan showing a multinodular goitre, with predominant involvement of the left lobe of the thyroid (anterior view with arrowed anatomical marker at the sternal notch). (B) Retrosternal goitre showing deviation and compression of the trachea (arrowed) on CT.
Solitary nodular goitre

Such a goitre presents a difficult problem of diagnosis. Malignancy should be of concern in any solitary nodule; however, the majority of such nodules are cystic or benign and, indeed, may simply be the largest nodule of a multinodular goitre. The diagnostic challenge is to differentiate the small minority of malignant nodules, which require surgery, from the majority of benign nodules, which do not. Sometimes a history of rapid enlargement, associated lymph nodes or pain may suggest an aggressive malignancy, but most thyroid cancers are painless and slow-growing so that investigations are paramount. Risk factors for malignancy include previous irradiation, longstanding iodine deficiency and occasional familial cases.

Solitary toxic nodules are quite uncommon and may be associated with T3 toxicosis.

Fibrotic goitre (Riedel's thyroiditis)

Fibrotic goitre is a rare condition, usually producing a ‘woody’ gland. It is associated with other midline fibrosis and is often difficult to distinguish from carcinoma, being irregular and hard. Clinical clues include systemic symptoms of inflammation and elevation in inflammatory markers; it has been shown to be an IgG4-related disease.

Malignancy

In addition to thyroid carcinomas (see later), the thyroid is rarely the site of a metastatic deposit or the site of origin of a lymphoma.

Investigations

Clinical findings will dictate the appropriate initial tests:

- **Thyroid function tests** should include measurement of TSH plus free T4 or T3 (see Box 21.7).
- **Thyroid antibodies** are assessed to exclude an autoimmune aetiology.
- **Ultrasound** with high resolution is a sensitive method for delineating nodules and can demonstrate whether they are cystic or solid. In addition, a multinodular goitre may be demonstrated when only a single nodule is palpable. Unfortunately, even cystic lesions can be malignant and thyroid tumours may arise within a multinodular goitre; therefore fine-needle aspiration (see below) is often required and is performed under ultrasound control at the same time as the scan.

- **Chest and thoracic inlet X-rays or CT scan** may detect tracheal compression and large retrosternal extensions in people with a very large goitre or clinical symptoms.
- **Fine-needle aspiration (FNA)** should be performed in the outpatient clinic or during ultrasound if the appearance is suggestive of potential malignancy, based on defined ultrasound criteria, as in people with a solitary nodule or a dominant nodule in a multinodular goitre, there is a 5% chance of malignancy. Cytology in expert hands can usually differentiate the suspicious or definitely malignant nodules. FNA reduces the necessity for surgery but there is a 5% false-negative rate, which must be borne in mind (and the patient appropriately counselled). Continued observation is required when an isolated thyroid nodule is assumed to be benign without excision.

- **Thyroid scan** (99mTc) can be useful to distinguish between functioning (hot) or non-functioning (cold) nodules. A hot nodule is only rarely malignant; however, a cold nodule is malignant in 10% of cases and FNA has largely replaced isotope scans in the diagnosis of thyroid nodules.

Management

**Euthyroid goitre**

Many goitres are small, cause no symptoms and can be observed (including self-monitoring by the patient in the long term). In particular, during puberty and pregnancy, a goitre associated with euthyroidism rarely requires intervention and the patient can be reassured that spontaneous resolution is likely. Indications for surgical intervention are:

- **The possibility of malignancy.** A positive or suspicious FNA makes surgery mandatory, and surgery may be necessary if doubt persists, even in the presence of a negative FNA (especially if the patient is concerned by the false-negative rate).
- **Pressure symptoms on the trachea, or, more rarely, the oesophagus.** The possibility of retrosternal extension should be excluded.
- **Cosmetic reasons.** A large goitre often causes considerable anxiety to the patient, even though it is functionally and anatomically benign.

RAI has also been advocated for the treatment of euthyroid goitre, particularly when surgery is an unattractive option.

**Toxic nodule**

This is initially treated with anti-thyroid drugs but surgery or radioiodine is often required.

**Thyroid carcinoma**

Types of thyroid carcinoma, with their characteristics and treatment, are listed in Box 21.33. While not common, these tumours are responsible for 400 deaths annually in the UK and there is an annual incidence of 30,000 cases in the USA. Over 75% occur in women. They present in 90% of cases as thyroid nodules (see above), but occasionally with cervical lymphadenopathy (about 5%), or with lung, cerebral, hepatic or bone metastases.

Carcinomas derived from thyroid epithelium may be papillary or follicular (differentiated), or anaplastic (undifferentiated). Medullary carcinomas (about 5% of all thyroid cancers) arise from the calcitonin-producing C cells. The pathogenesis of thyroid
epithelial carcinomas is not understood, except for occasional familial papillary carcinoma, and those cases related to previous head and neck irradiation or ingestion of RAI (e.g., post-Chernobyl). These tumours are minimally active hormonally and are extremely rarely associated with hyperthyroidism; over 90%, however, secrete thyroglobulin, which can therefore act as a tumour marker after thyroid ablation.

**Papillary and follicular carcinomas**

The primary treatment is surgical: normally total or near-total thyroidectomy for local disease. Regional or more extensive neck dissection is needed where there is local nodal spread or involvement of local structures.

Most tumours will take up iodine, and UK and other guidelines currently recommend RAI ablation of residual thyroid tissue postoperatively for most people with differentiated thyroid cancer. After ablation of normal thyroid in this way, RAI may be used to localize residual disease (scanning using low doses) or to treat it (using high doses: 5.5–7.5 GBq). When disease does recur, local invasion and lymph node involvement is most common, and lungs and bone are the most common sites of distant metastases.

**To minimize risk of recurrence** patients are treated with suppressive doses of levothyroxine (sufficient to suppress TSH levels below the normal range). Patient progress is monitored, both clinically and biochemically, using serum thyroglobulin levels as a tumour marker. The measurement of thyroglobulin is most sensitive when TSH is high but this requires the withdrawal of levothyroxine therapy. Recombinant TSH (thyrotropin alpha, rhTSH) 900 μg (2 doses over 48 h) is used to stimulate thyroglobulin without stopping levothyroxine therapy. Detectable thyroglobulin suggests recurrence, in which case whole-body 131I scanning is required. Unfortunately, the presence of anti-thyroglobulin antibodies can make the assay unreliable.

The **prognosis** is extremely good when differentiated thyroid cancer is excised while confined to the thyroid gland, and the specific therapies available lead to a relatively good prognosis even in the presence of metastases at diagnosis. Accepted markers of high risk include greater age (>40 years), larger primary tumour size (>4 cm) and macroscopic invasion of capsule and surrounding tissues. Recently, oral sorafenib has shown a good short-term response in locally advanced and metastatic differentiated thyroid cancers that were refractory to RAI.

**Medullary carcinoma**

Medullary thyroid carcinoma (MTC) is a neuroendocrine tumour of the calcitonin-producing C cells of the thyroid. This condition is often associated with MEN 2 (see p. 650). Approximately 25% of patients diagnosed with MTC have a mutation of the RET proto-oncogene, although the other manifestations of MEN 2 may be absent; hence the importance of genetic counselling and family screening. People with MEN 2 mutations are advised to have a prophylactic thyroidectomy as early as 5 years of age to prevent the development of MTC.

Total thyroidectomy and wide lymph node clearance are usually indicated in MTC. Local invasion or metastasis is frequent, and the tumour responds poorly to treatment, although progression is often slow. Recent biological therapy with vandetanib and cabozantinib has shown benefit in advanced medullary thyroid carcinoma.

**Anaplastic carcinomas and lymphoma**

These do not respond to RAI, and external radiotherapy produces only a brief respite.

**HYPOTHALAMO–PITUITARY–GONADAL AXIS**

The hypothalmo–pituitary–gonadal axis controls progress through puberty (p. 633) and the capacity for reproduction. Terminology in reproductive medicine is shown in Box 21.34.

**Anatomy and physiology**

**Embryology**

Up to 8 weeks of gestation, the sexes share a common development, with a primitive genital tract including the Wolffian and...
Müllerian ducts. Additionally, there are a primitive perineum and primitive gonads.

- In the presence of a Y chromosome, the potential testis develops while the ovary regresses.
- In the absence of a Y chromosome, the potential ovary develops and related ducts form a uterus and the upper vagina.

Production of Müllerian inhibitory factor from the early ‘testis’ produces atrophy of the Müllerian duct, while, under the influence of testosterone and dihydrotestosterone, the Wolffian duct differentiates into an epididymis, vas deferens, seminal vesicles and prostate. Androgens induce transformation of the perineum to include a penis, penile urethra and scrotum containing the testes, which descend in response to androgenic stimulation. At birth, testicular volume is 0.5–1 mL. The number of oocytes in the ovaries of a female fetus has reached a maximum by the end of the second trimester of in utero development. At birth, the ovaries contain about 3 million oocytes, of which only 400 000 will remain by the time puberty occurs. With the onset of menarche, these oocytes will activate and grow, leading to ovulation and then menstruation.

**Physiology**

An outline of the hypothalamic–pituitary–gonadal axis is shown in Fig. 21.27.

Pulses of gonadotrophin-releasing hormone (GnRH) are released from the hypothalamus and stimulate luteinizing hormone (LH) and follicle-stimulating hormone (FSH) release from the pituitary. LH and FSH are composed of two glycoprotein chains (α and β subunits). The α subunits are identical and are shared with TSH, while the β subunit confers specific biological activity (Box 21.35)

### The male

1. LH stimulates testosterone production from Leydig cells of the testis.
2. Testosterone acts via nuclear androgen receptors, which interact with co-regulatory proteins to produce the appropriate tissue responses: progress through puberty, anabolism and the maintenance of libido. It also acts locally within the testis to aid spermatogenesis. Testosterone circulates largely bound to sex hormone-binding globulin (SHBG) (see p. 588). Testosterone feeds back on the hypothalamus/pituitary to inhibit GnRH secretion.
3. FSH stimulates the Sertoli cells in the seminiferous tubules to produce mature sperm and the inhibins A and B.
4. Inhibin feeds back to the pituitary to decrease FSH secretion. Activin, a related peptide, counteracts inhibin.

### The female

Female physiology is more complex (see Figs 21.27 and 21.28).

1. During puberty in response to pulses of hypothalamic GnRH, pituitary secretes LH and FSH, which stimulate androgen and oestrogen production from the ovaries resulting in progress through puberty followed by menarche and the establishment of the menstrual cycle.
2. The menstrual cycle depends upon the activity of hypothalamic GnRH. Pulses of GnRH, at about 2-hour intervals, stimulate release of pituitary LH and FSH.
3. Menstrual cycles are often irregular during adolescence, particularly the interval from the first cycle to the second cycle as immaturity of the hypothalamic–pituitary–ovarian axis during the early years after menarche often results in anovulation and cycles may be somewhat long (90% of cycles: 21–45 days). By
the third year after menarche, 60–80% of menstrual cycles are 21–34 days long, as is typical of adults.

4. LH stimulates ovarian androgen production by the ovarian theca cells.

5. FSH stimulates follicular development and activity of aromatase (an enzyme required to convert ovarian androgens to estrogens) in the ovarian granulosa cells. FSH also stimulates release of inhibin from ovarian stromal cells, which inhibits FSH release. Activin counteracts inhibin (see Fig. 21.27).

6. Although many follicles are ‘recruited’ for development in early folliculogenesis, by day 8–10 a ‘leading’ (or ‘dominant’) follicle is selected for development into a mature Graafian follicle.

7. Oestrogens have a double feedback action on the pituitary (see Fig. 21.27). Initially, they inhibit gonadotrophin secretion (negative feedback) but, later, high-level exposure results in increased GnRH secretion and increased LH sensitivity to GnRH (positive feedback), which leads to the mid-cycle LH surge, inducing ovulation from the leading follicle (see Fig. 21.28).

8. The follicle then differentiates into a corpus luteum, which secretes both progesterone and oestriadiol during the second half of the cycle (luteal phase).

9. Oestrogen initially and then progesterone cause uterine endometrial proliferation in preparation for possible implantation; if implantation does not occur, the corpus luteum regresses and progesterone secretion and inhibin levels fall so that the endometrium is shed (menstruation), allowing increased GnRH and FSH secretion.

10. If implantation and pregnancy follow, human chorionic gonadotrophin (HCG) production from the trophoblast maintains corpus luteum function until 10–12 weeks of gestation, by which time the placenta will be making sufficient oestrogen and progesterone to support itself.

**Clinical features of disorders of sex and reproduction**

A detailed history and examination of all systems are required (Box 21.36). A man having regular satisfactory intercourse or a woman with regular ovulatory periods is most unlikely to have significant endocrine disease, assuming the history is accurate.

**Investigation of gonadal function**

In adults much can be deduced from basal measurements of the gonadotrophins, oestrogens/testosterone and prolactin:

- High gonadotrophins with low testosterone or oestradiol indicates primary gonadal disease.
- Low levels of testosterone/oestradiol with low or normal LH/FSH imply hypothalamic–pituitary disease.
- Demonstration of ovulation (by measurement of luteal phase serum progesterone and/or by serial ovarian ultrasound in the follicular phase) or a healthy sperm count (20–200 million/mL, >60% grade I motility and <20% abnormal forms) provides

adulthood may present with poor libido, erectile dysfunction and loss of secondary sexual hair (Box 21.38). Hypogonadism may also be an incidental finding, such as one that emerges during investigation for subfertility. Semen volume is usually maintained as sperm makes up for only a very small proportion of seminal fluid volume; most is prostatic fluid. The tests may be small and soft, and there may be gynaecomastia. Except with subfertility, the symptoms are usually those of androgen deficiency.

Causes of male hypogonadism are shown in Box 21.39.

Investigations

Hypogonadism may be immediately apparent but basal levels of testosterone, LH and FSH should be measured. These will allow the distinction to be made between primary gonadal (testicular) failure and hypothalamic–pituitary disease. If primary gonadal failure is identified, chromosomal analysis (e.g. to exclude Klinefelter’s syndrome) is required. In secondary gonadal failure, gonadotrophin deficiency, pituitary MRI scan, prolactin levels and other pituitary function tests are needed.

A frequent cause of referral is men with poor libido or erectile dysfunction with equivocal lowering of serum testosterone (7–10 nmol/L) without elevation of gonadotrophins. If the testosterone was taken in the morning, such test results can be interpreted as mild gonadotrophin deficiency or lower end of the normal, but may also be seen in people with obesity and diabetes mellitus, who commonly have low circulating SHBG levels associated with insulin resistance and therefore low total testosterone levels but normal free testosterone levels. Regular use of opiate analgesia may lead to gonadotrophin deficiency and should be considered. ‘Anabolic’ steroid (i.e. androgen) abuse causes similar biochemical findings and is likely if the patient appears well virilized. A therapeutic trial of testosterone replacement is often justified and forms part of the

Disorders in the male

Hypogonadism

History and examination

How a male presents depends on age. Hypogonadism in an adolescent would present with delayed puberty and/or growth, whereas an

• Absolute confirmation of normal female or male reproductive endocrinology, but these tests are not always essential.
• Pregnancy provides complete demonstration of normal male and female function.
• Hyperprolactinaemia can be confirmed or excluded by direct measurement. Levels may increase with stress; if this is suspected, a cannula should be inserted and samples taken through it 30 minutes later.
• More detailed tests are indicated in Box 21.37.

investigation in some patients; full pituitary evaluation may be required in such cases to exclude other pituitary disease.

Management
The cause of hypogonadism can rarely be reversed and testosterone replacement therapy should be commenced to control current symptoms and prevent osteoporosis in the long term. Replacement is usually given by transdermal gel or by intramuscular injection (Box 21.40). In gonadotrophin deficiency, LH and FSH (purified or synthetic) or pulsatile GnRH may be used when fertility is required.

Special instances of hypogonadism
Cryptorchidism
Cryptorchidism (or undescended testes) is usually treated by surgical exploration and orchidopexy in early childhood. After that age, the germinal epithelium is increasingly at risk, and lack of descent by puberty is associated with subfertility. A short trial of HCG occasionally induces descent; an HCG test with a testosterone response 72 hours later excludes anorchia. Intra-abdominal testes have an increased risk of developing malignancy; if presentation is after puberty, orchidectomy is advised. Patients may present in adulthood with a history of cryptorchidism with primary testicular failure (due to the testicular damage before or during surgery) or gonadotrophin deficiency (presumably the initial cause of maldescent).

Klinefelter's syndrome
Klinefelter's syndrome is a common chromosomal abnormality, affecting 1 in 1000 males (47XXY and variants, e.g. 46XY/47XXY mosaicism), i.e. a male with an extra X chromosome. There is both a loss of Leydig cells and seminiferous tubular dysgenesis. If not identified on amniocentesis, only 10% are diagnosed prepuberty; early indications of the condition include cryptorchidism, behavioural problems, and learning disabilities as well as tall stature. In adolescence, gynaecomastia and micro-orchidism (mostly from the age of 14 years), as well as a poor muscular bulk with excessive long legs (due to lack of epiphyseal closure), small shoulders and broad hips should raise suspicion. Most patients have a normal puberty; while in adulthood, infertility is one of the most common presentations. There is also a predisposition to diabetes mellitus, breast cancer, emphysema and bronchiectasis; these are all unrelated to the testosterone deficiency.

Clinical examination shows a wide spectrum of features with small, pea-sized but firm testes, usually gynaecomastia and other signs of androgen deficiency. Confirmation is by chromosomal analysis.

Treatment is androgen replacement therapy if deficient in testosterone. The majority of men with Klinefelter's syndrome have relative testosterone deficiency (low-normal levels). The evidence that testosterone replacement in these men has positive benefits is lacking but should be discussed and trialled. No treatment is possible for the abnormal seminiferous tubules and infertility, although advances in fertility techniques and microdissection testicular sperm extraction (microTESE), offers some hope to men wanting to father their own child.

Kallmann’s syndrome
This is isolated GnRH deficiency. It is associated with decreased or absent sense of smell (anosmia), and sometimes with other bony (cleft palate), renal and cerebral abnormalities (e.g. colour blindness). It is often familial and is usually X-linked, resulting from a mutation in the KAL1 gene, which encodes anosmin-1 (producing loss of smell); one sex-linked form is due to an abnormality of a cell adhesion molecule. Management is that of secondary hypogonadism (see p. 626). Fertility is possible with gonadotrophin therapy.

Normosmic idiopathic hypogonadotropic hypogonadism
This refers to isolated GnRH deficiency in the absence of anosmia. Known mutations account for less than 15% of normosmic idiopathic hypogonadotropic hypogonadism (niHH). Mutations include the KISS1 gene, which codes for kisspeptin, the protein that acts on the GPR54 receptor, and the FGFR1 gene.

Oligospermia and azoospermia
These may be secondary to gonadotrophin deficiency and can be corrected by gonadotrophin therapy. More often, they result from primary testicular diseases, in which case they are rarely treatable, although advances in fertility techniques and microdissection testicular sperm extraction (microTESE), offers some hope to men with primary hypogonadism wanting to father their own child.
Azoospermia with normal testicular size and low FSH levels suggests a vas deferens block, which is sometimes reversible by surgical intervention.

**Gynaecomastia**

Gynaecomastia is development of breast tissue in the male. Causes are shown in Box 21.41. It is due to an imbalance between free oestrogen and free androgen effects on breast tissue.

**Pubertal gynaecomastia**

This occurs in perhaps 50% of normal boys, often asymmetrically. It usually resolves spontaneously within 6–18 months, but after this duration may require surgical removal, as fibrous tissue will have been laid down. The cause is thought to be relative oestrogen excess, and the oestrogen antagonist tamoxifen is occasionally helpful.

**Gynaecomastia in the older male**

This requires a full assessment to exclude potentially serious underlying disease, such as bronchial carcinoma and testicular tumours (e.g. Leydig cell tumour). However, aromatase activity (see p. 624) increases with age and may be the cause of gynaecomastia in this group. Aromatase is an enzyme of the cytochrome P450 family and converts androgens to produce oestrogens. Drug effects are common (especially digoxin and spironolactone), and once these and significant liver disease are excluded, most cases have no definable cause. Painful gynaecomastia may be treated with a 3–6-month trial of tamoxifen, and surgery is occasionally necessary if the symptoms or cosmetic appearance are unacceptable.

**The ageing male**

In the male, there is no sudden ‘change of life’. However, there is a progressive loss of sexual function with reduction in morning erections and frequency of intercourse.

The age of onset varies widely. Typically, overall testicular volume diminishes and SHBG and gonadotrophin levels gradually rise, but other men present with low or borderline testosterone without elevation of LH/FSH. Low testosterone certainly increases the risk of osteoporosis and, in some studies, is associated with increased cardiovascular risk. It remains unclear to what extent general symptoms of lack of energy, drive, muscle strength and general wellbeing may relate to these hormonal changes, but a recent trial of testosterone replacement showed no benefit in general symptoms although there was an improvement in sexual function. Loss of libido and erectile dysfunction are, however, common symptoms, even when hormones are normal, and long-term outcome studies of testosterone replacement are still awaited. Therefore, the decision to offer testosterone replacement to an ageing male is currently based on full clinical and biochemical assessment and full discussion of potential risks (including prostate disease) as well as benefits. If testosterone is unequivocally low (<7 pmol/L) and there are symptoms specific to androgen deficiency (low libido, erectile dysfunction and loss of early morning erections), most authorities would recommend replacement. However, few would treat if testosterone is higher than 12 pmol/L with normal LH/FSH. Clinically, a large proportion of cases are in the borderline range (7–12 pmol/L), which can lead to difficulties in reaching a firm diagnosis. There is an increasing move towards measuring fasting testosterone levels, as food intake may decrease testosterone, leading to an incorrect diagnosis of androgen deficiency.

**Disorders in the female**

**Hypogonadism**

Impaired ovarian function, whether primary or secondary, will lead to both oestrogen deficiency and abnormalities of the menstrual cycle. The latter is very sensitive to disruption, cycles becoming anovulatory and irregular before disappearing altogether. Symptoms will depend on the age at which failure develops. Thus, before puberty, primary amenorrhoea will occur, possibly with delayed puberty; after puberty, secondary amenorrhoea and symptoms of oestrogen deficiency.

**Oestrogen deficiency**

The physiological effects of oestrogens and symptoms/signs of deficiency are shown in Box 21.42.

HCG, human chorionic gonadotrophin.
Amenorrhoea

Absence of periods or markedly irregular infrequent periods (oligomenorrhoea) is the most common presentation of female gonadal disease. The clinical assessment of such patients is shown in Box 21.43, and common causes are listed in Box 21.44. Causes can be divided into whether amenorrhoea is primary or secondary, whether associated with oestrogen deficiency or not, whether oestrogen deficiency is due to gonadotrophin deficiency or ovarian insufficiency, whether it is associated with another condition, and whether amenorrhoea is due to structural problems.

Polycystic ovary syndrome

Polycystic ovary syndrome is an example of amenorrhoea that could either be primary or secondary and is not associated with oestrogen deficiency. It is the most common cause of oligomenorrhoea and amenorrhoea (see below).

Hypothalamic and weight-related amenorrhoea

Amenorrhoea with low oestrogen and gonadotrophins in the absence of organic pituitary disease is described as hypothalamic amenorrhoea. This may be related to ‘stress’: low body weight, excessive exercise or previous weight loss; stopping the contraceptive pill; or severe illness. However, some patients appear to have defective cycling mechanisms without apparent explanation.

A minimum body weight is necessary for regular menstruation. While anorexia nervosa is the extreme form of weight loss (see p. 797), amenorrhoea is common and may be seen at weights within the ‘normal’ range. It is possible that alterations in leptin levels are responsible for the hypothalamic dysfunction seen in this situation. Restoration of body weight to above the 50th centile for height is usually effective in restoring menstruation, but in the many cases where this cannot be achieved then oestrogen replacement is necessary.

Premature ovarian insufficiency

Premature ovarian insufficiency is the preferred term to describe premature menopause or ovarian failure of onset before the age of 40. The cause may be autoimmune, and is rarely caused by identifiable genetic causes such as the fragile X pre-mutation or Turner’s syndrome; most commonly, however, it is of unknown aetiology, although often familial. Repeat measurements of LH/FSH levels are necessary before a diagnosis of premature ovarian insufficiency is given because of the psychological impact of this diagnosis and the possibility that a single elevation of LH/FSH might simply be the mid-cycle ovulatory surge. Iatrogenic causes, such as bilateral oophorectomy and following cancer therapy with radiotherapy and some chemotherapy agents also cause premature ovarian insufficiency. In some scenarios, ovarian function can fluctuate; therefore, in younger women, consideration needs to be given as to whether contraception is required, and the combined oral contraceptive pill is the best option for hormone replacement therapy (HRT).

Turner’s syndrome is a cause of premature ovarian insufficiency, frequently with delayed puberty and primary amenorrhoea, although some girls do undergo menarche and establish a menstrual cycle but remain at risk of premature ovarian insufficiency. The phenotype is female with female external genitalia. There is gonadal dysgenesis with streak ovaries. Features include short stature, webbing of the neck (up to 40%), a wide carrying angle of the elbows, high-arched palate and low-set ears. These patients also have an increased incidence of autoimmune disease (2%), bicuspid aortic valves, aortic coarctation and dissection, coronary artery disease, hypertension, type 2 diabetes, horseshoe kidneys, lymphoedema, reduced bone density, hearing problems and inflammatory bowel disease (0.3%).

Investigation of oligo-amenorrhoea

Basal levels of FSH, LH, oestrogen and prolactin allow initial distinction between primary gonadal and hypothalamic–pituitary causes (see Box 21.44). Elevation of LH and FSH to menopausal levels usually confirms the diagnosis. Subsequent investigations are also shown in Box 21.44.

Anti-Müllerian hormone (AMH) released from granulosa cells of preantral and small antral follicles in the ovary, a marker of ‘ovarian reserve’, is being increasingly used in context of secondary amenorrhoea, especially in infertility centres: PCOS (usually high level), premature ovarian insufficiency (low), hypogonadotropic hypogonadism (normal or low), and menopause (low). It is shown to be helpful in deciding the type of infertility treatment strategy to be adopted, specifically in premature ovarian insufficiency or hypogonadotropic hypogonadism cases where low AMH level indicates poor follicular reserve, therefore oocyte donation is recommended. Whereas adequate AMH level means there is hope for oocyte retrieval following gonadotrophin stimulation protocols to facilitate in vitro fertilization (IVF).

Management

Treatment is that of the cause wherever possible (e.g. hypothyroidism, low weight, stress, excessive exercise). Hyperprolactinaemia should be corrected (see below). Polycystic ovary syndrome is discussed in detail below.

When oestrogen deficiency is not reversed, HRT should almost always be given, as the risk of osteoporosis and other conditions related to oestrogen deficiency almost always outweighs the risks of HRT at this younger age. HRT may still also be actively recommended when normal menopause occurs relatively early (e.g. before the age of 50).

In younger and older women with premature ovarian insufficiency ovarian function may recover or fluctuate, and therefore consideration should be given to using the combined oral contraceptive pill if fertility is not desired.

### When fertility is desired, in gonadotrophin deficiency, gonadotrophins can be given to achieve ovulation. Ovarian insufficiency is rarely treatable and often the option for pregnancy is donor eggs. There is a rare condition called ‘resistant’ ovary, where high-dose gonadotrophin therapy can occasionally lead to folliculogenesis.

### Hirsutism

**Normal hair versus hirsutism**

The extent of normal hair growth varies between individuals, families and races, being more extensive in the Mediterranean and some Asian subcontinent populations. These normal variations in body hair, and the more extensive hair growth seen in patients...
complaining of hirsutism, represent a continuum from no visible hair to extensive cover with thick, dark hair. It is therefore impossible to draw an absolute dividing line between ‘normal’ and ‘abnormal’ degrees of facial and body hair in the female. Soft velvus hair is normally present all over the body; this type of hair on the face and elsewhere is ‘normal’ and is not sex hormone-dependent. Hair in the beard, moustache, breast, chest, axilla, abdominal midline, pubic and thigh areas is sex hormone-dependent. Any excess in the latter regions is thus a marker of increased ovarian or adrenal androgen production: most commonly, polycystic ovary syndrome (PCOS) but occasionally other rarer causes.

**Aetiology**
- **Idiopathic hirsutism.** People with hirsutism, no elevation of serum androgen levels and no other clinical features are sometimes labelled as having ‘idiopathic hirsutism’. However, studies suggest that most people with ‘idiopathic hirsutism’ have some radiological or biochemical evidence of PCOS on more detailed investigation, and several studies have demonstrated evidence of mild PCOS in up to 20% of the normal female population. Familial or idiopathic hirsutism does occur, but usually involves a distribution of hair growth that is not typically androgenic.
- **Ovarian hyperthecosis.** This is a non-malignant ovarian disorder characterized by luteinized thecal cells in the ovarian stroma, which secrete testosterone. The clinical features are similar to those of PCOS but tend to present in perimenopausal women, and serum testosterone levels are higher than typically seen in PCOS.
- **Iatrogenic hirsutism.** This occurs after treatment with androgens, or more weakly androgenic drugs such as progestogens or danazol.
- **Non-androgen-dependent hair growth (hypertrichosis).** This occurs with drugs such as phenytoin, diazoxide, minoxidil and ciclosporin.
- **Other causes.** Rarer and more serious endocrine causes of hirsutism and virilization include congenital adrenal hyperplasia (CAH; see p. 604), Cushing’s syndrome (p. 600), and androgen-secreting (virilizing) tumours of the ovary and adrenal.

**Management**
See page 631.

**Polycystic ovary syndrome**
Polycystic ovary syndrome (PCOS) is the most common cause of hirsutism in clinical practice, affecting about 1 in 5 women worldwide. It is characterized by multiple small cysts within the ovary (Fig. 21.29) (which represent arrested follicular development) and by excess androgen production from the ovaries (and to a lesser extent from the adrenals).

Measured levels of androgens in blood vary widely from patient to patient and may remain within the normal range, but SHBG levels are often low (due to insulin resistance and high insulin levels), leading to high free androgen levels. In PCOS, there is thought to be an increased frequency of the GnRH pulse generator, causing an increase in LH pulses and androgen secretion. The response of the hair follicle to circulating androgens also seems to vary between individuals with otherwise identical clinical and biochemical features, and the reason for this variation in end-organ response remains poorly understood.

PCOS is frequently associated with:
- **hyperinsulinaemia and insulin resistance**, the prevalence of type 2 diabetes being 10 times higher than in normal women
- **hypertension, hyperlipidaemia and increased cardiovascular risk** (the metabolic syndrome; see p. 1250), which is 2–3 times higher in PCOS, and studies suggest that PCOS per se confers an absolute increase in cardiovascular end-points.

Obesity with PCOS is an additional risk factor for insulin resistance. The precise mechanisms that link the aetiology of polycystic ovaries, hyperandrogenism, anovulation and insulin resistance are still to be elucidated, and whether the basic defect is in the ovary, adrenal or pituitary, or is a more generalized metabolic defect, remains unknown. Frequently, there is a family history of either PCOS or type 2 diabetes, suggesting a genetic component.

In routine clinical practice, the majority of people with objective signs of androgen-dependent hirsutism will have PCOS, and investigation is mainly required to exclude rarer and more serious causes of virilization.

**History and examination**
Most patients with PCOS present with amenorrhea/oligomenorrhea and/or hirsutism and acne, shortly after menarche. Frequently, patients are also obese with evidence of insulin resistance. Clinical, biochemical and radiological features of PCOS merge imperceptibly into those of the normal populations.
- **Hirsutism.** This should be recorded objectively, ideally using a scoring system, both to document the problem and to monitor treatment. The method and frequency of physical removal (e.g. shaving, plucking) should also be recorded. The development of hirsutism commonly provokes severe distress in young women and may lead to avoidance of normal social activities. Most patients who complain of hirsutism will have an objective excess of hair on examination, but occasionally very little will be found (and appropriate counselling is then indicated).
- **Age and speed of onset.** Hirsutism related to PCOS usually begins around the time of the menarche and increases slowly and steadily in the teens and twenties. Rapid progression and prepubertal or late onset suggest a more serious cause.
- **Accompanying virilization.** Hirsutism due to PCOS may be severe and affect all androgen-dependent areas on the face and body. However, more severe virilization (clitoromegaly, recent-onset
frontal balding, male phenotype) implies substantial androgen excess, and usually indicates a rarer cause rather than PCOS. Thinning of head hair in a male pattern – androgenic alopecia – occurs in a proportion of women with uncomplicated PCOS, typically with a familial tendency for premature androgen-related hair loss in both sexes.

**Menstruation.** Most people with PCOS will have some disturbance of menstruation, typically oligo-amenorrhoea, although more frequent erratic bleeding can also occur. However, PCOS can present as hirsutism with regular periods or as irregular periods, with no evidence of hirsutism or acne.

**Weight.** Many people with PCOS are also overweight or obese. The obesity worsens the underlying androgen excess and insulin resistance, and inhibits the response to treatment; it is an indication for appropriate advice on diet and exercise. In severe cases, the insulin resistance may have a visible manifestation as acanthosis nigricans on the neck and in the axillae. In addition to worsening the symptoms of PCOS, central obesity in PCOS significantly increases the likelihood of developing diabetes and cardiovascular disease.

**Investigations and differential diagnosis**

- **Serum total testosterone.** This is often elevated in PCOS and is invariably substantially raised in virilizing tumours (usually >5 nmol/L). People with hirsutism and normal testosterone levels frequently have low levels of SHBG, leading to high free androgen levels. The **free androgen index** ([testosterone/SHBG] *100) is often used and is high; free testosterone is difficult to measure directly.

- **Other androgens.** Androstenedione and dehydroepiandrosterone sulphate are frequently elevated in PCOS, and even higher in congenital adrenal hyperplasia (CAH) and virilizing tumours. **17α-Hydroxyprogesterone.** This is elevated in classical CAH, but may be apparent in late-onset CAH only after stimulation tests.

- **Gonadotrophin levels.** LH hypersecretion is a frequent feature of PCOS, but the pulsatile nature of secretion of this hormone means that a ‘classic’ increased LH/FSH ratio is not always observed on a random sample.

- **Oestrogen levels.** Oestradiol is usually normal in PCOS, but oestrone levels (which are rarely measured) are elevated because of peripheral conversion. Levels are variable in other causes.

- **Ovarian ultrasound.** This is a useful investigation (see Fig. 21.28). Typical features are those of a thickened capsule, multiple 3–5 mm cysts and a hyperechogenic stroma. Prolonged hyperandrogenization from any cause may lead to polycystic changes in the ovary. Ultrasound may also reveal virilizing ovarian tumours, although these are often small.

- **Serum prolactin.** Mild hyperprolactinaemia is common in PCOS but rarely exceeds 1500 mU/L.

  If an androgen-secreting tumour is suspected clinically or after investigation, then more complex investigations include dexamethasone suppression tests, CT or MRI of adrenals, and selective venous sampling.

**Diagnosis**

Most patients presenting with a combination of hirsutism and menstrual disturbance will be shown to have PCOS, but the rarer alternative diagnoses should be excluded; the latter include late-onset CAH (early onset, raised serum 17α-hydroxyprogesterone), Cushing’s syndrome (look for other clinical features), and virilizing tumours of the ovary or adrenals (severe virilization, markedly elevated serum testosterone).

The consensus (Rotterdam) criteria 2003 for diagnosis of PCOS are at least two of the following:

- clinical and/or biochemical evidence of hyperandrogenism
- oligo-ovulation and/or anovulation
- polycystic ovaries on ultrasound.

**Management**

**Local therapy for hirsutism**

Regular plucking, bleaching, use of depilatory cream, waxing or shaving is used. Such removal neither worsens nor improves the underlying severity of hirsutism. More ‘permanent’ solutions include electrolysis and a variety of ‘laser’ hair removal systems; all appear effective but have not been evaluated in long-term studies, are expensive, and still often require repeated long-term treatment. **Eflo rhetine cream** (an antiprotozoal) inhibits hair growth by inhibiting ornithine decarboxylase, but is effective in only a minority of cases and should be discontinued if there is no improvement after 4 months.

**Systemic therapy for hirsutism**

This always requires a year or more of treatment for maximal benefit, and long-term therapy is frequently required as the problem tends to recur when treatment is stopped. The patient must therefore always be an active participant in the decision to use systemic therapy and must understand the rare risks as well as the benefits. Weight loss (at least 5%) should also be encouraged, as many patients have improvement in symptoms.

- **Oestrogens** (e.g. oral contraceptives) suppress ovarian androgen production and reduce free androgens by increasing SHBG levels. Combined hormone pills will produce a slow improvement in hirsutism in a majority of cases and should normally be used first unless there is a contraindication, such as a history of thrombosis. After the menopause, HRT preparations that contain medroxyprogesterone (rather than more androgenic progestogens) may be helpful.

- **Cyproterone acetate** (50–100 mg daily) is an antiandrogen but is also a progesteron, teratogen and a weak glucocorticoid. Given continuously, it produces amenorrhoea, and so is normally given for days 1–14 of each cycle. In women of childbearing age, contraception is essential.

- **Spironolactone** (200 mg daily) also has antiandrogen activity and can cause useful improvements in hirsutism. In women of childbearing age, contraception is essential.

- **Finasteride** (5 mg daily), a 5α-reductase inhibitor that prevents the formation of dihydrotestosterone in the skin, has also been shown to be effective but long-term experience is limited. In women of childbearing age, contraception is essential.

- **Flutamide,** another antiandrogen, is less commonly used owing to the high incidence of hepatic side-effects. In women of childbearing age, contraception is essential.

**Treatment of menstrual disturbance**

- **Cyclical oestrogen/progesteron** administration will regulate the menstrual cycle and remove the symptom of oligo- or amenorrhoea. This is most frequently an additional benefit of the treatment of hirsutism, but may also be used when menstrual disturbance is the only symptom.

- **Metformin** (500 mg three times daily) is commonly used in this condition because of the recognized association between PCOS and insulin resistance. It may improve menstrual cyclicity and ovulation; some patients also report improvement in hirsutism and ease of weight loss, but gastrointestinal upset may limit use.

*Gonadectomy advised because of high risk of malignancy. i, isochromosome.

### Treatment for fertility in PCOS

- **Clomifene or letrozole** is given daily on days 2–6 of the cycle and is effective in 75% of women in achieving ovulation. It can occasionally cause the **ovarian hyperstimulation syndrome**, an iatrogenic complication of ovulation induction therapy, consisting of ovarian enlargement, oedema, hypovolaemia, acute kidney injury and possibly shock; specialist supervision is essential. It is recommended that clomifene and letrozole should **not normally be used** for more than six cycles (owing to a possible increased risk of ovarian cancer in patients treated for longer than recommended).
- **Low-dose FSH** is used for non-responders to clomifene.
- **Metformin** alone may improve ovulation and achieve conception.

Wedge resection of the ovary was a traditional therapy but is now rarely required, although laparoscopic ovarian electrodiathermy may be helpful.

### Disorders of sex development

Disorders of sex development (DSD) are a rare group of conditions that can be divided into 46XY and 46XX DSD and encompass conditions of abnormalities in androgen synthesis, action and excess and gonadal development and persistent Müllerian duct syndrome or sex chromosomal DSD (Box 21.45). Such cases always require extensive, multidisciplinary clinical management. An individual’s sex can be defined in several ways:

- **Chromosomal sex.** The normal female is 46XX, the normal male 46XY. The Y chromosome confers male sex; if it is not present, development follows female lines.
- **Gonadal sex.** This is determined predominantly by chromosomal sex but requires normal embryological development.
- **Phenotypic sex.** This describes the normal physical appearance and characteristics of male and female body shape. This, in turn, is a manifestation of gonadal sex and subsequent sex hormone production.

### GROWTH AND PUBERTY

#### Normal growth and puberty

There are factors other than GH axis and the hypothalamo-pituitary–gonadal axis that influence linear growth and adult height and timing of puberty in the human:

- **Genetic factors.** Children of two short parents will probably be short and similarly for tall parents. Timing of parental puberty is a strong determinant of timing of puberty in the child.
- **Nutritional factors.** Adequate nutrients must be available. Impaired growth can result from inadequate dietary intake or small bowel disease (e.g. coeliac disease). Puberty is affected by whether a child is undernourished or obese.
- **General health.** Any serious systemic disease in childhood is likely to reduce growth and/or delay puberty (e.g. chronic kidney disease or chronic infection).
• **Small for gestational age**: 15% of these infants do not catch up and can also have an earlier and more rapidly progressive puberty. There is some evidence that low birth weight may predispose to hypertension, diabetes, and other health problems in later adult life (see p. 1246).

• **Emotional deprivation and psychological factors**: These can impair growth by complex, poorly understood mechanisms, probably involving temporarily decreased GH secretion.

  In general, there are three overlapping phases of growth: infantile (0–2 years), which appears to be largely dependent on substrates (food); childhood (age 2 years to puberty), which is largely GH-dependent; and the adolescent ‘growth spurt’, dependent on GH and adequate sex hormone production during puberty.

**Fig. 21.30** The control of growth hormone (GH) and insulin-like growth factor-1 (IGF-1). Pituitary GH is secreted under dual control of growth hormone-releasing hormone (GHRH) and somatostatin, and stimulates release of IGF-1 in the liver and elsewhere. IGF-1 has peripheral actions, including bone growth, and exerts negative feedback to the hypothalamus and pituitary. REM, rapid eye movement.

**Physiology**

Growth hormone (GH) is the pituitary factor responsible for stimulation of body growth in humans. Its secretion is stimulated by GHRH, released into the portal system from the hypothalamus; it is also under inhibitory control exerted by somatostatin (Fig. 21.30). A separate GH-stimulating system involves a distinct receptor (GH secretagogue receptor), which interacts with ghrelin. It is not known how these two systems interact but, because ghrelin is synthesized in the stomach, a nutritional role is suggested for GH.

• **GH** acts by binding to a specific (single transmembrane) receptor located mainly in the liver (Box 21.46). This induces an intracellular phosphorylation cascade involving the Janus kinase/signal transducing activators of transcription (JAK/STAT) pathway (see p. 68). STAT proteins are translocated from the cytoplasm into the cell nucleus and cause GH-specific effects by binding to nuclear DNA.

• **Insulin-like growth factor-1** (IGF-1), a somatomedin, stimulates growth. Its hepatic secretion is stimulated by a tissue-specific effect of GH on the liver. There are multiple IGF-binding proteins (IGF-BP) in plasma; IGF-BP3 can be measured clinically to improve assessment of GH status, particularly in children.

The metabolic actions of the system are:

• increasing collagen and protein synthesis
• promoting retention of calcium, phosphorus and nitrogen, necessary substrates for anabolism
• opposing the action of insulin (a ‘counter-regulatory’ hormone effect).

GH release is intermittent and mainly nocturnal, especially during REM sleep. The frequency and size of GH pulses increase during the growth spurt of adolescence and decline thereafter. Acute stress and exercise both stimulate GH release, while, in the normal subject, hyperglycaemia suppresses it.

IGF-1 may, in addition, play a major role in maintaining neoplastic growth. A relationship has been shown between circulating IGF-1 concentrations and breast cancer in premenopausal women and prostate cancer in men.

**Puberty**

The mechanisms initiating puberty are thought to result from withdrawal of central inhibition of GnRH release and involve a complex interplay between hypothalamic peptides, as well as external factors. Environmental and physical factors (including body fat changes and physical exercise) are involved in the timing of puberty, as well as the genetic factors required for pubertal maturation. Kisspeptin is the endogenous ligand for kisspeptin receptor **KISS1R**, formerly known as **GPR54** (a G-protein-coupled receptor gene), and this...
peptide is believed to play a crucial role in the regulation of GnRH production and the timing of puberty.

LH and FSH are both low in the prepubertal child. In early puberty, FSH begins to rise first, initially in nocturnal pulses; this is followed by a rise in LH with a subsequent increase in testosterone/oestrogen levels. The milestones of puberty in the two sexes are shown here in relation to other data. Numbers 2–5 indicate stages of development.

Fig. 21.31 The age of development of features of puberty. Stages and testicular size show mean ages, and all vary considerably between individuals. The same is true of the height spurt, shown here in relation to other data. Numbers 2–5 indicate stages of development.

Further investigations are required if:

• height is below the 0.4th centile, unless already fully investigated at an earlier age
• height centile is more than three centile spaces below the mid-parental centile
• drop in height centile position of more than two centile spaces, as long as measurement error has been excluded
• smaller centile falls or discrepancies between child’s and mid-parental centile, if seen in combination, or if associated with possible underlying disease.

Puberty

A knowledge of the timing and tempo of normal puberty and the stages of puberty are essential.

In males:

• Puberty before 9 years in boys is likely to be precocious and further assessment is necessary.
• Between 9 and 14 years most boys will be either ‘pre-puberty’ or ‘in puberty’.
• If there are no signs of puberty by 14 years, then puberty is delayed and further assessment is indicated.
• From 14 to 17 years most boys will be either ‘in puberty’ or ‘completing puberty’
• After 17 years boys will usually be ‘completing puberty’. If this is not the case, maturation is delayed and further assessment may be needed.

In females:

• Puberty before 8 years in girls is likely to be precocious and further assessment is necessary.
• Between 8 and 13 years most girls will be either ‘prepuberty’ or ‘in puberty’.
• If there are no signs of puberty by 13 years, then puberty is delayed and further assessment is indicated.
• From 13 to 16 years most girls will be either ‘in puberty’ or ‘completing puberty’.
• After 16 years girls will usually be ‘completing puberty’ when menarche will have occurred. If this is not the case, maturation is delayed and further assessment may be needed.

Tanner staging

In males the first sign of puberty is testicular volumes reaching 4 mL; testicular volumes continue to increase until adult sizes are reached (15–25 mL). Other aspects that are staged from 1 to 5, with stage 1
Growth and puberty

prepubertal (no signs of puberty) and stage 5 adult appearance, are genitalia (changes in the scrotum and penis) and pubic hair (5 stages). Axillary hair has two stages. Spermarche happens around stage 4.

In girls the development of breast buds signals the start of puberty (Tanner stage 2), and continue to develop until adult shape of breasts and nipples (stage 5). As in boys, pubic hair and axillary hair are also staged, with menarche happening around stage 4.

During puberty is also a period of rapid growth, which happens earlier in girls than boys.

Disorders of stature

Short stature

When children or their parents complain of short stature, particular attention should focus on:
- small for gestational age
- possible systemic disorders – any system but especially small bowel disease
- evidence of skeletal, chromosomal or other congenital abnormalities
- possible symptoms and signs of a hypothalamic or pituitary tumour
- endocrine status – particularly thyroid
- dietary intake and use of drugs, especially steroids for asthma
- emotional, psychological, family and school problems.

School, general practitioner, clinic and home records of height and weight should be obtained, if possible, to allow growth-velocity calculation. If unavailable, such data must be obtained prospectively.

A child with normal growth velocity is unlikely to have significant endocrine disease and the most common cause of short stature in this situation is familial short stature or constitutional delay. However, low growth velocity without an apparent systemic cause requires further investigation. Sudden cessation of growth suggests major physical disease; if no gastrointestinal, respiratory, renal or skeletal abnormality is apparent, then a cerebral tumour or hypothyroidism is most likely.

Consistently slow-growing children require full endocrine assessment. Features of the more common causes of growth failure are given in Box 21.48.

GH, growth hormone; TSH, thyroid-stimulating hormone.
Around the time of puberty, if constitutional delay is clearly shown and symptoms require intervention, then very-low-dose sex steroids in 3- to 6-month courses will usually induce acceleration of growth.

Investigations

- **Thyroid function tests.** Serum TSH and free T₄ should be measured to exclude hypothyroidism.
- **Assessment of bone age.** Non-dominant hand and wrist X-rays allow assessment of bone age by comparison with standard charts. Bone age will be delayed in constitutional delay, endocrinopathies and chronic disease
- **Karyotyping in females.** Turner's syndrome (see p. 628) is associated with short stature. It is thought that this is due to a defect in the short stature homeobox (SHOX) gene, which has a role in non-GH-mediated growth.
- **GH status.** Not all children with short stature require this assessment, particularly as the test has a high false-positive rate, and therefore it should be considered only in ongoing growth failure with no other explanation. Basal levels of GH are of little value, therefore dynamic tests include the GH response to insulin (the ‘gold standard’; see Box 21.11), arginine + GHRH and glucagon are used. Tests should only be performed in centres experienced in their use and interpretation. Normal responses depend on test and GH assay used.
- **Blood levels of IGF-1 and IGF-BP3.** These may provide evidence of GH undersecretion.
- **MRI pituitary/brain.** If symptoms are suggestive of cerebral tumour or there is evidence of GH insufficiency this will be required to investigate for hypothalamic pituitary tumour.

Management of short stature

Systemic illness should be treated and primary hypothyroidism managed with levothyroxine.

A watch and wait approach to those with constitutional delay, potentially with a very-low-dose sex steroids in 3- to 6-month courses to kick-start puberty and induce acceleration of growth.

For GH insufficiency, recombinant GH (somatropin) is given as nightly injections in doses of 0.17–0.35 mg/kg per week, with dose adjustments made according to clinical response and IGF-1 levels. Treatment is expensive and should be supervised in expert centres.

Other indications for growth hormone are in conditions without GH insufficiency, such as Turner’s syndrome and SHOX gene haploinsufficiency (skeletal dysplasia), chronic renal failure on dialysis (resistance to GH-dependent IGFs), Prader–Willi syndrome (partial GH insufficiency), small for gestational age without catch-up. In some countries it is also offered to children with idiopathic short stature.

Familial cases of resistance to GH that is caused by an abnormal GH receptor (Laron-type dwarfism) are well described. They are very rare but may respond to therapy with synthetic IGF-1 (mecasermin).

Tall stature

The most common causes are hereditary (two tall parents), idiopathic (constitutional) or early developmental factors (eventually resulting in short stature). Tall stature can occasionally be due to hyperthyroidism. Other causes include chromosomal abnormalities (e.g. Klinefelter’s syndrome, Marfan’s syndrome) or metabolic abnormalities. GH excess secondary to a GH-secreting pituitary adenoma causing gigantism is a very rare cause and is usually clinically obvious.

Pubertal disorders

Deferred puberty

Causes of delayed puberty include the aforementioned causes of hypogonadism including hypogonadism as part of hypopituitarism but many cases represent constitutional delay, particularly in boys.

In constitutional delay, pubertal development, bone age and stature are in parallel. A family history may confirm that other family members experienced the same delayed development, which is common in boys but very rare in girls.

Investigations

These are similar to those for short stature which may coexist and should include thyroid function and bone age.

Assessment of LH, FSH, oestradiol or testosterone will identify primary hypogonadism. Low normal gonadotrophins with low oestradiol or testosterone may either represent secondary hypogonadism or constitutional delay. In paediatric practice an LHRH may also be performed, although the discriminatory value of this test is low.

In girls with primary amenorrhoea, assessment for pelvic abnormalities is essential and if the uterus is absent further investigations for disorders of sex development are warranted.

Management

In constitutional delay, if any progression into puberty is evident clinically, investigations are not required. When delay is great and problems are serious (e.g. severe teasing at school), low-dose, short-term sex hormone therapy is used to induce puberty.

In those with delayed puberty secondary to hypogonadism, pubertal induction is required. In girls, low-dose oral or transdermal oestrogen increased slowly to optimize breast development and, in those hoping for further height gain, introducing progesterone to induce withdrawal bleed when bleeding occurs, or after 2 years of unopposed oestrogen. In boys, pubertal induction is with testosterone. The dose is less critical unless optimizing height.

Precocious puberty

True precocious puberty can be divided into gonadotrophin-dependent and gonadotrophin-independent (secondary to exposure to either endogenous or sometimes exogenous sex steroids) types. Gonadotrophin-independent causes can also initiate gonadotrophin-dependent precocious puberty, as is the case in congenital adrenal hyperplasia. All cases require assessment by a paediatric endocrinologist.

True precocious puberty must be distinguished from normal variants:

- **Premature thelarche.** This is early breast development alone and is usually transient, at age 2–4 years. It may regress or persist until puberty. There is no evidence of follicular development.
- **Premature adrenarche.** This is early development of pubic hair without significant other changes, usually after the age of 5 years and more commonly in girls. It is also more common in obese children due to reduced SHBG levels, leading to higher free circulating androgens.

Gonadotrophin-dependent precocious puberty

- **Idiopathic precocity** is most common in girls and very rare in boys. This is a diagnosis of exclusion. With no apparent cause for premature breast or pubic hair development, and an early growth spurt, it may be normal and may run in families.
**Growth and puberty**

**Cerebral precocity** is when precocious puberty is associated with a cerebral abnormality, acquired or otherwise, such as a tumour, previously acquired brain injury, for example, radiotherapy. In boys, tumours must be rigorously excluded and MRI scan is almost always indicated to exclude this diagnosis. The most common finding is a hypothalamic hamartoma, a benign tumour that can be associated with seizures.

**Gonadotrophin-independent precocious puberty**

The most common cause is congenital adrenal hyperplasia. Other causes include testicular or ovarian disorders, such as testotoxicosis or McCune–Albright’s syndrome (MAS; see also p. 650). MAS usually occurs in girls, with precocity, polyostotic fibrous dysplasia and skin pigmentation (café-au-lait patches). HCG-secreting tumours, androgen- and oestrogen-secreting tumours, including teratomas, are important conditions to exclude.

**Management**

Treatment is often required to maximize adult height, reduce psychosocial impact, and delay menarche. Treatment depends on whether the cause is gonadotrophin-dependent or independent. If the cause is gonadotrophin-dependent, treatment with long-acting GnRH analogues (given by nasal spray, by subcutaneous injection or by implant) causes suppression of gonadotrophin release via downregulation of the receptor – and therefore reduced sex hormone production – and is moderately effective. If the cause is gonadotrophin-independent, inhibitors of steroidogenesis, antiandrogens, and aromatase inhibitors are also used.

**Further reading**

---

**Acromegaly and gigantism**

Growth hormone stimulates skeletal and soft tissue growth. GH excess therefore produces gigantism in children (if acquired before epiphyseal fusion) and acromegaly in adults. Both are due to a GH-secreting pituitary tumour (somatotroph adenoma) in almost all cases. Hyperplasia due to ectopic GHRH excess is very rare. Overall incidence is approximately 3–4/million per year and the prevalence is 50–80/million worldwide. Acromegaly usually occurs sporadically, although gene mutations can rarely give rise to familial acromegaly: typically, the AIP gene in familial isolated pituitary adenoma. In familial acromegaly, there is an increased onset before puberty compared with sporadic cases, leading to a higher prevalence of gigantism.

**History and examination**

Symptoms and signs of acromegaly are shown in **Fig. 21.33**. One-third of patients present with changes in appearance, and one-quarter with visual field defects or headaches; in the remainder, the diagnosis is made by an alert observer in another clinic: for example, in general practice, or in the diabetes, hypertension, dental, dermatology departments. Sleep apnoea is common and requires investigation and treatment if there are suggestive symptoms (see p. 960). Sweating, headaches and soft tissue swelling are particularly useful symptoms of persistent GH secretion. Headache is very common in acromegaly and may be severe, even with small tumours; it is often improved after surgical cure or with somatostatin analogues.

**Investigations**

- **GH levels** may exclude acromegaly if they are undetectable, but a detectable value is non-diagnostic taken alone. Normal adult levels are below 0.5 μg/L for most of the day, except during stress or a ‘GH pulse’.
- **A glucose tolerance test** is diagnostic if there is no suppression of GH. Acromegalics fail to suppress GH below 0.3 μg/L and...
some show a paradoxical rise; about 25% of acromegals have a positive diabetic glucose tolerance test.

- **IGF-1 levels** are almost always raised in acromegaly; a single plasma level of IGF-1 reflects mean 24-hour GH levels and is useful in diagnosis. A normal IGF-1, together with random GH of less than 1 μg/L, may be taken to exclude acromegaly if the diagnosis is clinically unlikely.
- **Visual field examination** commonly reveals defects, such as bitemporal hemianopia.
- **MRI scan** of the pituitary is carried out if the above tests are abnormal. This will almost always reveal the pituitary adenoma. In cases where no clear lesion is present, or in postoperative cases where residual disease is being sought, there is increasing interest in the use of functional imaging such as positron emission tomography (PET).
- **Pituitary function** commonly demonstrates partial or complete anterior hypopituitarism.
- **Prolactin** levels show mild to moderate hyperprolactinaemia in 30% of patients (Fig. 21.34). In some, the adenoma secretes both GH and prolactin.

**Management**

Untreated acromegaly results in markedly reduced survival. Most deaths occur from heart failure, coronary artery disease and hypertension-related causes. In addition, there is an increase in deaths due to neoplasia, particularly large bowel tumours; guidance advocates regular colonoscopy to detect and remove colonic polyps in order to reduce the risk of colonic cancer, although the evidence is inconclusive. Treatment is therefore indicated in all except the elderly or those with minimal abnormalities. The aim of therapy is to achieve a mean GH level below 2.5 μg/L; this is not always ‘normal’ but has been shown to reduce mortality to normal levels and is therefore considered a ‘safe’ GH level. A normal IGF-1 is also a goal of therapy. Occasionally, there can be discordance between GH and IGF-1 levels, which can create management dilemmas.

When present, hypopituitarism should be corrected and concurrent diabetes and/or hypertension should be treated conventionally; both usually improve with treatment of the acromegaly.

The general advantages and disadvantages of surgery, radiotherapy and medical treatment are discussed on page 597. Progress can be assessed by monitoring GH and IGF-1 levels.

**Surgery**

Trans-sphenoidal surgery is the appropriate first-line therapy. It will result in clinical remission in a majority of cases (60–90%) with pituitary microadenoma, but in only 50% of those with macroadenoma. Very high preoperative GH and IGF-1 levels are also poor prognostic markers of surgical cure. Surgical success rates are variable and highly dependent upon experience, and a specialist pituitary surgeon is essential. Transfrontal surgery is rarely required except for massive macroadenomas. There is a recurrence rate of approximately 10%.

**Pituitary radiotherapy**

External radiotherapy is normally used after pituitary surgery fails to normalize GH levels rather than as primary therapy. It is often combined with medium-term treatment using a somatostatin analogue, dopamine agonist or GH antagonist because of the slow biochemical response to radiotherapy, which may take 10 years or more; it is also often associated with hypopituitarism, which makes it unattractive in patients of reproductive age. Stereotactic (gamma-knife) radiotherapy is used in some centres, as it delivers a more concentrated field of radiation.

**Medical therapy**

There are three receptor targets for the treatment of acromegaly: pituitary somatostatin receptors and dopamine (D₂) receptors, and GH receptors in the periphery.

**Somatostatin receptor agonists**

Octreotide and lanreotide are synthetic analogues of somatostatin, which act selectively on somatostatin receptor subtypes (SSTR2 and SSTR5) and are highly expressed in GH-secreting tumours. These drugs were used as a short-term treatment while other modalities become effective, but now are sometimes used as primary therapy. They reduce GH and IGF levels in most patients but do not all achieve treatment targets. Both drugs are typically administered as monthly depot injections and are generally well tolerated; they are, however, associated with an increased incidence of gallstones and are expensive. Pasireotide (acting on SSTR 1, 2, 3 and 5) is a newer agent but its role in acromegaly is still being evaluated.

**Dopamine agonists**

Dopamine agonists act on D₂ receptors (see pp. 222–223) and can be given to shrink tumours prior to definitive therapy or to control symptoms and persisting GH secretion; they are probably most effective in mixed GH-producing (somatotroph) and prolactin-producing (mammothroph) tumours. Typical doses are bromocriptine 10–60 mg daily or cabergoline 0.5 mg daily (higher than for prolactinomas). Given alone, they reduce GH to ‘safe’ levels in only a minority of cases, but are useful for mild residual disease or in combination with somatostatin analogues. Drugs with combined somatostatin and dopamine receptor activity are under development.

**Growth hormone antagonists**

Pegvisomant (a genetically modified analogue of GH) is a GH receptor antagonist that exerts its effect by binding to and preventing dimerization of the GH receptor. It does not lower GH levels or reduce tumour size but has been shown to normalize IGF-1 levels in 90% of patients. It is given by daily injection and its main role at the present time is treatment of patients in whom GH and IGF levels
The role of prolactin outside pregnancy and lactation is not well defined, although there is some epidemiological evidence of a link between high prolactin levels and breast cancer, which has led to an interest in the development of prolactin receptor antagonists.

Physiological hyperprolactinaemia occurs in pregnancy, lactation and severe stress, as well as during sleep and coitus. The range of serum prolactin seen in common causes of hyperprolactinaemia is illustrated in Fig. 21.34. Mildly increased prolactin levels (400–600 mU/L) may be physiological and asymptomatic but higher levels require a diagnosis. Levels above 5000 mU/L always imply a prolactin-secreting pituitary tumour.

**Aetiology**

Hyperprolactinaemia has many causes:
- **Physiological.** These include pregnancy, lactation, stress, sleep, exercise and coitus.
- **Pathological.** These include prolactinoma, co-secretion of prolactin in tumours causing acromegaly, stalk compression due to pituitary adenomas and other pituitary masses, polycystic ovarian syndrome, primary hypothyroidism and idiopathic hyperprolactinaemia. Rarer causes include renal failure, liver failure, post-partum state and chest wall injury (e.g. following herpes zoster).
- **Drug-induced.** Drug causes include oestrogens (e.g. contraceptive pill), dopamine antagonists (e.g. antipsychotics such as phenothiazines), antidepressants (e.g. tricyclics, selective serotonin reuptake inhibitors (SSRIs)), antiemetics (e.g. metoclopramide, domperidone) and others (e.g. verapamil, cimetidine, methyldopa).

**History and examination**

Patients may present with features of hyperprolactinaemia or structural symptoms from a pituitary tumour with headaches and visual loss. This latter presentation is more common in males.

It usually presents with:
- Galactorrhoea, spontaneous or expressible (60% of cases). Note that many people with galactorrhoea do not have hyperprolactinaemia – ‘normoprolactinaemic galactorrhoea’ – and the causes are poorly understood.
- Oligomenorrhea or amenorrhoea.
- Decreased libido in both sexes.
- Decreased potency in men.
- Subfertility.
- Symptoms or signs of oestrogen or androgen deficiency – in the long term osteoporosis may result, especially in women.
- Delayed or arrested puberty in the peripubertal patient.
- Mild gynaecomastia – often seen in men due to the associated hypogonadism rather than being a direct effect of prolactin. Additionally, headaches and/or visual field defects occur if there is a pituitary macroadenoma (more common in men).

**Investigations**

Hyperprolactinaemia should be confirmed by repeat measurement. If there are no clinical features of hyperprolactinaemia, the
The possibility of macroprolactinaemia should be considered. This is a higher-molecular-weight complex of prolactin bound to IgG, which is physiologically inactive but occurs in a small proportion of normal people and can therefore lead to unnecessary treatment. Macroprolactinaemia can be diagnosed in the laboratory by precipitation of immunoglobulin G (IgG) with polyethylene glycol, after which prolactin levels will be normal on testing; most laboratories will do this routinely. Hyperprolactinaemia should be excluded in all patients presenting with a pituitary mass.

Further tests are appropriate after physiological and drug causes have been excluded:

- **Visual fields** should be checked.
- **Primary hypothyroidism** must be excluded since this is a cause of hyperprolactinaemia.
- **Anterior pituitary function** should be assessed if there is any clinical evidence of hypopituitarism or radiological evidence of a pituitary tumour (see Boxes 21.5, 21.7 and 21.11).
- **MRI of the pituitary** is necessary if there are any clinical features suggestive of a pituitary tumour, and desirable in all cases when prolactin is significantly elevated (>1000 mU/L).

In the presence of a pituitary mass on MRI, the level of prolactin helps determine whether the mass is a prolactinoma or a non-functioning pituitary tumour causing stalk-disconnection hyperprolactinaemia: levels of above 5000 mU/L in the presence of a macroadenoma, or above 2000 mU/L in the presence of a microadenoma (or with no radiological abnormality) strongly suggest a prolactinoma (see p. 593). Macroprolactinaemia refers to tumours above 10 mm in diameter, microprolactinoma to smaller ones. Tumours that are approximately 10 mm are termed mesoadenomas.

Occasionally, very large prolactinomas can be associated with such high serum prolactin levels that some assays give an artefactual falsely low result (known as the ‘hook effect’). If suspected, this can be excluded by serial dilutions of the serum sample.

**Management**

In all patients with a macroprolactinoma treatment is recommended to reduce the size of the tumour. It is also recommended in those with troublesome galactorrhoea. In those with sex steroid deficiency lowering prolactin levels should reverse hypogonadism and avoid the long-term effects, although for those intolerant of the medication sex steroid replacement is an alternative approach. Therefore some patients, for example, women postmenopause with microprolactinomas, may not require any treatment.

**Medical treatment**

Hyperprolactinaemia is controlled with a dopamine agonist.

- **Cabergoline** (500 μg once or twice a week) is the best-tolerated and longest-acting drug, and is the drug of choice.
- **Bromocriptine** is the longest-established therapy and is therefore preferred if pregnancy is planned; initial doses should be small (e.g. 1 mg), taken with food and gradually increased to 2.5 mg two or three times daily. Side-effects, which prevent effective therapy in a minority of cases, include nausea and vomiting, dizziness and syncope, constipation and cold peripheries.
- **Quinagolide** (75–150 μg once daily) is an alternative.

Complications, seen when cabergoline is used in higher doses in Parkinson’s disease, include pulmonary, pericardial fibrotic reactions, and cardiac valve lesions. Patients need monitoring, although studies suggest that adverse effects appear to be very rare in those on lower, ‘endocrine’ doses. In addition, patients can also develop neuropsychiatric side-effects, including compulsive behaviours such as gambling.

In most cases, a dopamine agonist will be the first and only therapy, and can be used in the long term, although a trial of discontinuation can be considered in microprolactinomas after 2–3 years, as a significant percentage may not recur, or in females at the onset of the menopause who are not on oestrogen replacement therapy. Prolactinomas usually shrink in size on a dopamine agonist, and in macroadenomas any pituitary mass effects commonly resolve (Fig. 21.36). Macroprolactinomas may not recur after several years of dopamine agonist therapy in a minority of cases, but in the majority, hyperprolactinaemia will return if treatment is stopped.

In patients planning pregnancy, it is useful to know the size of the pituitary lesion before starting dopamine agonist therapy. Rarely, tumours enlarge during pregnancy to produce headaches and visual field defects. Dopamine agonists, which are traditionally stopped after conception, particularly when used in the treatment of microprolactinomas, can be restarted if there are any signs of tumour growth during pregnancy.

**Trans-sphenoidal surgery**

Surgery may rarely be needed in patients who are intolerant of or unresponsive to dopamine agonists. Surgery may restore normoprolactinaemia in people with microadenoma, but is rarely completely successful in those with macroadenomas and risks damage to normal pituitary function. Therefore, most patients and
physicians elect to continue medical therapy rather than proceed to surgery. Prolactin should therefore always be measured before surgery on any mass in the pituitary region. Some surgeons believe that long-term bromocriptine increases the hardness of the adenoma and makes resection more difficult, but others dissent from this view.

Radiotherapy

Also rarely needed, radiotherapy usually controls adenoma growth and is slowly effective in lowering prolactin, but causes progressive hypopituitarism. It may be advocated after medical tumour shrinkage or after surgery in larger tumours, especially where families are complete or if the drug treatment is poorly tolerated, but most workers simply advocate continuation of dopamine agonist therapy in responsive cases.

## THE THIRST AXIS

Thirst and water regulation are largely controlled by vasopressin, also known as ADH, which is synthesized in the hypothalamus (see p. 591) and then migrates in neurosecretory granules along axonal pathways to the posterior pituitary. Pituitary disease alone without hypothalamic involvement therefore does not lead to ADH deficiency, as the hormone can still ‘leak’ from the damaged end of the intact axon.

At normal concentrations, the kidney is the predominant site of action of vasopressin. Vasopressin stimulation of the V2 receptors (Box 21.50) allows the collecting ducts to become permeable to water via the migration of aquaporin-2 water channels, thus permitting reabsorption of hypotonic luminal fluid (see p. 175). Vasopressin therefore reduces diuresis and results in overall retention of water. At high concentrations, vasopressin also causes vasoconstriction via the V1 receptors in vascular tissue.

Changes in plasma osmolality are sensed by osmoreceptors in the anterior hypothalamus. Vasopressin secretion is suppressed at levels below 280 mOsm/kg, thus allowing maximal water diuresis. Above this level, plasma vasopressin increases in direct proportion to plasma osmolality. At the upper limit of normal (295 mOsm/kg), maximum antidiuresis is achieved and thirst is experienced at about 298 mOsm/kg (Fig. 21.37).

Other factors affecting vasopressin release are shown in Box 21.51.

Disorders of vasopressin secretion or activity include:

- cranial diabetes insipidus with deficiency as a result of hypothalamic disease
- ‘nephrogenic’ diabetes insipidus – a rare condition in which the renal tubules are insensitive to vasopressin, and an example of a receptor abnormality
- inappropriate excess of the hormone, also called syndrome of inappropriate antidiuretic hormone (SIADH), a common cause of hyponatraemia in hospital patients.

While diabetes insipidus is uncommon, they need to be distinguished from the occasional patient with ‘primary polydipsia’, and whose renal tubular function has been impaired by electrolyte abnormalities, such as hypokalaemia or hypercalcaemia. Similarly other causes of hyponatraemia need to be excluded prior to diagnosing and investigating SIADH.

### Diabetes insipidus

#### History and examination

Deficiency of vasopressin (ADH) or insensitivity to its action leads to excess excretion of dilute urine with a compensatory increase

*Fig. 21.37 Plasma vasopressin response to increasing osmolality in normal subjects and in a patient with diabetes insipidus (DI).*

#### Box 21.51 Factors affecting vasopressin (ADH) release

**Increased by**

- Increased osmolality
- Hypovolaemia
- Hypotension
- Nausea
- Hypothyroidism
- Angiotensin II
- Adrenaline (epinephrine)
- Cortisol

**Decreased by**

- Nicotine
- Antidepressants
- Decreased osmolality
- Hypervolaemia
- Hypertension
- Alcohol
- α-Adrenergic stimulation

in thirst (polydipsia). Daily urine output may reach as much as 10–15 L, leading to dehydration that may be very severe if the thirst mechanism or consciousness is impaired or the patient is denied fluid.

Diabetes insipidus (DI) may be masked by simultaneous cortisol deficiency; cortisol replacement allows a water diuresis and DI then becomes apparent.

Aetiology

Causes of DI are listed in Box 21.52. The most common is hypothalamic–pituitary surgery, following which transient DI is common, frequently remitting after a few days or weeks. Typically, inflammatory lesions of the pituitary stalk are associated with DI (Fig. 21.38).

Familial isolated vasopressin deficiency causes DI from early childhood and is dominantly inherited, caused by a mutation in the AVP-NPII gene. DIDMOAD (Wolfram’s) syndrome is a rare autosomal recessive disorder comprising diabetes insipidus, diabetes mellitus, optic atrophy and deafness, and is caused by mutations in the WFS1 gene on chromosome 4. MRI may show an absent or poorly developed posterior pituitary.

Biochemistry

- High or high-normal plasma osmolality with low urine osmolality (in primary polydipsia, plasma osmolality tends to be low).
- Resultant high or high-normal plasma sodium (hypernatraemia).
- High 24-hour urine volumes (<2 L excludes the need for further investigation).
- Failure of urinary concentration with fluid deprivation.
- Restoration of urinary concentration with vasopressin or an analogue.

The latter two points are studied with a formal water deprivation test (Box 21.53). In normal subjects, plasma osmolality remains normal while urine osmolality rises above 600 mOsm/kg. In DI, plasma osmolality rises while the urine remains dilute, only concentrating after exogenous vasopressin is given (in ‘cranial’ DI), or not concentrating after vasopressin if nephrogenic DI is present. An alternative is measurement of plasma vasopressin during hypertonic saline infusion, but these measurements are not widely available.

Management

The synthetic vasopressin (ADH) analogue, desmopressin, is the treatment of choice in cranial DI. It has a longer duration of action

### Box 21.53 Water deprivation test

#### Indications
- Diagnosis or exclusion of diabetes insipidus (DI).

#### Procedure
- Fasting and no fluids from 07:30 h (or overnight if only mild DI is expected and polyuria is only modest).
- Monitor serum and urine osmolality, urine volume and weight hourly for up to 8 h.
- Abandon fluid deprivation if weight loss >3% occurs.
- If serum osmolality is >300 mOsm/kg and/or urine osmolality <600 mOsm/kg, give desmopressin 2 μg i.m. at end of test. Allow free fluid but measure urine osmolality for 2–4 h.

#### Interpretation
- **Normal response** – serum osmolality remains within normal range (275–295 mOsm/kg). Urine osmolality rises to >600 mOsm/kg.
- **Diabetes insipidus (DI)** – serum osmolality rises above normal without adequate concentration of urine osmolality (i.e. serum osmolality >300 mOsm/kg; urine osmolality <600 mOsm/kg).
- **Nephrogenic DI** – if desmopressin does not concentrate urine.
- **Cranial DI** – if urine osmolality rises by >50% after desmopressin.

![Fig. 21.38 MRI showing a thickened pituitary stalk in hypophysitis.](image-url)
than vasopressin and has no vasoconstrictive effects. It can be given intranasally as a spray 10–40 μg once or twice daily, and orally as 100–200 μg three times daily, or intramuscularly 2–4 μg daily. Response is variable and must be monitored carefully with enquiry about fluid input/output and plasma osmolality measurements. The main problem is avoiding water overload and consequent hyponatraemia (see p. 183). Where there is an underlying cause (e.g. a hypothalamic tumour), this should be investigated and treated.

Alternative agents in mild DI, probably working by sensitizing the renal tubules to endogenous vasopressin, include thiazide diuretics, carbamazepine (200–400 mg daily) or chlorpropamide (200–350 mg daily) but these are rarely used.

Nephrogenic diabetes insipidus
In this condition, renal tubules are resistant to normal or high levels of plasma vasopressin (ADH). Nephrogenic diabetes insipidus may be inherited as a rare sex-linked recessive, with an abnormality in the vasopressin-2 receptor, or as an autosomal post-receptor defect in an ADH-sensitive water channel, aquaporin-2. More commonly, it can be acquired as a result of renal disease, sickle cell disease, drug ingestion (e.g. lithium), hypercalcaemia or hypokalaemia. Wherever possible, the cause should be reversed (see Box 21.52). Polyuria is helped by thiazide diuretics.

Other causes of polyuria and polydipsia
Diabetes mellitus, hypokalaemia and hypercalcaemia should be excluded. In the case of diabetes mellitus, the cause is an osmotic diuresis secondary to glycosuria, which leads to dehydration and an increased perception of thirst owing to hypertonicity of the extracellular fluid.

Primary polydipsia
This is a relatively common cause of thirst and polyuria. It is a psychiatric disturbance characterized by the excessive intake of water. Plasma sodium and osmolality fall as a result and the urine produced is appropriately dilute. Vasopressin levels become virtually undetectable. Prolonged primary polydipsia may lead to the phenomenon of ‘renal medullary washout’, with a fall in the concentrating ability of the kidney.

Characteristically, the diagnosis is made by a water deprivation test. A low plasma osmolality is usual at the start of the test, and since vasopressin secretion and action can be stimulated, the patient’s urine becomes concentrated (although ‘maximum’ concentrating ability may be impaired); the initially low urine osmolality gradually increases with the duration of the water deprivation.

Syndrome of inappropriate antidiuretic hormone secretion
History and examination
Inappropriate secretion of ADH (also called vasopressin) leads to retention of water and hyponatraemia. The presentation of the syndrome of inappropriate antidiuretic hormone secretion (SIADH) is usually vague, with confusion, nausea, irritability and, later, fits and coma. There is no oedema. Mild symptoms usually occur with plasma sodium levels below 125 mmol/L and serious manifestations are likely below 115 mmol/L. The elderly may show symptoms with milder abnormalities.

The syndrome must be distinguished from dilutional hyponatraemia due to excess infusion of glucose/water solutions or diuretic administration (thiazides or amiloride; see p. 183).

Investigations
The usual features are:
- dilutional hyponatraemia due to excessive water retention
- euvoalaemia (in contrast to hypovolaemia of sodium and water depletion states)
- low plasma osmolality with ‘inappropriate’ urine osmolality >100 mOsm/kg (and typically higher than plasma osmolality)
- continued urinary sodium excretion >30 mmol/L (lower levels suggest sodium depletion or ‘hypovolaemic hyponatraemia’, and should respond to 0.9% saline infusion)
- absence of hypokalaemia (or hypotension)
- normal renal and adrenal and thyroid function.

The causes are listed in Box 21.54.

Hyponatraemia is very common during illness in frail elderly patients and it may sometimes be clinically difficult to distinguish SIADH from salt and water depletion, particularly when mixed clinical features are present. Under these circumstances, a trial infusion of 1–2 L 0.9% saline is given. SIADH will not respond (but will excrete the sodium and water load effectively); sodium depletion will respond. ACTH deficiency can give a very similar biochemical picture to SIADH; therefore it is necessary to ensure that the hypothalamic–pituitary–adrenal axis is intact, particularly in neurosurgical patients, in whom ACTH deficiency may be relatively common.

Management
The underlying cause should be corrected where possible. Symptomatic relief can be obtained by the following measures:
- **Fluid intake** should be restricted to 500–1000 mL daily. If tolerated and complied with, this will correct the biochemical abnormalities in almost every case.
- **Frequent measurement** of plasma osmolality, serum sodium and body weight is needed.
- **Demeclocycline** (600–1200 mg daily) is given if water restriction is poorly tolerated or ineffective; this inhibits the action of vasopressin on the kidney, causing a reversible form of nephrogenic diabetes insipidus. However, it often causes photosensitive rashes.
- **Hypertonic saline** may be indicated when the syndrome is very severe (i.e. acute and symptomatic), but this is potentially dangerous and should only be used with extreme caution (see p. 185).

Common causes of the syndrome of inappropriate antidiuretic hormone secretion (SIADH)
Serum calcium levels are mainly controlled by parathyroid hormone (PTH) and vitamin D. Hypercalcaemia is much more common than hypocalcaemia and is frequently detected incidentally with multichannel biochemical analysers. Mild asymptomatic hypercalcaemia occurs in about 1 in 1000 of the population, with an incidence of 25–30 per 100,000 population. It occurs mainly in elderly females and is usually due to primary hyperparathyroidism.

Parathyroid hormone
There are normally four parathyroid glands, which are situated posterior to the thyroid; occasionally, additional glands exist or they may be found elsewhere in the neck or mediastinum. PTH, an 84-amino-acid hormone derived from a 115-residue prohormone, is secreted from the chief cells of the parathyroid glands. PTH levels rise as serum ionized calcium falls. The latter is detected by specific G-protein-coupled, calcium-sensing receptors on the plasma membrane of the parathyroid cells. PTH has several major actions, all serving to increase plasma calcium by:

• increasing osteoclastic resorption of bone (occurring rapidly)
• increasing intestinal absorption of calcium (a slow response)
• increasing synthesis of 1,25-dihydroxyvitamin D₃
• increasing renal tubular reabsorption of calcium
• increasing excretion of phosphate.

PTH effects are mediated at specific membrane receptors on the target cells, resulting in an increase of adenylyl cyclase messenger activity. Vitamin D metabolism is discussed on page 474.

Hypercalcaemia
Pathophysiology and aetiology
The major causes of hypercalcaemia are listed in Box 21.55; primary hyperparathyroidism and malignancies are by far the most common (>90% of cases). Hyperparathyroidism itself may be primary, secondary or tertiary. Primary hyperparathyroidism is caused by single (>80%) parathyroid adenomas or by diffuse hyperplasia of all the glands (15–20%); multiple parathyroid adenomas are rare. Involvement of multiple parathyroid glands may be part of a familial syndrome (e.g. MEN type 1 or 2a). Parathyroid carcinoma is rare (<1%), though it usually produces severe and intractable hypercalcaemia. Hyperparathyroidism–jaw tumour syndrome is a rare familial cause of hyperparathyroidism that may be associated with parathyroid carcinoma and maxillary or mandibular tumours.

Primary hyperparathyroidism
Primary hyperparathyroidism is of unknown cause, though it appears that adenomas are monoclonal. Hyperplasia may also be monoclonal. Chromosomal rearrangements in the 5' regulatory region of the parathyroid hormone gene have been identified, and inactivation of some tumour suppressor genes at a variety of sites may also be involved.

Secondary hyperparathyroidism
Secondary hyperparathyroidism (see p. 1394) is physiological compensatory hypertrophy of all parathyroids because of hypocalcaemia, such as occurs in chronic kidney disease or vitamin D deficiency. PTH levels are raised but calcium levels are low or normal, and PTH falls to normal after correction of the cause of hypocalcaemia where this is possible.

Tertiary hyperparathyroidism
Tertiary hyperparathyroidism is the development of apparently autonomous parathyroid hyperplasia after longstanding secondary hyperparathyroidism, most often in renal failure. Plasma calcium and phosphate are both raised, the latter often grossly so. Parathyroidectomy is necessary at this stage.

Clinical features
Mild hypercalcaemia
Mild hypercalcaemia (e.g. adjusted calcium <3 mmol/L) is frequently asymptomatic, but more severe hypercalcaemia can produce a number of symptoms:

- Excessive parathyroid hormone (PTH) secretion
  - Primary hyperparathyroidism (most common by far), adenoma (common), hyperplasia or carcinoma (rare)
  - Tertiary hyperparathyroidism
  - Ectopic PTH secretion (very rare indeed)

- Malignant disease – low PTH levels (second most common cause)
  - Myeloma
  - Secondary deposits in bone
  - Production of osteoclastic factors by tumours
  - PTH-related protein secretion

- Excess action of vitamin D
  - Iatrogenic or self-administered excess
  - Granulomatous diseases, e.g. sarcoidosis, tuberculosis
  - Lymphoma

- Excessive calcium intake
  - ‘Milk-alkali’ syndrome

- Other endocrine disease (mild hypercalcaemia only)
  - Thyrotoxicosis
  - Addison’s disease

- Drugs
  - Thiazide diuretics
  - Vitamin D analogues
  - Lithium administration (chronic)
  - Vitamin A

- Miscellaneous
  - Long-term immobility
  - Familial hypercalciuric hypercalcaemia
• **General.** There may be tiredness, malaise, dehydra
tion and depression.
• **Renal.** Renal colic occurs from stones. Polyuria or nocturia, hae
maturia and hypertonpsis are seen. The polyuria results from the
effect of hypercalcaemia on renal tubules, reducing their concen
trating ability – a form of mild nephrogenic diabetes insipidus. Primary hyperparathyroidism is present in about 5% of pa
tients who present with renal calculi.
• **Bones.** There may be bone pain. Hyperparathyroidism mainly
affects cortical bone, and bone cysts and locally destructive
‘brown tumours’ occur but only in advanced disease. Only 5–10% of all cases have definite bony lesions even when sought.
Bone disease may be more apparent when there is coexisting
vitamin D deficiency.
• **Abdomen.** There may be abdominal pain.
• **Chondrocalcinosis** and ectopic calcification. These are occa
sional features.
• **Corneal calcification.** This is a marker of longstanding hyper
calcaemia but causes no symptoms.
There may also be symptoms from the underlying cause. Malign
ant disease is usually advanced by the time hypercalcaemia
occurs, typically with bony metastases. The common primary
mamorphs are bronchus, breast, myeloma, oesophagus, thyroid,
prostate, lymphoma and renal cell carcinoma. True ‘ectopic PTH
secretion’ by the tumour is very rare, and most cases are associated
with raised levels of PTH-related protein. This is a 144-amino-acid
polypeptide, the initial sequence of which shows an approximate
homology with the biologically active part of PTH, which is necesa
ry in fetal development but does not have a clearly defined role in
the adult. Bone-resorbing cytokines and prostaglandins may be
involved locally where there are metastatic skeletal lesions, leading
to local mobilization of calcium by osteolysis with subsequent
hypercalcaemia.

**Severe hypercalcaemia**
Severe hypercalcaemia (>3 mmol/L) is usually associated with
malignant disease, hyperparathyroidism, chronic kidney disease or
vitamin D therapy.

**Investigations and differential diagnosis**

**Biochemistry**
Several fasting serum calcium and phosphate samples should be
taken.
• **Serum PTH.** The hallmark of primary hyperparathyroidism is hy
percalcaemia and hypophosphataemia with detectable or ele
vated intact PTH levels during hypercalcaemia. When this com
bination is present in an asymptomatic patient, then further
investigation is usually unnecessary. However, an undetectable
PTH level in the context of hypercalcaemia always requires fur
ther investigation to exclude malignancy or other pathology (see
Box 21.54).
• **Hyperchloraemic acidosis.** This is often mild.
• **Renal function.** This is usually normal but should be measured
as a baseline.
• **24-h urinary calcium** or single calcium creatinine ratio. This
should be measured in a young patient with modest elevation in
calium and PTH to exclude familial hypocalciuric hypercalcae
mia (see p. 646).
• **Elevated serum alkaline phosphatase.** This is found in severe
parathyroid bone disease, but otherwise it suggests an alterna
tive cause for hypercalcaemia.

Where PTH is undetectable or equivocal, a number of other tests
may lead to the diagnosis:
• **Protein electrophoresis/immunofixation:** to exclude myeloma.
• **Serum TSH:** to exclude hyperthyroidism.
• **9am cortisol and/or ACTH test:** to exclude Addison’s disease.
• **Serum ACE:** helpful in the diagnosis of sarcoidosis.

**Imaging**
The success of parathyroid imaging is highly operator-dependent
and choice therefore depends on local skills and experience. Imag
ing is frequently far less accurate than parathyroid exploration by an
expert surgeon, where the success rate is at least 90%. Methods
include:
• **Radioisotope scanning using** 99mTc-sestamibi, which is approxi
mately 90% sensitive in detecting adenomas; it is enhanced with
single-photon emission computed tomography (SPECT).
• **Ultrasound,** which is simple and safe, although insensitive for
small tumours.
• **High-resolution CT scan or MRI** (more sensitive). A CT scan of
the thorax, abdomen and pelvis will often show malignancy or
granulomatous disease in patients with hypercalcaemia and a
suppressed PTH level.

Dual energy X-ray absorptiometry (DXA) bone density scan
ning is useful to detect bone effects in asymptomatic people with
hyperparathyroidism in whom conservative management is
planned.

Abdominal X-rays may show renal calculi or nephrocalcinosis.
High-definition hand X-rays can show subperiosteal erosions in
the middle or terminal phalanges. Neither is required as part of diagno
sis unless symptoms of renal calculi are present or there is evidence of
renal failure.

**Management of hypercalcaemia**
Details of emergency treatment for severe hypercalcaemia are given
in Box 21.56. This should be followed by oral therapy unless the
underlying disease can be treated.

**Management of primary hyperparathyroidism**

**Medical management**
There are no effective medical therapies at present for primary
hyperparathyroidism, but a high fluid intake should be maintained
and replacement of vitamin D in those that are deficient appears to
have no detrimental effect on calcium levels. New therapeutic
agents that target the calcium-sensing receptors (e.g. cinacalcet)
are of proven value in parathyroid carcinoma and in dialysis patients
(see p. 1396), and are used in primary hyperparathyroidism where
surgical intervention is contraindicated.

**Surgery**
There is agreement that surgery is indicated in primary hyperpara
thyroidism for:
• symptoms of hypercalcaemia such as thirst, frequent or exces
sive urination, or constipation or
• end-organ disease (renal stones, fragility fractures or osteoporo
sis) or
• an albumin-adjusted serum calcium level of 2.85 mmol/L or
above.

The situation where plasma calcium is mildly raised (2.65–
2.85 mmol/L) is more controversial. Most authorities feel that young
patients should be operated on, as should those who have reduced
cortical bone density or significant hypocalciuria, as this is associ
ated with stone formation.
In older patients without these problems, or in those unfit for or unwilling to have surgery, conservative management is indicated. Regular measurement of serum calcium and of renal function is necessary. Bone density of cortical bone should be monitored if conservative management is used. Hyperparathyroidism can cause non-specific symptoms of weakness, fatigue and depression, and it can be difficult to determine whether these symptoms are related to hypocalcaemia or coincidental.

Surgical technique and complications
Parathyroid surgery should be performed only by experienced surgeons, as the minute glands may be very difficult to define, and it is difficult to distinguish between an adenoma and normal parathyroid. In expert centres, over 90% of operations are successful, involving removal of the adenoma or removal of all four hyperplastic parathyroids. Minimal access surgery is used, and some centres measure PTH levels intraoperatively to ensure that the adenoma has been removed.

Other than postoperative hypocalcaemia (see below), the other rare complications are those of thyroid surgery: bleeding and recurrent laryngeal nerve palsies (<1%). Vocal cord function should be checked preoperatively.

**Box 21.56 Management of acute severe hypercalcaemia**

Acute hypercalcaemia often presents with dehydration, nausea and vomiting, nocturia and polyuria, drowsiness and altered consciousness. The serum Ca²⁺ is >3 mmol/L and sometimes as high as 5 mmol/L. While investigation of the cause is under way, immediate treatment is mandatory if the patient is seriously ill or if the Ca²⁺ is >3.5 mmol/L.

- **Rehydrate** using at least 4–6 L of 0.9% saline on day 1, and 3–4 L for several days thereafter. Central venous pressure (CVP) may need to be monitored to control the hydration rate.
- **Intravenous bisphosphonates** are the treatment of choice for the hypercalcaemia of malignancy or of undiagnosed cause. Pamidronate is preferred (60–90 mg as an intravenous infusion in 0.9% saline or glucose over 2–4 h or, if less urgent, over 2–4 days). Levels fall after 24–72 h, lasting for approximately 2 weeks. Zoledronic acid is an alternative.
- **Prednisolone** (30–60 mg daily) is effective in some instances (e.g. in myeloma, sarcoidosis and vitamin D excess) but in most cases is ineffective.
- **Calcitonin** (200 units i.v. 6-hourly) has a short-lived action and is little used.
- **Oral phosphate** (sodium cellulose phosphate 5 g three times daily) produces diarrhoea.

If initial exploration is unsuccessful, a full work-up, including venous catheterization and scanning, is essential, remembering that parathyroid tissue can be ectopic.

**Postoperative care**

The major danger after operation is hypocalcaemia, which is more common in patients who have significant bone disease and/or vitamin D deficiency – the ‘hungry bone’ syndrome. Some authorities pre-treat such patients with alfacalcidol 2 μg daily from 2 days pre-operatively for 10–14 days, and routine vitamin D replacement (preferably without calcium) is always indicated if deficiency is diagnosed. Chvostek’s and Trousseau’s signs (see below) are monitored, as well as biochemistry. Plasma calcium measurements are performed at least daily until stable, with or without replacement; a mild transient hypoparathyroidism often continues for 1–2 weeks. Depending on its severity, oral or intravenous calcium should be given temporarily, as only a few patients (<1%) will develop longstanding surgical hypoparathyroidism.

**Familial hypocalciuric hypercalcaemia**

This uncommon autosomal dominant, and usually asymptomatic, condition demonstrates increased renal reabsorption of calcium despite hypercalcaemia. PTH levels are normal or slightly raised and urinary calcium is low. Familial hypocalciuric hypercalcaemia is caused by loss-of-function mutations in the gene on the long arm of chromosome 3 encoding for the calcium-ion-sensing G-protein-coupled receptor in the kidney and parathyroid gland. Family members are often affected and this is detected by genetic analysis. Parathyroid surgery is not indicated, as the course appears benign. This diagnosis can be differentiated from hyperparathyroidism in an isolated case by the calcium:creatinine ratio in blood and urine.

**Hypocalcaemia**

**Pathophysiology**

Hypocalcaemia may be due to deficiencies of calcium homeostatic mechanisms, or secondary to high phosphate levels or other causes of hypocalcaemia (Box 21.57). All forms of hypoparathyroidism, except transient surgical effects, are uncommon.

**Aetiology**

- **Chronic kidney disease** is the most common cause of hypocalcaemia.
- **Severe vitamin D deficiency** may cause mild, and occasionally severe, hypocalcaemia.

**Box 21.57 Causes of hypocalcaemia**

- **Increased phosphate levels**
  - Chronic kidney disease (common)
  - Phosphate therapy
- **Hypoparathyroidism**
  - Surgical – after neck exploration (thyroidectomy, parathyroidectomy – common)
  - Congenital deficiency (DiGeorge’s syndrome)
  - Idiopathic hypoparathyroidism (rare)
  - Severe hypomagnesaemia
- **Vitamin D deficiency**
  - Osteomalacia/rickets
  - Vitamin D resistance
  - Resistance to PTH
    - Pseudohypoparathyroidism
  - Drugs
    - Calcitonin
    - Bisphosphonates
    - Other
      - Acute pancreatitis (quite common)
      - Citrated blood in massive transfusion (not uncommon)
      - Low plasma albumin, e.g. malnutrition, chronic liver disease
      - Malabsorption, e.g. coeliac disease

PTH, parathyroid hormone.
• **Hypocalcaemia after thyroid or parathyroid surgery** is common but usually transient; fewer than 1% of thyroidectomies leave permanent damage (see above).

• **Idiopathic hypoparathyroidism** is one of the rarer autoimmune disorders, and is often accompanied by vitiligo, cutaneous candidiasis and other autoimmune disease.

• **DiGeorge’s syndrome** (see p. 60) is a familial condition in which the hypoparathyroidism is associated with intellectual impairment, cataracts and calcified basal ganglia, and occasionally with specific autoimmune disease.

• **Pseudohypoparathyroidism** is a syndrome of end-organ resistance to PTH owing to a mutation in the Gβγ-protein (GNAS1), which is coupled to the PTH receptor. It is associated with short stature, short metacarpals, subcutaneous calcification and sometimes intellectual impairment. Variable degrees of resistance involving other G-protein-linked hormone receptors may also be seen (TSH, LH, FSH).

• **Pseudo-pseudohypoparathyroidism** describes the phenotypic defects but without any abnormalities of calcium metabolism. Individuals with this condition may share the same gene defect as those with pseudohypoparathyroidism and be members of the same families.

### Clinical features

Hypoparathyroidism presents as neuromuscular irritability and neuropsychiatric manifestations. Paraesthesias, circumoral numbness, cramps, anxiety and tetany (Box 21.58) are followed by convulsions, laryngeal stridor, dystonia and psychosis. Two signs of hypocalcaemia are Chvostek’s sign (gentle tapping over the facial nerve causes twitching of the ipsilateral facial muscles) and Trousseau’s sign (inflation of the sphygmonometer cuff above systolic pressure for 3 min induces tetanic spasm of the fingers and wrist). Severe hypocalcaemia may cause papilloedema and, frequently, a prolonged QT interval on the ECG.

### Investigations

The clinical history and picture is usually diagnostic and is confirmed by a low serum calcium (after correction for any albumin abnormality). Additional tests include:

- **Serum and urine creatinine.** These test for renal disease.
- **PTH levels** in the serum. These are absent or inappropriately low in hypoparathyroidism, high in other causes of hypocalcaemia.
- **Parathyroid antibodies.** These are present in idiopathic hypoparathyroidism.
- **25-hydroxyvitamin D serum level.** This is low in vitamin D deficiency.
- **Magnesium level.** Severe hypomagnesaemia results in functional hypoparathyroidism, which is reversed by magnesium replacement.
- **X-rays of metacarpals.** Short fourth metacarpals occur in pseudohypoparathyroidism.

### Management

In vitamin D deficiency, colecalciferol is the most appropriate treatment. In other cases, alpha-hydroxylated derivatives of vitamin D are preferred for their shorter half-life, and especially in renal disease, as the others require renal hydroxylation. Usual daily maintenance doses are 0.25–2 μg for alfacalcidol (1α-OH-D3). During treatment, plasma calcium must be monitored frequently to detect hypercalcaemia. Oral calcium supplements may be used in the early stages of treatment, and severe hypocalcaemia presenting as an emergency may occasionally require replacement with intravenous calcium gluconate. In hypoparathyroidism, PTH therapy is being used in clinical trials.

### Further reading

### HYPOGLYCAEMIA IN THE NON-DIABETIC PATIENT

Hypoglycaemia develops when hepatic glucose output falls below the rate of glucose uptake by peripheral tissues. Hepatic glucose output may be reduced by:

- inhibition of hepatic glycogenolysis and gluconeogenesis by insulin
- depletion of hepatic glycogen reserves by malnutrition, fasting, exercise or advanced liver disease
- impaired gluconeogenesis (e.g. following alcohol ingestion).

In the first of these categories, insulin levels are raised, the liver contains adequate glycogen stores and the hypoglycaemia can be reversed by injection of glucagon. In the other two situations, insulin levels are low and glucagon is ineffective. Peripheral glucose uptake is accelerated by high insulin levels and by exercise, but these conditions are normally balanced by increased hepatic glucose output.

The most common symptoms and signs of hypoglycaemia are neurological. The brain consumes about 50% of the total glucose produced by the liver. This high energy requirement is needed to generate ATP, used to maintain the potential difference across axonal membranes.

### Insulinomas

Insulinomas are pancreatic islet cell tumours that secrete insulin. Most are sporadic but some patients have multiple tumours arising from neural crest tissue (multiple endocrine neoplasia). Some 95% of these tumours are benign. The classic presentation is with fasting hypoglycaemia, but early symptoms may also develop in the late morning or afternoon. Recurrent hypoglycaemia is often present for months or years before the diagnosis is made, and the symptoms may be atypical or even bizarre; the presenting features in one series are given in Box 21.59. Common misdiagnoses include...
psychiatric disorders, particularly pseudodementia in elderly people, epilepsy and cerebrovascular disease. Whipple’s triad remains the basis of clinical diagnosis. This is satisfied when:
- symptoms are associated with fasting or exercise
- hypoglycaemia is confirmed during these episodes
- glucose relieves the symptoms.

A fourth criterion – demonstration of inappropriately high insulin levels during hypoglycaemia – may usefully be added.

The diagnosis is confirmed by the demonstration of hypoglycaemia in association with inappropriate and excessive insulin secretion. Hypoglycaemia is demonstrated by:
- Measurement of overnight fasting (16h) glucose and insulin levels on three occasions. About 90% of patients with insulinomas will have low glucose and non-suppressed (normal or elevated) insulin levels.
- A prolonged 72-hour supervised fast if overnight testing is inconclusive and symptoms persist.

Autonomous insulin secretion is demonstrated by lack of the normal feedback suppression during hypoglycaemia. This may be shown by measuring insulin, C-peptide or proinsulin during a spontaneous episode of hypoglycaemia.

**Management**

The most effective therapy is surgical excision of the tumour but insulinomas are often very small and difficult to localize. Many techniques can be used to attempt to localize insulinomas. Sensitivity and specificity vary between centres and between operators. These include highly selective angiography, contrast-enhanced high-resolution computed tomography scanning, scanning with radiolabelled somatostatin (some insulinomas express somatostatin receptors), and endoscopic and intraoperative ultrasound scanning. Venous sampling for the detection of ‘hot spots’ of high insulin concentration in the various intra-abdominal veins is still used occasionally.

Medical treatment with diazoxide is useful when the insulinoma is malignant, when a tumour cannot be located and when elderly patients have mild symptoms. Symptoms may also remit on treatment with a somatostatin analogue (octreotide or lanreotide).

**Hypoglycaemia with other tumours**

Hypoglycaemia may develop in the course of advanced neoplasia and cachexia, and has been described in association with many tumour types. Certain massive tumours, especially sarcomas, may produce hypoglycaemia owing to the secretion of insulin-like growth factor-1. True ectopic insulin secretion is extremely rare.

**Postprandial hypoglycaemia**

If frequent venous blood glucose samples are taken following a prolonged glucose tolerance test, about 1 in 4 subjects will have at least one value below 3mmol/L. The arteriovenous glucose difference is quite marked during this phase, so that very few are truly hypoglycaemic in terms of arterial (or capillary) blood glucose content. Failure to appreciate this simple fact led some authorities to believe that postprandial (or reactive) hypoglycaemia was a potential ‘organic’ explanation for a variety of complaints that might otherwise have been considered psychosomatic. An epidemic of false ‘hypoglycaemia’ followed, particularly in the USA. Later work showed a poor correlation between symptoms and biochemical hypoglycaemia. Even so, a number of otherwise normal people occasionally become pale, weak and sweaty at times when meals are due, and report benefit from advice to take regular snacks between meals.

True postprandial hypoglycaemia may develop in the presence of alcohol, which ‘primes’ the cells to produce an exaggerated insulin response to carbohydrate. The person who substitutes alcoholic beverages for lunch is particularly at risk. Postprandial hypoglycaemia sometimes occurs after gastric surgery, owing to rapid gastric emptying and mismatching of nutrient absorption and insulin secretion. This is referred to as ‘dumping’ but it is now rarely encountered (see p. 1176).

**Hepatic and renal causes of hypoglycaemia**

The liver can maintain a normal glucose output despite extensive damage, and hepatic hypoglycaemia is uncommon. It is, however, a particular problem with acute hepatic failure.

The kidney has a subsidiary role in glucose production (via gluconeogenesis in the renal cortex), and hypoglycaemia is sometimes a problem in terminal renal failure.

Hereditary fructose intolerance occurs in 1 in 20000 live births and can cause hypoglycaemia.

**Endocrine causes of hypoglycaemia**

Deficiencies of hormones antagonistic to insulin are rare but well-recognized causes of hypoglycaemia. These include hypopituitarism, isolated adrenocorticotrophic hormone (ACTH) deficiency and Addison’s disease.

**Drug-induced hypoglycaemia**

Many drugs have been reported to produce isolated cases of hypoglycaemia, but usually only when other predisposing factors are present:
- Sulphonylureas may be used in the treatment of diabetes or may be taken by people without diabetes in suicide attempts.
- Quinine may produce severe hypoglycaemia in the course of treatment for *falciparum* malaria.
- Salicylates may cause hypoglycaemia, usually after accidental ingestion by children.
- Propranolol can induce hypoglycaemia in the presence of strenuous exercise or starvation.
- Pentamidine, used in the treatment of resistant *Pneumocystis* pneumonia (see p. 1443), may produce hypoglycaemia.

**Alcohol-induced hypoglycaemia**

Alcohol inhibits gluconeogenesis. Alcohol-induced hypoglycaemia occurs in poorly nourished chronic alcohol users, binge drinkers, and children who have taken relatively small amounts of alcohol, since they have a diminished hepatic glycogen reserve. They present with coma and hypothermia (hypothermia is a feature of hypoglycaemia, due to the suppression of central thermoregulation, particularly the shivering response; children manifest hypothermia more frequently due to their high ratio of surface area to body mass).

**Factitious hypoglycaemia**

This is a relatively common variant of self-induced disease and is more common than an insulinoma. Hypoglycaemia is produced by surreptitious self-administration of insulin or sulphonylureas. Many patients in this category have been extensively investigated for an insulinoma. Measurement of C-peptide levels during hypoglycaemia should identify patients who are injecting insulin; sulphonylurea abuse can be detected by chromatography of plasma or urine.

**OTHER ENDOCRINE DISORDERS**

**Diseases of many glands**

**Polyglandular autoimmune syndromes**

Primary endocrine gland failure is commonly caused by autoantibodies (see Box 21.4) and there may be multiple gland deficiencies. Most common are the associations of primary hypothyroidism and...

>Fig. 21.39 Multiple liver metastases (arrowed) from a pancreatic endocrine tumour in multiple endocrine neoplasia type 1.

>Screening for MEN 1

The defect in MEN 1 is in a novel gene (menin) on the long arm of chromosome 11, which encodes for a 610-amino-acid protein. Menin represses a transcription factor (JunD), and lack of JunD suppression leads to decreased apoptosis and oncogenesis. People with the MEN1 gene carry one mutant gene and a wild-type gene (i.e., are heterozygous). When the wild-type gene undergoes a random somatic mutation during life, this leads to loss of heterozygosity and explains the late onset of tumours at any stage (the ‘two hit’ hypothesis). MEN 1 is classically associated with pancreatic, parathyroid and pituitary tumours, although other glands may be affected (see Box 21.60; Fig. 21.39).

**MEN 2a and 2b**

MEN 2a and 2b are caused by mutations of the RET proto-oncogene on chromosome 10 (see medullary thyroid cancer, p. 622). This gene encodes for a transmembrane glycoprotein receptor. For MEN 2a, the mutation is in the extracellular domain; for 2b, it is in the intracellular domain. MEN 2 is classically associated with parathyroid tumours, phaeochromocytoma and medullary thyroid carcinoma (see Box 21.60). Unlike MEN 2a, MEN 2b is associated with a marfanoid phenotype and intestinal and visceral ganglioneuromas, as well as neurorals around the lips and tongue.

**Management**

Management of established tumours in MEN is largely the same as treatment for similar tumours occurring sporadically. In MEN 1, four-gland parathyroidectomy is usually recommended when surgery is needed since all glands are typically involved. However, the essence of management in MEN is annual screening to detect tumours at an early, treatable stage.

**Screening**

A careful family history is essential. If the precise gene mutation has been identified in a particular family, then family members at risk can be offered genetic screening for the presence of the mutation, ideally in childhood. In affected individuals, biochemical screening and periodic imaging are then required.

**Screening for MEN 1**

Hyperparathyroidism is usually the first manifestation, and serum calcium is the simplest screening test in families with no identified mutation. In an established case (or gene-positive family member), other screening bloods include prolactin, GH/IGF-1 and ‘gut hormones’ (see Box 32.4). Periodic imaging of pancreas, adrenals and pituitary is usually performed. People with MEN 1 can develop type 1 diabetes, and either of these with Addison’s disease or pernicious anaemia.

**Autoimmune polyendocrinopathy type 1**

Autoimmune polyendocrinopathy type 1 (APS-1) is an autosomal recessive disorder and is caused by AIRE gene mutations. This condition is also associated with non-endocrine manifestations. The AIRE gene is present in the epithelium of the thymus and is involved in the presentation of self-antigens to thymocytes. Mutations will allow persistence of thymic lymphocytes, which react against self-antigens and cause development of autoimmune disorders. Mucocutaneous candidiasis often develops before the onset of endocrine deficiencies, such as hypothyroidism, Addison’s disease, type 1 diabetes, hypoparathyroidism, primary hypogonadism, nail dystrophy, vitiligo and dental enamel hypoplasia.

**Autoimmune polyendocrinopathy type 2**

Autoimmune polyendocrinopathy type 2 (APS-2) is not associated with candidiasis and is also known as Schmidt’s syndrome, typically when hypothyroidism, Addison’s disease, type 1 diabetes, myasthenia gravis and primary hypogonadism are present in combination; coeliac disease is also an association.

**Multiple endocrine neoplasias**

Multiple endocrine neoplasia (MEN) is the name given to the simultaneous or metachronous occurrence of tumours involving a number of endocrine glands (Box 21.60). The condition is inherited in an autosomal dominant manner and arises from the expression of recessive oncogenic mutations, most of which have been isolated. Affected persons may pass on the mutation to their offspring in the germ cell, but for the disease to become evident, a somatic mutation must also occur, such as deletion or loss of a normal homologous chromosome.
metastases to the liver from non-functional pancreatic tumours that are clinically silent; this emphasizes the need for regular screening imaging.

**Screening for MEN 2**
Serum calcium levels will easily detect hyperparathyroidism.
- **Medullary carcinoma of thyroid (MCT).** With the known presence of the gene defect, total thyroidectomy is recommended in early childhood or as soon as the gene defect is identified. Calcitonin is a useful tumour marker.
- **Phaeochromocytoma.** Metanephrine or catecholamine estimations are required.

**McCune–Albright syndrome**
This condition is associated with autonomous hypersecretion of a number of endocrine glands at a young age. Gonadotrophin-independent puberty occurs, with Leydig cell hyperplasia in males and ovarian oestrogen production in girls. Pituitary hypersecretion may lead to hyperprolactinaemia, acromegaly or gigantism. Cushing’s syndrome due to nodular hyperplasia of the adrenal cortex is observed, as well as autonomous functioning thyroid nodules. Non-endocrine manifestations include café-au-lait patches and increased bone deformity and fractures due to polyostotic fibrous dysplasia. The pathological basis is a point mutation of the GNAS1 gene that inhibits GTPase activity, leading to persistent activation of cAMP-mediated endocrine secretion.

**Ectopic hormone secretion**
This term refers to hormone synthesis, and normally secretion, from a neoplastic non-endocrine cell, most usually seen in tumours that have some degree of embryological resemblance to specialist endocrine cells. The clinical effects are those of the hormone produced, with or without manifestations of systemic malignancy. The most common situations seen are the following:
- **Hypercalcaemia of malignant disease,** often from squamous cell tumours of lung and breast, often with bone metastases. Where metastases are not present, most cases are mediated by secretion of PTH-related protein (PTHrP), which has considerable sequence homology to PTH; a variety of other factors may sometimes be involved but very rarely PTH itself. Treatment is discussed on page 645.
- **SIADH** (see p. 643). Again, this is most commonly caused by a primary lung tumour.
- **Ectopic ACTH syndrome** (see p. 601). Small-cell carcinoma of the lung, carcinoid tumours and medullary thyroid carcinomas are the most common causes, though many other tumours rarely cause it.
- **Production of insulin-like activity.** This may result in hypoglycaemia (see p. 716).
- **Carcinoid syndrome.** This is the collection of symptoms (diarrhoea, abdominal pain and loss of appetite; flushing of the skin, particularly the face; tachycardia; breathlessness and wheezing) when a neuroendocrine tumour, usually one that has spread to the liver, releases hormones such as serotonin into the bloodstream. Measurement of 24 hour urinary SHIAA is required for diagnosis.

### Endocrine treatment of other malignancies
See Chapter 6.

Skin diseases are common and their burden on a population level is significant. They cause considerable distress to patients and a few are life-threatening, including pemphigus, severe drug reactions and melanoma, the fifth most common cancer in the UK.

Dermatology is primarily an outpatient specialty, although admission is sometimes needed for severe inflammatory or infectious skin disease when associated with systemic symptoms. The demand for specialist care exceeds supply and teledermatology is evolving as a means of triaging referrals and offering remote access to specialist advice. Dermatologists work in multidisciplinary teams with oncologists, pathologists, radiotherapists and plastic or maxillofacial surgeons to provide diagnosis and treatment.

Key skills include:
- examining the skin and describing common skin lesions and rashes accurately
- understanding the management of common skin complaints, including acne, eczema, psoriasis, skin infections and malignancies
- recognizing life-threatening skin conditions, including melanoma, severe drug reactions and aggressive skin and soft tissue infection
- understanding the role of topical therapies, oral immunosuppressants, phototherapy and biological drugs in the treatment of skin disease.

Dermatology is best learned by practical experience gained through interviewing and examining patients in outpatient clinics. Attending a skin cancer multidisciplinary team meeting gives insight into the expanding range of anti-cancer therapy available. Talking with patients who are receiving day treatment and phototherapy sheds light on the importance of improving chronic skin disease and its impact on quality of life.
History and examination

Skin complaints generally consist of lesions (‘lumps and bumps’) and rashes. Diagnosis is by taking a detailed history (Box 22.1) and examining the whole skin surface, as well as the hair, nails and oral cavity. Diagnostic accuracy can be increased by palpation (to assess depth of lesions) and by use of a dermatoscope (a handheld magnifying device with strong and sometimes polarized light.)

The distribution (Box 22.2 and Fig. 22.1), pattern (Fig. 22.2) and appearance (Fig. 22.3) of disease should be described.

Box 22.1 Taking a history in dermatology

History of the presenting complaint
• Time course: duration, changes in distribution/appearance over time
• Local symptoms: itching, pain and tenderness, bleeding
• Involvement of mouth, nails, hair or genitalia
• Provoking factors: temperature, sunlight, medication
• Features of systemic inflammatory disease, e.g. malaise, fever
• Symptoms in other systems: eyes, joints, internal organs

Risk factors
• History of autoinflammatory or autoimmune disease
• Current and recent medications, previous history of drug allergy
• Family history of skin disease (e.g. psoriasis, skin cancer) and atopy
• Skin type, cumulative sunlight exposure, use of sunbeds
• Time spent in tropical countries

Psychological factors*
• Depression and anxiety
• Disturbed body image, effect on relationships and self-confidence

*Screening tools for psychological distress, e.g. patient health questionnaire (PHQ)-9 and generalized anxiety disorder (GAD)-7, may be useful in assessment.

INTRODUCTION

Skin diseases affect all ages and are among the most common human ailments. Though rarely fatal, many are chronic and constitute a leading cause of disability worldwide. The World Health Organization International Classification of Disease (ICD) 10 lists more than 1000 skin or skin-related diseases, but most burden comes from a few diseases (Fig. 22.4). These include eczema/dermatitis, acne, psoriasis, urticaria, and superficial fungal, bacterial (impetigo, cellulitis, abscesses) and viral infections (warts, molluscum contagiosum).

People with a skin complaint seek advice from various sources, including the Internet, pharmacists, primary care practitioners and specialists in intermediate or secondary care. The estimated number of people using dermatology health services in the UK at various entry points for a population of 100 000 over a 1-year period is summarized in Box 22.3.

The psychosocial impact of chronic skin disease can be great and should always be considered, including its effect on work, schooling, recreation and relationships. The dermatology life quality index (DLQI) and children’s DLQI are simple validated tools for assessing health-related quality of life for patients with skin disease. The SWIFT check-up tool (see Further reading) can also be used to identify areas of difficulty and what support is needed.

SKIN STRUCTURE AND FUNCTION

Understanding the structure and function of the skin helps make sense of the signs and symptoms of skin disease. The skin can be biopsied to diagnose rashes or remove lesions, and dermatology offers a great opportunity for clinico-pathological correlation, where clinician and pathologist work together and share expertise.

¹Excludes skin neoplasms, viral warts, herpes simplex and scabies.
²Includes people dying from cellulitis, chronic ulcer of the skin and severe drug reactions who might not have been admitted under a dermatologist’s care.

The skin is comprised of three distinct layers: the epidermis, dermis and subcutis (Fig. 22.5).

An overview of the functions of the skin is provided in Box 22.4.

### Epidermis

The epidermis functions as a renewable dynamic barrier again the environment and pathogens, and plays an essential role in homeostasis. Its thickness ranges from 0.05 to 1.5 mm, depending on body site, and it is tethered to the underlying dermis by the dense protein network of the basement membrane zone (BMZ, see Fig. 22.43). Inherited or autoimmune-induced deficiencies of BMZ proteins lead to fragility and blistering of the skin and mucous membranes (see p. 686).

The epidermis is a stratified squamous epithelium, composed mostly of keratinocytes (keratin-synthesizing cells) that originate from a proliferating basal layer. They differentiate and migrate out to the surface to be shed as dead, flattened squames. Epidermal differentiation is a highly complex process involving ‘switching on’ and ‘off’ genes that regulate protein and lipid synthesis. Basal keratinocytes synthesize the keratin filaments of the cytoskeleton and desmosomal proteins (desmoplakin, desmoglein) for cell-to-cell cohesion. Lipids are synthesized in the granular layer and secreted to form a watertight intercellular layer. Filaggrin is expressed in the outer stratum corneum, where it acts as a ‘natural moisturizing factor’, keeping the skin hydrated and pliable. The stratum corneum provides most of the skin’s barrier function, and deficiency in filaggrin leads to ‘leaky’, dry skin that cracks, allowing entry of allergens and pathogens. Filaggrin gene mutations are common and have been identified as a major risk factor for atopic eczema and other atopic diseases. Changes in lipid and protease activity in the outermost epidermis lead to shedding (desquamation). The keratinocyte’s journey from basal cell to skin surface normally takes about 30 days but is considerably faster in psoriasis (see p. 664), leading to thickened, scaly skin.

Keratinocytes also secrete cytokines, such as interleukins, interferon-gamma (IFN-γ) and tumour necrosis factor-alpha (TNF-α), in response to injury; these stimulate wound healing and protect against microbial invasion. They also produce antimicrobial peptides that form part of the innate immune system. Deficiency of these peptides may increase susceptibility to staphylococcal and viral infection in people with atopic eczema. The epidermis contains a network of Langerhans cells (dendritic cells) that capture and process antigens for presentation to T lymphocytes. Melanin-synthesizing melanocytes reside in the basal layer and transfer ultraviolet (UV)-protecting pigment to adjacent keratinocytes. The epidermis also contains nerve endings and sensory cells (Merkel cells).

### Dermis

The dermis is a tough matrix of collagen and elastin fibres, surrounded by a gel-like ground substance. These fibres give skin its strength and elasticity. It also contains cells (fibroblasts, mast cells, lymphocytes and dendritic cells), blood and lymphatic vessels, nerves, muscle and appendages (sweat glands, sebaceous glands and hair follicles). The upper papillary dermis has finger-like projections that contain terminal capillary networks. The lower reticular dermis is thicker and denser. Eccrine sweat glands are found throughout the skin, except for the mucosal surfaces, and carry out thermoregulatory sweating. Apocrine sweat glands are found in the axillae and anogenital area, and do not function until puberty. Sebaceous glands are also inactive until puberty, when they excrete the oily substance sebum, under the influence of androgens. They are most numerous on the ‘greasy’ (seborrhoeic)
sites of the central face, scalp and upper torso. Sebum flows on to the skin surface via the pilosebaceous duct of the hair follicle. It contributes to skin barrier function and has antimicrobial actions.

The skin is richly innervated with sensory fibres (transmitting touch, pain/itch, vibration, pressure and temperature) and autonomic fibres that innervate sweat glands, blood vessels and arrector pili for thermoregulation.

The skin surface is covered with hair, except for the mucous membranes, palms and soles. Hair grows from follicles, which are modified epidermal structures deeply rooted in the dermis. The lower portion of the hair follicle (bulb) surrounds a richly innervated and vascularized dermal papilla. Hair grows from the stem cells in the bulb. If this area is damaged by an inflammatory process or trauma, this leads to permanent hair loss. Follicles go through a cycle of anagen (growth), catagen (involution) and telogen (shedding). At any one time, most hairs (>90%) will be in the anagen phase, which is usually 3–5 years for scalp hair. Miniaturization of coarse terminal scalp hairs with age leads to hair thinning, or ‘baldness’.

Nails are modified epidermal structures that contain specialized tough keratin proteins. It takes about 6 months to grow a fingernail and 1 year to grow a toenail.

**Subcutis**

The subcutaneous layer consists of lobules of adipose tissue separated by fibrous septa with sparse blood vessels and nerves. This layer provides insulation and cushioning against trauma.

**INVESTIGATION OF SKIN DISEASE**

The most common dermatological investigations are microscopy and culture of microbial swabs and fungal tests (mycology) of skin, hair or nail clippings (Box 22.5). Skin lesions may be removed by shaving, curetting or excision, depending on their depth and the suspected diagnosis. This can be done under local anaesthetic as an outpatient procedure. All skin specimens should be sent for histology. Immunofluorescence tests on skin and serum are indicated in suspected immunobullous diseases (see p. 686).

**PRINCIPLES OF DERMATOLOGICAL THERAPY**

**Topical therapy**

The skin is easily accessible to topical therapy and this is an effective and generally safe way of treating many rashes and some low-grade malignancies with a reduced risk of systemic adverse effects compared with oral therapy. Attention to cosmetic acceptability, clear instructions about how and when to apply, duration of treatment and anticipated effects (including how quickly the complaint should settle and likely side-effects) will optimize patient adherence. It is helpful to specify quantities in simple terms, such as a ‘pea-sized’ portion to treat half a face or the ‘fingertip unit’ for topical corticosteroids in eczema management. Topical medicaments consist of an active ingredient, in a vehicle or base, and excipients such as preservatives or emulsifiers to maintain stability and efficacy. The following formulations exist:

- **Creams** (oil-in-water emulsions) are light and easily absorbed. They usually contain preservatives, such as parabens (hydroxybenzoates), which can cause allergic contact dermatitis (see below). Aqueous cream is a popular and inexpensive soap substitute.
- **Ointments** are greasy preparations based in vehicles such as polyethylene glycol (water-soluble) or petrolatum (insoluble). They feel sticky and are useful for treating dry, flaky rashes.
- **Lotions** contain water or alcohol that evaporates after application, giving a cooling effect. They are useful for weeping skin conditions and hairy sites (e.g. the scalp). Alcohol based- lotions should be avoided on broken skin, as they sting.
- **Gels** are semi-solid preparations of high-molecular-weight polymers. They are non-greasy and liquefy on contact with the skin. They are used to treat oily or hairy areas (e.g. scalp).
- **Pastes** are thick, adherent ointments containing a powder, e.g. Lassar’s paste. They are rarely used now due to poor cosmetic acceptability.

**Adverse effects of topical therapies**

- **Systemic absorption** may occur when large areas of inflamed skin are treated, especially with occlusive bandages or dressings. Neonates are particularly susceptible due to their relatively high body surface area and immature skin barrier.
- **Contact allergy** may develop to the drug (e.g. hydrocortisone, neomycin), vehicle (e.g. lanolin, cetearyl alcohol) or excipients (e.g. chlorocresol, parabens). It should be considered in any patient with an unresponsive dermatitis or new dermatitis following topical treatment. Ointments contain fewer excipients and so are less likely to cause contact allergy.
- **Folliculitis** can occur due to blockage of hair follicles, especially with ointments in hot weather and on sweaty, occluded skin (bandages, tight clothing). Corticosteroids can cause a range of adverse effects (see p. 661) but have a very good safety profile when used correctly.

**Phototherapy**

Phototherapy with sunlight has been used to treat skin diseases since ancient times. Modern phototherapy uses specific wavelengths in the UV spectrum for anti-inflammatory or pigment-inducing effects. The conditions most commonly treated with phototherapy are psoriasis, eczema, polymorphic light eruption, cutaneous T-cell lymphoma and vitiligo. Narrow-band UVB (311 nm / TL01) was developed specifically to treat psoriasis and is the treatment of choice in most cases. UVA therapy is given with systemic or topical psoralens (psoralen + UVA = PUVA) to enhance its photobiological effects. Commercial tanning beds predominantly deliver low doses of UVA and have limited effectiveness in treating skin disease.

Narrow-band UVB therapy is given two or three times a week for 6–10 weeks. It has superseded broad-band UVB, as it is more effective. PUVA is usually given twice a week. If the psoralen is taken orally, UV-protective glasses must be worn for the day of treatment.
to protect the retina. PUVA is used less widely nowadays because it is associated with an increased risk of skin cancer, especially squamous cell carcinoma. The maximum recommended lifetime dose of UVA is 1000 joules (approximately 200 treatments).

Unaffected regions of skin or high-risk areas like the scrotum should be covered during phototherapy. To avoid adverse effects, patients should be carefully selected and their skin cancer risk assessed. People with very fair skin and freckles are at increased risk of burning and the UV dosage has to be carefully adjusted and escalated according to skin type.

Systemic therapy

A wide range of systemic drugs are used to treat skin disease. Some are used off-licence, especially for uncommon diseases where no licensed option exists. The risks and benefits should be carefully considered and discussed with the patient, so they can share in treatment decisions. Drugs include:

- antibiotics (antibacterial, antiviral and antifungal therapy)
- antiandrogens
- anti-inflammatory (anti-histamines, antimalarials, colchicine, corticosteroids, dapsone, phosphodiesterase inhibitors, thalidomide)
- immunosuppressants (azathioprine, cyclosporin, cyclophosphamide, methotrexate, mycophenolate mofetil)
- retinoids (acitretin, alitretinoin, isotretinoin)
- biologics (for psoriasis, eczema, urticaria).

ERYTHRODERMA AND LOSS OF SKIN FUNCTION (‘SKIN FAILURE’)

Erythroderma (‘red skin’) is a term used to describe widespread inflammation affecting 90% or more of the body surface. There are several causes (Box 22.6), of which underlying skin disease and drug hypersensitivity are the most common. Extensive skin inflammation causes pain, soreness and irritation, and leads to loss of normal skin function, especially fluid and temperature regulation. Symptoms include thirst, fever and chills, malaise and dizziness. Erythroderma requires urgent medical treatment to avoid life-threatening complications (see next section). Examination should seek features of an underlying dermatosis, such as scalp or nail psoriasis. There may be associated generalized lymphadenopathy and a skin biopsy may be indicated, especially in suspected cutaneous lymphoma. In non-malignant disease, lymph nodes are often mildly enlarged and histology shows non-specific, reactive changes.

Complications

These include:

- high-output cardiac failure from increased blood flow
- hypothermia from heat loss
- pre-renal acute kidney injury from fluid depletion
- hypoalbuminaemia
- catabolism and increased basal metabolic rate
- secondary bacterial infection
- capillary leak syndrome: the most severe complication and potentially fatal, though rare. Release of inflammatory mediators from the skin causes extensive vascular leakage with oedema, hypovolaemic shock and acute respiratory distress syndrome (ARDS) (see p. 232).

Management

Intensive supportive treatment includes maintaining body temperature (with space blankets and heaters) and close monitoring of vital signs and fluid and electrolyte balance. Skin swabs should be taken if secondary infection is suspected. All non-essential medication should be stopped. Topical therapy with a bland emollient or mild topical steroid can be initiated while the underlying cause is identified, at which point systemic therapy may be indicated: for example, ciclosporin for psoriasis (see p. 666).

COMMON RASHES

Acne and related disorders

Acne

Acne is one of the most common skin complaints globally, affecting over 85% of adolescents and often persisting into adulthood. In women, a late-onset chronic variant starting in the twenties is increasingly recognized. Acne can have a profound effect on self-esteem and mood, leading to anxiety, depression and even suicidal ideation. This may have little correlation with apparent disease severity. Lesions arise in the pilosebaceous follicle, which becomes blocked due to abnormal keratinization and increased production of altered sebum, leading to comedones. Microcomedones (microscopic comedones) can be found in biopsies of normal-looking acne-prone skin. Blockage of the pilosebaceous duct is followed by alteration in its microbiome, especially involving Cutibacterium acnes (formerly Propionibacterium acnes), leading to activation of innate immunity (Fig. 22.6A). This causes an inflammatory response with influx of neutrophils that release elastase, causing connective tissue damage. Scarring may follow with profound long-term psychological consequences. Post-inflammatory hyperpigmentation (see p. 693) is also a common sequela in dark-skinned people.

Clinical features

Acne affects the face and upper torso, where the sebaceous glands are dense and affected skin is usually greasy (seborrhoea). Lesions are classified as:

- non-inflammatory – open comedones (blackheads) or closed comedones (whiteheads)
- inflammatory – papules, pustules (Fig. 22.6B), nodules and cysts
- scars – raised (hypertrophic) or depressed/pitted (box, rolling and ice-pick).

Uncommon acne variants are shown in Box 22.7. Severe acne may be associated with various autoinflammatory syndromes characterized by fever and aseptic inflammation (Box 22.8).
Management

The diagnosis of acne is usually straightforward. Treatment should target the primary pathogenic lesion: the microcomedone and associated inflammatory response. The choice depends on whether lesions are predominantly non-inflamed or inflamed, disease severity or scarring, response to previous treatment and degree of psychological upset (Box 22.9).

Topical retinoids, azelaic acid, salicylic acid and benzoyl peroxide (BPO) are keratolytic and help unblock pores but also cause dry, flaky skin. This can be managed with a non-comedogenic/oil-free moisturizer. Tetracyclines and erythromycin are licensed for oral use in acne but their prolonged use may encourage the emergence of resistant bacteria. They should not be prescribed long term or without non-antibiotic topical therapy, as the latter reduce the emergence of resistant bacteria (Box 22.10). In females, the combined oral contraceptive pill and a formulation containing additional cyproterone acetate (a mild antiandrogen) may be of benefit due to a reduction in sebum excretion. Low-dose spironolactone is another useful option. Progesterone-only pills (‘mini-pills’) may aggravate acne.

Oral isotretinoin is a highly effective treatment licensed for severe inflammatory acne, especially with scarring. It is also used in milder recalcitrant cases associated with severe psychological upset. It causes dryness of the mucous membranes and has a range of other potential adverse effects. A major concern is its potent teratogenicity, so females of childbearing age must use highly effective contraception and follow a specific pregnancy prevention programme. Oral isotretinoin has been associated with depression and rare cases of suicide, so mood should be carefully monitored. However, for most acne sufferers, emotional wellbeing improves as their acne clears.

High-intensity light treatment (blue light, intense pulsed light) has also been reported to lessen inflammatory lesions, and ablative laser therapy and physical treatment, such as dermabrasion, may improve the appearance of scars. However, these are not ‘magic wands’ and a key goal of acne treatment is to prevent scar formation.

Hidradenitis suppurativa (‘acne inversa’)

Hidradenitis suppurativa (HS) is a chronic inflammatory disorder that affects the apocrine pilosebaceous follicles of the axillae, the inguinal...
Box 22.7 Clinical variants of acne

Infantile acne
- Typically starts between 3 and 12 months of age
- Triggered by maternal androgens

Acne excoriée
- Mostly affects young women who pick mild acne spots, leaving prominent excoriations
- There is usually underlying psychological upset

Drug-induced acneiform eruptions
- May be caused by corticosteroids, vitamin B12, isoniazid and epidermal growth factor receptor (EGFR) inhibitors
- Comedones are absent

Pomade acne
- Caused by oily scalp cosmetics
- Typically affects the forehead

Oil acne
- Caused by prolonged (e.g. occupational) contact with oils

Box 22.8 Acne-associated autoinflammatory syndromes

- SAPHO syndrome: synovitis, acne, pustulosis, hyperostosis, osteitis
- PAPA: PG, acne, pyogenic arthritis
- PASH: PG, acne, supplicative hidradenitis (hidradenitis suppurativa)
- PAPASH: PG, psoriatic arthritis, supplicative hidradenitis (hidradenitis suppurativa)
- PASS: PG, acne, aeronegative spondyloarthritis

Box 22.9 Treatment of acne

Mild/physiological acne
- Step 1: Provide acne-friendly/oil-free skin care: salicylic acid washes (keratolytic)

Comedonal acne
- Step 2: Add topical retinoid or azelaic acid (keratolytic)

Inflammatory acne
- Step 3: Give topical retinoid + BPO
  - BPO ± topical or oral antibiotic (antimicrobial)

Severe acne
- Step 4: Consider oral isotretinoin
  - Antiandrogen therapy (cyproterone acetate, spironolactone) may be useful in females with moderate acne and seborrhoea

Box 22.10 Prescribing antibiotics for acne

- Avoid long-term prescription (>6 months) of oral antibiotics
- Do not use topical antibiotic monotherapy (co-prescribe with retinoid or benzoyl peroxide)
- Avoid prescribing dissimilar oral and topical antibiotics

Rosacea

Rosacea (Fig. 22.7) is a common inflammatory rash predominantly affecting the central face. It usually starts in mid-adult life and is more common in fair-skinned people. The cause is unknown but pathogenesis may involve chronic sun damage, and an increased innate immune response triggered by the commensal mite Demodex folliculorum and leading to synthesis of pro-angiogenic and pro-inflammatory mediators.

Clinical features

The main features are diffuse erythema and inflammatory papules and pustules. Flushing and telangiectasia may be early features and can be aggravated by hot drinks, alcohol, sunlight and changes in temperature (erythematous-telangiectatic rosacea). This may be followed by papules and pustules (papulopustular rosacea) but, unlike acne, there are no comedones. Occular involvement can lead to blepharitis, keratitis and conjunctivitis. Later complications include sebaceous gland and soft tissue overgrowth (phymatous rosacea), especially of the nose in men, causing rhinophyma and facial lymphoedema. Use of topical steroids can exacerbate or trigger rosacea.

Management

Treatment is suppressive rather than curative. Topical metronidazole, azelaic acid or ivermectin may be used for long-term control, with intermittent courses of oral tetracyclines. Subantimicrobial doses of doxycycline are effective due to an anti-inflammatory effect. Flushing and erythema do not respond to antibacterial drugs and treatment options include cosmetic concealers, topical brimonidine and vascular laser therapy. Rhinophyma can be debulked surgically or with an ablative laser (e.g. CO₂ laser).
Perioral dermatitis
Perioral dermatitis is a distinctive rosacea-like rash that typically affects the nasolabial fold and area around the mouth in young women in a ‘diamond’ distribution. It is characterized by small inflammatory papules and pustules with overlying scaling. Topical steroids may trigger the complaint in susceptible individuals and are often continued inadvertently as the rash flares when they are discontinued. Treatment is with an oral tetracycline, as for rosacea, and with weaning off topical steroids.

Other rarer causes of facial rashes
These include autoimmune rheumatic diseases, lymphocytic and granulomatous infiltrates.

Eczema/dermatitis
The terms ‘eczema’ and ‘dermatitis’ are used interchangeably to describe an extremely common type of inflammatory rash. In the developed world, eczema may affect about 10% of the population at any one time, with up to 40% experiencing an episode of eczema during their lifetime. Eczema is classified as constitutional or endogenous, and contact or exogenous (Box 22.11). It can also be classified according to duration (acute, subacute or chronic).

The cardinal features of inflammation are manifest in eczema as erythema, swelling, itch/soreness and loss of normal (skin barrier) function. In acute eczema, oedema is prominent and tiny vesicles or larger bullae may be seen within inflamed skin. Skin swelling subsides to leave dry, flaky skin. Scratching leads to excoriations with serosanguinous exudate. Repeated scratching or rubbing causes thickened skin with the prominent lines (lichenification) of chronic eczema. The thickened skin is not supple and cracks easily, predisposing to fissures, secondary bacterial infection may occur and cause crusts, papules and pustules. The histology of eczema correlates with the clinical features: in acute eczema the keratinocytes are swollen with increased intercellular fluid (‘spongiosis’), while in chronic disease there is little oedema but prominent thickening of the epidermis (acanthosis) and scaling (hyperkeratosis). Inflammatory cells are present around the upper dermal vessels in all patterns.

Atopic eczema
This type of constitutional eczema is extremely common, affecting up to 20% of children. It usually starts under the age of 2 years and is often associated with other atopic diseases, which present in a sequence described as the ‘atopic march’. The majority (80–90%) of children with early-onset atopic eczema will spontaneously improve and ‘clear’ before the teenage years, 50% being free of the condition by the age of 6. Recurrence may occur in adulthood, especially as a localized hand eczema. Onset in later childhood or adulthood is often associated with a more chronic relapsing course.

Aetiology
Atopic eczema is a highly prevalent chronic inflammatory skin disease that arises from a combination of genetic, immunological and environmental factors that lead to skin barrier dysfunction and an altered skin microbiome. A positive family history of atopic disease is often present: there is 90% concordance in monozygotic twins but only 20% in dizygotic twins. If one parent has atopic disease, the risk of a child developing eczema is about 20–30%. If both parents have atopic eczema, the risk is more than 50%.

Genetic studies have identified a primary abnormality in skin barrier function: in particular, loss-of-function mutations in the filaggrin gene, which are associated not only with atopic eczema but with other atopic diseases and food allergy. Filaggrin deficiency leads to impaired skin barrier function and dry skin, allowing antigens and microbes to penetrate the epidermis. There is an initial activation of Th2 CD4 lymphocytes in the skin, with increased interleukin (IL)-4, IL-5 and IL-13 levels that lead to raised levels of immunoglobulin E (IgE) and IL-31, a key mediator of itch. Scratching leads to further epidermal damage. The later chronic inflammatory phase is more complex and also involves Th1, Th17/IL-23, Th22 cells and the Janus kinase (JAK)/STAT pathway (see p. 68).

Defects in the innate immune system have also been identified in atopic eczema, including epidermal antimicrobial peptides, Toll-like receptor 2 expression and epidermal tight junctions. This may explain the predisposition to cutaneous infection, particularly with Staphylococcus spp. and herpes simplex virus. Paradoxically, a lack of infection (in infancy) may skew the immune system towards a Th2 axis, favouring development of eczema (‘hygiene hypothesis”).

Blockade of the IL-4/IL-13 pathway is being used therapeutically in the management of eczema and asthma, and anti-IL-31 therapy shows promise in the treatment of itch.

Exacerbating factors
Exposure to soap and detergent skin cleansers dries and damages the epidermis and promotes inflammation. In some patients, repeated infections with Staph. aureus induce flares, which may be mediated by superantigen exotoxins that cause widespread T-cell activation. Teething, dribbling and lip licking may trigger facial eczema in infancy and childhood. Severe anxiety or stress may exacerbate eczema in some individuals. Pet dander can aggravate eczema. The role of house dust mites and diet is less clear-cut. Immediate/type 1 hypersensitivity to food allergens (cow’s milk, egg, soya, wheat, fish and nuts) is common in young children with severe atopic eczema. Ingestion of food causes perioral and sometimes generalized urticaria (hives) and gastrointestinal symptoms (reflux, vomiting and diarrhoea). Rarely, there may be a delayed hypersensitivity to foods such as cow’s milk that manifests with an eczema flare after 12–24 hours. This cannot be investigated with prick tests or blood tests and the mechanism is unclear. The diagnosis is made by taking a careful dietary history, followed by oral food challenge tests. There is some evidence that food allergens may play a role in triggering atopic eczema and that dairy products or eggs can worsen eczema in a minority of infants under 12 months of age.

Clinical features
Atopic eczema has a variable clinical presentation. The characteristic sites involved are the flexures of the elbows, knees, ankles and

wrist (Fig. 22.8), and around the neck. In infants, eczema often starts on the cheeks before spreading to the body. Clinical features of acute or chronic eczema (see earlier) may predominate and the pattern can change with time. Pruritus is usually severe, leading to excoriation and lichenification. In dark skin types the distribution may be different, with an ‘inverse pattern’ predominantly affecting the extensor surfaces, and follicles can be prominent. Pigmentary changes – hyper- and hypopigmentation – may follow the inflammatory phase of eczema and are often slow to resolve.

In some atopic individuals the skin of the upper arms and thighs feel rough due to follicular hyperkeratosis (‘keratosis pilaris’). Prominent skin creases on the palms (‘hyperlinear palms’) and dry, ‘fish-like’ scaling of the skin of the lower legs (ichthyosis vulgaris) point to underlying deficiencies in filaggrin.

**Secondary infection**

Secondary bacterial infection with *Staph. aureus* and/or streptococci is common, especially in moist flexural areas such as the neck and groin. Pustules, oedema and golden-crusted inflamed papules strongly suggest secondary infection.

**Cutaneous viral infections** (e.g. viral warts and molluscum) may be more widespread in atopic eczema. Herpes simplex virus (HSV) can cause widespread infection of the skin, *eczema herpeticum*. This appears as multiple small blisters or painful, punched-out crusted papules (Fig. 22.9) that are associated with malaise and pyrexia. Urgent systemic antiviral therapy is indicated to reduce the risk of disseminated life-threatening infection. An extensive form of hand, foot and mouth disease may also occur in children with eczema, with blisters and crusts extending over large areas of the limbs and face (eczema coxsackium). Ocular complications of atopic eczema include conjunctival irritation and, less commonly, keratoconjunctivitis and cataract.

**Investigations**

Atopic eczema is diagnosed on the history and clinical features. About 80% of patients also have laboratory features of atopy (raised total IgE and allergen-specific IgE and mild eosinophilia).

**Management**

General measures include avoiding irritants (especially bar and liquid soap). Clothing should be made of soft, ‘breathable’ fabric such as cotton (see Box 22.12). Manipulating the diet (e.g. following a dairy-free or egg-free diet) may help a minority of infants with moderate to severe eczema. However, this should be done only under the expert guidance of a dietician, to ensure adequate intake of nutrients such as calcium.

**Topical therapies**

Topical therapies (see p. 656) are sufficient to control atopic eczema in most people. The key components are moisturizers/emollients and topical corticosteroids. Fragrance-free moisturizers should be used liberally on all dry skin areas and reapplied as often as needed. Some can also be used as soap substitutes. Dermatology nurse-led education of eczema sufferers and their families provides psychological support and improves adherence to treatment.

Topical corticosteroids remain the bedrock of eczema treatment and for most patients they provide reasonable disease control. They are usually applied once or twice a day to inflamed skin. Topical corticosteroids are classified into four groups, according to potency (Box 22.13). Select an appropriate potency, according to the body site, surface area and patient age, to minimize the risk of adverse effects (Box 22.14) and allow safe, intermittent long-term treatment. Unfortunately, ‘steroid phobia’ is common among patients or their carers, and leads to under-use of an otherwise effective treatment. Potent steroids should be used for short periods only and weaned down to milder steroids, or used intermittently as the eczema settles. Regular use of emollients may reduce steroid usage.

Mild steroids rarely cause skin atrophy but this is a significant risk with potent and superpotent steroids, especially if applied under occlusion or with a keratolytic such as salicylic acid. Mild steroids are used to treat eczema on the face and flexures, especially...
in the periorcular area and in young children. Potent steroids are usually required to treat palmoplantar eczema due to the thick stratum corneum at this site. The ‘fingertip unit’ can be used to guide topical steroid dosage.

Moisturizers with or without topical steroids can be applied under occlusive damp tubular gauze bandages (‘wet wraps’). These can improve efficacy but are time-consuming to apply. Paste bandages containing ichthammol can also be useful for resistant or lichenified eczema of the limbs.

**Topical calcineurin inhibitors (TCIs)** (tacrolimus ointment and pimecrolimus cream) are licensed for the treatment of atopic eczema in adults and children over the age of 2 years. They do not cause skin atrophy and are therefore useful for delicate areas such as the face and eyelids. They are less effective on thick skin due to poor penetration. The main adverse effect is a burning or pricking sensation that usually improves with continued treatment. Initial concerns that the immunosuppressant effects of TCIs would increase the risk of skin cancer have not proved to be founded, but patients are advised to avoid sun exposure and vaccinations. Tacrolimus ointment can also be used prophylactically twice a week to prevent eczema flares.

**Antibiotics and antiseptics**

Antibiotics are indicated if there are clinical signs of infection and are usually given orally for 7-10 days. Flucloxacinill is the treatment of choice for staphylococcal infection and phenoxymethylpenicillin for streptococcal disease. Erythromycin is an alternative for those with penicillin allergy. Topical antiseptics are often used as emollient washes or bath additives, or in the form of ‘bleach baths’. They may cause irritation.

**Sedating antihistamines**

These may be useful at bedtime, but as histamine is not a key mediator in the itch of eczema they are often of limited benefit.

**Second-line therapy and new drugs**

These are used in severe, unresponsive eczema, especially if it is interfering with an individual’s life (e.g. growth, sleeping, schoolwork or job). Ultraviolet phototherapy (see p. 656) and systemic immunosuppressants (ciclosporin, azathioprine and methotrexate) can be helpful. Short, tapering courses of oral prednisolone usually provide rapid disease control but relapse is common on withdrawal. The risks and benefits of long-term systemic therapy require careful evaluation and should be discussed with the patient or their carer.

The anti-IL-4/IL-13 monoclonal antibody dupilumab, given by subcutaneous injection every 2 weeks, has been shown to be a highly effective and safe treatment for adult atopic eczema and is now licensed in the UK to treat moderately severe disease. Various other biological drugs and small-molecule drugs are under investigation, and include phosphodiesterase-4 inhibitors and JAK inhibitors.

**Seborrhoeic eczema**

**Clinical features**

Seborrhoeic eczema is extremely common in adults of all ages and in its mildest form is often overlooked. As the name implies, it affects greasy areas. On the face, it presents with scaling and erythema around the nose (Fig. 22.10), medial eyebrows, hairline and ear canals. Itch is variable. Dandruff is thought to be a mild variant of scalp seborrhoeic dermatitis. More severe scalp involvement can look like psoriasis (sebo-psoriasis). The perioral area may be affected in men and other sites include the large flexures and anogenital area. A generalized form of seborrhoeic eczema presents as erythroderma in the elderly (see p. 657). Children are not affected until puberty. Cradle cap and a non-itchy napkin dermatitis may represent infantile variants of seborrhoeic eczema.

**Aetiology**

It is thought that a lipophilic commensal yeast, Malassezia (see p. 674), triggers the inflammatory skin changes of seborrhoeic dermatitis in susceptible individuals. Host immunity is also involved, and seborrhoeic dermatitis is one of the earliest skin manifestations of HIV infection (see p. 676). Its prevalence is also increased in Parkinson’s disease.

**Management**

Seborrhoeic dermatitis usually runs a chronic relapsing course and treatment is suppressive rather than curative. Topical azole antifungal creams, with short-term use of mild- to moderate-potency steroids according to body site, are usually helpful. TCIs are an effective option but are unlicensed for this form of dermatitis. Ketoconazole-containing shampoo is useful to treat scalp involvement and as maintenance therapy.

**Venous eczema (varicose eczema, stasis, gravitational eczema)**

Venous eczema usually affects the elderly and those with varicose veins or a history of venous thrombosis. The inner calf is involved and there are usually coexistent signs of venous hypertension, including haemosiderin deposition, lipodermatosclerosis and varicose ulceration. The eczematous changes range from mild erythema and scaling to an acute exudative inflammatory rash. It may be complicated by allergic contact dermatitis to medicated creams or bandages, and patch tests should be done if there is an inadequate response to treatment.
Management

This includes use of bland (perfume-free) emollients such as a 50:50 liquid paraffin: white soft paraffin mix, and short-term prescription of a moderately potent topical steroid. Underlying venous hypertension should be managed with compression hosiery or vascular surgery. Paraffin-containing emollients are a fire hazard as they impregnate clothes and bedding, making them highly flammable.

Discoid eczema (nummular eczema)

Discoid eczema is characterized by well-demarcated, inflamed scaly patches, sometimes with tiny vesicles. It usually affects the limbs and torso, and is intensely itchy, which helps differentiate it from psoriasis. Lesions may be secondarily infected with Staph. aureus. The cause is unknown. Potent topical steroids are usually required to clear individual lesions.

Asteatotic eczema (winter eczema, eczema craquelé)

This form of eczema often affects older people in wintertime and can be intensely pruritic. It involves the lower legs, lower back and other areas that have few sebaceous glands. These areas are particularly vulnerable to the drying effects of soap and water. The rash resembles crazy paving with dry scales and inflamed cracks. Frequent use of a bland moisturizer and soap substitute is usually all that is needed.

Hand eczema

Hand eczema (Fig. 22.11) is a common problem that has a significant impact on quality of life. It often runs a chronic relapsing course for many years, with a reported lifetime prevalence of up to 15%. Different clinical patterns are recognized, and the morphology may be mixed and can vary with time in an affected individual.

The underlying causes are:

- **Contact dermatitis/eczema** – due to an external harsh substance (irritant) or allergy-provoking substance (allergen).
- **Endogenous dermatitis/eczema** – where no external factors can be identified. There may also be involvement of the feet.

In reality, hand eczema often has a complex and mixed aetiology due to an inherent endogenous eczema tendency and an additional irritant and/or allergic component.

Mild irritant hand eczema typically causes dry, sore, chapped skin on the dorsal hands and the finger webs. It is extremely common in cold, dry weather and in people who wash their hands frequently, either at home (especially when caring for young children) and/or in occupations such as catering, healthcare and hairdressing. Hand eczema is a common finding in people with atopic eczema and the hand may be the only site involved in adulthood. Vesicular hand eczema or ‘pompholyx’ is characterized by multiple intensely itchy blisters, especially on the sides of the fingers and palms (Fig. 22.12). A hyperkeratotic form of eczema is characterized by dry, scaly plaques and cracks on the palms and soles, and shares similarities with psoriasis at these sites. Localized eczema of the finger pulps is called ‘pulpitis’.

Severe chronic hand eczema often leads to sick leave and job loss. It is a considerable financial and societal burden, as it impairs the ability to work and to carry out the tasks of daily living. Patch testing should be considered in all patients with chronic hand eczema to identify contact allergies, as it is not possible to distinguish which patients have an allergic contact dermatitis from the clinical appearance. A careful history of occupation and recreational activities may indicate the need to test with extra allergens: for example, plants in a gardener or rubber glove chemicals in a surgeon.

Management of chronic hand eczema includes use of emollients and moderate to potent topical corticosteroids (see p. 660), minimizing contact with irritants and avoiding exposure to allergens (Box 22.15). This may involve wearing protective gloves and sometimes a change of occupation. The oral retinoid alitretinoin is an effective treatment for topical steroid-refractory severe chronic hand eczema. It leads to clearance or significant improvement in over half of all patients over a 6-month course. Like all oral retinoids, it is a teratogen, and a pregnancy prevention programme must be followed.

Allergic and irritant contact eczema

**Allergic contact eczema** is an example of a delayed-type hypersensitivity. The rash does not usually appear until at least 12–24 hours after skin contact and may even be delayed by several days, so the cause is often unsuspected. The hands, face and neck (Fig. 22.13) are commonly involved due to their frequent contact with allergens. Other body sites that are often affected by allergic contact dermatitis include the lower leg, ear canal and anogenital area (due to medicaments) and the feet (from footwear). Patch testing should be considered in all patients with suspected allergic contact eczema or where this cannot be excluded.

**Irritant contact eczema** is a common complaint and mainly affects the hands. People with a history of atopic eczema are at significantly increased risk. The most common cause is frequent contact with soap or detergents and water at work (‘wet work’). Occupations with increased risk include hairdressing, catering and healthcare.

Lichen simplex

This is a chronic form of eczema in which the skin is thickened and lined (lichenified) in response to repeated rubbing and scratching (Fig. 22.14). Common sites are the nape of the neck, outer calves and anogenital area. Short-term use of a potent or superpotent topical steroid and topical antipruritics (e.g. menthol) often helps to break the itch–scratch cycle, along with habit reversal techniques. There may be underlying emotional stress: hence the alternative name, ‘neurodermatitis’.

**Nodular prurigo**

This is a chronic, widespread, intensely itchy, nodular eruption that is perpetuated by picking and scratching. It may develop on a background of atopic eczema. Scattered eroded and hyperkeratotic nodules are typically found on the upper trunk and the extensor surfaces of the limbs. Unfortunately, topical corticosteroids, sedating antihistamines and antipruritics have limited effectiveness. The diagnosis is made by exclusion of other pathologies and may require a skin biopsy. Medical causes of pruritus should be excluded (see Box 22.20).

**Chronic actinic dermatitis**

This uncommon form of eczema mainly affects older men and is caused by excessive sensitivity to UV radiation in sunlight. The rash is prominent on sun-exposed sites and worse in summer, but patients may not be aware of their underlying photosensitivity. A clear cut-off line can usually be found between clothed (unaffected) and exposed (affected) sites. Specialist assessment is needed. Monochromator phototesting across the solar spectrum can be done to confirm UVB sensitivity and other causative wavelengths.

**Further reading**

**Psoriasis**

Psoriasis is a common chronic inflammatory skin disease that affects 2% of the population. It is characterized by well-demarcated, red plaques with a thick, silver scale. Various clinical patterns are recognized and severity is highly variable. There are two peak ages of onset: early (age 16–22) is more common and is often associated with a positive family history, while late-onset disease peaks around 55–60 years. Moderate to severe psoriasis is often associated with an inflammatory arthritis, metabolic syndrome and increased risk of cardiovascular disease. Depression and impaired body image are common co-morbidities.

**Aetiology**

The condition appears to be polygenic, with epigenetic and environmental triggers. Twin studies show 73% concordance in monozygotic twins, compared with 20% in dizygotic pairs. Multiple genetic psoriasis susceptibility loci have been identified, including PSORS1 (which accounts for 35–50% of the heritable component).

The pathogenesis of psoriasis is complex and incompletely understood, but there have been considerable advances in recent years. Abnormalities of T-cell homeostasis – in particular, the pro-inflammatory T17 axis – are believed to be involved in creating an inflammatory loop with dendritic cells and keratinocytes. This causes overproduction of antimicrobial peptides, inflammatory cytokines and chemokines, amplifying the immune response and driving abnormally rapid keratinocyte proliferation. The end result is thickened, inflamed skin (plaques) with thick overlying scale.

**Clinical features**

Different patterns of psoriasis are recognized and can occur together. Certain drugs can aggravate psoriasis, particularly lithium, antimalarials and beta-blockers.
• **Chronic plaque psoriasis** is the most common variant and is characterized by pink–red, well-demarcated plaques with silver–white scales, seen especially on extensor surfaces of the knees (Fig. 22.15A) and elbows (Fig. 22.15B). The lower back, ears and scalp are often also involved. New plaques of psoriasis occur at sites of skin trauma (Köbner phenomenon). The lesions can become itchy or sore, and bleed easily when scales are removed.

• **Flexural psoriasis** tends to affect older adults with a raised body mass index. It is characterized by well-demarcated, shiny plaques with little, if any, scaling affecting the large flexures of the groin, natal cleft, axillae and submammary area. The rash is often misdiagnosed as candida intertrigo (see p. 674) but has a sharp margin and lacks satellite lesions. Anogenital involvement is common and can cause considerable psychosexual upset.

• **Guttate psoriasis** is the term given to a ‘raindrop-like’ pattern of psoriasis, most commonly seen in children and young adults (Fig. 22.15C). The rash develops over days and consists of very small circular or oval plaques on the torso. It is usually triggered by a streptococcal throat infection. Guttate psoriasis resolves spontaneously and in up to one-third of individuals does not recur. However, the remainder experience recurrent guttate attacks or develop chronic plaque psoriasis.

• **Erythrodermic and pustular psoriasis** are the most severe variants and are manifestations of extensive inflammatory skin disease. They may occur together and may be preceded by unstable widespread chronic plaque disease. There is often associated systemic upset with malaise, fever and circulatory disturbance (see p. 657). The pustules are sterile and can be triggered by sudden withdrawal of potent topical or systemic corticosteroids. A more common localized, pustular rash on the palms and soles (palmoplantar pustulosis) is considered to be a variant of psoriasis. It occurs almost exclusively in heavy cigarette smokers.

Nail changes affect up to 50% of people with psoriasis (Fig. 22.16). Features include:

• pitting of the nail plate

• distal separation of the nail plate (onycholysis) and, rarely, loss of the nail plate

• pink- (salmon patch) to yellow–brown (oil-drop) discoloration

• subungual hyperkeratosis.

Topical therapy is usually ineffective but systemic medication and biologics can improve nail dystrophy. Toenail psoriasis can be difficult to distinguish from nail tinea (see p. 673) and the two diseases may coexist.

Psoriatic arthritis and enthesitis (see p. 450) may affect up to 40% of individuals with moderate to more severe psoriasis. Joint symptoms can present before skin disease but most individuals have scalp or nail psoriasis. People with psoriasis should be asked specifically about joint symptoms and the Psoriasis Epidemiology Screening Tool (PEST) score can be used as a guide for rheumatological referral.

**Management**

There is no curative treatment and the choice of therapy is determined on an individual basis, according to the site and severity of
Disease, its psychological impact, co-morbidities such as cardiovascular or liver disease, and the individual’s wishes (Fig. 22.17). Most people with chronic plaque psoriasis will have the condition for life, though it may fluctuate in severity. A supportive and empathic approach is needed, as people with psoriasis often feel stigmatized by their skin disease.

**Topical therapy**

This is given for chronic plaque psoriasis, usually as a vitamin D analogue (calcipotriol, calcitriol, tacalcitol) and an emollient to reduce scaling. Moderate or potent corticosteroids may also be used. Other topical agents include coal tar and tazarotene (a retinoid), though these are less popular due to irritancy. Dithranol is seldom used nowadays, as it stains the skin and clothing. Salicylic acid can help remove scales but increases steroid potency when used concurrently. Topical therapy is usually applied once or twice daily to skin plaques. Vitamin D analogues should be limited to less than 100 g per week as higher doses may cause hypercalcaemia. Topical therapy is often not practical for widespread plaque psoriasis and the next option is usually narrow-band UVB phototherapy. Traditional regimes combining tar or dithranol and UVB were once common but newer therapies have taken their place. Treatment of difficult-to-treat sites is outlined in Box 22.16.

**Phototherapy**

Guttate psoriasis is usually treated with topical therapies and/or UVB phototherapy (see p. 656). Chronic plaque psoriasis may also respond to phototherapy with UVB or PUVA. Topical PUVA can be helpful for palmoplantar psoriasis, including palmoplantar pustulosis.

**Systemic therapy**

Systemic therapy is usually indicated for widespread disease that has failed to respond to topical agents and phototherapy. It may also be needed to manage associated psoriatic arthritis and milder disease with psychological upset. All medication has potential adverse effects and toxicities and patients should be provided with user-friendly information, such as the British Association of Dermatologists patient leaflets.

**Methotrexate** is given orally or by subcutaneous injection in low dose (up to 25 mg) once a week, with folic acid on other days to reduce gastrointestinal upset. It is a teratogen, so pregnancy must be avoided. Regular blood tests are needed to check liver function and monitor for bone marrow suppression. Measurement of serum procollagen 3 peptide levels and liver fibroelastography (see p. 1270) have evolved as routine non-invasive alternatives to liver biopsy to monitor for hepatotoxicity. Non-steroidal anti-inflammatory drugs (NSAIDs) should be avoided, especially in the elderly, as they reduce renal excretion of methotrexate metabolites and may cause toxicity.

**Ciclosporin** is a selective immunosuppressant that inhibits T lymphocytes. It has been widely used in the treatment of severe psoriasis and is a useful drug in unstable or erythrodermic disease due to its rapid onset of action. However, long-term use is often complicated by nephrotoxicity and hypertension.

**Acitretin** is an oral retinoid used to treat psoriasis and rarer inherited scaly skin diseases (Darier disease, congenital ichthyosis). It is less effective than ciclosporin or methotrexate but lacks immunosuppressant effects and may be used in combination with UVB and PUVA. All oral retinoids are potent teratogens. Acitretin’s metabolites have an extremely long half-life and pregnancy must be avoided for 3 years after completing treatment, so this drug is not suitable for women of childbearing age. New immunomodulator drugs licensed for use in psoriasis include the phosphodiesterase-4 inhibitor **apremilast** and **dimethyl fumarate**. Other drugs in clinical trials include the JAK pathway inhibitor tofacitinib.

**Biological therapy**

Advances in understanding the immunopathogenesis of psoriasis have led to development of an expanding and increasingly effective group of targeted biological drugs that block pro-inflammatory cytokines or their receptors. The UK’s National Institute for Health and Care Excellence (NICE) restricts use of these drugs to patients with severe psoriasis (defined by a Psoriasis Area Severity Index (PASI) of >10 and DLQI of >10), in whom phototherapy and conventional systemic drug therapy have failed, are contraindicated or are not tolerated. Anti-TNF-α drugs (infliximab, etanercept, adalimumab) were the first group of biologics licensed for use in psoriasis. These have been followed by IL-12/23, IL-17 and selective IL-23 inhibitors. The latest allow the majority of patients to achieve a 90% reduction in PASI score (PASI 90). However, all biologic drugs remain expensive and have potential toxicity, as the long-term safety of the newer agents remains unknown.

**Further reading**

patients with cutaneous LP and the oral mucosa may also be affected in isolation. LP-like (lichenoid) rashes may be caused by drugs (e.g. antihypertensives, antimalarials, NSAIDs) and contact allergens.

LP appears as clusters of intensely pruritic, purple-pink, polygonal papules (Fig. 22.18) that usually affect the flexural aspect of wrists, forearms and lower legs. The rash may be widespread and lead to scarring hair loss and nail damage.

Close inspection of the papules shows fine white streaks (Wickham’s striae). Lesions can fuse into plaques, especially on the lower legs, where they turn warty and hyperkeratotic. After resolution, post-inflammatory hyperpigmentation is common, especially in people with darker skin. LP may köbnerize: that is, localize to areas of superficial trauma.

Mucosal involvement ranges from asymptomatic, reticulate white streaks on the buccal mucosa and lateral tongue to a severe, painful, erosive gingivitis and glossitis (erosive LP). Delayed-contact allergy to metals in amalgam fillings may cause localized LP-like changes on the oral mucosa. The anogenital mucosa may be affected by LP and lesions on the penis are often annular. A severe erosive variant can affect the vulva and vagina in women.

Histology of LP is usually diagnostic and shows a dense infiltrate of lymphocytes along the dermo-epidermal junction, which becomes damaged with degenerate (apoptotic) basal keratinocytes. Cutaneous LP usually resolves within 1–2 years, though it may relapse. Hypertrophic disease and mucosal disease are usually more persistent. Malignant change and development of squamous cell carcinoma may rarely complicate chronic ulcerated LP. Skin and mucosal lesions usually respond to potent or superpotent topical corticosteroids and topical tacrolimus (see p. 656). Widespread skin disease may require tapering courses of oral steroids, phototherapy, oral retinoids or systemic immunosuppressants.

Granuloma annulare
Granuloma annulare usually affects children and young adults. It is usually asymptomatic and characterized by clusters of small flesh-coloured or slightly erythematous papules (with no scaling) in a ring shape with a dusky centre. These typically affect the dorsal hands and/or feet. The cause is unknown; several systemic associations have been proposed but not proven, including diabetes mellitus and thyroid disease. Localized granuloma annulare is usually self-limiting and resolves after a few years. Potent topical or intralesional steroids can be tried if needed.

Lichen sclerosus
Lichen sclerosus (LS) is a common inflammatory dermatosis of the genital area. The cause is unknown but may be autoimmune, and preceding infection or trauma and an occluded, moist environment may act as triggers. In females, the usual age of onset is before puberty or after the menopause. Males may develop LS at any age. Lesions are intensely pruritic or sore, and appear as shiny, ivory–white, fissured patches on the vulva, or on the glans penis and distal foreskin or penile shaft. Additional perianal involvement is common in females, leading to a ‘figure-of-eight’ distribution. Telangiectasia may be evident, and early lesions in girls can present with haemorrhagic blisters that are occasionally mistaken for signs of sexual abuse.

The scarring and atrophy that accompany longstanding LS cause changes in the vulval structure, with loss and fusion of the labia minora and scarring of the clitoral hood. Involvement of the foreskin can cause phimosis, and urethral disease may cause strictures and impaired micturition. Profound sexual dysfunction can result from LS in both men and women.

Pityriasis rosea
Pityriasis rosea is an acute, self-limiting exanthem, which is thought to be caused by a viral infection, possibly human herpesvirus (HHV)-6 and HHV-7. It usually affects older children or young adults and there is an increased incidence in spring and autumn. The rash is most prominent on the torso and proximal limbs, and consists of circular or oval pink macules with a collarette of fine scale. It is usually preceded by a larger solitary ‘herald patch’. Lesions tend to run along dermatomal lines of the back, giving a ‘Christmas tree’ pattern. The rash is usually asymptomatic or mildly itchy and resolves within 4–8 weeks. Treatment is not usually required but emollients and a mild steroid cream may be used for pruritus. Severe pityriasis rosea in the first trimester of pregnancy has been associated with fetal loss, and off-label use of aciclovir may be considered.

Polymorphic light eruption (‘prickly heat’)
This sun-induced rash is common in young women and is usually triggered by unusually intense exposure to strong sunshine on holiday. In most cases it is mild and is usually attributed to heat (‘prickly heat’). Typically, an itchy papular rash develops on sun-exposed areas, particularly the ‘V’ of the neck, shoulders and arms, several hours after sun exposure. Vesicles or plaques may occur: hence ‘polymorphic’. A minority of people with polymorphic light eruption (PLE) are severely affected and develop the rash in temperate zones, starting in spring or early summer. It is thought to be caused by a delayed-type hypersensitivity to an endogenous antigen that occurs in the skin after UV exposure (photoantigen). Mild cases can be managed by avoiding the sun (with high sun protection factor (SPF) sunscreens and clothing) and gradually building up tolerance to sunlight. Short courses of prednisolone can be given for prophylaxis or treatment. People who are troubled by severe PLE can be ‘desensitized’ with a short course of UVB phototherapy in early spring, which enables them to tolerate subsequent sun exposure.

Lichen planus (LP)
Lichen planus (LP) is a chronic inflammatory skin disease affecting the skin and mucosal membranes. It is thought to be a cytotoxic T-cell-mediated autoimmune disease and potential triggers include hepatitis B virus and hepatitis C virus. However, in most cases there is no identifiable cause. Mucosal involvement is seen in about 50% of
The diagnosis is usually made by the clinical appearance. Histology shows thickened ("hyalinized") dermal collagen and a thin, flat (atrophy) epidermis.

Short-term courses of potent or superpotent topical corticosteroids improve the signs and symptoms of LS. TCIs may also be helpful. The condition may remit spontaneously after several years, especially in children. Unresponsive phimosis may necessitate circumcision. Longstanding anogenital LS is associated with an increased risk of squamous cell carcinoma in affected sites.

**Further reading**

**Urticaria and angio-oedema**

*Urticaria* (hives, ‘nettle rash’) is a common skin condition characterized by short-lived, itchy swellings or ‘weals’ that clear within minutes to hours without residual dryness or skin flaking (Fig. 22.19). The short-lived nature of individual swellings and lack of skin surface changes help distinguish urticaria from other inflammatory rashes, especially eczema. *Angio-oedema* is a similar disorder involving deeper tissues and usually affecting the lips, tongue and eyelids. Urticaria and angio-oedema may occur together or separately, and have a range of causes.

**Aetiology and clinical features**

Urticaria and angio-oedema with weals are caused by dermal mast cell degranulation and release of a range of pro-inflammatory mediators (including histamine) that cause vasodilation and increased capillary permeability. Mast cell degranulation may be triggered by various stimuli, including *drugs* (opiates, aspirin), *physical triggers* (friction, pressure, sweating), *allergens* and *autoantibodies*. Urticaria is classified as acute or chronic (>6 weeks’ duration). Chronic urticaria is divided into spontaneous (or idiopathic) and inducible types (Fig. 22.20).

*Acute urticaria* is often triggered by infections. It may also be the presenting feature of immediate (type 1) allergy, especially in young children with atopic eczema (see p. 64). Common causes include food (nuts, egg, milk), drugs (penicillin) and natural rubber latex. Allergic urticaria may be localized to an area of skin (contact urticaria) – for example, due to latex gloves, or take the form of a more widespread reaction that can evolve to anaphylaxis (see p. 69). Measurement of allergen-specific IgE and/or skin prick tests and allergen challenge tests can be done to confirm an allergic cause.

*Chronic inducible urticaria* has a range of causes, including friction (symptomatic dermographism), *pressure* (delayed pressure urticaria), *cold* (cold urticaria), sunshine (solar urticaria) and sweating (cholinergic urticaria). Physical tests, such as lightly scratching the skin for dermographism or an ice cube test for cold urticaria, are helpful in demonstrating the cause.

**Chronic spontaneous urticaria (CSU)** is thought to have an underlying autoimmune basis, and in some individuals functional autoantibodies against the high-affinity IgE receptor on mast cells and basophils or against IgE antibodies can be identified. There is also an association with autoimmune thyroid disease. Chronic urticaria is seldom caused by food allergy, and food allergy tests are not indicated.

Angio-oedema without weals is classified into hereditary and acquired variants. *Hereditary angio-oedema (HAE)* is a rare autosomal dominant condition that can cause recurrent and severe swellings of the skin, upper airways and intestinal tract. Laryngeal involvement may be life-threatening. Attacks usually start in childhood and can be spontaneous or triggered by minor trauma. Skin swellings are not itchy and usually last for several days. HAE types I and II are caused by mutations in the *SERPING1* gene that result in decreased plasma levels of functional C1 esterase inhibitor (C1NH). This allows unchecked activation of the complement cascade. Serum complement C4 can be measured as a screening test. C1NH activity is normal in type III HAE. All forms of HAE are caused by increased levels of bradykinin.

*Acquired angio-oedema* may be idiopathic or associated with lymphoproliferative or autoimmune disorders. Drugs can also cause angio-oedema, especially angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor antagonists. The rate is up to four times higher in Afro-Caribbean patients and onset may be delayed by months or years after starting therapy, so a careful drug history is essential.

**Management**

*Acute urticaria* is usually self-resolving. Allergic urticaria and angio-oedema may require emergency treatment with intramuscular adrenaline (epinephrine) and intravenous steroids (see Box 3.22). *Chronic urticaria* is managed with non-sedating antihistamines. Treatment of acute attacks was with fresh frozen plasma. Montelukast may also be helpful in those with aspirin sensitivity. NSAIDs and opiate analgesics should be avoided, as they can aggravate urticaria. The biological anti-IgE drug omalizumab is licensed for antihistamine-refractory CSU.

Management of *HAE* used to be limited to prophylaxis with attenuated androgens (stanozolol, danazol), which were poorly tolerated, and treatment of acute attacks was with fresh frozen plasma. Newer selective therapies include plasma-derived and recombinant C1NH, a kallikrein inhibitor (ecallantide) and a bradykinin B2 receptor inhibitor. C1NH, a kallikrein inhibitor (ecallantide) and a bradykinin B2 receptor inhibitor.
antagonist (icatibant). These newer products can be used for treatment of acute attacks of HAE, and C1*NH is also used for prophylaxis.

**Urticarial vasculitis**
If urticarial weals are painful and last for more than 24 hours, leaving bruising or a blemish, this may indicate an underlying vasculitis rather than ordinary urticaria. The patient should be thoroughly assessed with a vasculitis screen of blood tests, skin biopsy and urinalysis.

**Further reading**

**SKIN INFECTIONS**
The skin is home to a diverse population of microbes (microbiome), most of which are commensals (permanent non-pathogenic residents) or transients (temporary residents). Many skin pathogens can also be found on living skin as commensals, and microbial dysregulation, altered environmental factors, trauma, host immunity and host genetic variation may drive the transition from commensal to pathogen and subsequent skin disease. The microbiome of the skin varies greatly, according to body site and between individuals, and its role in health and disease is the subject of considerable interest.

**Bacterial infections**
(See also Chapter 20.)

**Impetigo**
Impetigo is a highly contagious infection that usually affects children (Fig. 22.21) and is spread by direct contact. Infected areas appear as inflamed plaques with a golden, crusted surface, typically around the mouth and nose. It is caused by *Staphylococcus aureus* or *Streptococcus pyogenes*. Toxin-producing strains of *staphylococcus* can also cause blisters (bullous impetigo; see later). Skin and nasal swabs should be taken if the complaint is extensive or recurrent, or constitutes a suspected outbreak.

**Management**
Localized impetigo may be treated with topical fusidic acid. Mupirocin should be reserved for cases caused by meticillin-resistant *Staphylococcus aureus* (MRSA). The new topical antibiotic retapamulin is effective but expensive, and is used as second-line treatment. Widespread infection or bullous impetigo should be treated with oral antibiotics for 7 days (fluclaxacillin or erythromycin or clarithromycin if the patient is penicillin-allergic). Affected individuals should avoid school or work until the lesions are dry or for 48 hours after starting antibiotics.

**Toxin-mediated skin disease**
*Staphylococcal* scalded skin syndrome (SSSS) and toxic shock syndrome (TSS) are diseases caused by bacterial secretion of toxins, the latter representing a life-threatening illness requiring urgent medical treatment. Blistering lesions seen in SSSS can resemble toxic epidermal necrolysis (TEN, see p. 697) but the mucous membranes are not involved in SSSS and blistering occurs higher in the epidermis. The intra-epidermal split of SSSS can be demonstrated by histology of a frozen section of skin. Further details of management and prognosis are given on page 537.

**Cellulitis and erysipelas**
Cellulitis and erysipelas are caused by superficial and deeper infection of the dermis and subcutaneous tissues, respectively. It is not always possible to make a clear distinction. Both complaints present with tender confluent areas of inflamed skin and are often associated with fever and malaise. Cellulitis typically affects the lower leg or arm and may spread proximally. Other sites that may be affected include the abdomen and perianal and periorbital areas. Erysipelas is more common on the face and is more sharply demarcated. Localized blistering (clear or blood-stained), necrosis, abscess formation, lymphangitis and lymphadenopathy may occur. The most common infective organisms are β-haemolytic streptococcus and *Staph. aureus*. Gram-negative or anaerobic bacteria may cause infection in immunocompromised people and those with diabetes.

Lymphoedema, obesity, venous stasis and toe-web fungal infection are risk factors for lower limb cellulitis. The skin should be carefully examined to look for fissures or erosions that can allow entry of pathogens. Skin swabs are usually negative unless taken from broken skin. Serological tests can confirm a streptococcal infection (antistreptolysin O titre (ASOT) and anti-DNAse B titre).

**Management**
Systemic antibiotics (fluclaxacillin or erythromycin) are indicated; they may be given as high-dose oral therapy, or intravenously via ambulatory care or as an inpatient, depending on the patient’s age, disease severity and co-morbidities. Single-dose dalbavancin may be an alternative to conventional antibiotics in the treatment of acute bacterial skin infections in adults, avoiding the need for hospitalization or repeat attendance.

Up to 50% of people with cellulitis experience repeat episodes. Prophylactic antibiotic therapy reduces the risk of further attacks during treatment but the effect wears off after discontinuation.

**Necrotizing fasciitis**
This fulminant, rapidly spreading, life-threatening bacterial infection of the subcutaneous and deep soft tissues causes severe tissue destruction and is associated with a high mortality. A number of organisms can cause necrotizing fasciitis: spontaneous disease that arises in previously health people is often caused by group A streptococcus (GAS), while disease related to abdominal surgery or immunosuppression is often caused by mixed aerobic and anaerobic populations.

Necrotizing fasciitis is characterized by severe pain that is out of proportion to the apparent signs of skin inflammation. Infection tracks...
rapidly along tissue planes, causing spreading erythema, swelling, pain and sometimes tissue crepitus. Patients are typically febrile and severely unwell, and urgent surgical intervention (with extensive debridement or amputation) and intravenous antibiotic therapy are required. High-dose benzylpenicillin and clindamycin are used in confirmed GAS infection, and a broad-spectrum antibiotic combination with additional metronidazole is used where the pathogen is unknown. Typically, the C-reactive protein (CRP) and white cell count are significantly raised. Imaging is sometimes helpful (e.g. by revealing gas in deep tissues) but should not delay urgent surgical intervention. Multiorgan failure is common and mortality is high.

Gas gangrene
Gas gangrene is caused by deep tissue infection with *Clostridium* spp. (especially *C. perfringens*), following contaminated penetrating injuries – historically, battlefield wounds but now commonly found in intravenous drug users and patients who have undergone gastrointestinal tract surgery. Initial infection develops in damaged, necrotic tissue; toxins secreted by the bacteria destroy surrounding tissue and permit rapid spread of infection, contributing to severe systemic effects. Treatment is by surgical debridement of necrotic tissue and intravenous benzylpenicillin and clindamycin.

Folliculitis
Folliculitis is a common superficial inflammatory disorder of the hair follicle, which presents as itchy or tender small papules and pustules (pimples). It may be caused by trauma, chemical irritation and infection with a range of pathogens, most commonly *Staphylococcus aureus*. Predisposing factors include friction, occlusion, sweating, obesity and diabetes. A deeper variant affecting beard follicles (‘sycosis barbae’) causes multiple swollen pustules that may coalesce to form pustule-studded plaques. The main differential diagnosis is pseudofolliculitis barbae, which is caused by ingrowth of curly hairs.

Extensive, itchy folliculitis may be a manifestation of human immunodeficiency virus (HIV) infection (see p. 1431). The Gram-negative bacterium *Pseudomonas aeruginosa* may cause outbreaks of folliculitis stemming from inadequately disinfected hot tubs and pools.

**Treatment** is with topical antiseptics, topical antibiotics or oral antibiotics; management should address the underlying predisposing factors.

Boils (furuncles) and carbuncles
Boils or furuncles are deeper infections of hair follicles and surrounding tissue, and appear as painful, red, pus-filled swellings. They are usually caused by *Staphylococcus aureus*. Boils may coalesce to form carbuncles, which are larger swellings with multiple pus-discharging openings and systemic upset. They may spread from person to person due to poor hygiene or overcrowding, and are more common in people with diabetes, malnutrition and immunosuppression. A recent increase in UK hospital admissions for boils stemming from inadequately disinfected hot tubs and pools.

**Management** is with topical antiseptics, topical antibiotics or oral antibiotics; management should address the underlying predisposing factors.

**Ecthyma gangrenosum** presents with distinctive necrotic skin ulcers with a central thick, dark brown or black eschar. It is typically caused by *Pseudomonas septicemia* in an immunocompromised or neutropenic patient. Invasion of a microbe through the subcutaneous vasculature leads to a haemorrhagic occlusive vasculitis. Intensive parenteral antibiotic therapy is imperative to reduce the associated high mortality.

Erythrasma and pitted keratolysis
**Erythrasma** is a superficial skin infection caused by *Corynebacterium minutissimum*. It presents as orange–beige scaly plaques in the large flexures (axillae and groin) or maceration in the toe webs (Fig. 22.22) and is often misdiagnosed as a fungal infection. Corynebacteria are part of the normal skin microbiome but can also act as pathogens. They show a characteristic coral-pink fluorescence when examined with Wood’s light (UV). Corynebacteria are also implicated in **pitted keratolysis**, which appears as multiple punched-out areas and maceration of the skin on weight-bearing plantar surfaces. There is usually associated hyperhidrosis and malodour.

**Management** of erythrasma is with topical or oral macrolides. Pitted keratolysis responds to astringents such as potassium permanganate soaks, antiperspirants and topical imidazoles or fusidic acid.

Mycobacterial infections

Leprosy (Hansen's disease)
Leprosy (see p. 550) typically involves the skin and peripheral nerves. The clinical features depend on the host's immune response to the infecting organism, *Mycobacterium leprae*.

**Tuberculoid leprosy** presents with a few larger, hypopigmented (see Fig. 20.24) or erythematous plaques with an inflamed border. Sensation is absent within lesions, which are dry and hairless due to nerve damage. Nerves may be enlarged and palpable. Biopsy shows a granulomatous infiltrate around nerves but no organisms.

**Indeterminate leprosy** presents with small, hypopigmented or erythematous, circular, scaly macules with reduced sensation. It may resolve spontaneously or progress to one of the other types. Biopsy reveals a perineural granulomatous infiltrate and scant acid-fast bacilli.

**Lepromatous leprosy** presents with multiple inflammatory papules, plaques and nodules. Loss of the eyebrows ("madarosis") and nasal stuffiness are common. Skin thickening and severe disfigurement may follow. Biopsy shows numerous acid-fast bacilli.

**Diagnosis and management** are discussed on page 551.

Skin manifestations of tuberculosis
Tuberculosis (see p. 967) can occasionally cause skin manifestations:

- **Lupus vulgaris** usually arises as a post-primary infection. It commonly presents on the head or neck with red-brown nodules that look like apple jelly when pressed with a glass slide ("diascopy"). They heal with scarring, and new lesions slowly spread out to form a chronic solitary, erythematous plaque. Chronic lesions are at high risk of developing into squamous cell carcinoma.

- **Tuberculosis verrucosa cutis** arises in people who are partially immune to the organism but suffer further skin inoculation. It presents as warty lesions on a 'cold' erythematous base.

- **Scrofuloderma** occurs due to discharge from an affected lymph node into the skin with ulceration and scarring.

- **The tuberculides** are a group of rashes caused by a hypersensitivity response to underlying *Mycobacterium tuberculosis* infection. Erythema nodosum is the most common (see p. 677). Erythema induratum (Bazin's disease) is a similar rash with deep inflammatory nodules on the calves rather than the shin that may ulcerate.

**Mycobacterium marinum** infection (fish tank/swimming pool granuloma)
This atypical/non-tuberculous mycobacterial infection presents with one or more painless inflammatory nodule on a hand or upper limb. Infection is usually acquired by coming into contact with non-chlorinated water or by cleaning out a fish tank without gloves. The diagnosis is usually made from the occupational or recreational history and clinical features. A skin biopsy shows granulomatous inflammation, and *Mycobacterium marinum* may be identified by prolonged culture at low temperature or polymerase chain reaction (PCR) of skin lesions.

**Treatment** is with combination oral antibiotics (e.g. clarithromycin and ciprofloxacin) for 8–12 weeks, according to microbiological guidance.

Viral infections

**Viral exanthem**
The most common cutaneous manifestation of viral infections is a widespread maculopapular rash or exanthem that predominantly affects the torso and proximal limbs. It is probably caused by deposition of immune complexes of antibody and viral antigen within dermal blood vessels. Many different viruses can cause exanthems, e.g. echovirus (see p. 517), measles (see p. 517) human herpesvirus 6 (see p. 519) and Epstein–Barr virus (see p. 524). The rash resolves spontaneously in 7–10 days.

**Slapped cheek syndrome (erythema infectiosum, fifth disease)**
See page 519.

**Herpes simplex virus**
Most people are infected with herpes simplex virus (HSV) type 1 in childhood, and infection is often subclinical. Overt primary infection causes clusters of painful blisters on the face (Fig. 22.23) or a painful ulcerative gingivostomatitis. HSV infection can also affect other sites, such as the neck in people who play contact sports or the fingers of healthcare workers ('herpetic whitlow'). Some individuals experience recurrent attacks of HSV ('cold sores') around the lips. HSV 2 infection (see p. 1421) is usually sexually acquired and associated with anogenital ulceration. Recurrence may cause skin lesions at non-genital sites such as the buttock and lower back. Immunosuppression and UV exposure can trigger a recurrence of HSV.

Complications of HSV infection include corneal ulceration, eczema herpeticum (see p. 661), chronic severe anogenital ulceration in HIV infection, and erythema multiforme.

**Management**
Oral antiviral therapy (aciclovir, valaciclovir) may be given for severe primary HSV and painful genital HSV. Eczema herpeticum, neonatal infection and infection in immunocompromised patients require parenteral antiviral therapy. Cold sores may be treated with aciclovir cream, used early to shorten an attack. Frequent recurrences can be treated with prophylactic oral therapy.

**Varicella zoster virus**
Varicella zoster virus (VZV) causes the common childhood infection chickenpox and also herpes zoster (see p. 515).

**Herpes zoster (shingles)**
'Shingles' results from reactivation of latent VZV infection. It may be preceded by a prodromal phase of itch, tingling or pain, followed by a painful, unilateral, blistering eruption in a dermatomal distribution...
**Management**

Herpes zoster requires adequate analgesia and antibiotics (if secondary bacterial infection is present). Oral antiviral therapy should be started within 72 hours of the onset of the rash and continued for 7–10 days to reduce pain, severity and viral shedding. Parenteral therapy is indicated in immunocompromised patients. A live-attenuated shingles vaccine is available to boost immunity against VZV in the elderly and reduce the risk of developing herpes zoster.

**Human papillomavirus**

Human papillomavirus (HPV) infection causes skin and anogenital ‘viral’ warts.

- **Common warts** are papules with a keratotic rough surface, often seen on the hands and feet but also at other sites. Small black dots (thrombosed vessels) may be visible on close examination (Fig. 22.25). Warts on the face may become elongated (‘filiform’). Children and adolescents are usually affected. Spread is by direct contact and is facilitated by trauma. They may also affect the beard area in men and spread due to shaving.

- **Plantar warts** affect the soles of the feet. They are flattened due to pressure but still have a characteristic warty (papillomatous) surface. Black dots can be seen if the skin is pared down (unlike callosities). Warts may be tender if they affect pressure points or are sited around nail folds.

- **Plane warts** are much less common and are caused by certain HPV subtypes. They are smaller and flatter than common warts and often flesh-coloured or lightly pigmented; they are best seen with side-on lighting. They are usually multiple and are frequently found on the face or the backs of the hands.

- **Anogenital warts** (see p. 1420).

**Molluscom contagiosum**

Molluscum contagiosum is a common childhood skin infection and is caused by a pox virus. Lesions are multiple small (1–3 mm), translucent, firm papules with a central dimple (‘umbilicated’) containing soft, white, keratinous matter that can be extruded by squeezing. Mollusca may exhibit the Köbner phenomenon (see p. 665) and can affect any body site. Occasionally, larger (‘giant’) lesions of up to a centimetre in diameter may occur.

Lesions usually appear in crops over 6–12 months before resolving spontaneously. Treatment is not required, but destructive therapies such as cryotherapy or curettage may be helpful in older children. Potassium hydroxide 5% lotion can be used in younger children. Genital mollusca are usually sexually transmitted in adults. Widespread infection should raise the possibility of immunosuppression, especially HIV infection (see Chapter 37).

**Orf**

Orf is a pox virus infection of young sheep and goats. People who handle the infected animal may become infected themselves. Orf has long been recognized in farm workers but may also affect children, who catch the infection at ‘petting stations’ in city farms. Lesions appear as 1–2 cm red papules on the hands with an inflamed border that blisters; alternatively, they turn into pustules and resolve spontaneously after 4–6 weeks, conferring life-long immunity. Occasionally, orf is complicated by erythema multiforme (see p. 677).

**Further reading**

**Fungal infections**

Fungal skin diseases have a high prevalence in humans, ‘thrush’ and ‘athlete’s foot’ being two extremely common examples. In most cases, infection is superficial and limited to the stratum corneum, which elicits no inflammation, or the deeper layers of the epidermis, including hair and nails, where inflammation may be triggered by the fungus or its products. Subcutaneous mycoses include a range of...
infections of the subcutaneous tissues, usually following traumatic inoculation. The inflammatory response may extend upwards to the epidermis.

There are three groups of pathogenic fungi that commonly affect the outer layer of skin or keratinizing epithelium: dermatophytes, Candida albicans and Malassezia (formerly Pityrosporum).

**Dermatophyte infection**

Dermatophyte (tinea) fungi invade and grow in dead keratin. The three main genera that affect humans are *Trichophyton*, *Microsporum* and *Epidermophyton*. They tend to form an expanding annular lesion due to lateral growth: hence the name ‘ringworm’.

Tinea may be transmitted to humans by other people (anthropophilic), animals (zoophilic) or soil (geophilic). The clinical appearance depends on the infecting organism, the site affected and the host reaction.

Tinea of the body usually presents with asymmetrical, scaly, inflamed patches with clearer centres and a scaly, raised border. Occasionally, vesicles or pustules may be seen. Treatment with topical steroids reduces inflammation and masks clinical signs, while allowing spread of the infection – ‘*tinea incognito*’. The rash typically flares when steroids are stopped, which often prompts further use of steroids and leads to widespread infection. Tinea infections are classified according to body site: tinea corporis (body), tinea faciei (face), tinea barbae (beard), tinea cruris (groin), tinea manuum (hand), tinea pedis (foot), tinea capitis (scalp) and tinea unguium (nails). Multiple sites may be affected and skin, hair and nails should be examined.

Asymmetrical scaly rashes should be investigated for fungal infection by mycology of skin scrapings.

- **Tinea cruris** is more common in men than women and presents with an intensely itchy rash in the groin, with a scaly border that extends on to the thighs (*Fig. 22.26*).

- **Tinea pedis** (athlete’s foot) is extremely common in adults and is often confined to the toe webs, where the skin looks white, macerated and fissured. It may extend more widely on to the soles and sides of the feet, causing dryness, scaling and erythema, and the toenails are also often affected. Tinea pedis frequently flares in hot weather, causing pustules or blisters, and this can be misdiagnosed as eczema. Infection may also spread to the palm (*tinea manuum*), especially in manual workers. Annular lesions are rarely seen on palmoplantar skin.

- **Tinea capitis** is the most common dermatophyte infection in young children, especially those of black African origin, whose hair and scalp seem more susceptible to fungal invasion. Adults and the elderly are rarely affected. Fungus may confine itself to the hair shaft (endothrix) or spread out over the hair surface (ectothrix). The latter may fluoresce under a Wood’s lamp (UV light). Scalp ringworm is spread by close contact (especially in schools and households) and by sharing of brushes or clippers. Migration has led to changing patterns of fungal infections in Europe (e.g. *Trichophyton tonsurans* from Central America, *Trichophyton violaceum* from India and Pakistan). The majority of UK cases are due to *T. tonsurans* (which does not fluoresce).

The clinical appearance of scalp ringworm varies from mild diffuse scaling with no hair loss (similar to dandruff) to the more typical appearance of bald, scaly patches with broken hairs. An increased host response causes pustules and an inflammatory exudate, and certain types of tinea can trigger a severe inflammatory reaction with a swollen purulent mass or ‘kerion’. This may be mistaken for a bacterial infection and inappropriately treated with an antibiotic. Extensive infection is occasionally accompanied by a widespread papulopustular rash on the trunk. This so-called ‘id reaction’ probably relates to the host immune response to the fungus. It resolves when the infection is treated.

**Tinea unguium and onychomycosis**

Onychomycosis is a broad term for fungal nail infection. Tinea unguium refers to a dermatophyte infection of the fingernails or toenails (*Fig. 22.27*). *Trichophyton rubrum* is the most common pathogen.

Tinea toenail infection is a common finding in the elderly and is usually asymptomatic. Fingernail infection is less common. Affected nails are dystrophic, thick (subungual hyperkeratosis) and discoloured (white–yellow–beige). Infection usually starts at the distal or lateral nail edges and then spreads proximally. The whole nail plate may be destroyed in advanced disease. The **differential diagnoses** include nail psoriasis and traumatic nail dystrophy (which may coexist with fungal infection).

**Management**

Localized tinea of the body or flexures is treated with an antifungal cream (clotrimazole, miconazole or terbinafine for 1–2 weeks). Nystatin is ineffective. More widespread infection, tinea pedis, tinea manuum and tinea capitis require oral antifungal therapy with itraconazole or terbinafine for 1–2 months. The diagnosis should be confirmed with skin scrapings taken from the active margin or across the affected area. Clippings should be taken from the proximal crumbly, white area of affected nails and plucked hairs or scrapings for diagnosis of scalp
tinea. Specimens are transported in folded paper to keep them dry and prevent bacterial contamination. Microscopy and mycological culture confirm the diagnosis and identify the organism. Molecular diagnostic techniques, including PCR, analysis are gaining in popularity as they can offer high sensitivity and rapid results.

Toenail tinea infection requires prolonged oral antifungal therapy. Oral terbinafine for 3–6 months can clear up to 80% of cases but relapses are common. Itraconazole may be given as a continuous or pulsed regimen. Griseofulvin is a less effective drug but is still used for childhood tinea capitis.

Candidosis

Candida is a common species of yeast that causes a variety of skin infections. Candida albicans (see also p. 559) is a commensal in the gastrointestinal tract and vagina. It can overgrow on occluded moist skin, causing nappy rash, intertrigo of the large flexures in obese people (Fig. 22.28), and vulvovaginal candidiasis or ‘thrush’. The glans penis may be affected in uncircumcised males (candidal balanitis). Other species of Candida may be isolated from vaginal infections and immunocompromised hosts.

Candidal intertrigo causes irritation and soreness; affected areas are glazed and inflamed, with a ragged, peeling edge that may contain a few small pustules. Spotty erythema may extend beyond the affected border (satellite lesions).

Candida may also affect the moist interdigital clefts of the toes and mimic tinea pedis. In people who frequently immerse their hands in water (e.g. cleaners, caterers), Candida may cause chronic infection of the nail folds (‘paronychia’) and nail infection (candida onychomycosis). Candida can also infect the oral mucosa, especially after broad-spectrum antibiotics and in the immunocompromised and older denture wearers. Affected mucosal surfaces are inflamed with superficial white or creamy pseudomembranous plaques, which can easily be scraped away. The diagnosis can be confirmed with microscopy and culture of a specimen taken with a routine microbial swab.

Management

Predisposing factors should be treated. Diabetes should be excluded. Topical therapy (azoles or nystatin) is usually adequate, except for nail infection, and may take the form of creams, pessaries, lozenges or powder, depending on body site. Recurrent vulvovaginal candidiasis (see p. 1444) is a common complaint in women and may require oralazole antifungal therapy.

Malassezia

This lipophilic yeast family (formerly called Pityrosporum, see p. 562) is part of the normal skin microbiome. Colonization is prominent at areas rich in sebaceous glands: the scalp, large flexures and upper trunk. Over a dozen different species of Malassezia have been identified and there is increasing evidence of their causal role in three common dermatoses:

- pityriasis versicolor
- seborrhoeic eczema (see p. 662)
- Pityrosporum (Malassezia) folliculitis.

Pityrosporum folliculitis is a common complaint in young adults, especially in warm climates. It causes widespread pink–beige scaly macules on the torso. Variable pigmentation is characteristic, with pale areas developing after tanning and in darker-skinned individuals as the yeast impairs melanin synthesis. The diagnosis is usually made clinically but can be confirmed by microscopy of skin scrapings, which shows spherical yeast and short pseudohyphae (‘meatballs and spaghetti’). Treatment is with topical azoles or oral itraconazole for resistant cases. Anti-dandruff shampoos containing selenium sulphide or ketoconazole may also be used as a body wash. The pigment changes take months to resolve and recurrences are common.

Pityrosporum folliculitis is also common in young men and causes small, itchy, monomorphic papules and pustules on the upper back, shoulders and face. It may be confused with acne. Topical and oralazole antifungals can be effective but the complaint often relapses quickly.

Subcutaneous mycoses

Subcutaneous mycoses (see p. 561) are a rare group of localized infections of the skin and subcutaneous tissues that follow traumatic implantation of the fungal agent, a soil saprophyte. The causative organisms vary geographically and disease examples include sporotrichosis (worldwide), chromoblastomycosis and mycotic mycetoma (tropical and subtropical). Sporotrichosis, or ‘rose gardener’s disease’, usually causes a slowly growing, inflamed nodule at the site of skin inoculation, with new lesions developing along lymphatics and blood vessels – ‘sporotrichoid spread’. Treatment is with oral itraconazole.

Further reading

Skin infections

considerable morbidity. Scabies is spread by close or prolonged contact, such as within households or care homes, and by sexual contact. It presents with a widespread, intensely itchy, excoriated, eczematous rash that is triggered by a hypersensitivity (‘allergy’) response to mite antigens. Pruritus is usually worse at night and disturbs sleep. Small, red papules, vesicles and occasionally pustules occur anywhere on the body but rarely on the face, except in neonates. The distribution of lesions is helpful in making a diagnosis (Fig. 22.29). Sites of predilection are the finger webs, palms, soles, wrists, axillae, male genitalia, and around the nipples and umbilicus. The rash may be complicated by secondary bacterial infection.

The diagnostic sign is fine linear or curved burrows a few millimetres long, but these are not always visible and dermoscopy may help. Scabies can be confirmed by demonstrating the mite and/or eggs on microscopy of potassium hydroxide-treated skin scrapings from the tip of a burrow, but this is time-consuming and treatment is usually based on clinical features and risk factors.

Management

A topical scabicide (e.g. 5% permethrin) is applied overnight. For the treatment to be successful, the measures listed in Box 22.17 should be followed.

Malathion can be used if permethrin is unavailable; benzyl benzoate is employed occasionally but is irritant and should not be used in children. Oral ivermectin, as 2 doses 2 weeks apart, is effective, especially for use in communal settings (e.g. residential homes), but is unlicensed for this indication. Pruritus takes a few weeks to settle and can be managed with antihistamines and cooling creams such as 2% menthol.

Crusted scabies (Norwegian scabies)

Crusted scabies is a variant that affects elderly or immunocompromised people who are infested with a large number of mites (Fig. 22.30). Pruritus may be mild or absent. Individuals are highly infectious and may be the source of outbreaks if the diagnosis is delayed—which it often is, due to lack of symptoms. Hyperkeratotic crusted lesions characteristically affect the hands and feet. There may be a widespread inflammatory rash with scaly, crusted plaques resembling infected eczema or psoriasis. Meticulous barrier nursing is needed to protect staff against infestation. Hyperkeratotic scales should be removed with a keratolytic agent before application of a scabicide. Oral ivermectin is often required for effective eradication of all mites.

Lice

Lice are blood-sucking ectoparasites that cause three patterns of infection in humans.

Head lice (pediculosis capitis) infestation is an extremely common problem in schoolchildren, especially girls. Lice spread by close contact and cause pruritus, leading to excoriations and papules around the hairline of the neck and ears. The diagnosis is made by identifying eggs (‘nits’), which are firmly stuck to the hair shaft, or the adult lice, which can be caught between the teeth of a fine comb. Management aims at eradication but this is difficult because treatment is time-consuming and re-infestations are common. Lotions containing traditional topical insecticides, such as malathion, carbaryl and phenothrin, are used less widely because of resistance and are being replaced by physical treatments such as dimeticone and isopropyl myristate. Fine combing of wet hair after applying conditioner can also be done repeatedly to remove young lice before they mature. Treatment needs to be repeated meticulously until all eggs have hatched.

Body lice (pediculosis corporis) are associated with poverty and neglect, and are seldom seen in developed countries except in long-term homeless people. They are spread by direct contact or by sharing of infested clothing. The lice and eggs are not usually seen on the patient’s skin but can be found on close inspection of clothing. Infestation presents with itchy papules and excoriations. Management consists of malathion or permethrin for the patient and high-temperature washing and drying of clothing.
**Pubic lice** (crabs, phthiriasis pubis) are transmitted by direct contact, usually sexual (see p. 1425). Infestation presents with itching, especially at night. Lice can be seen near the base of the hair with eggs somewhat further up the shaft. Occasionally, eyebrows, eyelashes and the beard area are affected. **Management** is as for head lice, but all sexual contacts should be treated and the patient screened for other sexually transmitted diseases.

**Arthropod-borne diseases (‘insect bites' or papular urticaria)**

These stem from contact with an animal (e.g. dog, cat, bird) that is infested with fleas (Cheyletiella) or from bites from flying insects (e.g. midges, mosquitoes). Animals infested with fleas usually scratch vigorously, leading to scaly, thickened skin. Flea eggs can lie dormant in soft furnishings (e.g. carpets) for many months, hatching when disturbed by vibrations. Bites present as itchy, urticated lesions, which are often grouped in clusters or lines. The legs are most commonly affected and lesions can blister in hot weather. Some individuals react more vigorously to bites while others appear unaffected. Anti-flea treatment of the animal and furnishings is required. Repellents and appropriate clothing help reduce bites from flying insects.

Bed bug infestation is a common problem worldwide and is caused by bites from small, brown/black, apple seed-sized insects that emerge from the seams of bedding at night when attracted to the warmth and carbon dioxide emissions of a sleeping human body. Their bites occur in groups or lines as intensely itchy papules on exposed areas, including the face and neck. Infestations usually require expert pest control for eradication. Further advice may be obtained in the UK from the National Pest Technicians Association, a professional trade body (see Further reading).

**Further reading**

**Tropical dermatoses**

Skin diseases that feature among the ‘neglected tropical diseases' defined by the World Health Organization (WHO) include scabies, leprosy, leishmaniasis, dracunculiasis (guinea worm), lymphatic filariasis and onchocerciasis. These are endemic in poor countries and constitute a huge physical and financial burden on their societies. Travellers who have visited tropical or subtropical countries may also be affected by skin diseases, especially cutaneous leishmaniasis, cutaneous larva migrans and myiasis. Rashes may also be a feature of systemic tropical infections such as dengue, schistosomiasis and rickettsial diseases.

**Leishmaniasis** (see p. 569) is caused by a protozoon, Leishmania, and is acquired from the bite of a sandfly vector. Cutaneous, mucocutaneous and visceral disease (kala azar) may occur, depending on the infecting organism and host response. **Cutaneous leishmaniasis** (see p. 570) is the most common form and presents as a chronic ulcer (oriental sore), which heals slowly over many months with scarring.

**Cutaneous larva migrans** is caused by direct contact with the larvae of hookworm from animal faeces, usually acquired by walking or lying on sandy beaches. Larvae penetrate the skin and cause an intensely itchy serpiginous lesion, which migrates as the larva burrows within the epidermis.

**Myiasis** is an infestation of the skin with development fly larvae (maggots). Species that can penetrate intact skin to cause boil-like lesions include botfly and tumbu fly.

**HUMAN IMMUNODEFICIENCY VIRUS AND THE SKIN**

HIV infection is associated with a range of infective, inflammatory and malignant skin diseases that may be severe, atypical, difficult to diagnose and recalcitrant (see p. 1431). Advances in highly active anti-retroviral therapy (ART, see p. 1435) have dramatically reduced the prevalence of these diseases in recent years in countries with early access to therapy. However, awareness must be maintained, as they may be a presenting feature of undiagnosed HIV infection.

**Seroconversion rash**

This non-specific maculopapular exanthem affects up to 75% of individuals a few weeks after contracting HIV. There may be associated fever, malaise, myalgia, lymphadenopathy and mouth ulceration (or oral candidiasis). Symptoms usually resolve within a few weeks. This episode is often dismissed as ‘flu' and the diagnosis missed. Patients are highly infectious at this time due to very high viral loads.

**Cutaneous infection and opportunistic infection**

These are increased due to HIV-induced immune deficiency. Molluscum contagiosum is common, especially on the face, and lesions may be large (>1 cm in diameter) and extensive (a pattern rarely seen in immunocompetent adults). Other viral infections that are typically more severe or widespread include herpes simplex, shingles and viral warts. Bacterial infections (e.g. staphylococcal boils) and fungal infections (tinea and Candida) are also common. Recalcitrant and recurrent oropharyngeal candidiasis is a particular problem.

**Opportunistic infections** that may affect the skin include cytomegalovirus (pustules or necrotic ulcer) or Cryptococcus (red papules, psoriasiform or molluscum-like lesions). Diagnosis can be difficult and depends on skin biopsies and culture.

**Inflammatory dermatoses**

Severe, extensive seborrhoeic eczema (see p. 662) is common and may be the presenting sign of HIV. Psoriasis is typically more severe in patients with HIV and close liaison between dermatologist and HIV physicians is needed, especially with low CD4 counts (<200/mm³), due to the risk of further immunosuppression with systemic therapy (e.g. ciclosporin) and drug interactions.

**Drug rashes**

These are much more common in HIV patients. Reactions (maculopapular rash) to co-trimoxazole, dapsone (used in Pneumocystis prophylaxis) and anti-retroviral drugs appear to be particularly frequent. Drug rashes may be severe (especially with nevirapine and efavirenz), resulting in erythromerma (see p. 656) or toxic epidermal necrolysis (see p. 697). Other unusual conditions include nail or mucosal pigmentation from zidovudine, paronychia from indinavir and lipodystrophy (of the face and abdomen/buttocks) from protease inhibitors. As protease inhibitors and zidovudine are now used much less often in first-line drug combinations, the latter side-effects are rare today.
Cutaneous malignancy

HIV infection is associated with an increased risk of several malignancies. Cutaneous malignancy (Kaposi’s sarcoma, see p. 692) was one of the earliest recognized manifestations of HIV infection that led to the description of the acquired immune deficiency syndrome (AIDS). Most HIV-related cancers are associated with co-infection with oncogenic viruses; Kaposi’s sarcoma (HHV-8), lymphoma (Epstein–Barr virus) and epithelial squamous cell carcinoma (HPV). Pre-malignant conditions, such as the intraepithelial dysplasias ( cervix – CIN, penis – PIN, anal – AIN), are also increased in HIV infection. The risk of malignant transformation at all three sites is high and should be assessed by screening. Kaposi’s sarcoma is much more common in men who have sex with men who have HIV than in other groups, but is infrequently seen nowadays in patients on ART.

‘Specific’ HIV dermatoses

‘Itchy folliculitis’ / HIV folliculitis (also called papular pruritic eruption or eosinophilic folliculitis) is commonly found in association with declining CD4 counts. It presents with intensely itchy papules and excoriations around hair follicles and occurs most commonly over the upper trunk and upper arms (Fig. 22.31).

Oral hairy leucoplakia presents with fixed white plaques with vertical ridges on the sides of the tongue. Unlike candidiasis, the lesions cannot be scraped off. It was first recognized in HIV disease but can rarely occur in other forms of immunosuppression and is thought to be due to co-infection with Epstein–Barr virus.

Immune reconstitution inflammatory syndrome

Several infections can be unmasked or can paradoxically worsen 2–4 months after commencing ART as the CD4 lymphocyte count recovers – the so-called immune reconstitution inflammatory syndrome (IRIS). Most commonly described are ano-genital HSV infection, viral warts, tinea folliculitis, molluscum and genital warts. IRIS affects up to 25% of patients on ART and is thought to reflect the response of a recovering immune system against pathogens that were already present. IRIS may also be responsible for an increase in inflammatory rashes, such as folliculitis and subacute lupus erythematosus.

Further reading

Pyoderma gangrenosum

Pyoderma gangrenosum (PG) is a rare ulcerating skin disease of unknown cause, often associated with systemic inflammatory conditions, especially inflammatory bowel disease. It may also be associated with inflammatory arthritis and haematological malignancies. It is classified as a ‘neutrophilic’ disease and shares clinicopathological similarities with autoinflammatory diseases in which there is an infection-like host response in the absence of a microbial trigger. The most common presentation is with painful inflammatory nodules that rapidly turn into enlarging purulent ulcers (‘pyoderma’) with a purple undermined edge. PG may occur spontaneously or postoperatively in a surgical wound or stoma, when it can be misdiagnosed as a wound infection.

Skin lesions are rich in neutrophils but histological features are non-specific and so the diagnosis is made on clinical features. Superpotent topical corticosteroids may help in very mild cases. Systemic therapy with moderate to high-dose systemic corticosteroids and/or ciclosporin is usually needed. Anti-TNF therapy, such as infliximab, may be used for refractory cases. The clinical course is unpredictable and unrelated to underlying inflammatory bowel disease activity. PG ulcers heal with mesh-like (cribriform) scars (Fig. 22.34).

Sweet’s syndrome (acute febrile neutrophilic dermatosis)

Sweet’s syndrome is a rare disorder characterized by fever, malaise and an acute eruption of tender, red-purple lumps on the head, neck and upper body (Fig. 22.35). As in PG, the skin lesions contain abundant neutrophils (neutrophilic dermatosis). There is usually no underlying illness, but the syndrome may be associated with haematological malignancy and can be induced by drugs, including granulocyte colony stimulating factor. It is usually treated with systemic corticosteroids or anti-neutrophil drugs (dapsone, colchicine).

Behçet’s syndrome

Behçet’s syndrome (see p. 466) is an inflammatory disorder characterized by recurrent oral ulcers and eye lesions, genital ulcers or skin lesions. Skin changes include erythema nodosum, papulopustular acne-like lesions, thrombophlebitis and skin pathergy (prolonged inflammation or pustulation at the site of needle-prick or other minor skin injuries). The syndrome is probably a vasculitis and many organs can be involved. Milder disease and skin lesions may respond well to colchicine or dapsone.

Sarcoidosis

Sarcoidosis (see also p. 985) is a multisystem granulomatous disorder of unknown aetiology. Skin involvement occurs in 20–30% of cases and usually presents with red–brown papules, nodules and plaques. The nose may be extensively involved (lupus pernio). Lesions may hypo- or hyperpigmented, especially in dark skin. Erythema nodosum (see p. 677) is sometimes seen in acute sarcoidosis. Although sarcoidosis may be localized to the skin, all patients should be investigated for systemic involvement (see p. 987). Cutaneous sarcoid responds poorly to topical therapy but superpotent or intralesional corticosteroids or topical tacrolimus may occasionally help.

| Box 22.19 Clinical spectra of erythema multiforme, Stevens–Johnson syndrome and toxic epidermal necrolysis |
|---|---|---|---|
| Diagnosis | Skin lesions | Mucosal lesions | Other signs/symptoms |
| Erythema multiforme (EM) | Three-ring target lesions, often hands and feet | EM major only | Recent infection (herpes simplex virus, Mycoplasma) |
| Stevens–Johnson syndrome (SJS) | Scattered macules/blisters scattered over face, trunk, proximal limbs (10% body surface area) Occasional two-ring target lesion | Always | Fever Skin tenderness Recent drug exposure |
| Toxic epidermal necrolysis (TEN) | As for SJS but >30% body surface area involved | Always | As for SJS Respiratory and gastrointestinal lesions Hypotension Decreased consciousness |
| SJS/TEN overlap | As for SJS (10–30% body surface area involved) | Always | |
Skin signs of systemic disease

**Endocrine disease**

**Thyroid disease**

(See also Ch. 21.) Individuals with hypothyroidism have cold, dry skin and brittle hair with diffuse thinning and loss of the outer third of the eyebrows. There may be a jaundice-like appearance due to carotene excess with firm, gelatinous (myxoedematous) skin. Hyperthyroidism may be associated with hyperhidrosis, onycholysis and diffuse alopecia. The extrathyroid manifestations of Graves’ disease include dermopathy (pretibial myxoedema), which classically presents with non-pitting infiltration, plaques on the shins and, in severe cases, thyroid acropachy, characterized by clubbing and soft tissue swelling of the fingers and toes with periosteal reaction of the bones.

**Diabetes mellitus**

Diabetes mellitus (see also p. 735) can have a number of skin manifestations and complications, mediated mainly by hyperglycaemia and hyperinsulinaemia. They include:

- fungal infection (e.g. candidiasis, see p. 674)
- bacterial infections (e.g. recurrent boils, see p. 670)
- arterial and neuropathic ulcers

- poor or delayed healing
- xanthomas

Specific dermatoses of diabetes include:

- necrobiosis lipoidica (a patch of spreading erythema over the shin, which becomes yellowish and atrophic in the centre and may ulcerate, Fig. 22.36)
- diffuse granuloma annulare (see p. 667)
- diabetic stiff skin/cheiroarthropathy (tight, waxy skin over the fingers with limitation of joint movement owing to thickened collagen).

**Cushing’s syndrome**

Skin manifestations due to high cortisol include hirsutism, central obesity, moon face and buffalo hump. Florid purple striae distensae, or ‘stretch marks’, skin atrophy, telangiectasia and increased susceptibility to folliculitis and candidiasis may occur (see pp. 670 and 674). Hyperpigmentation also occurs in cases with increased circulating adrenocorticotropic hormone (ACTH; ectopic ACTH syndromes or Cushing’s disease, see p. 602). Striae distensae are caused by ruptures in dermal collagen and elastic tissue. They are a common finding over the abdomen, hips and breasts in normal female puberty and pregnancy, and in obesity, and over the lumbosacral area in adolescent males. The cause is unclear but they are associated with rapid growth. There is no effective treatment but they fade from pink/purple to pale silvery lines with time. Striae are also seen in Marfan’s syndrome.

**Addison’s disease**

Generalized hyperpigmentation occurs secondary to raised circulating ACTH levels (see also p. 599). This may be prominent in the palmar creases, oral mucosa, lips, large flexures, genitals and nail beds.

**Acanthosis nigricans**

Acanthosis nigricans presents with thickened, hyperpigmented, velvet-textured skin around the large flexures (Fig. 22.37). It can appear warty when advanced. The most common and mildest
form is associated with obesity and insulin resistance. Late-onset, severe disease with mucosal involvement is usually a paraneoplastic phenomenon caused by underlying malignancy, especially gastrointestinal tumours. Acanthosis nigricans may also be triggered by niacin therapy.

**Flushing**

Facial flushing in response to emotional stimuli (blushing) is a normal physiological response that can cause embarrassment and may be associated with social phobia. Pathological causes include carcinoid syndrome, other neuroendocrine tumours and drugs. Treatment of idiopathic flushing includes cosmetic camouflage, beta-blockers and clonidine. Cognitive therapy and selective serotonin reuptake inhibitors may help with associated depression and anxiety.

**Metabolic disease**

**Hyperlipidaemias**

Hyperlipidaemia (see also p. 746) may present with xanthomas, which are abnormal lipid deposits in the skin. A fasting lipid profile should be checked in all patients, though it may be normal in the most common type, xanthelasma, which presents with asymptomatic yellow plaques around the eyes. There are a number of other clinical variants of xanthoma, including:

- **tuberosus xanthoma** (firm orange–yellow nodules and plaques on extensor surfaces)
- **tendon xanthoma** (firm subcutaneous swellings attached to tendons)
- **plane xanthoma** (orange–yellow macules often affecting palmar creases)
- **eruptive xanthoma** (numerous small, yellowish papules, commonly on the buttocks).

**Porphyria cutanea tarda**

Porphyria cutanea tarda (PCT, see p. 755) is a rare metabolic disorder associated with liver disease; it is usually precipitated by alcohol excess or hepatitis C virus (HCV) infection, and 20% of cases have underlying haemochromatosis (see p. 1300). PCT presents with sun-induced blisters, fragile skin, scarring and milia, especially on the dorsal hands, and hypertrichosis.

**Management** is with repeated venesection to reduce iron overload, alcohol avoidance and low-dose antimalarial drugs. Antiviral therapy is indicated for underlying HCV infection.

**Box 22.20 Medical conditions associated with pruritus**

- Iron deficiency anaemia
- Malignancy (especially lymphoma)
- Diabetes mellitus
- Chronic kidney disease
- Chronic liver disease (especially primary biliary cholangitis)
- Thyroid disease
- Human immunodeficiency virus infection
- Polycythaemia vera

**Pruritus**

The pathophysiology of pruritus (itch) is complex and incompletely understood. It may be caused by peripheral mechanisms (as in skin disease), central or neuropathic mechanisms (as in multiple sclerosis), neurogenic mechanisms (as in cholestasis/μ-opioid receptor stimulation) or psychogenic mechanisms (e.g. parasitophobia). Evidence suggests that low stimulation of unmyelinated C-fibres in the skin is associated with the sensation of itch; high stimulation produces pain. Histamine, tachykinins (e.g. substance P) and cytokines (e.g. IL-31) may also play a role. In the central nervous system μ-opioid receptors may regulate the perception and intensity of itch.

Pruritus is a characteristic feature of many inflammatory rashes, especially atopic eczema, scabies and lichen planus. It also occurs with asteatotic eczema (see p. 663) and cholinergic urticaria, where the rash may be subtle and overlooked. Pruritus is common in the elderly and usually due to skin dryness (xerosis). Generalized pruritus without a rash can be caused by a number of medical problems (Box 22.20).

**Management** involves use of soap substitutes and symptomatic measures (as for asteatotic eczema). Phototherapy, low-dose amitriptyline or gabapentin may help in intractable cases. If a pruritic skin disease is not evident, patients should be fully investigated for underlying systemic disease.

**Haematological disease**

Anaemia (especially iron-deficient), iron overload, polycythaemia vera and lymphoproliferative diseases such as lymphoma can present with generalized pruritus. Iron deficiency can also present with hair shedding (see p. 331), glossitis, angular cheilitis and brittle or spoon-shaped nails (koilonychia).

**Amyloidosis**

Amyloid may be deposited in the skin in localized cutaneous forms due to repeated scratching (macular amyloid) or in association with underlying systemic disease. About 50% of patients with systemic amyloid will have skin involvement. Amyloid deposits in the oral cavity present with macroglossia and mucosal papules. Deposition in and around blood vessels causes fragility with petechiae and purpura, especially in the periorcular skin and large flexures. In primary systemic amyloid, there is usually an underlying monoclonal plasma cell proliferation. Multidisciplinary treatment of the underlying disease is required.
Chronic liver disease

Chronic liver disease may present with jaundice, palmar erythema, spider naevi, white nails and hyperpigmentation. Pruritus is common in cholestatic disease, including cholestasis of pregnancy (see p. 1455).

Chronic renal disease

End-stage renal disease (ESRD, see also p. 1397) is commonly associated with intractable pruritus. Pallor, hyperpigmentation and ecchymoses also occur. ESRD may rarely be associated with non-inflammatory, PCT-like blistering and fragility (pseudo-porphyria). Longstanding renal transplant recipients are at high risk of recurrent viral warts and squamous cell carcinomas (see p. 690) due to immunosuppression. Calciphylaxis is a rare life-threatening disorder caused by vascular calcification and occlusion, and characterized by extremely painful, ulcerating plaques (see p. 1396). Nephrogenic fibrosing dermopathy/nephrogenic systemic fibrosis is a severe scleroderma-like skin disease that affects people with severe renal impairment. The disease can develop rapidly, with swelling and woody thickening of the skin, and internal organs may be affected. Exposure to gadolinium-containing contrast agents used in magnetic resonance imaging (MRI) has been identified as a trigger.

Further reading

Autoimmune rheumatic disease

Dermatomyositis

The rash of dermatomyositis (see also p. 462) has a lilac colour, likened to that of a heliotrope, and is often in a photosensitive, cape-like distribution. It can itch and there may be prominent oedema around the eyes and poikiloderma (reticulate pigmentation, atrophy and telangiectasia). Purple nodules or plaques appear over the knuckles (Gottron’s papules, see Fig. 18.38) and extensor surfaces. The nail folds and cuticles are ragged with dilated capillaries. Investigations include serum muscle enzymes, myositis-specific antibodies, MRI scan, muscle biopsy and electromyography. Skin biopsy changes are non-specific. Myositis-specific antibody tests include anti-Mi-2 (highly specific for dermatomyositis), anti-MDA-5 (interstitial lung disease) and anti-TIF1-gamma (malignancy-associated disease, see p. 463).

Juvenile dermatomyositis usually starts before the age of 10. It is associated with cutaneous calcinosis and muscle contractures. The adult form usually occurs after the age of 40. Some cases are associated with malignancy, especially gynaecological, and this requires thorough investigation. Other cases are associated with connective tissue diseases, including scleroderma and lupus erythematosus (see p. 456).

Skin disease may respond to sunscreens and the antimarial drug hydroxychloroquine. Myositis usually requires high-dose corticosteroids and immunosuppressant drugs.

Scleroderma

The term scleroderma refers to a thickening or hardening of the skin due to abnormal dermal collagen. It is not a diagnostic entity in itself. Systemic sclerosis and morphea both show sclerodermatous changes but are distinct conditions:

• Systemic sclerosis (often called scleroderma) has cutaneous and systemic features, and is discussed on page 460. Skin changes may be the presenting feature in the localized CREST variant.

• Morphea (localized cutaneous scleroderma) is confined to the skin or subcutis and usually presents in children or young adults. It is more common in females and the cause is unknown. Lesions usually appear on the trunk as bluish-red thickened plaques with a shiny white indurated or atrophic centre (Fig. 22.38). A severe linear variant in childhood is associated with atrophy of underlying deep tissues and can lead to unequal limb growth or scarring alopecia.

Rarely, scleroderma-like skin changes may occur in chronic Borrelia infection (acrodermatitis chronica atrophicans), chronic graft-versus-host disease and eosinophilic myalgia syndrome (due to tryptophan therapy).

Potent topical steroids, oral (or pulsed intravenous) steroids, methotrexate or phototherapy can be helpful. Systemic treatment is indicated for subcutaneous disease to minimize scarring.

Lupus erythematosus

Lupus is a chronic multisystem autoimmune inflammatory disease (see p. 461). Skin involvement falls into three broad categories:

• chronic discoid lupus erythematosus (CDLE)

• subacute cutaneous lupus erythematosus (SCLE)

• systemic lupus erythematosus (SLE)

The cause is unknown but inherited factors, UV exposure and drugs may be relevant. All forms of lupus are more common in women.

Chronic discoid lupus erythematosus

Chronic discoid lupus erythematosus (CDLE) is characterized by chronic erythematous, scaly, atrophic plaques with telangiectasia, especially on the face or other sun-exposed sites (Fig. 22.39). Lesions are often hypopigmented and close examination may show plugged follicles. Scalp involvement leads to patchy scarring alopecia. Oral involvement (erythematous patches or ulcers) occurs in 25% of cases. A minority of patients also suffer with Raynaud’s phenomenon or chilblain-like lesions (chilblain lupus). About 30% of patients have positive antinuclear antibodies and about 5% develop overt systemic disease.

Skin biopsy shows a dense infiltration of lymphocytes around the hair follicles and damage to the basal layer of the epidermis. Direct immunofluorescence may demonstrate granular deposits of IgM and C3 at the dermo-epidermal junction (“lupus band”). CDLE usually lasts for many years, with fluctuations in severity before ‘burning out’.

Treatment is with high-factor sunscreens and potent topical steroids. Widespread or unresponsive disease and associated arthritis may require antimarial therapy (hydroxychloroquine),
systemic steroids or immunosuppressants. Thalidomide has been used for recalcitrant CDLE.

**Subacute cutaneous lupus erythematosus**

Subacute cutaneous lupus erythematosus (SCLE) is an uncommon variant that presents with widespread annular, papulosquamous lesions and plaques on the upper torso and upper limbs. It typically flares a few weeks after sun exposure. Systemic symptoms, such as arthralgia and mouth ulceration, are seen but significant organ involvement is rare. It may be drug-induced. Anti-Ro and anti-La antinuclear antibodies are usually positive (see p. 459).

**Treatment** is with antimalarials, dapsone or systemic steroids.

**Systemic lupus erythematosus**

Systemic lupus erythematosus (SLE; see also p. 457) seldom presents with skin features, as other organ involvement (arthritis, nephritis) usually predominates. The classical ‘butterfly’ rash affects the central face in a rosacea-like distribution (Fig. 22.40). Palmar erythema, dilated nail-fold capillaries, splinter haemorrhages, digital infarcts, purpura and livedo reticularis (see later) may be evident due to vascular inflammation or occlusion.

**Treatment** is described on page 459.

**Disorders of blood vessels and lymphatics**

**Vasculitis**

Vasculitis (see also p. 464) is an inflammatory disorder of blood vessels that causes endothelial damage. Cutaneous vasculitis may be an isolated problem or part of a multisystem disease with involvement of other organs. The most commonly used classification is based on the size of blood vessel involved (see **Boxes 18.39 and 18.40**) and the presence or absence of antineutrophil cytoplasmic antibody (ANCA).

The features of cutaneous vasculitis are haemorrhagic papules, pustules, nodules or plaques, which may erode and ulcerate. Lesions are purpuric and do not blanch with pressure. Blotchy erythema in a broken livedo/reticulate pattern (see next section) may be seen, with areas of infarction and necrosis. Pyrexia and arthralgia are common associated features. Other clinical features depend on the underlying cause. A thorough clinical evaluation will determine the likely causes and guide further investigations. Routine bloods and urinalysis should be carried out to exclude renal involvement.

**Leucocytoclastic vasculitis** is the most common cutaneous vasculitis and involves small vessels. It usually affects the lower legs as a symmetrical palpable purpura and is rarely associated with systemic involvement. It can be caused by drugs (15%), infection (15%), inflammatory disease (10%) or malignant disease (<5%) but often no cause is found (55–60%). Histology of an early lesion confirms blood vessel inflammation (rather than primary occlusion) and indicates the size of the blood vessel involved, as well as the presence of additional diagnostic features such as granulomas. Treatment is with analgesia, support stockings, and dapsone or prednisolone to control inflammation and heal ulceration.

**Livedo reticularis**

The term livedo reticularis describes a mesh-like (reticulate), blotchy, purple–red discoloration of the skin. It usually affects the lower limbs and is more noticeable in the cold but does not disappear on rewarming (unlike physiological livedo). The colour change is due to sluggish blood flow in dermal venules. This may be caused by blood abnormalities of the blood (high viscosity, coagulopathy, cryoglobulinaemia) or vessel wall (vasculitis, e.g. polyarteritis nodosa, calcification). If the network or mesh pattern is broken and irregular (‘livedo racemosa’), underlying systemic disease is likely. Livedoid vasculopathy is characterized by broken livedo, painful leg ulcers and atrophie blanche (see later). It may be associated with antiphospholipid syndrome and SLE.

**Leg ulcers**

Leg ulcers are common and can have many causes (Box 22.21). Venous ulcers are the most common type in developed countries (Fig. 22.41).

**Venous ulcers**

Venous ulcers are the result of sustained venous hypertension in the superficial veins, due to incompetent valves in the deep or perforating veins or to previous deep vein thrombosis. The increased pressure causes extravasation of fibrinogen through the capillary
Box 22.21 Causes of leg ulceration

- Venous hypertension
- Arterial disease (e.g. atherosclerosis)
- Neuropathic disease (e.g. diabetes, leprosy)
- Neoplastic disease (e.g. squamous or basal cell carcinoma)
- Vasculitis (e.g. rheumatoid arthritis, systemic lupus erythematosus, pyoderma gangrenosum)
- Infection (e.g. eczema, tuberculosis, deep mycoses, Buruli ulcer, syphilis, yaws)
- Haematological disease (e.g. sickle cell disease, spherocytosis)
- Drug (e.g. hydroxycarbamide)
- Other (e.g. necrobiosis lipoidica, trauma, artefact)

Fig. 22.41 Types of leg ulcer. (From Griffiths C, Barker J, Bleiker T et al. (eds). Rook’s Textbook of Dermatology, 9th edn. Chichester: John Wiley & Sons; 2016.)

walls, giving rise to perivascular fibrin deposition, which leads to poor oxygenation of the surrounding skin.

Venous ulcers are common in later life, affecting 1% of the population over the age of 70. They are often chronic or recurrent and create a significant burden on healthcare resources. Ulceration is most common on the lower leg above the medial malleolus (Fig. 22.42). Dilated foot, leg and thigh veins are usually evident. Other signs include:
- oedema of the lower legs
- venous/stasis/gravitational eczema (see p. 662)
- brown pigmentation from haemosiderin
- lipodermatosclerosis (the combination of induration, reddish-brown pigmentation and inflammation) – a fibrosing panniculitis of the subcutaneous tissue
- scarring white atrophy with telangiectasia (atrophie blanche).

Management is with graduated multilayer compression bandaging and leg elevation to improve venous return. Three- or four-layer bandaging is suitable for people who are immobile, and two-layer bandaging for those who are mobile. Doppler studies (ankle:brachial pressure index) should be performed before compression to exclude significant arterial disease. Treatment can be delivered effectively in the community by appropriately trained nurses. Non-adherent dressings are used to keep the ulcer moist. Alternative dressings (alginate, hydrogel, hydrocolloid) may be helpful for heavy exudate and slough. With adequate compression, up to 80% of ulcers can be healed within 6 months. Slower healing rates occur in patients with poor mobility, bilateral disease and very large ulcers that have been present for over 6 months. Diuretics are sometimes indicated to reduce oedema, and pentoxifylline may be a useful adjunct. Microbial swabs and antibiotics are indicated only when there are clinical signs of infection or cellulitis.

Painful venous leg ulcers require adequate analgesia. Split-thickness skin grafting can aid healing in resistant cases. Support stockings (individually fitted) should be worn for life after healing, to lessen recurrence. Underlying venous disease should be assessed. Modern vascular surgical interventions may accelerate healing and reduce the risk of ulcer recurrence.

Arterial ulcers

Arterial ulcers present as punched-out, painful lesions higher up the leg or on the feet in people with underlying peripheral vascular disease, particularly smokers. The affected leg is cold and pale with loss of hair. Peripheral pulses are absent or weak and Doppler ultrasound studies can confirm underlying arterial disease.

Management depends on keeping the ulcer clean and covered, adequate analgesia and vascular surgical intervention if appropriate. Compression bandaging must be avoided.

Neuropathic ulcers

Neuropathic ulcers usually occur over pressure areas of the feet, such as the metatarsal heads, owing to repeated trauma. They are usually associated with diabetes and peripheral neuropathy. In some developing countries, leprosy is a common cause.

Management involves keeping the ulcer clean and reducing pressure or trauma to the affected area. People with diabetes need meticulous foot care and correctly fitting shoes (see p. 733).

Pressure ulcers (decubitus ulcers, bedsores)

Pressure ulcers or sores are a severe manifestation of pressure-induced skin and soft tissue injury. They affect elderly, immobile, unconscious or paralysed patients and are due to skin and soft tissue ischaemia from sustained pressure over a bony prominence: most commonly, the heel and sacrum. Healthy individuals feel the discomfort of continued pressure, even during sleep, and relieve pressure by changing body position. Pressure injuries may be graded and range from non-blanchable erythema of intact skin (stage 1) to deep ulcers extending to the bone (stage 4).

There are numerous risk factors for the development of pressure ulcers (Box 22.22). The majority of ulcers arise in hospital, with approximately 70% appearing in the first 2 weeks of hospitalization and 70% occurring in orthopaedic patients, especially those on
traction. Deep ulcers are associated with a high mortality rate. The early sign of red/blue skin discoloration can lead rapidly to ulcers within hours. Leaving patients on hard emergency room trolleys or sitting them in chairs for prolonged periods must be avoided.

**Management**

See Box 22.23.

**Prevention**

Prevention is better than cure and a risk assessment should be undertaken on newly admitted patients. The best-known risk assessment tools are the Norton Scale and Waterlow Pressure Ulcer Risk Assessment, which yield a numerical score (Box 22.24). Specialist tissue viability nurses help assess risk, deliver care and train other clinical staff.

### Lymphatic disease

#### Lymphoedema

Impaired lymphatic fluid drainage leads to chronic non-pitting oedema with reduced tissue immunity and increased fat deposition. It most commonly affects the legs and tends to progress with age. It is associated with an increased risk of cellulitis, which often becomes recurrent. The subcutaneous tissues become thickened and indurated, and the overlying skin develops a warty texture. Affected limbs may become grossly enlarged. Lymphoedema can be primary (and present early in life) and due to an inherited

  - Diabetes mellitus
  - Scleroderma
  - Vasculitis
- Poor nutrition
  - Anaemia
  - Hypoalbuminaemia
  - Vitamin C or zinc deficiency

---

**Box 22.23 Management of pressure ulcers**

- Ensure bed rest with pillows and fleeces to keep pressure off bony areas (e.g. sacrum and heels) and prevent friction
- Provide air-filled cushions for patients in wheelchairs
- Provide special pressure-relieving mattresses and beds
- Maintain regular turning but avoid pressure on hips
- Give adequate nutrition
- Apply non-irritant occlusive moist dressings (e.g. hydrocolloid)
- Prescribe adequate analgesia (may need opiates)
- Consider plastic surgery (debridement and grafting in selected cases)
- Treat the underlying condition

abnormality of lymphatic vessels (e.g. Milroy’s disease), or can be secondary and due to obstruction of lymphatic vessels (e.g. filarial infection or malignant disease).

**Management** is with compression stockings and physical massage. Causes of high central venous pressure, low albumin and local inflammation should be treated. Long-term antibiotics are indicated for recurrent cellulitis (see p. 669), as each episode of cellulitis causes further damage to the lymph vessels. Surgery should be avoided.

**Further reading**

**Systemic malignant disease**

Certain rashes may be a non-metastatic manifestation of an underlying malignancy: these are the *paraneoplastic dermatoses* (Box 22.25). Rarely, internal malignancies can metastasize to the skin, where they usually present as papules or nodules that may ulcerate.

**Genetic disease**

**Neurofibromatosis type 1**

Type 1 neurofibromatosis (von Recklinghausen’s disease) is an autosomal dominant condition caused by mutations in the *NF1* gene. It often presents in childhood with multiple café-au-lait spots (brown macules, >5 mm in diameter, and more than five lesions) and axillary freckling. Learning difficulties and skeletal dysplasia can occur. Iris Lisch nodules may be seen on slit-lamp examination. Neurofibromas appear in adulthood as fleshy skin polyps and smooth soft dermal tumours, and can be extensive. A number of endocrine disorders are rarely associated, including phaeochromocytoma, acromegaly and Addison’s disease.

**Tuberous sclerosis**

The tuberous sclerosis complex (TSC) is an autosomal dominant condition of variable severity, characterized by a range of benign or hamartomatous tumours. The main clinical features are learning and behavioural difficulties, epilepsy and skin lesions:

- adenoma sebaceum (reddish papules or fibromas around the nose)
- periungual fibroma (nodules arising from the nail bed)
- shagreen patches (firm, flesh-coloured plaques on the trunk)
- ash-leaf hypopigmentation (pale macules best seen with Wood’s UV lamp)
- forehead plaque (indurated, flesh-coloured patch)
- café-au-lait patches.

Internal hamartomas can arise in the heart, lung, kidney, retina and central nervous system. Inhibition of the mammalian target of rapamycin (mTOR) signalling pathway with drugs such as rapamycin may help to shrink TSC-associated tumours.

**Ehlers–Danlos syndrome**

Ehlers–Danlos syndrome (see also p. 432) refers to a group of inherited disorders of connective tissue that affect the structure and function of the skin, eyes, ligament, joints, blood vessels and internal organs. The underlying defects are varied and involve abnormalities of collagen fibril synthesis and extracellular matrix molecules. They are characterized by joint hypermobility, easy bruising and lax skin that heals with tissue paper scars.

**Pseudoxanthoma elasticum**

Pseudoxanthoma elasticum is a rare autosomal recessive disease involving fragmentation and calcification of elastic tissue in the dermis, blood vessels and eye. The skin changes of slackness, wrinkling and yellowing (resembling plucked chicken skin) are most evident in the flexures, especially the sides of the neck. Non-cutaneous features include recurrent gastrointestinal bleeding, vascular occlusion and aneurysms, and angioid streaks on the retina.

**PHOTOSENSITIVITY**

Photosensitivity disorders are characterized by abnormal sensitivity to the UV and sometimes the visible range of the solar spectrum. Several rare skin diseases are primarily caused by sunlight (primary photodermatoses) and a larger number are aggravated by sun exposure (photoaggravated photodermatoses), including connective tissue diseases (dermatomyositis and cutaneous lupus). The rashes of pellagra (see p. 1241) and the porphyrias (see p. 755), and certain drug hypersensitivities, are also triggered by UV exposure (see p. 697) (Box 22.26).

**Plant photoxins**

- Phytophotodermatitis (photosensitivity induced by contact of the skin with certain plants, e.g. celery, hawthweed, rue, lime, fig tree)

**Skin disease**

- Rarely, atopic eczema, psoriasis, lichen planus (these usually improve in sunlight)

**Idiopathic photodermatoses**

- Polymorphic light eruption
- Chronic actinic dermatitis
- Solar urticaria
There are many causes of skin blisters, the most common being infection (HSV, chickenpox, impetigo, cellulitis), insect bites – especially on the lower legs – and trauma (burns and friction). Blistering may also be a feature of eczema, especially on the hands and feet (pompholyx, see p. 663).

Very rarely, blistering is due to skin fragility caused by genetically determined abnormalities in the structural proteins of the dermo-epidermal junction and basal keratinocytes (mechanobullous diseases) or their destruction by antibodies in autoimmune (immunobullous) disease. The level at which fragility and blistering occur varies according to disease and affects the clinical presentation (see Fig. 22.43). It can be demonstrated by light and electron microscopy and immunofluorescence (IMF) studies. Autoantibody deposits (at the BMZ or between keratinocytes) can be identified by direct IMF of affected (perilesional) skin, and indirect IMF identifies autoantibodies in serum.

Immunobullous diseases

Pemphigus

Pemphigus vulgaris is a rare and potentially life-threatening blistering disease. It is more common in Ashkenazi Jews and people from the Indian subcontinent. It may affect all ages but usually starts in adulthood. Pathogenic IgG4 antibodies against desmosomal proteins (desmoglein 1 and 3) lead to loss of keratinocyte adhesion in the skin and mucous membranes, causing superficial (intraepidermal) blisters, erosions and mucosal ulcers.

Oral involvement is common and is the presenting sign in up to 50% of patients. Skin lesions appear as flaccid blisters that rupture easily, leaving weeping and crusted erosions. Blisters can be extended with gentle lateral pressure (Nikolsky’s sign).

Pemphigus foliaceus is a rarer variant, in which the target antigen is desmoglein 1. This antigen is not expressed in the oral mucosa, which is therefore unafected. Desmoglein 1 is predominantly expressed in the upper epidermis, which detaches, leaving crusts and erosions rather than blisters. It usually affects the seborrheic areas before becoming more widespread. Endemic pemphigus foliaceus occurs in the Limão Verde area of Brazil and is thought to be triggered by an infectious agent carried by biting insects. A pemphigus foliaceus-like rash can be induced by drugs (e.g. captopril, penicillin).

Paraneoplastic pemphigus is a very rare malignancy-associated disorder characterized by painful oral erosions and a polymorphic inflammatory ash. It is usually associated with a lymphoproliferative neoplasm.

Direct IMF of perilesional skin in pemphigus shows intercellular IgG deposition. Circulating anti-epidermal antibodies can also be detected and their titre correlates with disease activity. Histology of affected skin shows intraepidermal cleavage above the basal cell layer with separation of individual keratinocytes (acantholysis) in pemphigus vulgaris. The split occurs higher in the epidermis in pemphigus foliaceus.

Management

High-dose systemic corticosteroids are usually effective in controlling pemphigus, followed by longer-term, steroid-sparing immunosuppressive drugs including azathioprine, cyclophosphamide, methotrexate and rituximab (an anti-CD20 monoclonal antibody).

Bullous pemphigoid

Bullous pemphigoid is more common than pemphigus in Western Europe and usually affects adults over 60. Pemphigoid gestationis is a rare variant that occurs in pregnancy and post-partum. Autoantibodies against a 230 kDa or 180 kDa hemidesmosomal protein (‘bullous pemphigoid antigen 1’ and ‘type XVII collagen’)

fig. 22.43 section of the basement membrane zone. The structural sites of damage in bullous disorders. EB, epidermolysis bullosa; K, keratin; LAD, linear IgA disease; LE, lupus erythematosus.
play a pathogenic role and cause a split through the epidermal BMZ (see p. 654). This can be seen on routine histology as a subepidermal split. Direct IMF shows deposition of IgG and complement at the dermo-epidermal junction. Lesions are often itchy and present as large, tense, serous or haemorrhagic blisters (bullae) with an inflamed (‘urticated’) base. Blistering may be widespread, affecting the torso and limbs, especially the lower abdomen and thighs (Fig. 22.44). Mucosal ulceration is not prominent, except in a rare variant of pemphigoid, mucous membrane pemphigoid (formerly called cicatricial pemphigoid). This presents with erosions and ulceration of the mucosal surfaces and scarring eye disease, with fusion of the eyelids, corneal damage and visual loss.

**Management**

Oral corticosteroids (prednisolone 0.5 mg/kg per day) are usually initiated for disease control, with a steroid-sparing drug such as azathioprine or mycophenolate mofetil for long-term management. These drugs require careful monitoring in the elderly due to their increased risk of adverse drug effects, which contributes to the increased mortality associated with pemphigoid. Oral tetracyclines are also used for their anti-inflammatory actions and may be safer drugs. Mild localized pemphigoid can be managed by daily application of a very potent topical steroid to drained (popped) blisters. Treatment can usually be withdrawn after a few years but the disease often relapses.

**Linear IgA disease**

Linear IgA disease (LAD) is a rare pemphigoid-like disorder of adults and children caused by pathogenic IgA autoantibodies that target various BMZ proteins, including type XVII collagen and laminin-332 (see Fig. 22.43). The cause is unknown but LAD may be induced by drugs, especially vancomycin. Direct IMF of skin shows linear IgA deposition along the dermo-epidermal junction. LAD characteristically presents with circular clusters of golden blisters, described as a ‘string of jewels’ (Fig. 22.45). It usually responds to treatment with dapsone (see below).

**Dermatitis herpetiformis**

Dermatitis herpetiformis (DH) is a cutaneous manifestation of coeliac disease (see p. 1189). Both conditions are genetically determined and triggered by dietary gluten. DH presents with an intensely itchy, eczematous rash that predominantly affects the elbows, knees, scalp and buttocks. Small blisters may be visible but are often scratched away, leaving excoriations and crusted erosions. DH is more common in males (whereas coeliac disease has a female predominance); it can present at any age but usually appears in early adulthood. Nearly all patients with DH have small intestinal changes of coeliac disease (villous atrophy/inflammation) but lack gastrointestinal symptoms. Autoantibodies against tissue transglutaminase (TG) 2 occur in the serum and bowel in DH and coeliac disease, with additional IgA antibodies against TG3 occurring in DH. The latter can be demonstrated in the skin by direct IMF, which reveals granular IgA deposits in the dermal papillae and along the BMZ. Histology of DH shows subepidermal blistering and a florid infiltrate of neutrophils causing micro-abscesses in the dermal papillae.

**Management**

Patients should avoid all dietary gluten (see p. 1191). Treatment with dapsone or sulphonamides, sometimes at low dose, usually gives rapid relief from itch. If a strict gluten-free diet is followed, oral medication can usually be withdrawn after 2 years. Dapsone causes mild dose-related haemolysis, which is usually well tolerated except in cardiorespiratory disease. It is contraindicated in people with glucose-6-phosphate dehydrogenase deficiency, as they are at risk of severe drug-induced haemolysis. Other rare adverse effects of dapsone include hepatitis, drug hypersensitivity syndrome (including DRESS, see p. 698) and peripheral neuropathy.

**Further reading**

Mechanobullous diseases (epidermolysis bullosa)

This rare group of inherited skin diseases is caused by defective or absent structural skin proteins, leading to fragile skin that blisters with minimal trauma. Blisters and erosions usually appear at or shortly after birth. The degree of skin fragility is highly variable, ranging from mild friction blisters to severe, extensive and life-limiting skin loss (‘butterfly babies’). There are three broad groups of disorders:

- **Epidermolysis bullosa simplex** is the mildest form and causes localized blisters on the hands and feet that heal without scarring. It is inherited as an autosomal dominant trait and caused by synthesis of abnormal cytoskeleton proteins (e.g. keratins 5 and 14) in the basal epidermis.

- **Dystrophic epidermolysis bullosa** is a debilitating, life-limiting disease characterized by deep erosions, blisters and scarring. The underlying abnormality is mutations in the type VII collagen gene that cause impaired or absent synthesis of anchoring fibrils in the deep part of the BMZ. Mucosal involvement can affect the larynx and oesophagus, causing voice loss and dysphagia. Nails are absent and the digits may become fused by the scarring, causing mitten-like deformities. Affected individuals have a high risk of developing aggressive squamous cell carcinomas within chronically inflamed skin. There is no curative therapy at present and management is supportive.

- **Junctional epidermolysis bullosa** is the most severe form and is characterized by a split in the lamina lucida of the BMZ due to mutations in genes controlling synthesis of various structural proteins (laminin-332, α6β4 integrin, type XVII collagen). It presents at birth with widespread blistering and areas of absent skin, and is usually fatal in early childhood.

**Investigations and management**

Investigation and treatment of epidermolysis bullosa should be carried out in a specialist centre. Ultrastructural skin tests and genetic testing provide a precise diagnosis and prognosis, and are required for genetic counselling. Prenatal diagnosis and pre-implantation diagnosis are available for severe forms of epidermolysis bullosa. Treatment options are limited to pain management and skin grafting with cultured keratinocytes. Gene therapy and bone marrow transplantation are two new approaches that are undergoing clinical trials.

**SKIN TUMOURS**

**Benign skin tumours**

**Melanocytic naevi**

Melanocytic naevi are the most common benign neoplasm in humans. **Congenital melanocytic naevi** are present at birth in 1–2% of newborns. Small solitary lesions are common and harmless, but larger lesions (>20 cm diameter) and multiple smaller naevi may be associated with neurological complications, including epilepsy and an increased risk of melanoma. **Acquired melanocytic naevi (moles)** appear in childhood, adolescence and early adult life, increasing in size and number. Benign naevi usually have even pigmentation and regular borders. They start as flat brown macules with proliferation of melanocytes at the dermo-epidermal junction (junctional naevi). With later downward growth of melanocytes into the dermis (compound naevi), the mole becomes raised and palpable, eventually maturing into an intradermal naevus with loss of pigment. Although the risk of malignant transformation of a benign mole is extremely low, the presence of more than 100 common naevi is associated with a sevenfold increase in the risk of melanoma.

**Atypical naevi** are acquired moles that have irregular pigmentation and are larger (>5 mm) than common naevi, often with ill-defined, ‘fuzzy’ borders. They may show dysplastic features on histology but the clinical and microscopic features do not always tally. Atypical naevi are associated with an increased risk of melanoma. Individuals with **familial atypical mole syndrome (FAMM)** have a large number of atypical naevi and a high lifetime risk of melanoma. They require long-term follow-up with serial photography and dermoscopy of atypical lesions. Atypical naevi that lack features of melanoma and do not warrant excision on presentation can be reviewed and rephotographed at 3-monthly intervals to detect early features of malignant change.

**Blue naevus** is an acquired blue–grey mole caused by a deeper proliferation of melanocytes in the mid-dermis.

**Basal cell papilloma (seborrhoeic keratosis/wart)**

This is an extremely common, harmless growth that affects older adults and is caused by overgrowth of the basal keratinocytes. Lesions range from flesh-coloured to very dark brown, and have a greasy, ‘stuck-on’ appearance (Fig. 22.46). The surface is rough and warty, and may contain tiny keratin cysts. They can be removed under local anaesthetic with curettage, or treated with cryotherapy or electrodesiccation.

**Dermatofibroma (histiocytoma)**

Dermatofibromas are firm, smooth, pink–beige nodules, which have a peripheral pigmented margin. They are often found on the leg and are more common in females. There is sometimes a history of trauma or an insect bite. The lesion consists of histiocytes, blood vessels and varying degrees of fibrosis. Excision is not needed unless lesions are symptomatic or there is diagnostic uncertainty.

**Epidermoid cyst (‘sebaceous cyst’) and pilar cyst**

Epidermoid cysts are cystic swellings derived from an occluded follicle. They have a central punctum and contain ‘cheesy’ keratinous matter. Cysts may enlarge and can become secondarily infected and inflamed. Pilar cysts are similar lesions that occur on the scalp. They may be multiple and familial. Symptomatic cysts can be excised under local anaesthetic.
**Pyogenic granuloma**

Pyogenic granulomas are benign vascular proliferations that present as rapidly growing, friable, red nodules that bleed easily. They may follow minor trauma and often occur on the face or fingers. Excision is advisable and lesions should always be sent for histology to exclude amelanotic malignant melanoma.

**Cherry angioma (Campbell de Morgan spots)**

Cherry angiomas are benign angiokeratomas that appear as tiny, pinpoint, red papules, especially on the trunk, and increase with age. No treatment is required.

**Keloids and hypertrophic scars**

Abnormal wound healing with excessive dermal fibrosis leads to hypertrophic scars and keloid formation. Hypertrophic scars remain confined to the borders of the original wound and usually regress spontaneously. Keloids (Fig. 22.47) can arise spontaneously or after minimal trauma, and proliferate and enlarge beyond the wound margins. They are often itchy and tend to affect young, dark-skinned adults. Sites of predilection include the shoulders, upper back and chest, earlobes and chin. Treatment options include silicone gel or dressings, pressure garments, cryotherapy and intralesional corticosteroids. Non-essential surgery should be avoided.

**Dysplastic/pre-malignant skin lesions**

**Actinic (solar) keratoses**

These are common on the sun-exposed areas of fair-skinned individuals in later life, especially bald scalps. They appear as scaly, erymematous papules or patches and feel gritty and rough. The surrounding skin usually shows signs of chronic sun damage (Fig. 22.48), with wrinkles and solar lentigines. A small minority (<1%) of actinic keratoses undergo malignant transformation into squamous cell carcinoma. Lesion-based treatments include cryotherapy and curettage and cautery. Field treatments, aimed at clearing visible and subclinical lesions over a larger area, include topical 5-fluorouracil, imiquimod and diclofenac.

**Bowen's disease (intraepithelial carcinoma)**

This is an indolent form of intraepidermal (in situ) squamous cell carcinoma that rarely progresses to invasive disease. It typically affects the lower legs in fair-skinned women or the torso in men, and is thought to be caused by chronic UV exposure. Lesions appear as a slowly enlarging, well-demarcated, scaly red patch or plaque resembling psoriasis but lacking thick silvery scale. A variant of Bowen's disease can affect the genital mucosa and is referred to as vulval, penile or anal intraepithelial neoplasia. This presents with non-specific erythematous patches ('erythroplasia', Fig. 22.49) or warty papules (Bowenoid papulosis). There is a strong link with HPV-16 and 18 infection. Genital Bowen's disease is more common in immunosuppressed individuals, including those with HIV, and perianal disease may extend into the rectum. Treatment options are similar to those for actinic keratosis.

**Keratoacanthoma**

Keratoacanthomas are rapidly growing epidermal tumours that develop as a red papule with a central crater-like, crusty keratinous plug (Fig. 22.50). They occur on sun-exposed skin in later life and often reach 2–3 cm in diameter. Although they regress spontaneously after about 3 months, leaving a pitted scar, they are usually excised, as it can be extremely difficult to distinguish them from squamous cell carcinoma.
Malignant skin tumours

Basal cell carcinoma
Basal cell carcinomas (BCCs) are the most common form of skin cancer and their incidence is increasing by 10% a year worldwide. Fair-skinned elderly individuals in sunny climates are at greatest risk but other genetic factors are also involved. The exact aetiology of BCCs is unknown but they are thought to arise from pluripotential cells in the basal epidermis or follicular structures. Mutations in PTCH1, the human homologue of the ‘Patched’ gene that regulates the Hedgehog intracellular signalling pathway, have been detected in sporadic BCCs and Gorlin’s syndrome (hereditary BCC syndrome). BCCs typically appear as a slowly enlarging, pearly or shiny nodule on the head and neck area, which bleeds easily with minor trauma and fails to heal (nodulocystic BCC). The border of ulcerated lesions is raised, with a pearly appearance (Fig. 22.51) and overlying, branch-like (arborizing) telangiectasia. Pigmented, superficial and morpheic (scar-like) variants exist. Although BCCs have minimal metastatic potential, they cause significant morbidity by local invasion into adjacent tissues; hence the common term ‘rodent ulcer’.

Management
The treatment of choice for most BCCs is a wide excision with histology to ensure complete removal of the tumour with adequate margins. Mohs micrographic surgery is preferred for morpheic BCCs and tumours involving the nasal creases, as these are more likely to recur. Superficial BCCs can be managed with non-surgical treatment, including cryotherapy, photodynamic therapy and topical imiquimod. Radiotherapy remains an option in those who are unable to tolerate surgery. Vismodegib inhibits the Hedgehog signalling pathway and normalizes keratinocyte proliferation. It can halt or even clear advanced or inoperable BCC, but is very expensive and may be poorly tolerated due to its adverse effects.

Squamous cell carcinoma
Squamous cell carcinoma (SCC) is the second most common skin cancer. Like BCC, it is derived from keratinocytes. It has a higher metastatic potential than BCC and a clearer correlation with chronic cumulative UV-induced skin damage. SCC mainly affects the exposed sites of fair-skinned older people. It can arise in pre-existing solar keratoses or Bowen’s disease, and can also complicate areas of chronic inflammation, as in lupus vulgaris. Rarely, multiple tumours may arise due to arsenic ingestion in early life. Multiple aggressive tumours also occur in people who are immunosuppressed, such as transplant recipients.

Clinically, SCCs are enlarging, ill-defined, keratotic or warty, inflamed plaques or nodules that may ulcerate and bleed easily (Fig. 22.52). The risk of metastasis to lymph nodes increases in SCC with ‘high-risk’ features, which guides the need for long-term follow-up (Box 22.27).

Management
In the UK, patients with suspected SCC should be referred urgently for specialist assessment by the local hospital’s multidisciplinary skin cancer team. Treatment is complete surgical excision with a wide margin (≥5 mm). Radiotherapy is also used. Education about sun avoidance is key to reducing the risk of further SCC development.

Lentigo maligna
This pigmented macule occurs on sun-damaged skin, usually of the face, in elderly people (‘Hutchinson’s melanotic freckle’). At first it resembles a solar lentigo (see p. 693) but it enlarges considerably
over several years and has an asymmetrical border and irregular pigmentation. Lentigo maligna represents a slow-growing intraepidermal form of melanoma, similar to a melanoma in situ, where malignant cells grow radially without dermal invasion. However, invasive disease, lentigo maligna melanoma (see next section), may occur, especially in larger lesions. Treatment is by excision if possible but tumour margins are difficult to define clinically. Confocal microscopy or excision by Mohs’ technique can help improve margin control. Complete removal with wide margins may involve disfiguring surgery, and although its cure rate is low, topical imiquimod may be an alternative when surgery is contraindicated.

**Malignant melanoma**

Malignant melanoma (or just ‘melanoma’) is the most serious form of skin cancer, as although it represents only 4% of cases of skin cancer, it causes 80% of skin cancer deaths. The incidence increases with age but it may also affect young people. The increasing incidence in recent years is thought to be due to more extensive recreational sun exposure, especially intermittent intense exposure (sunbathing in particular) and sunburn in childhood. Other risk factors include fair skin, multiple melanocytic naevi, a family history of melanoma and immunosuppression. About 75% of cutaneous melanomas arise de novo from normal skin, the remainder arising from a pre-existing naevus. A number of oncogenes and tumour suppressor proteins have been implicated in the pathogenesis. About 60% of human melanomas have an activating mutation in the BRAF V600 protein kinase, which is now a target for ‘personalized’ chemotherapy (see later).

**Diagnosis** of melanoma is not always easy but the clinical signs listed in **Box 22.28** help distinguish malignant from benign moles. Examination with a dermatoscope (a hand-held polarized light source with magnification) aids clinical diagnosis and is an essential skill for clinicians who assess pigmented lesions.

Four clinical types exist:

- **Lentigo maligna melanoma** is invasive tumour that develops within pre-existing lentigo maligna. It is usually apparent as a new nodule.
- **Superficial spreading malignant melanoma** is a large, flat, irregularly pigmented lesion that grows laterally before vertical invasion develops.
- **Nodular malignant melanoma** (Fig. 22.53) is the most aggressive type. It presents as a rapidly growing pigmented nodule, which bleeds or ulcerates. Rarely, it is amelanotic (non-pigmented) and can mimic pyogenic granuloma.
- **Acral lentiginous malignant melanomas** arise as pigmented lesions on the palm or sole or under the nail, and usually present late. They may not be related to sun exposure.

**Management**

In the UK, all people with suspected melanoma should be referred urgently (2-week wait pathway) to the local hospital’s multidisciplinary skin cancer team. Surgery remains the definitive treatment for primary melanoma and early wide excision of thin tumours is usually curative. Suspicious lesions should be completely and promptly excised with a narrow (2 mm) margin for review by a dermatopathologist experienced in melanoma diagnosis. The pathological staging of the primary melanoma depends on the Breslow thickness of the melanoma – that is, the depth of dermal invasion – and whether the tumour is ulcerated. The 8th American Joint Committee on Cancer (AJCC) melanoma staging system, published in 2017, defines four broad categories of tumour, T1–4, ranging from T1a (<0.8 mm thickness without ulceration) to T4b (>4.0 mm with ulceration). These categories guide the margins of the subsequent wide local excision and the likely benefit from a sentinel lymph node biopsy (SLNB) to detect occult metastases in the adjacent lymph nodes. The latest NICE guidelines recommend that SLNB should be offered to patients with stage 1B–2C melanoma with a Breslow thickness of more than 1 mm. Patients with clinically evident lymphadenopathy or positive SLNB are further evaluated with positron emission tomography–computed tomography (PET-CT) to detect distant metastases.

**Treatment** for metastatic melanoma (stages 3 and 4) has been revolutionized in the last few years with the advent of targeted therapy. This includes the oral tyrosine kinase inhibitors vemurafenib and dabrafenib, and the MEK inhibitor trametinib for patients whose melanomas demonstrate the BRAF V600 mutation. They are more effective than conventional chemotherapy when given in combination, but toxicity and tumour resistance are limitations. Immunotherapy with immune checkpoint-blocking agents, including CTLA4 antibody (ipilimumab) and programmed death 1 protein antibody (PD-1 antibody – pembrolizumab, nivolumab), has led to significant improvements in survival for patients with advanced melanoma with tolerable toxicity.
UV exposure and photoprotection

The solar spectrum at the earth’s surface includes visible light and medium- and long-wave ultraviolet (UV): that is, UVB and UVA. Short-wavelength UVC is filtered out by the atmosphere (Box 22.29). UVB and UVA are potentially mutagenic and carcinogenic, especially in fair-skinned people. They cause sunburn (predominantly UVB), premature ageing or photodamage (predominantly UVA). UV radiation has immunosuppressive effects that enhance skin cancer development. Systemic medication may lead to abnormal sensitivity to UV and phototoxic or photoallergic rashes. This is thought to be the underlying mechanism behind the recently identified increase in risk of non-melanoma skin cancer among patients on long-term thiazide therapy.

Sunscreens protect against UVA and UVB irradiation but are no substitute for protective clothing and restriction of exposure, especially in young children. They work by absorbing or filtering UV radiation (e.g. benzophenones, cinnamates, salicylates) or reflecting it (zinc/titanium dioxide). New sunscreen chemicals have been developed to give better protection, and the particle size of reflective sunscreens can be reduced (micronized) to improve their cosmetic acceptability. Modern creams are formulated to provide broad-spectrum protection against UVA and UVB. The sun protection factor (SPF) is a measure of UVB protection and the degree to which exposure can be prolonged before burning. However, in many cases, sunscreens are not applied in adequate amounts and so do not provide the SPF as labelled. UV-absorbing chemicals may occasionally cause allergic contact dermatitis and, in rare instances, photoallergic contact dermatitis (where the sunscreen becomes allergenic with UV exposure).

Sunlight is the main source of vitamin D and individuals who do not have photosensitivity benefit from short-term sun exposure (without burning) to maintain levels. This is particularly necessary for people with darker skins living in temperate climates, who are at risk of vitamin D deficiency. Advice about sun protection therefore needs to take into account the individual’s skin type.

Further reading

Primary cutaneous T-cell lymphoma (mycosis fungoides)

Mycosis fungoides is a rare lymphoproliferative disease that usually follows an indolent course. It presents with pruritic, scaly patches, which typically start on the buttocks and can resemble eczema, psoriasis or fungal infection; asymmetry and atrophy are useful clues (Fig. 22.54). Skin biopsy shows invasion of the epidermis by atypical T lymphocytes (exocytosis), and T-cell receptor gene rearrangement studies show that the infiltrate is clonal.

Occasionally, patches evolve into nodules or tumours, which may metastasize to lymph nodes and internal organs. Sézary’s syndrome (see p. 407) is a rare erythrodermic variant of cutaneous T-cell lymphoma with peripheral lymphadenopathy and peripheral blood involvement; it is seen mostly in elderly men. Mycosis fungoides and Sézary’s syndrome usually run chronic relapsing courses. Treatment choices depend on disease stage and extent. Patch and plaque-stage mycosis fungoides usually responds to potent topical corticosteroids and UV phototherapy. Advanced disease treatment options include radiotherapy, oral retinoids (bexarotene) and chemotherapy. Sézary’s syndrome is treated with extracorporeal photopheresis, in which the patient’s leucocytes are mixed with psoralen and irradiated with UVA ex vivo.

Kaposi’s sarcoma

This tumour of vascular and lymphatic endothelium presents as purplish nodules and plaques. There are three types:

- The ‘classic’ or ‘sporadic’ form occurs in elderly males, especially Jewish people from Eastern Europe. It presents as slow-growing macules, plaques or nodules on the foot and lower limb.
- The ‘endemic’ form occurs in males from Central Africa and has more widespread skin and lymph node involvement. Oedema is a prominent feature.
- The immunosuppression-related form is more severe and is most common in HIV-positive men who have sex with men. Lesions are widespread with additional involvement of the oral cavity, bowel and lungs.

All three types have a strong association with human herpesvirus-8 (HHV-8) but other factors must be involved, as HHV-8 seroprevalence is up to 10% in the USA and 50% in some African countries. ART (see p. 1435) significantly reduces the incidence of Kaposi’s sarcoma in people with HIV infection.

Treatment of advanced Kaposi’s sarcoma is with radiotherapy, immunotherapy or chemotherapy.
Pigment may be lost from overlying hair. Lesions are hypopigmented and may occur in mycosis fungoides (see p. 692) and in pityriasis versicolor (see p. 674). Lesions may also show hair loss and decreased sweating. Post-inflammatory hypopigmentation

This phenomenon occurs in dark-skinned individuals at the sites of skin trauma or inflammatory rashes, such as acne, lichen planus and eczema. It improves slowly over many months.

Metabolic/endocrine effects

Generalized skin darkening can occur with chronic liver disease, especially haemochromatosis (see p. 1300), and endocrine disease.

Urticaria pigmentosa (cutaneous mastocytosis)

This disorder is caused by a benign proliferation of cutaneous mast cells. It presents most commonly in childhood as multiple pigmented macules that become red, itchy and urticated if they are rubbed (Darier’s sign), and occasionally blister. Extensive mast cell degranulation can lead to systemic symptoms, such as wheeze, flushing, syncope, diarrhoea and, very rarely, anaphylaxis. This may be considered in people from endemic regions. Lesions may also show hair loss and decreased sweating.

Oculocutaneous albinism

This rare group of autosomal recessive disorders is caused by reduced or absent pigment synthesis in the skin, hair and eyes. It can affect all races. Individuals have pale skin, white or yellow hair, and a pink iris. Ocular manifestations include photophobia, nystagmus and a squint. Meticulous UV protection is required to prevent sunburn and reduce the risk of skin cancer.

Further reading

Fig. 22.55 Vitiligo of the hands. Areas of depigmentation.

DISORDERS OF PIGMENTATION

Hyperpigmentation

Freckles (ephelides)

These extremely common pigmented macules appear in childhood after sun exposure. They fade in the winter.

Lentigines

These persistent pigmented macules look similar to freckles. They may rarely be associated with systemic syndromes (e.g. Peutz–Jeghers, see p. 1197; LEOPARD/Noonan’s) (lentigines, ECG abnormalities, ocular hypertension, pulmonary stenosis, abnormalities of genitalia, retardation of growth and deafness). Solar lentigines (‘age spots’, ‘liver spots’) are common on the dorsal hands and face and on bald scalps in older, fair-skinned people.

Café-au-lait macules

These may occur as an isolated abnormality. Multiple lesions are also a feature of neurofibromatosis types 1 and 2, tuberous sclerosis, ataxia telangiectasia, multiple endocrine neoplasia type 1 and McCune–Albright syndrome.

Melasma (chloasma)

This is a common complaint in pregnant women and in women taking hormonal contraception. Asymptomatic beige–brown patches develop on the forehead, temples and cheeks. Topical azelaic acid, retinoic acid or 2–5% hydroquinone may help reduce pigmentation. Meticulous sun protection with high SPF sunscreens is needed to prevent relapse.

Post-inflammatory hyperpigmentation

This phenomenon occurs in dark-skinned individuals at the sites of skin trauma or inflammatory rashes, such as acne, lichen planus and eczema. It improves slowly over many months.

Metabolic/endocrine effects

Generalized skin darkening can occur with chronic liver disease, especially haemochromatosis (see p. 1300), and endocrine disease.

Urticaria pigmentosa (cutaneous mastocytosis)

This disorder is caused by a benign proliferation of cutaneous mast cells. It presents most commonly in childhood as multiple pigmented macules that become red, itchy and urticated if they are rubbed (Darier’s sign), and occasionally blister. Extensive mast cell degranulation can lead to systemic symptoms, such as wheeze, flushing, syncope, diarrhoea and, very rarely, anaphylaxis. This may be considered in people from endemic regions. Lesions may also show hair loss and decreased sweating.
be triggered by drugs, including aspirin and opiates, and allergens. Childhood urticaria pigmentosa usually resolves spontaneously but adult-onset disease is often persistent. Histology of skin lesions shows increased numbers of mast cells. Most cases are due to somatically acquired activating mutations of the KIT receptor that controls mast cell proliferation and apoptosis. Rarely, in adult and neonatal disease, mast cell infiltration may involve internal organs (bone, gastrointestinal tract, liver, spleen — systemic mastocytosis). There is a small risk of developing mast cell leukaemia. Treatment of cutaneous mastocytosis is aimed at controlling the symptoms of mast cell mediator release with antihistamines and cromoglicate, and minimizing the risk of anaphylaxis.

## NAIL DISORDERS

- **Psoriasis** (see p. 664), **fungal infection** (p. 672) and **trauma** are the most common causes of abnormal nail growth (dystrophy).
- **Pitting** can be caused by psoriasis, alopecia areata, atopic eczema and trauma.
- **Onycholysis** (distal nail plate separation) is caused by psoriasis, thyrotoxicosis, trauma and, rarely, a phototoxic drug reaction (e.g. with tetracyclines).
- **Koilonychia** (thin, spoon-shaped nails) can be caused by iron deficiency anaemia.
- **Leuconychia** (white nails) is seen in hypoalbuminaemia.
- **Beau’s lines** (transverse lines) are horizontal grooves in the nail due to a temporary growth arrest associated with an acute severe illness.
- **Yellow-nail syndrome** is a rare disorder based on the triad of thickened, slow-growing, yellow nails, pulmonary manifestations (cough, bronchiectasis, pleural effusion) and lower limb lymphoedema.
- **Subungual hyperkeratosi** is thickening of the nail plate, usually due to tinea infection (see p. 673), psoriasis, trauma or a combination of these.
- **Onychogryphosis** is severe nail thickening and curvature (ram’s horn), which is common in the elderly, especially in the big toe-nail, where trauma from ill-fitting footwear may be relevant.
- **Longitudinal melanonychia** (brown streaks) of multiple nails is a common finding in dark-skinned people. An acquired solitary pigmented streak may be caused by a melanocytic naevus and needs to be differentiated from subungual melanoma (see p. 688), especially if the pigmentation spreads on to the adjacent nail fold (‘Hutchinson’s sign’).
- **Subungual haemorrhage** is common in the great toe-nails after trauma (football, running downhill). The red–brown pigmentation grows out with the nail over several months with clear proximal growth.
- **Clubbing** is discussed on page 937.

Nail dystrophy is also a feature of various genodermatoses including **nail patellar syndrome**, **ectodermal dysplasias** (abnormal hair, teeth and nail) and **pachyonychia congenita**.

## HAIR DISORDERS

### Hair loss (alopecia)

There are many causes of hair loss, or alopecia (Box 22.30). They are broadly divided into localized and diffuse patterns, and non-scarring alopecia (where follicles are preserved) and scarring alopecia (where an inflammatory process causes permanent destruction of follicles). Patients may complain of increased hair shedding and/ or thinning. Dermoscopic (trichoscopic) examination can help to identify whether follicles are still present and histology of scalp biopsies is helpful when there is diagnostic uncertainty.

### Androgenic alopecia

Androgenic alopecia (male-pattern baldness) is the most common cause of non-scarring hair loss and a feature of normal human ageing. It is thought to be caused by a genetically determined increased sensitivity to androgens and there is often a positive family history. It may present in adolescence with a receding frontal hairline, followed by thinning over the vertex. Women may be similarly affected, but usually later in life, with milder loss and preservation of the frontal hair margin (female-pattern alopecia). If acne, hirsutism and menstrual disturbance are also present, there may be underlying polycystic ovary syndrome or an androgenic disorder.

**Treatment** options include topical minoxidil or oral 5-alpha-reductase inhibitors (finasteride or dutasteride). These can halt progression and may induce modest regrowth, if used early in disease and continued indefinitely. Approximately one-third of patients will not respond to either therapy. Finasteride is well tolerated but may cause sexual adverse effects, such as loss of libido in about 1% of men; it should not be taken or handled by pregnant women, as it can cause feminization of a male fetus. Oral antiandrogen therapy (e.g. cyproterone acetate or spironolactone) may help some women.

### Alopecia areata

Alopecia areata is a non-scarring hair loss disorder with a lifetime prevalence of about 2%. It is thought to be an organ-specific autoimmune disease of the hair follicle that occurs due to loss of hair follicle immune privilege. It is associated with other organ-specific autoimmune diseases and runs an unpredictable course ranging in severity from a temporary small, solitary patch of scalp hair loss (alopecia areata) to total loss of scalp hair (alopecia totalis) and, rarely, scalp and body hair (alopecia universalis). Hair loss can have a major impact on body image and quality of life, with associated depression and social isolation.

Alopecia areata usually presents in children or young adults with patches of baldness (Fig. 22.56). These may regrow spontaneously, to be followed by new areas of hair loss. The presence of broken hairs and ‘exclamation mark’ hairs (narrow at the scalp and wider...

Birth marks and neonatal rashes

and more pigmented at the tip) at the edge of a bald area is diagnostic. The nails may be pitted or roughened.

Management has no effect on the long-term disease course. Potent topical or injected steroids may trigger regrowth of localized patchy hair loss. Repeated application of a contact sensitizer (contact immunotherapy) such as diphencyprone can be helpful in more extensive disease. Oral JAK inhibitors have recently been shown to reverse hair loss in moderate to severe alopecia areata. In the UK, patients with extensive hair loss are eligible for prescribed wigs and may benefit from joining patient support groups.

Traction alopecia
This form of scarring hair loss is caused by mechanical damage to the hair follicle from pulling the hair back into a bun or tight plaits. It is more common in black Africans.

Telogen effluvium
This type of diffuse, non-scarring hair loss is associated with increased hair shedding and usually presents 2 or 3 months after pregnancy or a severe illness. It occurs when a larger percentage of scalp hairs enters the telogen phase of hair shedding at the same time. Spontaneous recovery is usual after a few months, though a chronic variant is recognized.

Metabolic causes of hair loss
Iron deficiency may be associated with increased hair shedding and hair thinning, and is a common finding in menstruating women who do not eat red meat. The exact relationship between serum iron or ferritin levels and optimum hair growth is unclear.

Dissecting cellulitis
This is a chronic scarring folliculitis of the scalp that predominantly affects black men and may be associated with severe acne and hidradenitis suppurativa. Crusted papules and pustules occur with underlying diffuse swelling (Fig. 22.57). Prolonged courses of anti-staphylococcal oral antibiotics such as rifampicin and clindamycin may be helpful. Treatment has been revolutionized by the use of oral propranolol to shrink infantile haemangiomas rapidly. Topical timolol may also be effective. The mechanism of action is unclear. Treatment needs to be continued for at least 6 months.

BIRTH MARKS AND NEONATAL RASHES

Infantile haemangiomas (strawberry naevus, cavernous haemangioma)
Infantile haemangiomas are the most common benign tumour of infancy with a prevalence of 4.5% (Fig. 22.58). They present shortly after birth as a single red, lumpy nodule that grows rapidly for the first few months. Multiple lesions can also occur. They resolve spontaneously over several years. Parental reassurance is usually all that is required.

Treatment is indicated for lesions associated with:

• visual obstruction or feeding difficulties
• ulceration or bleeding
• life-threatening lesions associated with high-output cardiac failure from vascular shunting or consumptive coagulopathy (Kasabach–Merritt syndrome).

Treatment has been revolutionized by the use of oral propranolol to shrink infantile haemangiomas rapidly. Topical timolol may also be effective. The mechanism of action is unclear. Treatment needs to be continued for at least 6 months.
Port-wine stain (naevus flammeus)

Port-wine stain (‘capillary haemangioma’) is not a true haemangioma but an abnormal dilation of dermal capillaries. It presents at birth as a flat, red area and is commonly found on the face. It does not improve and may become thickened with age. If the lesion occurs in the distribution of the first division of the trigeminal nerve, it may be associated with ipsilateral meningeal vascular anomalies that can cause epilepsy and even hemiplegia (Sturge–Weber syndrome). Periocular lesions may be associated with glaucoma and so ophthalmological follow-up is required.

Treatment of port-wine stains is with a vascular laser: for example, a pulsed dye laser. Facial lesions respond best but lesions can darken after several years and require retreatment.

Congenital melanocytic naevi

See page 688.

Mongolian blue spot

This appears in infants as a deep blue–grey, bruise-like area, usually over the sacrum or back (Fig. 22.59); it is occasionally mistaken for a sign of child abuse. Mongolian blue spot is due to the presence of melanocytes in the deeper dermis. It is very common in Oriental children, less common in black Africans and rare in Caucasians. It usually disappears by the age of 7 years.

Toxic erythema of the newborn (erythema neonatorum)

Toxic erythema of the newborn describes a common transient, blotchy, maculopapular rash in newborns. The rash is occasionally pustular and the child is not well, but the complaint resolves spontaneously within a few days.

Milia

‘Milk spots’ are small follicular epidermal cysts. These pinhead white papules are commonly found on the face of infants. They resolve spontaneously.

Nappy rash (‘diaper dermatitis’)

This is an irritant contact dermatitis caused by prolonged skin contact with faeces and urine. It is much less common nowadays due to the high absorbency of disposable nappies. The flexures are usually spared, which is a useful differentiating feature from atopic eczema. Satellite lesions around the edge may indicate secondary infection with Candida. A recalcitrant purpuric nappy rash in the groins and axillae should be biopsied to exclude rarer pathology such as Langerhans cell histiocytosis.

Management involves frequent changing of the nappy and regular application of a barrier cream.

Acrodermatitis enteropathica

This rare but distinctive rash (see p. 1244) is a manifestation of zinc deficiency, which can occur in three settings:

- an inherited defect in zinc transporter protein in the gastrointestinal tract (presents after breast-feeding finishes)
- low levels in breast milk in breast-fed infants (presents during breast-feeding)
- patients on total parenteral nutrition without adequate zinc replacement.

There is an erythematous, sometimes blistering, rash around the perineum, mouth, hands and feet. It may be associated with photophobia, diarrhoea and alopecia.

In the inherited form the rash presents when breast-feeding finishes, as breast milk usually has high levels of zinc that over-ride the poor absorption. These patients will need life-long oral zinc replacement therapy to improve the skin and ensure normal neurological development. The second type needs replacement only until breast-feeding finishes. The response to zinc is rapid and dramatic.

DRUG ERUPTIONS

Cutaneous adverse drug reactions are common and range from mild, and predictable, dose-related effects such as phototoxicity from doxycycline or mucocutaneous dryness from oral isotretinoin, to idiosyncratic, severe and life-threatening eruptions (severe cutaneous adverse drug reactions, SCAR). The diagnosis of drug eruptions can be challenging because individual drugs can cause different rashes and these sometimes mimic constitutional inflammatory rashes or viral rashes. The clinical features can also be mixed. A high index of suspicion and a detailed drug history are essential. Underlying viral infection, especially HIV, and systemic disease, such as systemic lupus and leukaemia, may also increase the risk of drug rashes (see Fig. 22.32). Allergy
tests (prick tests and patch tests) have a limited role, especially in the acute setting, and drug challenge tests are time-consuming and potentially risky.

**Maculopapular (morbilliform) exanthems**

These are the most common type of hypersensitivity rash (Fig. 22.60). They start on the torso and spread to the face and limbs, but spare the mucosae. They are self-limiting and usually clear within 1–2 weeks.

**Fixed drug eruptions**

These inflamed patches recur at the same site each time a drug is taken. They may blister, and often resolve with hyperpigmentation.

**Drug-induced and drug-exacerbated dermatoses**

Drugs may exacerbate pre-existing skin disease and can also trigger or induce skin disease that resembles a constitutional dermatosis (Box 22.31).

**Severe cutaneous adverse drug reactions**

Severe drug rashes are listed in Box 22.32. Common causes include antibiotics, NSAIDs, anticonvulsants, allopurinol, dapsone and nevirapine. Early recognition and drug withdrawal can minimize morbidity and mortality. Recent advances in pharmacogenetics have identified human leucocyte antigen (HLA) associations, and cytochrome P450 polymorphisms that are associated with an increased risk of reaction to certain drugs.

**Stevens–Johnson syndrome and toxic epidermal necrolysis**

Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are severe mucocutaneous disorders that are considered variants of a disease spectrum. They are characterized by varying extents of blistering/epidermal detachment and mucosal ulceration (see Box 22.19):

- **SJS**: <10% skin detachment; one or two mucosal sites involved (oral, genital, ocular)
- **SJS–TEN** overlap: 10–30% skin detachment
- **TEN**: >30% skin detachment; all mucosal sites involved in most cases.

The onset is usually 1–2 weeks after drug exposure. Initial symptoms are non-specific (malaise, myalgia, fever and cough). These are followed by tender maculopapular erythematous lesions on the torso and inflamed mucosal surfaces. Target lesions usually affect the hands and feet in SJS. In TEN there is widespread flaccid blistering with skin that wrinkles like wet wallpaper on gentle pressure (Nikolsky’s sign). Features of skin failure can ensue (see p. 657). Respiratory mucosal and pulmonary involvement may require ventilation, and upper gastrointestinal involvement can cause haemorrhage. Patients are at high risk of sepsis and require expert intensive supportive care, as for extensive burns. Multiorgan failure may occur and the mortality for TEN ranges from 30% to 50%. ‘SCORTEN’ is
a clinical severity score that can help assess prognosis (Box 22.33). All potential causative drugs should be stopped.

**Drug reaction with eosinophilia and systemic symptoms/drug hypersensitivity syndrome**

Drug reaction with eosinophilia and systemic symptoms (DRESS)/drug hypersensitivity syndrome usually starts 2–6 weeks after initial exposure and is characterized by widespread erythema, facial oedema, fever, lymphadenopathy and hepatosplenomegaly. Blood eosinophilia is usual with elevated hepatic transferases. Pneumonia and nephritis can develop and a mortality rate of 10% has been reported. Treatment is with systemic steroids tapered over at least 3 months. Aromatic anticonvulsants are one of the most common causes of DRESS and, as they cross-react, all drugs of this group must be avoided in the future. Sodium valproate is a suitable alternative.

**Acute generalized exanthematous pustulosis/toxic pustulodermia**

Acute generalized exanthematous pustulosis (AGEP)/toxic pustuloderma is an exanthem with numerous small, non-follicular, sterile pustules around the neck, axillae and groin. It usually starts a few days after drug exposure and resolves with peeling. There may be mild systemic upset but internal organs are not involved. Localized forms can occur. Florid cases can resemble pustular psoriasis. Topical steroids and emollients can be used to relieve symptoms.

Diabetes is the most prevalent and clinically important endocrine disorder, affecting around 10% of the adult population in most countries. Many go on to develop life-limiting complications including cardiovascular, renal, eye and neurological disease. Most consultant diabetologists will be trained in both diabetes and endocrinology as well as general internal medicine; although many diabetes specialists focus solely on diabetes. Some sub-specialize in areas including inpatient care, diabetes in pregnancy, technology (insulin pumps and continuous glucose monitoring), and pancreas or islet-cell transplantation.

Most people with diabetes will be seen in outpatient clinics either in primary or secondary care, although approximately 15% of all inpatients have diabetes. Many are admitted for other reasons but diabetes may complicate their hospital stay.

Key skills within diabetes include:
- listening to people with diabetes (as with any patient with a long-term condition), and involving them actively in the management of their illness, and understanding the role of the multidisciplinary team in preventing and managing long-term diabetic complications
- learning about the acute management of diabetic emergencies (hypoglycaemia, diabetic ketoacidosis and hyperosmolar, hyperglycaemic state)
- developing confidence in prescribing insulin therapy and the wide range of oral hypoglycaemic agents

Diabetes is best learned in outpatient settings by listening to people with diabetes. As diabetes is a long-term condition, there is an opportunity to build up long-term patient relationships. Diabetic emergencies are common reasons for admission to hospital and people presenting with these may be found in the hospital emergency department or acute admissions unit.

**CORE SKILLS AND KNOWLEDGE**

Diabetes mellitus is a chronic condition and people with diabetes may present to healthcare services for routine monitoring of their condition, or for a host of reasons related or unrelated to their diabetes. Treatment for diabetic emergencies, which may be the presentation when diabetes is first diagnosed, is covered on page 722. This section outlines an approach to people with diabetes in non-emergency settings (Box 23.1).

**CLINICAL SKILLS FOR DIABETES MELLITUS**

Diabetes mellitus is a chronic condition and people with diabetes may present to healthcare services for routine monitoring of their condition, or for a host of reasons related or unrelated to their diabetes. Treatment for diabetic emergencies, which may be the presentation when diabetes is first diagnosed, is covered on page 722. This section outlines an approach to people with diabetes in non-emergency settings (Box 23.1).

**Routine checks in people with diabetes**

All people with diabetes should be screened regularly to assess for their level of glycaemic control and the emergence of any complications. Box 23.2 shows the checks (covering history, examination and selected investigations) that should form part of the annual screening process.
700 Diabetes mellitus

Examination

The physical examination carried out in people with diabetes will be determined by the clinical context and any presenting complications. The figure presents a range of physical signs seen in people with diabetes: some are a direct result of complications of hyperglycaemia, and some are conditions associated with diabetes (e.g. vitiligo, an autoimmune disease sometimes found in people with type 1 diabetes). Box 23.3 lists features to look for when examining the feet of a person with diabetes.

Box 23.1 Taking a history in diabetes mellitus (see also Box 1.7)

Presenting complaint
- Why has the patient attended?
- Could their presenting complaints be related to a complication of diabetes?

Diagnosis of diabetes
- When were they diagnosed?
- Did they present as an emergency, or with symptomatic hyperglycaemia, or was diabetes picked up without symptoms through routine screening?
- What type of diabetes do they have?
  - Might it be secondary to another disease process (p. 704)?
  - Is there any reason to suspect monogenic diabetes (p. 709)?

Management of the disease
- What do they understand about the role of self-management in diabetes?
- Do they monitor their capillary or interstitial glucose?
  - Do they keep a diary of the results?
  - What are the usual readings?
  - Is there evidence of hypoglycaemia or hyperglycaemia?
- Have they ever required hospital (or intensive care) admission for diabetic emergencies?
- Do they ever suffer from hypoglycaemic episodes?
  - Are they aware if they are becoming hypoglycaemic?
  - Have they needed external help to manage an episode of hypoglycaemia?
- Do they drive, or engage in any other activities that may raise safety concerns in the context of hypoglycaemia?

Medications
- Do they see a primary care clinician or hospital specialist to manage their diabetes?
  - Are they in contact with a specialist nurse or dietitian?
- What medication do they use to control their blood glucose?
- If they inject insulin, do they rotate injection sites?
  - What size needles do they use?
- Are they able to adjust doses of insulin or other medications according to blood glucose levels and carbohydrate intake?
- What other medications are they taking?

Complications
- Have they suffered any cardiovascular events?
  - What is their cardiovascular risk, and is this being appropriately managed?
- Are they undergoing regular retinal screening?
  - Have they required any retinal intervention?
- Do they supply regular urine samples to screen for diabetic nephropathy?
  - Are they taking ACE inhibitors or angiotensin receptor blockers?
- Have they had any problems with neuropathy or vascular disease affecting their feet?
  - Have they experienced a foot ulcer?
  - Have they needed an amputation?

Social history
- Do they smoke? If so, have they tried to quit?
- Are they aware of key lifestyle interventions around healthy eating, weight reduction and exercise?

Box 23.2 Annual screening checks in people with diabetes

**General health**
- Level of knowledge about diabetes
- Weight and BMI
- Diet and eating habits
- Exercise

**Glycaemic control**
- Glycated haemoglobin (HbA\textsubscript{1c})
- Glucose monitoring
- Medication
- Review of insulin injection sites

**Development of complications**
- Retinal screening, ideally by retinal photography
- Visual acuity
- Urine albumin : creatinine ratio (ACR)
- Serum urea and electrolytes; estimated glomerular filtration rate (eGFR)
- Examination of feet for vascular disease and neuropathy
- Full blood count
- Thyroid function
- Liver function

**Cardiovascular risk**
- Smoking status
- Blood pressure
- Lipid profile
- Overall cardiovascular risk using validated risk model, e.g. QRISK

Box 23.3 Examination of feet

**Features of vascular disease**
- Pale discoloration
- Loss of hair
- Cool temperature
- Absent pulses (begin in foot and proceed up legs)
- Reduced capillary refill time
- Evidence of gangrene or infection

**Features of neuropathy**
- Clawing of toes, loss of plantar arch
- Neuropathic ulcers
- Joint deformity (Charcot’s joint)
- Glove and stocking sensory loss (check with monofilament)
- Loss of vibration sense, proprioception and pain
- Loss of ankle jerk
Clinical skills for diabetes mellitus

**Aims of physical examination in diabetic patients:**

* Assessing for diabetic emergencies - diabetic ketoacidosis, hypoglycaemia.
* Establishing the presence of complications - neuropathy, eyes and retinopathy, kidney disease, skin changes including ulceration, cardiovascular disease including peripheral vascular disease, foot complications, soft tissue infection.
* Assessment of cardiovascular risk factors — blood pressure, stigmata of hyperlipidaemia, weight and Body Mass Index
* Revealing signs of auto-immune disease — vitiligo, thyroid disease
* Assessment of injection sites

**Eyes**

- Fundoscopy - Cataracts, against red reflex
- Retinopathy (p. 726)
- Visual acuity

**Eyelids** — xanthelasma

**Mouth**

- Candidiasis

**Insulin injection sites**

- Bruising
- Lipohypertrophy
- Lipatrophy (rare)

**Hips**

- Carpal tunnel
- Dupuytren’s contracture
- Muscle wasting
- Limited joint movement

**Feet**

- Feel for peripheral pulses
- Skin — colour, ulcers, gangrene
- Look between toes for infection
- Sensory loss
- Neuropathic foot ulcer
- Charcot neuroarthropathy

**General observation**

- Does patient look well/unwell?
- Weight loss (T1DM)
- Weight gain (T2DM)
- Dehydrated?
- Breathing (air hunger, Kussmaul breathing)

**Face**

- Cranial nerve palsy, particularly CNIII
- Eye movements
- Ptosis

**Neck**

- Carotid pulses/bruits
- Check thyroid gland for goitre (autoimmune)

**Hands**

- Carpal tunnel
- Dupuytren’s contracture
- Muscle wasting
- Limited joint movement

**Dupuytren’s contracture**

(From Palastanga N. Anatomy and Human Movement, 6th edn, with permission.)

**Abdomen**

- Hepatomegaly (fatty liver)

**Skin**

- Vitiligo (autoimmune)
- Pigmentation (e.g. axillary acanthosis nigricans in insulin resistance)
- Granuloma annulare
- Bullosis

**Vitiligo**

(From Palastanga N. Anatomy and Human Movement, 6th edn, with permission.)

**Legs**

- Muscle wasting
- Hair loss
- Sensory neuropathy (glove and stocking)
- Reflexes (lost in sensorimotor neuropathy)
- Necrobiosis lipoidica

**Feet**

- Neuropathic ulcer

(From Miller MD. Presentation, Imaging and Treatment of Common Musculoskeletal Conditions, Saunders 2011, with permission.)
INTRODUCTION

Diabetes mellitus is a complex metabolic disorder characterized by chronic hyperglycaemia due to relative insulin deficiency, resistance or both. In 2017, the International Diabetes Federation estimated that 425 million people (1 in 11 of the global population) had diabetes, and estimates an increase to 693 million by 2045 (Fig. 23.1).

Diabetes is associated with a number of short- and long-term complications that reduce quality of life and life expectancy, and are associated with major health costs. These include acute metabolic disturbance, macrovascular disease (leading to an increased prevalence of coronary artery disease, peripheral vascular disease and stroke), and microvascular damage causing retinopathy, nephropathy and neuropathy.

Diabetes was responsible for approximately 4 million deaths or 10.7% of all deaths in 2017, outnumbering the combined number of global deaths from human immunodeficiency virus (HIV)/acquired immune deficiency syndrome (AIDS), tuberculosis and malaria. A diagnosis of diabetes in a man or woman at the age of 55 years reduces life expectancy by 5 and 6 years, respectively. By contrast, type 2 diabetes diagnosed after the age of 80 years has a limited effect on life expectancy. Heart disease is the most common cause of death and accounts for two-thirds of all deaths in people with diabetes aged 65 years or older.

PHYSIOLOGY OF INSULIN
STRUCTURE, SECRETION AND ACTION

Insulin is the key hormone involved in the regulation of cellular energy supply and macronutrient balance derived from food. It is a 51-amino acid peptide hormone comprising two polypeptide chains, the A and B chains (Fig. 23.2), and is synthesized in the β cells of the pancreatic islets of Langerhans (Fig. 23.3). The synthesis, intracellular processing and secretion of insulin by the β cell is typical of the way that the body produces and manipulates many peptide hormones. Fig. 23.4 illustrates the cellular events triggering the release of insulin-containing granules. After secretion, insulin enters the portal circulation and is carried to the liver, its prime target organ. About 50% of secreted insulin is extracted and degraded in the liver; the remainder is broken down by the kidneys. C-peptide is only partially extracted by the liver (and hence provides a useful index of the rate of insulin secretion) but is mainly degraded by the kidneys.

Insulin is secreted at a slow background rate throughout the day, resulting in a low plasma insulin concentration between meals and overnight. In response to eating, there is a rapid rise in circulating insulin concentration, which falls back to baseline within 2 hours (Fig. 23.5).

The insulin receptor

Insulin exerts its actions through binding to a receptor, which straddles the cell membrane of many cells (Fig. 23.6). The receptor comprises a dimer with two α-subunits, which include the binding sites for insulin, and two β-subunits, which traverse the cell membrane. When insulin binds to the α-subunits, it induces a conformational change in the β-subunits, resulting in activation of tyrosine kinase and initiation of a cascade response involving a host of other intracellular substrates. The insulin-receptor complex is then internalized by the cell, insulin is degraded, and the receptor is recycled to the cell surface.

Glucose metabolism

Blood glucose levels are tightly regulated in health and rarely stray outside the range of 3.5–8.0 mmol/L (63–144 mg/dL),
Physiology of insulin structure, secretion and action

Fig. 23.2 Amino acid structure of insulin. (A) Human insulin. (B) Modification of human insulin produces rapid-acting insulin analogues. Lispro is created by reversing the order of the amino acids proline and lysine in positions 28 and 29 of the B chain. Aspart is a similar analogue created by replacing proline at position 28 of the B chain with an aspartic acid residue. Glulisine is a similar analogue created by replacing asparagine at position B3 with lysine and the lysine in position B29 is replaced by glutamic acid. (C) Modification of human insulin produces long-acting insulin analogues. Insulin glargine is created by replacing asparagine in position 21 of the A chain with a glycine residue and adding two arginines to the end of the B chain. Detemir discards threonine in position 30 of the B chain and adds a fatty acyl chain to lysine in position B29. Degludec is created by removing the threonine at position 30 of the B chain and the attachment, via a glutamic acid linker of a 16-carbon fatty diacid to the lysine at position 29 of the B chain.

despite the widely varying effects of food, fasting and exercise. Tight control of glucose is necessary because some tissues, particularly the brain, are highly dependent on glucose as an energy source while high glucose concentration irreversibly damages cellular proteins.

The principal organ of glucose homeostasis is the liver, which absorbs and stores glucose (as glycogen) in the post-absorptive state and releases it into the circulation between meals to match the rate of glucose utilization by peripheral tissues. The liver also combines three-carbon molecules derived from breakdown of fat (glycerol), muscle glycogen (lactate) and protein (e.g. alanine) into the six-carbon glucose molecule by the process of gluconeogenesis.

Glucose production

More than 90% of the approximately 200 g of glucose utilized daily is derived from liver glycogen and hepatic gluconeogenesis, with the remainder coming from renal gluconeogenesis.

Glucose utilization

The major consumer of glucose is the brain, whose function depends on an uninterrupted supply of this substrate. Its
requirement is 1 mg/kg body weight per minute, or approximately 100 g daily in a 70 kg person. Glucose uptake by the brain is obligatory and is not dependent on insulin, and the glucose used is oxidized to carbon dioxide and water. Tissues such as muscle and fat have insulin-responsive glucose transporters and absorb glucose in response to postprandial peaks in glucose and insulin. At other times, energy requirements are largely met by fatty acid oxidation. Glucose taken up by muscle is stored as glycogen or metabolized to lactate or carbon dioxide and water. Fat uses glucose as a substrate for triglyceride synthesis; lipolysis releases fatty acids from triglyceride together with glycerol, a substrate for hepatic gluconeogenesis.

**Glucose transport**

Cell membranes are not inherently permeable to glucose. A family of specialized glucose-transporter (GLUT) proteins carry glucose through the membrane into cells. The function of GLUT-1 to -3 is insulin-independent but insulin stimulates glucose uptake into muscle and adipose tissue through GLUT-4. GLUT-4 is normally present in the cytoplasm, but after insulin binds to its receptor, GLUT-4 moves to the cell surface where it creates a pore for glucose entry (see Fig. 23.6).

**Hormonal regulation**

Insulin is a major regulator of intermediary metabolism but its actions in the fasting and postprandial states differ (Fig. 23.7). In the fasting state, insulin’s main action is to regulate glucose release by the liver, while in the postprandial state, it additionally promotes glucose uptake by fat and muscle.

A number of ‘counter-regulatory hormones’ that antagonize the action of insulin are also important in maintaining normoglycaemia. As glucose concentration falls below the normal range, glucagon is secreted from the pancreatic α-cells. At the same time, a number of other hormones, including noradrenaline (norepinephrine), cortisol and growth hormone, are released. These counter-regulatory hormones increase hepatic glucose production and reduce its utilization in fat and muscle for any given insulin concentration.

**CLASSIFICATION OF DIABETES**

Diabetes may be primary (idiopathic) or secondary (Box 23.4). Gestational diabetes refers to glucose intolerance appearing for the first time in pregnancy and is described in more detail on page 740. Primary diabetes is classified into:

- **Type 1 diabetes**, which usually has an immune pathogenesis and is characterized by severe insulin deficiency.
- **Type 2 diabetes**, which results from a combination of insulin resistance and less severe insulin deficiency.

Secondary diabetes can be subdivided into:

- diabetes secondary to genetic defects
- diabetes secondary to exocrine pancreatic disease
- diabetes secondary to endocrine disease
- diabetes secondary to drugs and chemicals
- diabetes secondary to infection
- uncommon forms of immune-mediated diabetes
- other genetic syndromes sometimes associated with diabetes.

Box 23.5 lists the key features of the different types of diabetes. Type 1 diabetes and type 2 diabetes represent two distinct diseases from the epidemiological point of view, but from a clinical perspective, the two conditions appear as a spectrum – distinct at the two ends but overlapping in the middle.

Approximately 1–3% of cases of diabetes diagnosed under the age of 30 years are caused by mutations in a single gene (monogenic mutation). Although uncommon, it is important to recognize because the treatments and implications are different from type 1 diabetes or type 2 diabetes.

All forms of diabetes result from inadequate insulin secretion relative to the body’s needs, and progressive insulin secretory failure is characteristic of both common forms of diabetes. Thus, some people with immune-mediated type 1 diabetes may not require insulin at the point of diagnosis, whereas many with type 2 diabetes will eventually do so.

**Type 1 diabetes mellitus**

**Epidemiology**

Type 1 diabetes is a disease of insulin deficiency and accounts for 5–10% of all cases of diabetes. It typically presents in
classification of diabetes

childhood and young adulthood, reaching a peak incidence around the time of puberty, but can present at any age. In 2017, globally over a million children and adolescents had type 1 diabetes with approximately 132,600 new cases every year. The incidence of type 1 diabetes varies dramatically throughout the world, with the highest rates being in northern Europe and the Middle East.

Type 1 diabetes is subdivided into type 1A (immune-mediated) and type 1B (non-immune-mediated). The vast majority of those affected, especially in Western countries, have type 1A disease. A ‘slow-burning’ variant with slower progression to insulin deficiency occurs in later life and is termed latent autoimmune diabetes in adults (LADA).
Aetiology

Type 1 diabetes belongs to a family of immune-mediated organ-specific diseases, which include autoimmune thyroid disease, coeliac disease, Addison’s disease and pernicious anaemia. The precise molecular mechanisms that lead to type 1 diabetes are incompletely understood but involve the triggering of a selective autoimmune destruction of the insulin producing cells of a genetically predisposed individual. Initially, autoantibodies directed against pancreatic islet constituents appear in the circulation and often predate clinical onset by many years. The islet antigens include insulin itself, the enzyme glutamic acid decarboxylase (GAD), protein tyrosine phosphatase (IA-2, also known as ICA512), the cation transporter ZnT8 and tetraspanin 7 (Fig. 23.8).

This is followed by a phase of asymptomatic loss of β cell secretory capacity; histologically, this is characterized by a chronic inflammatory mononuclear cell infiltrate of T lymphocytes and macrophages in the islets, known as insulitis (Fig. 23.9). Eventually, when the remaining β cells are no longer able to produce enough insulin to meet the body’s needs, diabetes symptoms start to develop.

Some recovery of endogenous insulin secretion may occur over the first few months after diagnosis and treatment initiation (the ‘honeymoon period’). During this time, the insulin dose may need to be reduced or even stopped. Recent studies have shown that some people with type 1 diabetes continue to produce small amounts of insulin for many decades after diagnosis. It is unclear why this occurs but it seems that strict glucose control from diagnosis can prolong β cell function.

The ability to detect autoantibodies in children prior to the development of type 1 diabetes is paving the way for trials to prevent the disease by immune modulation, but these interventions are still in early development.

Genetic susceptibility and inheritance

Increased susceptibility to type 1 diabetes is inherited but the disease is not genetically predetermined. The identical twin of a person with type 1 diabetes has a 30–50% chance of developing the disease, which implies that non-genetic factors must also be involved. The risk of developing diabetes by age 20 years is greater with a father with diabetes (5–7%) than with a mother with diabetes (2–5%). If one child in a family has type 1 diabetes, each sibling has a 4–6% risk of developing diabetes. This risk rises to about 20% in siblings with the same human leucocyte antigen (HLA) genotype as the proband.
Human leucocyte antigen system

Genetic susceptibility is polygenic but the greatest contribution comes from polymorphisms in the HLA region. HLA genes are highly polymorphic and modulate the body’s immune defence system. More than 90% of people with type 1 diabetes carry HLA-DR3-DQ2, HLA-DR4-DQ8 or both, as compared with some 35–40% of the background population. By contrast, certain HLA alleles confer protective effects, for example DQB1*0602.

Other genes or gene regions

Genome-wide association studies have greatly broadened our understanding of the genetic background to type 1 diabetes and have identified more than 50 non-HLA genes or gene regions that influence risk to a minor extent. These include the gene encoding insulin and other genes involved in immune responses.

Environmental factors

Despite the genetic susceptibility to type 1 diabetes, 80–90% of people with newly diagnosed type 1 diabetes do not have a close family history of diabetes and only 10% of individuals with HLA-susceptible genes develop type 1 diabetes. This implies that genetic factors do not account entirely for the development of type 1 diabetes, and environmental triggers are also important.

A large number of putative environmental factors have been identified but none of these is either necessary or sufficient to cause type 1 diabetes. These include:

- **maternal factors**, such as gestational infection and older age
- **viral infections**, including enteroviruses such as Coxsackie B4
- **exposures to dietary constituents**, such as early introduction of cow’s milk and relative deficiency of vitamin D
- **environmental toxins**, e.g. alloxan, Vacor
- **childhood obesity**
- **psychological stress**.

**Fig. 23.9** Pancreatic islet showing infiltration by chronic inflammatory cells (insulitis).
How these environment factors interact with the immune system is uncertain and there are several theories to explain this:

- The environmental factor damages the β cells leading to presentation of self-antigens to the T-helper cells, which trigger the autoimmune response against the remaining healthy β cells.
- The self-antigens may be modified and become antigenic.
- An immune response against the environment factor may cross-react with self-antigens, so-called ‘molecular mimicry’.
- The ‘hygiene hypothesis’ proposes that a cleaner environment with less early stimulation of the immune system in childhood may lead to a relatively immature immune system prone to autoimmunity.

### Type 2 diabetes mellitus

**Epidemiology**

Type 2 diabetes is the most common form of diabetes, accounting for around 90% of all cases; it is also one of the most common non-communicable diseases. The prevalence of type 2 diabetes is rising rapidly because of a combination of population growth, an ageing population and longer survival with type 2 diabetes, earlier age at onset and better diagnosis. Type 2 diabetes is a disease of nutrient excess and the incidence has increased with the obesity epidemic, poor quality diet and reduced physical activity.

The prevalence of type 2 diabetes varies markedly across the world with the highest rates being in the Middle East and Pacific Islands, and lowest in Africa and Europe. Although often viewed as a disease of affluence, around three-quarters of those with type 2 diabetes live in low- and middle-income countries and the most rapid rise in incidence is occurring in countries with rapidly growing economies, such as India and China. Two-thirds of people with diabetes live in urban areas.

**Aetiology**

**Genetic susceptibility and inheritance**

Identical twins of people with type 2 diabetes have more than a 50% chance of developing diabetes; the risk to non-identical twins or siblings is approximately 25%, confirming a strong inherited component to the disease. Type 2 diabetes is a polygenic disorder and, as with type 1 diabetes, genome-wide studies of association between common DNA variants and disease have allowed identification of numerous susceptibility loci. Several of these loci define β cell development or function, and there is no overlap with the immune function genes identified for type 1 diabetes. Transcription factor-7-like 2 (TCF7-L2) is the most common variant observed in type 2 diabetes in Europeans, and KCNQ1 (a potassium voltage-gated channel) in Asians. Most of the identified genetic markers exert very modest risk and together explain less than 20% of the heritability of type 2 diabetes.

**Ageing**

Pancreatic β-cell function declines with age and so the incidence of type 2 diabetes increases with age; most people are diagnosed after the age of 40 and one-third of those living with type 2 diabetes are older than 65. However, type 2 diabetes is becoming increasingly common in children and young adults.

**Fetal origins of diabetes**

There is a J-shaped relationship between low weight at birth and at 12 months of age and glucose intolerance later in life, particularly in those who gain excessive weight in adulthood. The concept is that poor nutrition early in life impairs β-cell development and function, predisposing to diabetes later on. Low birth weight also predisposes to a number of other chronic diseases in adulthood including heart disease, hypertension and osteoporosis.

**Obesity**

Obesity increases the risk of type 2 diabetes up to 80–100-fold and accounts for 80–85% of the overall risk of developing type 2 diabetes. In Western Europe and North America, 80–90% of adults with type 2 diabetes are overweight and nearly a half are obese. A central distribution of fat increases the risk of type 2 diabetes, and so for any given level of obesity, the more visceral fat an individual has, the higher the risk of type 2 diabetes.

**Diet**

Although diet can affect the risk of diabetes through changes in body weight, certain dietary patterns are associated with higher or lower risks of type 2 diabetes. Components that increase the risk include: dietary fat, particularly saturated fat, red and processed meat, consumption of fried food, including French fries, increased intake of white rice and sugar-sweetened beverages. Wholegrains, increased fruit and vegetable intake, fermented dairy products, oily fish and a Mediterranean dietary pattern are associated with lower rates of type 2 diabetes.

**Physical inactivity**

Physical inactivity and sedentary behaviour are also associated with an increased risk of diabetes.

**Other factors**

Other risk factors include urbanization, poverty, abnormal sleep patterns, environmental toxins and mental illness.

**Pathogenesis**

The relative role of defects in insulin secretion and action in the pathogenesis of type 2 diabetes has been much debated and likely differs between different people. However, both defects are necessary to develop diabetes.

**Abnormalities of insulin action**

Insulin action is diminished in type 2 diabetes through the development of insulin resistance, which is defined as the inability of insulin to produce its usual biological effects at physiological concentrations. It is characterized by an impaired ability of insulin to:

- inhibit hepatic glucose output
- stimulate glucose uptake into skeletal muscle, and
- suppress lipolysis in adipose tissue.

The underlying mechanisms of insulin resistance are not fully understood but result from nutrient excess. Intracellular triglyceride accumulates in the liver and skeletal muscle and impedes the phosphorylation of the post-receptor insulin receptor substrate, IRS-1. Although this defect reduces insulin action with regards to glucose and lipid metabolism, insulin is still able to activate the mitogen-activated protein (MAP) kinase pathway, which regulates a number of intracellular pathways involved in inflammation, cellular proliferation and atherosclerosis.

**Abnormalities of insulin secretion**

Insulin resistance alone does explain the development of diabetes as only one-fifth of those with the degree of insulin resistance characteristic of diabetes develop the condition. As insulin resistance develops, the body’s response is to increase insulin secretion and so early diabetes is often associated with insulin hypersecretion. This observation led some to question the role of β-cell function in the aetiology of diabetes. Nevertheless, insulin secretory abnormalities
manifest early in the course of type 2 diabetes and progress with time; an early sign is loss of the first phase of the normal biphasic insulin secretion. Even though circulating insulin concentrations are higher in people without diabetes, they are still inadequate to restore glucose homeostasis. By the time of diagnosis, at least 50% of β-cell mass and function has been lost. Relative insulin lack is associated with increased glucose production from the liver (owing to inadequate suppression of gluconeogenesis) and reduced insulin-mediated glucose uptake by peripheral tissues. Hyperglycaemia and lipid excess are toxic to β cells, at least in vitro, a phenomenon known as glucotoxicity, which is thought to cause further β-cell loss and further deterioration of glucose homeostasis. With time, insulin secretion declines, an observation referred to as the ‘Starling curve’ of the pancreas. This time course varies widely between individuals.

Type 2 diabetes is thus a condition in which insulin deficiency relative to increased demand leads to insulin hypersecretion by a depleted β-cell mass and progression towards absolute insulin deficiency, requiring insulin therapy.

Other hormonal abnormalities

Glucagon secretion is increased in type 2 diabetes, likely because of diminished intra-islet insulin, and leads to increased hepatic glucose output.

The insulin response to oral glucose is greater than the response to intravenous glucose, a phenomenon known as the incretin effect. The effect is mediated by two hormones, glucagon like peptide-1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP), which are released by the gastrointestinal tract following eating. Their major action is to increase glucose-induced β-cell insulin secretion, while suppressing glucagon secretion, but they also slow gastric emptying and induce satiety. Both hormones have short half-lives in the circulation, being degraded within minutes predominantly by the enzyme dipeptidyl peptidase-4 (DPP4). The incretin effect is impaired in type 2 diabetes.

Glucose reabsorption in the kidney

The sodium-glucose transporter 2 (SGLT2) is a sodium-dependent glucose transport protein located in the proximal renal tubules, whose function is to reabsorb glucose from the renal filtrate and restore it to the circulation. Its activity thus determines the renal threshold for glucose, which normally averages approximately 10–11 mmol/L (180–200 mg/dL). This prevents urinary glucose loss but is maladaptive in type 2 diabetes as this process is upregulated and serves to maintain hyperglycaemia.

Monogenic diabetes mellitus

Approximately 1–3% of people with diabetes diagnosed under the age of 30 years have monogenic diabetes, previously called ‘maturity-onset diabetes of the young’ (MODY (Box 23.6)). Monogenic diabetes is caused by a single gene mutation, which is dominantly inherited and predominantly affects β-cell function. Extra-pancreatic features may also be present. Many people with monogenic diabetes are misdiagnosed with either type 1 or type 2 diabetes and so monogenic diabetes should be considered in people presenting with early-onset diabetes in association with an affected parent, and early-onset diabetes in approximately 50% of relatives. It is likely that as awareness improves, the diagnosis rate will increase.

Type 1 diabetes does not present in children before 6 months of age and so infants who develop diabetes at this age are likely to have a monogenic defect. Transient neonatal diabetes mellitus occurs soon after birth and resolves at a median of 12 weeks; around 50% of people ultimately relapse later in life. Most have an abnormality of imprinting of the ZAC and HYMAI genes on chromosome 6q. The most common cause of permanent neonatal diabetes mellitus is mutations in the KCNJ11 gene encoding the Kir6.2 subunit of the β-cell potassium–adenosine triphosphate (ATP) channel.

Neurological features are seen in 20% of children. Diabetes results from defective insulin release rather than β-cell destruction, and can be treated successfully with sulphonylureas, even after many years of insulin therapy.

*The glucokinase gene is intimately involved in the glucose-sensing mechanism within the pancreatic β cell. The hepatic nuclear factor (HNF) genes and the insulin promoter factor-1 (IPF-1) gene control nuclear transcription in the β cell, where they regulate its development and function. Abnormal nuclear transcription genes may cause pancreatic agenesis or more subtle progressive pancreatic damage. A handful of families with autosomal dominant diabetes have been described with mutations in neurogenic differentiation factor-1 (NeuroD1).
CLINICAL APPROACH TO THE PATIENT WITH DIABETES

Presentation

Presentation may be acute, subacute or asymptomatic, or an individual may present with a complication of diabetes.

Acute presentation

Children and young adults often present with a 2–6-week history of the classic triad of symptoms:

- polyuria due to the osmotic diuresis that results when blood glucose levels exceed the renal threshold
- thirst and polydipsia due to the resulting loss of fluid and electrolytes
- weight loss due to fluid depletion and accelerated breakdown of fat and muscle secondary to insulin deficiency.

Ketonuria is often present in young people and may progress to ketoacidosis if these early symptoms are not recognized and treated.

Subacute presentation

The clinical onset may be prolonged over several months or years, particularly in older people. Thirst, polyuria and weight loss are usually present, but the individual may complain of other symptoms such as lack of energy, visual blurring (owing to glucose-induced changes in refraction), or pruritus vulvae or balanitis due to Candida infection.

Complications as the presenting feature

These include:

- staphylococcal skin infections
- retinopathy noted during a visit to the optician
- a polyneuropathy causing tingling and numbness in the feet
- erectile dysfunction
- arterial disease, resulting in myocardial infarction or peripheral gangrene.

Asymptomatic diabetes

It is estimated that approximately half of people with diabetes are unaware of their condition. This proportion varies across the world, from about a third in high-income countries to three-quarters in some low-income countries. Consequently, up to one-third of diagnoses are made as an incidental finding and several countries have introduced screening programmes to identify those with asymptomatic undiagnosed diabetes.

Physical examination at diagnosis

Evidence of weight loss and dehydration may be present, and the breath may smell of ketones. Older people may present with established complications. Occasionally, there will be physical signs of an illness causing secondary diabetes (see Boxes 23.4 and 23.5). People with severe insulin resistance may have acanthosis nigricans, which is characterized by blackish pigmentation at the nape of the neck and in the axillae (see Fig. 22.37). Hypertension is present in 50% of people with type 2 diabetes and in a higher proportion of people of African and Caribbean ethnicity.

Box 23.7 World Health Organization diagnostic criteria for diabetes

- Fasting plasma glucose > 7.0 mmol/L (126 mg/dL)
- Random plasma glucose > 11.1 mmol/L (200 mg/dL)
- HbA1c > 6.5% (48 mmol/mol)

One abnormal laboratory value is diagnostic in symptomatic individuals; two values are needed in asymptomatic people. The glucose tolerance test (see Box 23.8) is only required where there is diagnostic uncertainty and for diagnosis of cystic fibrosis-related diabetes and gestational diabetes.

aOnly a fasting and a 120-min sample are needed. Results are for venous plasma; whole-blood values are lower.
bAdult 75 g glucose in 300 mL water; child 1.75 g glucose/kg body weight.

Diagnosis and investigations

Once considered, diabetes is easy to diagnose. This may be by a laboratory measurement of fasting plasma glucose (FPG), random glucose or a 2-hour plasma glucose after a 75-g oral glucose tolerance test (OGTT). The use of glycated haemoglobin (HbA1c; also called A1c in the USA) was introduced as an alternative method in 2011. HbA1c is an integrated measure of an individual’s prevailing blood glucose concentration over several weeks and is also used to guide treatment decisions.

Diabetes can be diagnosed if the fasting plasma glucose is higher than or equal to 7.0 mmol/L (126 mg/dL) or the random or 2-hour glucose tolerance test plasma glucose is more than or equal to 11.1 mmol/L (200 mg/dL) or the HbA1c is higher than or equal to 48 mmol/mol (6.5%).

When overt symptoms are present, only one biochemical test is needed but in the absence of clear symptoms, two abnormal glucose or HbA1c tests are required (Boxes 23.7 and 23.8). Fasting, 2-hour glucose and HbA1c identify slightly different populations of people with diabetes; that is, someone may be diagnosed by one criterion but not another. However, with time, people will eventually cross the diagnostic threshold for the other tests.

The diagnostic criteria recognize two further categories of abnormal glucose concentrations: impaired fasting glycaemia (IFG) and impaired glucose tolerance (IGT). Collectively these have been described as ‘pre-diabetes’ but this is not strictly accurate because the majority will never develop diabetes. Neither IFG nor IGT are clinical entities in their own right but they identify people who are at high risk of diabetes and cardiovascular disease. Individuals with IGT have a similar risk of cardiovascular disease as those with frank diabetes, but do not develop microvascular complications. Impaired fasting glucose (IFG) only overlaps with IGT to a limited extent, and the associated risks of cardiovascular disease and future diabetes are not directly comparable.
Impaired glucose tolerance can only be diagnosed with a glucose tolerance test (see Box 23.8) and is complicated by poor reproducibility of the key 2-hour value in this test. Impaired fasting glucose is defined as a fasting plasma glucose between 6.1 and 6.9 mmol/L (110–126 mg/dL) and has the practical advantage that it avoids the need for a glucose tolerance test. The ADA definition of IFG differs slightly from the WHO criteria in that the ADA threshold is 100 mg/dL (5.6 mmol/L).

Glycosuria cannot be used to diagnose diabetes, but requires further investigation. It is commoner in older people, who have an altered renal threshold for glucose. It may also occur in familial renal glycosuria, which is a monogenic disorder affecting function of the sodium–glucose co-transporter (SGLT2) and found in about 1:400 of the population.

Other investigations
No further tests are needed to diagnose diabetes, but measurement of C-peptide and islet auto-antibodies can help determine the type of diabetes. C-peptide can be measured in blood or urine; it is often present when type 1 diabetes is diagnosed but disappears with time and is a more useful investigation in people with a duration of diabetes longer than 5 years. Other routine investigations include urine testing for protein, a full blood count, urea and electrolytes, liver biochemistry and random lipids. The latter test is useful to exclude associated hyperlipidaemia and, if elevated, should be repeated as a fasting measurement after diabetes has been brought under control. Investigations of secondary causes of diabetes or associated autoimmune disease may be appropriate (see Box 23.4).

PREVENTION OF TYPE 2 DIABETES

A dramatic reduction in the incidence of adult-onset diabetes was documented during the Second World War when food was scarce. More recently, clinical trials in individuals with IGT have shown that it is possible to prevent or at least delay the development of type 2 diabetes by lifestyle and/or pharmacological interventions. The lifestyle interventions aim to reduce body weight, reduce dietary fat intake, in particular saturated fat, while increasing dietary fibre and moderate physical activity to approximately 30 minutes a day. Several drugs, including metformin and orlistat, reduce incident diabetes but these are less effective than lifestyle change and should be reserved for those who cannot change their lifestyle or whose glucose concentration continues to rise despite lifestyle change. Bariatric surgery to treat morbid obesity can normalize elevated blood glucose; the effect on glucose precedes weight loss, suggesting a direct metabolic effect of surgery, possibly mediated by gut hormones, as well as an effect of long-term weight loss.

Given limited healthcare resources, interventions are targeted at those at highest risk and who will benefit most. Several risk assessment algorithms are available to identify those at highest risk of diabetes. Measurement of blood glucose will identify people with IFG or IGT.

MANAGEMENT OF DIABETES

Aims of diabetes care
For most people, diabetes is a life-long condition. Except for a few hours a year spent in contact with healthcare professionals, the majority of people with diabetes will look after their condition themselves for most of the time. It is therefore vital that people develop the skills to manage their condition effectively. The aims of diabetes care and management are fourfold:

- Prevention of life-threatening diabetes emergencies, such as diabetic ketoacidosis and hypoglycaemia with effective management when they do occur
- Treatment of hyperglycaemic symptoms
- Minimization of long-term complications through screening and effective control of hyperglycaemia and other cardiovascular risk factors
- Avoidance of iatrogenic side-effects, such as hypoglycaemia.

Fortunately, individuals with diabetes usually do not experience life-threatening diabetes emergencies frequently (the incidence of diabetic ketoacidosis is roughly two episodes per 100 person-years while the rate of severe hypoglycaemia is ≈2.5 events per person-year) and hyperglycaemic symptoms are easily treated. Therefore, most of the discussions regarding diabetes management revolve around maintaining good diabetes control to prevent long-term complications whilst balancing the short-term adverse events associated with treatment. Hyperglycaemia drives microvascular complications and it is unsurprising that the impact of improved glucose control on small-vessel complications, such as retinopathy and nephropathy, has been compellingly demonstrated.

The Diabetes Control and Complications Trial (DCCT) compared standard and intensive insulin therapy in a large trial of young people with type 1 diabetes, some of whom had no evidence of retinopathy or microalbuminuria (primary prevention group) at the beginning of the trial and others who already had evidence of these complications (secondary prevention group). Despite intensive therapy, mean blood glucose levels were still 40% above the non-diabetic range, but even at this level of control, the risk of primary progression to retinopathy was reduced by 60%, nephropathy by 30% and neuropathy by 20% over 7 years with intensive insulin therapy. These benefits persisted beyond the end of the trial despite equivalent levels of glucose control in the post-trial period.

The UK Prospective Diabetes Study (UKPDS) compared standard and intensive treatment in a large trial in people with recently diagnosed type 2 diabetes. Intensive treatment was associated with a 25% overall reduction in microvascular disease end-points, a 33% reduction in albuminuria and a 30% reduction in the need for laser treatment for retinopathy in the more intensively treated people. Similar to the DCCT, these benefits persisted for many years after conclusion of the trial (the ‘legacy effect’). This study also showed blood pressure control to be equally necessary in the prevention of retinopathy, but there is no legacy effect and good blood pressure control needs to be maintained.

Although there is an association between glucose and large-vessel disease, which extends well into the glucose range of the...
general population, with no clear cut-off for risk, the benefits of reducing hyperglycaemia are less certain for macrovascular disease. In this context, we should remember that diabetes affects not only carbohydrate metabolism, but also lipid and protein metabolism. People with diabetes often have other cardiovascular risk factors, such as dyslipidaemia, hypertension and obesity, and these risk factors may play a more important role than hyperglycaemia. Both the DCCT and UKPDS studies showed a reduction in cardiovascular events in the post-trial follow-up period in the intensive treatment groups, suggesting that early control of hyperglycaemia may improve the long-term risk of cardiovascular disease.

In both the DCCT and UKPDS, the achieved levels of glycaemic control were above those of people without diabetes and so further trials were undertaken in people with type 2 diabetes to assess whether further lowering of glucose to normoglycaemia would yield greater benefits. These trials confirmed the benefits for microvascular disease but did not improve cardiovascular outcomes and in the Action to Control Cardiovascular Risk in Diabetes (ACCORD) study, more people died in the intensively treated group than the standard arm. Exactly why this occurred is uncertain, but it seems likely that any benefit of improved glucose control was outweighed by iatrogenic side-effects, such as hypoglycaemia and weight gain.

Most guidelines advocate HbA1c targets between 48 mmol/mol and 58 mmol/mol (6.5–7.5%) but as the benefits and risks of improved glycaemic control differ between people with diabetes, the actual glycaemic targets should be determined for each individual taking into account the factors shown in Box 23.9. Realistic goals should be agreed with each person, considering what is likely to be achievable. This applies particularly to older people and those with a limited prognosis.

### Role of self-management education

As the onus of diabetes management lies with the individual with diabetes, it is essential that the individual is equipped with the skills for this task. People with diabetes need to understand the risks of diabetes and the potential benefits of glycaemic control and other measures such as maintaining a lean weight, stopping smoking and taking care of their feet. If healthcare professionals do not provide accurate information, misinformation from others will take its place. In order to address this need, diabetes self-management education has become an important cornerstone of diabetes care, delivered by all members of the diabetes multidisciplinary team (Fig. 23.10). The education needs to be tailored to the individual by embracing a 'patient-centred approach'.

Structured educational programmes with a clear philosophy, such as ‘Dose Adjustment for Normal Eating’ (DAFNE), that employ trained facilitators using a written curriculum are seen as the gold standard. These programmes improve diabetes knowledge and quality of life, glycaemic control and reduce mortality. Education should not be viewed as a once-off inoculation and regular ongoing support and updates will be needed.

### Diet

Diet plays a key role in the management and clinical care of all people with diabetes. However, there has been a lot of controversy about what constitutes an ideal or optimal diet for a person with, or at risk of, diabetes. Previous guidance focused on the ideal macronutrient composition of the diet, but the latest guidance highlights the role of certain foods and dietary patterns. In common with the general population, people should be encouraged to eat more vegetables, fruits, wholegrains, fish, nuts and pulses while reducing the consumption of red and processed meat, refined carbohydrates and sugar-sweetened beverages. As no one diet is effective in managing diabetes, it is important to adopt an individualized approach taking into consideration the person’s personal and cultural preferences. Box 23.10 summarizes the latest Diabetes UK dietary recommendations for people with diabetes.
Importance of weight loss in type 2 diabetes

For many years, it was thought that type 2 diabetes was an incurable progressive condition; however, the latest evidence challenges this view. People who can be supported to lose 10–15 kg of body weight through lifestyle, pharmacological or surgical treatment can enter remission.

Bariatric or metabolic surgery (see p. 1252) is a treatment option for people with severe obesity. The National Institute for Health and Care Excellence (NICE) recommends consideration of surgery in those with a body mass index (BMI) higher than 40 kg/m², or in those with a BMI of more than 35 kg/m² and co-morbidities, such as diabetes. In the USA, the Food and Drug Administration (FDA)-recommended BMI thresholds are lower. The most common operations are gastric bypass and sleeve gastrectomy. These operations lead to a mean weight loss of approximately 30% and diabetes remission in up to 70% of people, depending on the duration of diabetes. Surgery also improves quality of life and reduces cardiovascular disease and mortality. The operative mortality is low (1 in 1000) but there are long-term consequences for nutrition, bone health and suicide.

Physical activity

No treatment for diabetes is complete without exercise as physical activity has profound benefits, including improved fitness, reduced insulin requirement and better glycaemic control, lower cardiovascular risk and greater life expectancy. The maxim that some exercise is better than no exercise and more exercise is better than some exercise applies. People with diabetes should be advised to take at least 150 minutes of aerobic exercise and resistance training per week spread over a minimum of 3 days. Prior to exercise, however, it is important to ascertain whether the individual has either macrovascular or microvascular complications as these may be exacerbated by unaccustomed activity.

People with type 1 diabetes should be advised that physical activity can reduce the insulin requirement and lead to unstable glucose levels during and immediately after exercise and a later risk of severe hypoglycaemia.

Tobacco smoking

Smoking can adversely affect glucose management as well as increasing the risk of a number of medical conditions and so healthcare professionals should support people who smoke to quit.

Insulin

Prior to discovery of insulin in 1921, the life expectancy of people with type 1 diabetes was only 3–4 months. Many people died from diabetic ketoacidosis but it was possible to survive for several years on diets of around 500–700 calories/day; these individuals had a wretched existence until either the person broke their diet or died from starvation. The discovery of insulin is rightly considered one of the greatest medical advances of the 20th century as the lives of millions of people with diabetes have been transformed by its discovery. Insulin is always indicated in people with type 1 diabetes and is often needed in those with type 2 diabetes as the condition progresses.

The philosophy of insulin therapy is to mimic the normal physiological secretion of insulin as closely as possible (see Fig. 23.5). This involves the use of both long-acting insulin to replicate the basal secretion of insulin and short-acting insulin to cover mealtimes.

Insulin was historically derived from beef or pig pancreas but this has been replaced by highly purified biosynthetic insulin, which is produced by adding a DNA sequence coding for insulin or proinsulin into cultured yeast or bacterial cells.

Short-acting insulins

Soluble human insulin is absorbed slowly, reaching a peak 60–90 minutes after subcutaneous injection. Its action tends to persist after meals, predisposing to hypoglycaemia. Absorption is delayed because soluble insulin forms stable hexamers (six insulin molecules around a zinc core), which need to dissociate to monomers or dimers before it can enter the circulation.

This delay is inconvenient for people with diabetes because the insulin should be injected 20–30 minutes prior to a meal.
which often is not feasible. **Short-acting insulin analogues (insulin lispro, insulin aspart and insulin glulisine)** have been engineered that dissociate more rapidly following injection without altering the biological effect (see Fig. 23.2). These insulin analogues enter and disappear from the circulation more rapidly than soluble insulin. A newer formulation of insulin aspart has been developed that dissociates and enters the circulation even more rapidly.

The use of short-acting insulin analogues in people with type 1 diabetes reduces total and nocturnal hypoglycaemic episodes and improves glycaemic control as judged by postprandial glucose concentrations and HbA1c. The benefits in people with type 2 diabetes are more modest but short-acting insulin analogues seem to provide better control of HbA1c and postprandial glucose than soluble human insulin.

**Intermediate and longer-acting insulins**

The action of human insulin can be prolonged by the addition of zinc or protamine. The most widely used form is NPH (neutral protamine Hagedorn) or isophane insulin but its use is hampered by variability from one injection to another, the need to re-suspend the insulin prior to injection and a peak action, which generally occurs in the middle of the night. Long-acting analogues have been developed to delay absorption and prolong the duration of action (see Fig. 23.2). Insulin glargine is soluble in the vial as a slightly acidic (pH 4) solution but precipitates at subcutaneous pH, thus prolonging its duration of action. A concentrated formulation of insulin glargine is now available with a longer and flatter duration of action than the standard preparation. Insulin detemir and insulin degludec have a fatty acid ‘tail’ that binds to serum albumin; the slow dissociation from the bound state prolongs the duration of action. In the case of insulin degludec, it forms long multihexamer chains at the site of injection, which only dissociate very slowly. Long-acting insulin analogues reduce hypoglycaemia for people with both type 1 diabetes and type 2 diabetes, particularly at night.

As insulin analogues are more expensive than NPH insulin, in the case of type 2 diabetes NICE recommends that insulin analogues are reserved for people who do not respond well to NPH insulin. The European Association of the Study of Diabetes and American Diabetes Association consensus report on the management of type 2 diabetes notes the benefits of insulin analogues but highlights that the way in which insulin is used has a greater impact on the effectiveness and adverse effects of insulin than differences between insulin formulations.

**Strengths of insulin**

Most insulin is formulated as 100 units/mL but more concentrated forms are available, for example insulin glargine is available as U300 (300 units/mL) as described above. Insulin degludec is available in two concentrations: 100 and 200 units/mL. The pen devices for these insulins indicate how many units of insulin are given but there is a significant danger of overdose if the insulin is withdrawn from the pen and administered using an insulin syringe. A number of warnings have been issued to prevent this practice.

Some people with diabetes experience severe insulin resistance and require massive insulin doses. U500-strength insulin is available for these individuals allowing them to inject the same dose of insulin in one-fifth of the usual volume. Rare syndromes of insulin resistance exist, but most cases are unexplained (see Box 23.4). Insulin resistance associated with antibodies directed against the insulin receptor has been reported in people with acanthosis nigricans.

### Insulin regimens

Many different combinations of insulin are used to treat people with diabetes but there are several regimens that are more commonly used. The possible treatment options should be discussed with the individual to find the one that is most suitable to their needs and lifestyle.

**Basal-bolus regimen**

The basal-bolus regimen involves the administration of both short- and long-acting insulin. Long-acting insulin is injected 1–2 times per day to provide the background (basal) insulin to keep the glucose concentration consistent during periods of fasting (Fig. 23.11). Short-acting insulin is given shortly before eating as a bolus to control glucose concentration following a meal. This regimen most closely mimics normal insulin physiology and is more flexible than other regimens as each injection can be adjusted individually.

This regimen is the treatment of choice for people with type 1 diabetes but is increasingly used in younger people with type 2 diabetes. The flexibility is of great value to people who have busy jobs, work shifts and travel regularly. The main disadvantage of a basal-bolus regimen is the number of injections.

**Twice-daily mixed insulin regimen**

A mixture of short- and long-acting insulin is injected before breakfast and the evening meal (see Fig. 23.11). There are a number of
insulin preparations with premixed insulin but it is also possible to self-mix the insulin. This regimen is used more commonly for people with type 2 diabetes but may be used by people with type 1 diabetes when it is not possible inject four times a day. The main disadvantage of this regimen is the lack of a lunch-time bolus and higher basal levels between meals, which increase the risk of hypoglycaemia.

**Basal-only and basal-plus insulin regimens**

As people with type 2 diabetes are able to produce insulin, it may be possible to use a less intensive insulin regimen. Basal long-acting insulin at night, together with other non-insulin treatments during the day, is initially as effective as multidose insulin regimens and is less likely to promote weight gain. Addition of mealtime insulin may become necessary to control postprandial hyperglycaemia.

**Insulin administration**

Insulin is administered subcutaneously by intermittent injection or by insulin pumps (continuous subcutaneous insulin infusion, CSII). The usual injection sites are the front and upper outer side of the thigh, the abdominal wall, buttocks and upper outer arms. Injection technology has improved dramatically since insulin was first discovered; although insulin may be drawn up from a vial into special plastic insulin syringes, an increasing number of people now use insulin pens, which may be disposable with pre-filled insulin or re-usable by changing the insulin cartridge when empty. The pens are portable, use a fine 4–5-mm needle and have a simplified procedure for dialing the insulin dose. Compared with needles and syringes, pens are more convenient, more accurate, easier to use and produce a less painful injection. Even though most injections are virtually painless, people are understandably apprehensive and must learn how to give insulin safely and effectively.

Introduced over 35 years ago, insulin pumps are small devices that continuously infuse insulin into the subcutaneous tissue. The technology has progressively improved and allows the user to give varying amounts of basal insulin throughout the day with mealtime boluses, guided by the pump software. The latest pumps connect with continuous glucose monitors that allow the pump to suspend the insulin infusion if the glucose levels are low or predicted to become low. The long-term goal is to develop a completely ‘closed loop’ system or ‘artificial pancreas’ where the glucose monitor and pump automatically control the insulin infusion rate to maintain normal glucose concentrations without input from the wearer. Pump therapy in people with type 1 diabetes improves glycaemic control, reduces hypoglycaemia and leads to better quality of life compared with multiple daily injections. These benefits have led to an increasing number of pump users although the uptake of CSII varies across the world; up to 40% of people with type 1 diabetes use pumps in the USA compared with 12.2% in the UK.

The disadvantages of pump therapy include the nuisance of being attached to a gadget, skin infections, the risk of ketoacidosis if the flow of insulin is interrupted (since there is no protective reservoir of injected basal insulin) and cost.

**Lipohypertrophy and lipoatrophy**

Fatty lumps, known as lipohypertrophy, may occur following the overuse of a single injection site with any type of insulin. Local allergic responses sometimes occur early in therapy but usually resolve spontaneously. As modern insulin is highly purified, insulin allergy is rare. However, immunoglobulin G immune complexes against the insulin can be formed that can produce local atrophy of fat tissue (lipoatrophy).

As well as being unsightly, lipohypertrophy and lipoatrophy interfere with insulin absorption thereby compromising insulin action. Generalized allergic responses and injection site abscesses are exceptionally rare.

**Inhaled insulin**

The first inhaled insulin was withdrawn from the market in 2007 on the grounds of limited clinical demand, although lung cancer was also observed. The FDA approved a new formulation (Afrezza) in July 2014.

**Challenges of insulin therapy**

Although insulin and the means of administering insulin continue to improve, achieving optimal glycaemic control is extremely challenging for people living with diabetes for a number of reasons:

- The therapeutic index of insulin is low, meaning that when too little insulin is administered, glucose concentrations rise outside the normal range while if too much insulin is administered, glucose concentrations fall in the hypoglycaemic range.
- Insulin requirements are highly variable from one person to another and vary within the same individual within a day and between days.
- In people without diabetes, insulin is secreted directly into the portal circulation and reaches the liver in high concentration where 50% is cleared on first passage. By contrast, insulin injected subcutaneously passes into the systemic circulation. People treated with insulin therefore have lower portal insulin levels and higher systemic levels relative to normal physiology.
- Subcutaneous insulin takes longer to enter and achieve peak plasma levels and it is slower to leave the circulation.
- The absorption of subcutaneous insulin into the circulation from one injection to the next is variable.
- Basal insulin levels adapt to the metabolic needs of people without diabetes but injected insulin peaks and declines, resulting in swings in metabolic control in those with diabetes.
- Bolus insulin doses should ideally be adjusted to the carbohydrate content of the meal.
- Carbohydrate counting is difficult because many foods do not list the carbohydrate content.
- It is not always possible to determine how much will be eaten, as appetite may change.
- The rate of absorption of glucose is affected by the glycaemic index and amount of protein and fat in the meal.
- Calculating the appropriate dose of insulin requires advanced mathematical skills.
- There are no holidays from diabetes; an individual using a basal bolus regimen will need to inject approximately 1500 times a year.
- The price of giving too much insulin is hypoglycaemia, which is unpleasant and often embarrassing.
- The pens or devices can fail.
- It is critically important that people are trained to use their insulin effectively and safely and this forms a central component of diabetes self-management education for people with diabetes. As their insulin requirement changes, people should be encouraged to adjust their insulin doses with a view to maintaining blood glucose values between 4 mmol/L and 7 mmol/L (70–126 mg/dL) before meals and between 4 mmol/L and 10 mmol/L (70–180 mg/dL) after meals, assuming that this can be achieved without troublesome hypoglycaemia (Box 23.11). Professional advice should be available to support people with diabetes who experience problems; alongside this is a responsibility
Hypoglycaemia

Hypoglycaemia (low blood glucose) is the most common side-effect of insulin therapy and is the major limitation to what can be achieved with insulin treatment. A recent consensus report defined a glucose concentration below 3.0 mmol/L (54 mg/dL) as ‘clinically significant hypoglycaemia’ but recognized that any value below 4.0 mmol/L (70 mg/dL) represented an ‘alert value’ that required treatment. ‘Severe hypoglycaemia’ is defined as hypoglycaemia requiring external help for recovery. Most people treated with insulin will experience several episodes of symptomatic hypoglycaemia per week and one to two severe episodes per year. Despite the advances in insulin therapy, the incidence of hypoglycaemia has not changed over the last 25 years. Interestingly with the advent of continuous glucose monitoring, it is apparent that asymptomatic hypoglycaemia occurs much more frequently than previously thought. Hypoglycaemia is more common in people with type 1 diabetes, where there is absolute insulin deficiency, and with longer duration of diabetes. It occurs more frequently in young children and those trying to achieve tight glycaemic control.

Hypoglycaemia greatly impairs quality of life and induces fear and anxiety in the person with diabetes, their family and carers. In an older study, the fear of severe hypoglycaemia was worse than the fear of developing blindness or end-stage renal disease. Nocturnal hypoglycaemia can be particularly disruptive. In addition to the psychological effects, hypoglycaemia is associated with a number of long-term medical consequences, including cardiovascular events and falls (Box 23.13).

Hypoglycaemia is caused when more insulin is injected than is needed. Irregular eating habits, unusual exertion and alcohol excess may all precipitate hypoglycaemic episodes but insulin errors and variation in insulin absorption, for example as a result of lipohypertrophy, are also important. The times of greatest risk are before meals, during the night, and during and after exercise.

The mechanisms that protect against hypoglycaemia in people without diabetes are compromised because of abnormal islet cell function or defective counter-regulatory hormone secretion. The delivery of insulin after injection cannot be halted and glucagon secretion is impaired because its main regulator is a fall of intra-islet insulin. Even the third line defence of counter-regulatory hormones and other sympathetic nervous system responses to hypoglycaemia may become diminished in people with long-standing diabetes or recurrent hypoglycaemia.

Symptoms and signs

The symptoms of hypoglycaemia can be divided into two main categories, autonomic and neuroglycopenic, although non-specific symptoms may also be experienced (see Box 23.13). Autonomic symptoms and signs occur because of activation of the adrenergic and cholinergic parts of the autonomic nervous system. As the brain is dependent on glucose as its primary fuel source, neuroglycopenic symptoms arise from inadequate glucose supply to the brain.

Usually, autonomic symptoms develop before cognitive impairment. This is clinically important as these symptoms alert the individual to hypoglycaemia and prompt them to take corrective action. In longstanding diabetes or after repeated episodes of hypoglycaemia, the autonomic symptoms may only develop at glucose levels below the threshold for neuroglycopenic symptoms. When this occurs, hypoglycaemia awareness becomes impaired and the person is at increased risk of severe hypoglycaemia. Awareness improves if hypoglycaemia is scrupulously avoided.

The symptoms and signs of hypoglycaemia resolve once the hypoglycaemia is treated and the glucose returns to within the normal range.
Management of hypoglycaemia

Hypoglycaemia is an acute medical emergency that requires immediate treatment with 15–20g of oral glucose. This should be repeated after 15 minutes if the glucose concentration has not risen above 4.0mmol/L (70mg/dL). The glucose can be taken either as a liquid or solid food containing fast acting carbohydrate, such as glucose tablets or sugary sweets, e.g. Jelly Babies. More carbohydrate than necessary should not be taken in order to prevent rebound hyperglycaemia.

The diagnosis of severe hypoglycaemia resulting in confusion or coma is simple and usually made on clinical grounds, backed by a bedside blood test. Many people with diabetes carry a card or wear a bracelet or necklace saying that they have diabetes, and these should be sought in unconscious patients. The treatment is either intramuscular glucagon or intravenous glucose. Glucagon acts by mobilizing hepatic glycogen and works almost as rapidly as glucose. It is simple to administer and can be given at home by relatives. It does not work when liver glycogen levels are low, for example, after a prolonged fast. Once the individual revives, they should eat some longer-acting carbohydrate to replenish glycogen reserves.

After the acute event has been treated, it is important to ascertain why the hypoglycaemia occurred in order to try to prevent future episodes.

Weight gain

As insulin is an anabolic hormone and the absence of insulin leads to profound weight loss, it is unsurprising that many people gain weight whilst treated with insulin. Restoration of normal weight is a therapeutic effect, but some individuals experience excessive weight gain, especially if the insulin dose is increased inappropriately. Excessive weight gain may be the consequence of frequent hypoglycaemia if an individual takes excess carbohydrate to treat or prevent hypoglycaemia (so called ‘defensive eating’). Weight gain can be offset, to some extent, by dietary measures and exercise.

Oral non-insulin treatments for type 2 diabetes

Unlike type 1 diabetes, there are alternative pharmacological treatments for type 2 diabetes when dietary and other lifestyle changes do not adequately bring the glucose into the target range. These treatments are adjuncts rather than alternatives to dietary and lifestyle management.

Biguanides: metformin

Metformin is currently the only available biguanide. It was introduced into clinical practice in the 1950s alongside two other biguanides, phenformin and buformin, but these latter two agents were withdrawn because of a high risk of lactic acidosis.

Mode of action

The precise mechanism of action of metformin remains unclear but may involve the activation of the enzyme adenosine monophosphate (AMP) kinase, which regulates cellular energy metabolism. Metformin reduces the rate of gluconeogenesis, and hence hepatic glucose output, and increases insulin sensitivity. It does not affect insulin secretion, does not induce hypoglycaemia and does not predispose to weight gain. In addition to its effects on glucose, it may also suppress appetite and stabilize weight.

Clinical use

Metformin is the best-validated treatment for type 2 diabetes and appears as the first-line pharmacological agent in all type 2 diabetes guidelines. Metformin may be given in combination with all other oral diabetes treatments as well as GLP-1 receptor agonists or insulin. It lowers fasting plasma glucose by 2–4mmol/L (36–72mg/dL), corresponding to a fall in HbA1c of 11–22mmol/mol (1–2%). In UKPDS, metformin treatment led to an unexpected reduction in cardiovascular events. Metformin has been used alongside insulin in people with type 1 diabetes but only with limited efficacy.

Adverse effects

Unwanted effects include gastrointestinal side-effects (10–20%), such as anorexia, nausea, abdominal discomfort and diarrhoea. The effects can be mitigated by starting at low dose and gradually increasing until the desired therapeutic effect is achieved. A slow-release preparation of metformin appears to be better tolerated.

Metformin is contraindicated in renal impairment, cardiac failure and hepatic failure because of the risk of lactic acidosis. Metformin should not be started in someone whose estimated glomerular filtration rate (eGFR) is less than 45mL/min per 1.73m² and should be stopped if the eGFR falls below 30mL/min per 1.73m².

Metformin must be stopped prior to intravenous administration of iodinated contrast agent because of the risk of renal failure and subsequent lactic acidosis. Treatment can be restarted 48 hours after the test if there has been no deterioration in renal function. Similarly, metformin should be stopped temporarily around surgery or during other intercurrent illnesses that may affect lactate clearance. Metformin should be avoided in people with a history of alcohol misuse.

Metformin reduces gastrointestinal vitamin B₁₂ absorption, but only rarely causes anaemia.

 Sulphonylureas

Sulphonylureas were originally derived from sulfonamide antibiotics after it was recognized that the latter caused hypoglycaemia during a typhoid epidemic in Marseilles, France in 1942 (Box 23.14).

Mode of action

Sulphonylureas act on the β cell to induce insulin secretion. They are ineffective in people without a functional β-cell mass and therefore have no effect in people with type 1 diabetes. Sulphonylureas bind to the sulphonylurea receptor on the β-cell membrane, which closes ATP-sensitive potassium channels and blocks potassium efflux. The resulting depolarization promotes calcium influx and stimulates insulin release (see Fig. 23.4).

Clinical use

Most clinical guidelines recommend that sulphonylureas can be used as an alternative first-line agent where metformin is contraindicated or not tolerated. As monotherapy, sulphonylureas typically reduce fasting plasma glucose by 2–4mmol/L (36–72mg/dL), corresponding to a fall in HbA₁c of 11–22mmol/mol (1–2%). Although this is more effective than many other oral agents in the short term (1–3 years), the sulphonylurea effect wears off as the β-cell mass declines. Sulphonylureas can also be used in combination with other oral antidiabetes agents or basal insulin, although it is usually stopped when the individual requires short-acting insulin at mealtimes.

Adverse effects

Weight gain, typically 1–4kg, and hypoglycaemia are the most common side effects. Hypoglycaemia affects about one-fifth of those taking the drug but severe hypoglycaemia is uncommon.
The risk of hypoglycaemia is increased with longer acting sulphonylureas, excessive alcohol intake, older age and during intercurrent infection. Severe sulphonylurea-induced hypoglycaemia should be managed in hospital for up to 48 hours with glucose support until the drug has cleared from the circulation. Sulphonylureas should be used with care in people with liver or renal disease.

**Meglitinides or post-prandial insulin releasers**

Meglitinides are short-acting agents that promote insulin secretion in response to meals.

**Mode of action**

Like sulphonylureas, meglitinides act by closing the K⁺-ATP channel in the β cells (see Fig. 23.4). They are rapidly metabolized and have a short duration of action of less than 3 hours. They were designed to restore early-phase post-prandial insulin release without prolonged stimulation during subsequent periods of fasting.

**Clinical use**

Meglitinides may be used to treat people with post-prandial hyperglycaemia with normal fasting glucose levels. They may be useful in older frail people where there is an imperative to avoid hypoglycaemia. However, meglitinides are less effective than other drugs and their role in diabetes management is not well established.

**Adverse effects**

Hypoglycaemia and weight gain are the most common adverse effects but these are generally less severe than with sulphonylureas.

---

**Thiazolidinediones or ‘glitazones’**

Three thiazolidinediones have been launched but troglitazone was withdrawn because of liver toxicity and rosiglitazone has been withdrawn or restricted because of concerns about cardiovascular safety. In many countries, pioglitazone is the only available thiazolidinedione.

**Mode of action**

Thiazolidinediones reduce insulin resistance by interaction with peroxisome proliferator-activated receptor-gamma (PPAR-γ), a nuclear receptor that regulates large numbers of genes, including those involved in lipid metabolism and insulin action. The paradox that glucose metabolism should respond to a drug that binds to nuclear receptors mainly found in fat cells is still not fully understood. One suggestion is that these drugs act indirectly via the glucose–fatty acid cycle, lowering free fatty acid levels and thus promoting glucose consumption by muscle. They reduce hepatic glucose production, an effect that is synergistic with that of metformin, and also enhance peripheral glucose uptake. Like metformin, the glitazones potentiate the effect of endogenous or injected insulin.

**Clinical use**

Thiazolidinediones can be used as monotherapy or in combination with other antidiabetes drugs, including insulin. Thiazolidinediones do not cause hypoglycaemia as monotherapy and pioglitazone may specifically benefit people with non-alcoholic fatty liver disease, a frequent co-morbidity of type 2 diabetes. As the effect on plasma glucose is indirect, thiazolidinediones may take up to 3 months to reach their maximal effect.

**Adverse effects**

The most common adverse effect is weight gain of 5–6 kg, but pioglitazone may cause fluid retention precipitating heart failure. Mild anaemia and osteoporosis resulting in peripheral bone fractures have been reported.

**Dipeptidyl peptidase-4 inhibitors or ‘gliptins’**

Dipeptidyl peptidase-4 (DPP4) inhibitors have been used since 2006 and are one of two classes of drug that improve glycaemic control by enhancing the incretin effect (see p. 709).

**Mode of action**

These drugs inhibit the enzyme DPP4, which prevents the rapid inactivation of glucagon-like peptide-1 (GLP-1), which in turn increases insulin secretion and reduces glucagon secretion.

**Clinical use**

DPP-4 inhibitors are most effective in the early stages of type 2 diabetes, when insulin secretion is relatively preserved, and are currently recommended for second-line use in combination with metformin or a sulphonylurea. Although they only have relatively modest effects on glucose lowering, they are included in most type 2 diabetes treatment algorithms because they are well tolerated. DPP-4 inhibitors do not promote weight gain, have a low risk of hypoglycaemia and can be used safely in people with renal impairment.

**Adverse effects**

Nausea may occur and there have been occasional reports of acute pancreatitis. DPP-4 inhibitors do not alter the incidence of myocardial infarction, but saxagliptin may increase the risk of heart failure.
**Sodium-glucose transporter 2 inhibitors (‘flozins’)**

SGLT2 inhibitors have been available since 2011 (see Box 23.14). In addition to their effects on blood glucose, they lower body weight, improve renal dysfunction and reduce the risk of atherosclerotic cardiovascular events and heart failure.

**Mode of action**

SGLT2 inhibitors lower the renal threshold for glucose, consequently increasing urinary glucose excretion. This has the effect of removing both glucose and calories from the circulation, thus lowering blood glucose by 7–13 mmol/mol (0.6–1.2%) and facilitating weight loss (=2–4 kg over 6–12 months). They alter glomerular haemodynamics, which may underlie the observed benefits on renal function.

Exactly how SGLT2 inhibitors reduce the risk of myocardial infarction, stroke, cardiovascular death and heart failure is uncertain; however, several hypotheses have been suggested including:

- increased natriuresis leading to fluid loss and small reductions in systolic blood pressure
- increased production of ketones acting as a ‘superfuel’ for the heart
- vasodilation through blockade of the renin–angiotensin system
- direct effects on the heart.

**Clinical use**

SGLT2 inhibitors can be used as monotherapy but are used more typically in combination with all other antidiabetes drugs. This class has become rapidly established in clinical practice and in type 2 diabetes guidelines because of their cardiovascular benefits, weight loss and low risk of hypoglycaemia. The glucose lowering effect is dependent on good renal function but the renoprotective benefits are seen in people with lower eGFR. This is leading to an expansion of their use in people with reduced eGFR.

SGLT2 inhibitors are licensed as adjunctive therapy to insulin in type 1 diabetes. In this context, SGLT2 inhibitors confer additional benefits by lowering HbA1c by 5–6 mmol/mol (0.4–0.5%) despite lower total daily insulin doses and weight loss. The reduction in HbA1c does not increase the risk of hypoglycaemia but does carry a higher risk of diabetic ketoacidosis and fungal infections.

**Adverse effects**

The most common adverse effects are genital candidiasis and dehydration. Rarer side effects include diabetic ketoacidosis, Fournier’s gangrene and lower limb amputation. Diabetic ketoacidosis may occur in people with diagnosed type 2 diabetes. In general, these people are insulin deficient and may have unrecognized type 1 diabetes. A diagnostic trap is that glucose concentrations may be normal or minimally raised in this situation.

**Alpha-glucosidase inhibitors**

Alpha-glucosidase inhibitors, such as acarbose, are designer drugs that reduce carbohydrate absorption after a meal.

**Mode of action**

Alpha-glucosidase inhibitors prevent α-glucosidase, the last enzyme involved in carbohydrate digestion, from breaking down disaccharides to monosaccharides. This slows the absorption of glucose after a meal and lowers post-prandial glucose.

**Clinical use**

Although α-glucosidase inhibitors can be used as monotherapy or in combination with all other antidiabetes drugs, they are not widely used because of their limited efficacy and gastrointestinal side-effects.

**Adverse effects**

The major side-effects are gastrointestinal and include flatulence, abdominal distension and diarrhoea, as unabsorbed carbohydrate is fermented in the bowel.

**Other oral therapies**

**Quick-release bromocriptine**

Abnormal circadian rhythm is associated with the development of insulin resistance, obesity and diabetes. When administered at daybreak, quick-release bromocriptine appears to reset hypothalamic dopamine circadian rhythms. It lowers HbA1c by 5–8 mmol/mol (0.5–0.7%) either as monotherapy or in combination with other antidiabetes medications. The drug is well tolerated.

**Colesvelam**

Colesvelam is a bile acid-binding resin that lowers cholesterol, and can reduce blood glucose concentrations by an unknown gastrointestinal mechanism.

## Non-insulin injectable therapies for type 2 diabetes

**GLP-1 receptor agonists**

GLP-1 receptors are a heterogeneous class of drugs that act by enhancing the incretin effect. The class is divided into two main groups; the first are drugs that are derived from the protein exendin, which is found in the saliva of an Arizonaan desert lizard. Exendin has 53% sequence homology with human GLP-1 and is resistant to cleavage by DPP-4. The second group are analogues of human GLP-1.

The pharmacokinetics has been modified to prolong the duration of action. The first GLP-1 receptor agonists were given twice daily but now there are once-weekly preparations. At present GLP-1 receptor agonists require injection but oral formulations are in late development.

Clinical trials have demonstrated that human GLP-1 analogues, but not exendin-based GLP-1 receptor agonists, reduce the risk of myocardial infarction, stroke, cardiovascular death and heart failure.

**Mode of action**

GLP-1 receptor agonists enhance the incretin effect by activating the GLP-1 receptor. Unlike DPP-4 inhibitors that restore physiological GLP-1 levels, GLP-1 receptor agonists achieve pharmacological levels and are therefore more potent that DPP-4 inhibitors. In addition to their effects on the pancreas to increase insulin secretion and decrease glucagon, they also act on the hypothalamus to reduce appetite and food intake leading to weight loss. The size of effect has led to the licensing of liraglutide as an anti-obesity treatment. Short acting GLP-1 receptors agonists also slow gastric emptying.

GLP-1 receptors are widely expressed in the cardiovascular system and GLP-1 analogues appears to protect the heart against ischaemic damage, both through direct effects on the heart as well as indirect effects, such as lowered blood pressure and free fatty acids.
Clinical use
Despite the need for injection, clinical guidelines endorse their use and GLP-1 receptor agonists are now widely used in combination with other antidiabetes agents, as second- or third-line therapies. They should not be combined with DPP-4 inhibitors as the DPP-4 inhibitor does not confer any additional benefit. There are differences in efficacy between GLP-1 receptor agonist and head-to-head clinical trials have shown reductions of HbA_1c_ in the ranges 9–19 mmol/mol (0.8–1.8%) and reduction of weight from 0.6–4.3 kg. As GLP-1 receptor agonists cause weight loss, they are particularly suitable for people with obesity.

Adverse effects
The most common side-effects of GLP-1 receptor agonists are gastrointestinal and include nausea and vomiting, bloating and diarrhoea. These tend to diminish with time and occur less frequently with longer-lasting GLP-1 receptor agonists. There is a low risk of hypoglycaemia but this may occur if GLP-1 receptor agonists are combined with insulin or sulphonylureas. GLP-1 receptor agonists should not be used in people with a history of pancreatitis because of a risk of acute pancreatitis. Recent studies have not confirmed earlier concerns about links with pancreatic and thyroid cancer.

Amylin analogues
Amylin is co-secreted with insulin and delays gastric emptying, suppresses post-prandial glucagon secretion and increases satiety. It is not widely used.

**Which drug and when?**

With the introduction of increasing numbers of drugs to treat type 2 diabetes, the choice of which drug and when becomes more and more relevant. As type 2 diabetes is characterized by progressive β-cell failure and glucose control deteriorates over time, this requires a progressive and pre-emptive escalation of diabetes therapy. There is strong evidence of delays in treatment escalation, which exposes the individual with diabetes to prolonged periods of hyperglycaemia and the inherent risks of complications.

All guidelines currently recommend metformin as the first-line treatment for most people with type 2 diabetes whose glucose levels remain above target despite optimal lifestyle management. However, what comes next is more contentious. As new treatments and new evidence of the effectiveness of these treatments, guidance about how to use these is continually updated. The European Association for the Study of Diabetes and American Diabetes Association have recently produced a comprehensive consensus report about the management of hyperglycaemia in diabetes.

Decisions about treatment should be individualized and shared with the person with diabetes. The importance of diabetes self-management education is highlighted to enable the person with diabetes to make an informed choice. Clinicians are advised to consider specific patient characteristics and factors that will inform the discussion (Box 23.15).

Where the individual has established atherosclerotic cardiovascular disease, a GLP-1 receptor agonist or SGLT2 inhibitor with proven cardiovascular benefit is recommended. Where heart failure or chronic kidney disease is present, an SGLT2 inhibitor is the treatment of choice. Approximately a quarter of individuals with diabetes will fall into this category. For the remaining three-quarters, if there is a pressing need to minimize weight gain or promote loss, again GLP-1 receptor agonists or SGLT2 inhibitors are recommended. In addition to GLP-1 receptor agonists and SGLT2 inhibitors, DPP4 inhibitor and thiazolidinediones may be used if there is a need to avoid hypoglycaemia. Sulphonylureas or thiazolidinediones are preferred when cost is a major issue.

When triple therapy is needed, other recommended drugs can be added. For example, if a GLP-1 receptor agonist is first added to metformin in someone with established atherosclerotic cardiovascular disease, an SGLT2 inhibitor would be an appropriate third-line choice. Beyond triple therapy, insulin is required as further additional treatments have only a minimal effect, if any.

Several fixed dose oral combinations and fixed ratio injectable combinations of insulin and GLP-1 receptor agonists are available and reduce the pill or injection burden for the person with diabetes as treatment is escalated.

### Measuring the metabolic control of diabetes

Measures of glycaemic control are needed to help people with diabetes and their healthcare professionals make rational choices about therapy. There have been considerable advances in methods for monitoring over the last 30 years. Blood testing has now superseded the original urinary testing and it is possible to measure interstitial glucose continuously. Measurements of metabolic control can be divided into short-term measures that provide an almost instantaneous record of the current glucose concentration and long-term measures that provide an assessment of average glucose concentration over the preceding weeks or months.

### Short-term measures of metabolic control

**Self-monitoring of capillary blood glucose**

The availability of hand-held meters has allowed people with diabetes to measure their capillary blood glucose concentration regularly throughout the day wherever they are. Blood is taken from the side of a fingertip (not from the top, which is densely innervated) using
a special lancet. Single blood glucose concentrations are of limited value because of their wide variability, but repeated glucose measurements offer invaluable feedback that permits appropriate adjustment of treatment to be made. Some meters include bolus calculators that advise the individual on the appropriate dose of mealtime insulin based on the current glucose and estimated carbohydrate of the meal. The parameters of the automated bolus calculator (the ratio of insulin dose to carbohydrate intake and the amount that one unit of insulin will reduce glucose by) need to be programmed into the meter, usually during a consultation.

Self-monitoring of capillary blood glucose is recommended for everyone treated with insulin but some people with diet- or tablet-treated type 2 diabetes may also find testing a useful guide to therapy. Like any investigation, measuring capillary blood glucose should inform future management and so if individuals are unable or unwilling to adjust their treatment then ‘testing for testing’s sake’ should be discouraged. Blood glucose monitoring does not, in itself, result in better control but is essential to those wishing to achieve it.

Continuous glucose monitoring (CGM) systems measure interstitial glucose every few minutes allowing the user to see trends in glucose levels throughout the day, in particular at times when testing is not usually done, for example at night. By tracking the glucose, the user can act earlier if the glucose starts to rise or fall. These devices have three parts, a sensor that sits just underneath the skin, a transmitter attached to the sensor and a display device that shows the glucose level. The sensors need to be changed frequently but with some devices can be worn for up to 14 days.

There are two types of continuous glucose monitoring:

- Real time, which allows the user to check the glucose levels at any time, as well as being able to download the results
- Retrospective, which does not allow the user to check the glucose levels in real time but the user can look back at results by downloading them.

The technology is developing extremely rapidly; some systems have alarms that alert the user to either high or low glucose levels while the latest CGM devices can be linked to pumps allowing the insulin infusion to be suspended if the glucose levels are low or predicted to become low. Clinical studies have shown that the use of CGM improves HbA\textsubscript{1c} while reducing glucose variability and thereby lowering the risk of hypoglycaemia in type 1 diabetes.

The main disadvantage of CGM is the lag of 15–20 minutes between changes in blood glucose and interstitial glucose. Caution is needed if the glucose levels are changing rapidly and, if an individual experiences hypoglycaemic symptoms, they should test their capillary glucose even if the CGM reading is normal. Although many people with type 1 diabetes find CGM incredibly helpful, the wealth of data and alarms can overburden others.

Continuous glucose monitoring is recommended for people with type 1 diabetes who have problematic hypoglycaemia, including recurrent severe hypoglycaemia, impaired awareness of hypoglycaemia, or extreme fear of hypoglycaemia. CGM is also recommended for those who suffer persistent hyperglycaemia despite very frequent capillary glucose monitoring.

Long-term measures of metabolic control

Glycated haemoglobin (HbA\textsubscript{1c})

As discussed on page 710, glycated haemoglobin (HbA\textsubscript{1c}) is a measure of an individual’s average blood glucose concentration over the previous 6–8 weeks. The glycation occurs as a two-step reaction, resulting in the formation of a covalent bond between the glucose molecule and the terminal valine of the \(\beta\) chain of the haemoglobin molecule. The rate at which this reaction occurs is related to the prevailing glucose concentration. HbA\textsubscript{1c} is expressed as a percentage of the normal haemoglobin or as the mmol concentration of HbA\textsubscript{1c} per mol of normal haemoglobin (standardized range 4–6%; 20–42 mmol/mol).

As HbA\textsubscript{1c} provides an integrated measure of blood glucose concentration over the life of the haemoglobin molecule (=6 weeks), the result may be misleading if the lifespan of the red cell is altered (Box 23.16).

Fructosamine

Glycation albumin measured as fructosamine relates to glycaemic control over the preceding 2–3 weeks. It may be useful in people with anaemia or haemoglobinopathy but is only rarely used.

Whole-pancreas and pancreatic islet transplantation

Islet transplantation

Since 2000, there has been remarkable progress regarding the technical aspects of islet cell processing and the outcomes of islet cell transplantation. The process involves harvesting pancreatic islets from cadavers (two or three pancreata are usually needed), which are then injected into the portal vein and seed themselves into the liver. It is one of the safest and least invasive transplant procedures. Islet cell transplantation is indicated for people with type 1 diabetes who have hypoglycaemia unawareness, severe hypoglycaemic episodes and marked glucose variability. The goal of treatment is to prevent severe hypoglycaemia but about 50–70% of people receiving islet cell transplants also achieve insulin independence after 5 years.

Whole-pancreas transplantation

Worldwide, over 42,000 whole-pancreas transplantations have been performed. They are most often undertaken in people with type 1 diabetes and end-stage kidney disease at the same time as kidney transplantation. Pancreas transplant may be performed less frequently after a kidney transplant or alone. Pancreatic transplantation can establish normoglycaemia and greatly improve quality
of life. There is some evidence of protection against or reversal of some diabetes complications, but this comes at the cost of long-term immunosuppression.

Pathogenesis
Ketoacidosis is a state of uncontrolled catabolism associated with marked insulin deficiency and elevated counter-regulatory hormones, which accelerate the effects of insulin deficiency (Fig. 23.12). The insulin deficiency leads to hyperglycaemia secondary to increased hepatic glucose output and diminished insulin-mediated peripheral glucose uptake, which in turn causes an osmotic diuresis and profound dehydration and loss of electrolytes (Fig. 23.13). However, the most important biochemical abnormality in DKA is not the hyperglycaemia but the uncontrolled lipolysis in adipose tissue and uncontrolled ketogenesis in the liver. Marked insulin deficiency is a necessary precondition for DKA since very little insulin is needed to inhibit hepatic ketogenesis and the breakdown of adipose triglycerides to non-esterified fatty acids (NEFAs). NEFAs are transported to the liver where they are partially oxidized to acidic ketones bodies, such as acetocetoic acid and 3-hydroxybutyric acid, and acetone. This occurs because the absence of insulin impairs hepatic re-esterification of NEFA to triglyceride. The liver exports the ketone bodies as an alternative fuel supply, but these build up in the circulation because of impaired uptake into peripheral tissues, such as muscle. The excess ketones are excreted in the urine but also appear in the breath, producing a distinctive smell similar to that of acetone. Ketone bodies are strong organic acids that rapidly exceed the body’s buffering capacity and cause severe metabolic acidosis. Ketone bodies are nauseating and many people will vomit, worsening the dehydration and electrolyte loss further. Plasma osmolality rises and renal perfusion falls, which impairs renal excretion of hydrogen ions and ketones, aggravating the acidosis. Respiratory compensation for the acidosis leads to hyperventilation, graphically described as ‘air hunger’.

As the pH falls below 7.0 ([H+] >100nmol/L), pH-dependent enzyme systems in many cells function less effectively and, untreated, severe ketoacidosis is invariably fatal.

Clinical features
The features of ketoacidosis are those of uncontrolled diabetes with acidosis, and include prostration, dehydration, nausea, vomiting and, occasionally, abdominal pain. The latter is sometimes so severe that it can be confused with a surgical acute abdomen. Although some people are mentally alert at presentation, others

**Diabetic ketogenic acidosis**

Ketoacidosis is a frequent and life-threatening complication of diabetes, with a mortality rate of approximately 1%. Population studies suggest that there are 5–8 episodes annually per 1000 people with diabetes. It occurs more frequently in younger people but the mortality is higher in older people. Although treatment has improved with better outcomes, the incidence is rising. As DKA results from marked insulin deficiency, it mostly occurs in people with type 1 diabetes but may occasionally present in people with type 2 diabetes. It is usually seen in the following circumstances:

- previously undiagnosed diabetes (10–20% of cases)
- interruption of insulin therapy (15–30% of cases)
- the stress of intercurrent illness and infection (30–40%).

The majority of cases could have been prevented by earlier diagnosis, better communication between the person with diabetes and their healthcare professional, and better self-management education. The most common error is to reduce or omit insulin because the individual feels unable to eat, owing to nausea or vomiting. This is a factor in at least 25% of all hospital admissions. Although insulin infusion adjustment is necessary, it should never be stopped. The UK National Diabetes Inpatient Audit found that a large number of people developed DKA whilst in hospital, suggesting that healthcare professionals also make the same mistakes.

The term used are defined in Box 23.17.

**Diabetic ketoacidosis**

Diabetic ketoacidosis (DKA) remains a frequent and life-threatening complication of diabetes, with a mortality rate of approximately 1%. Population studies suggest that there are 5–8 episodes annually per 1000 people with diabetes. It occurs more frequently in younger people but the mortality is higher in older people. Although treatment has improved with better outcomes, the incidence is rising. As DKA results from marked insulin deficiency, it mostly occurs in people with type 1 diabetes but may occasionally present in people with type 2 diabetes. It is usually seen in the following circumstances:

- previously undiagnosed diabetes (10–20% of cases)
- interruption of insulin therapy (15–30% of cases)
- the stress of intercurrent illness and infection (30–40%).

The majority of cases could have been prevented by earlier diagnosis, better communication between the person with diabetes and their healthcare professional, and better self-management education. The most common error is to reduce or omit insulin because the individual feels unable to eat, owing to nausea or vomiting. This is a factor in at least 25% of all hospital admissions. Although insulin infusion adjustment is necessary, it should never be stopped. The UK National Diabetes Inpatient Audit found that a large number of people developed DKA whilst in hospital, suggesting that healthcare professionals also make the same mistakes.

**Diabetic metabolic emergencies**

The main terms used are defined in Box 23.17.
Diabetic metabolic emergencies

Diabetic metabolic emergencies may be confused and up to 5% present in coma. Although hyperventilation (Kussmaul respiration) may be present, it becomes less marked in very severe acidosis, owing to respiratory depression. The smell of ketones on the breath allows an instant diagnosis to be made by those able to detect the odour.

Diagnosis

This is confirmed by demonstrating hyperglycaemia with ketonaemia or heavy ketonuria, and acidosis as follows:

- Ketonaemia ≥3 mmol/L (31 mg/dL) or significant ketonuria (≥2 on standard urine sticks)
- Blood glucose >11 mmol/L (200 mg/dL) or known diabetes mellitus
- Bicarbonate (HCO₃⁻) below 15 mmol/L (15 mEq/L) and/or venous pH <7.3.

Blood glucose and ketones can be checked urgently at the bedside using portable meters. Blood electrolytes should be assessed as potassium abnormalities occur frequently; metabolic acidosis causes hyperkalaemia as potassium is exchanged for hydrogen ions moving into the cell. As insulin promotes the co-transport of potassium along with glucose into cells, this further exacerbates hyperkalaemia. Although serum potassium may be elevated, there is a severe whole-body potassium deficiency as significant quantities of potassium are lost in vomit and urine. The indicators of severe DKA are shown in Box 23.18.

Management

See Box 23.19; these measures should be carried out with the involvement of a specialist diabetes team. If the patient has severe DKA, they should be managed in a high dependency unit environment.

Replacement of the fluid losses

Individuals with DKA have a typical water deficit of 100 mL/kg, equivalent to 7.5 litres in a 75 kg adult. The replacement fluid of choice is 0.9% sodium chloride but Hartmann’s solution is an acceptable alternative provided there are local policies to ensure the safe administration of additional potassium chloride (potassium cannot be added to Hartmann’s solution). The aim of the first few litres of fluid is to correct any hypotension, replenish the intravascular deficit, and counteract the effects of the osmotic diuresis with correction of the electrolyte disturbance. Over-rapid fluid replacement may lead to cerebral oedema in children and young adults and so the remainder of the fluid should be replaced more cautiously over the next 2 days. The rate and volume of fluid replacement need to be modified in older people and in those with renal or heart failure.

Replacement of the electrolyte losses

Typical electrolytes deficits are sodium 7–10 mmol/kg, chloride 3–5 mmol/kg and potassium 3–5 mmol/kg. After the initiation of treatment with insulin, potassium levels can fall rapidly as
Box 23.19 Guidelines for the management of diabetic ketoacidosis (DKA)

Immediate measures (0–60 min after diagnosis and initiation of intravenous fluids)
1. Carry out clinical assessment to determine the severity of the DKA episode
2. Perform initial investigations, including blood ketones, capillary and venous glucose, serum creatinine and electrolytes, venous blood gases, full blood count, cultures, ECG, chest X-ray if indicated and cardiac monitoring
3. Initiate the intravenous infusion with 0.9% sodium chloride.
   a. Give 1 L over the first hour unless there is hypotension requiring more rapid correction of fluid deficit
   b. Add 40 mmol/L if the potassium is <5.5 mmol/L. Senior review is needed if the potassium is below 3.5 mmol/L
4. Commence a fixed-rate intravenous insulin infusion at a rate of 0.1 unit/kg per hour using soluble human insulin. Estimate the weight if necessary
5. Continue the long-acting basal insulin at the usual dose and time

Management from 60 min to 6 h
1. Reassess the patient
   a. Consider urinary catheterization if the patient is incontinent or anuric after 2–4 h
   b. Consider nasogastric tube insertion if the patient is obtunded or persistently vomiting
2. Continue intravenous fluids
   a. 0.9% sodium chloride 1 L with potassium chloride over 2 h
   b. 0.9% sodium chloride 1 L with potassium chloride over 2 h
   c. 0.9% sodium chloride 1 L with potassium chloride over 4 h
   d. 0.9% sodium chloride 1 L with potassium chloride over 4 h
   e. 0.9% sodium chloride 1 L with potassium chloride over 6 h
3. Measure blood ketones and capillary glucose hourly
   a. If blood ketones are not falling by at least 0.5 mmol/L per hour, increase the insulin infusion rate by 1.0 unit per hour increments hourly until the ketones are falling at target rates. Seek senior review
   b. An alternative to blood ketones is venous bicarbonate which should rise by at least 3.0 mmol/L per hour
   c. A further alternative is glucose that should fall by at least 3.0 mmol/L per hour (50 mg/dL)
   d. If the glucose falls below 14.0 mmol/L (250 mg/dL), commence 10% glucose given at 125 mL/hour alongside the 0.9% sodium chloride solution
4. Measure venous blood gas for pH, bicarbonate and potassium at 60 min and hourly thereafter
   a. Adjust the potassium replacement accordingly
5. Identify and treat precipitating factors

Management from 6 to 12 h
1. Reassess the patient and review biochemical and metabolic measurement to check for resolution of DKA

Conversion to subcutaneous insulin
1. Convert the patient to an appropriate subcutaneous regimen when biochemically stable (blood ketones less than 0.6 mmol/L, pH over 7.3) and ready and able to eat.

Insulin replacement
Insulin should be given by an intravenous infusion using a fixed rate 0.1 units/kg per hour (typically 6–10 units per hour). This modest insulin dose is sufficient to suppress ketogenesis, lower the glucose and correct the electrolyte disturbance. For those already treated with insulin, the long-acting basal subcutaneous insulin should be continued.

As the intravenous insulin should be continued until the ketosis has resolved, intravenous glucose alongside the 0.9% sodium chloride is often needed to prevent hypoglycaemia; 10% glucose is recommended once the blood glucose falls below 14.0 mmol/L (250 mg/dL) and should be continued until the person is eating and drinking normally.

Monitoring progress
The aim of treatment is lower the blood ketone concentration by 0.5 mmol/L per hour, increase the venous bicarbonate by 3.0 mmol/L per hour and reduce capillary blood glucose by 3.0 mmol/L per hour (50 mg/dL per hour) while maintaining potassium between 4.0 and 5.5 mmol/L. If these targets are not met, the insulin infusion rate should be increased.

Seeking the underlying cause
Physical examination may reveal a source of infection. Two common markers of infection are misleading: fever is unusual, even when infection is present; and polymorphoerythrocytosis is present, even in the absence of infection. Relevant investigations include a chest X-ray, urine and blood cultures, and an electrocardiogram (to exclude myocardial infarction). If infection is suspected, broad-spectrum antibiotics are started once the appropriate cultures have been taken.

Other measures
As patients are significantly dehydrated on admission, it is unlikely that they will pass urine for several hours after the initiation of fluid replacement. However, if no urine is passed within 2–4 hours of admission, the insertion of a urinary catheter should be considered.

A central venous cannula may be required to monitor fluid balance in older people and those with cardiac disease.

Aspiration of vomit may be fatal in people with an impaired conscious level and so a nasogastric tube should be considered.

The dehydration, increased blood viscosity and coagulability of DKA increase the risk of a potentially fatal thromboembolism and so thromboprophylaxis with low-molecular-weight heparin should be considered in older or high-risk individuals unless contraindicated.

Complications of diabetic ketoacidosis
Cerebral oedema is a rare but serious complication with high mortality and mostly happens in children or young adults. Severe hypothermia with a core temperature of more than 33°C may occur and can be overlooked unless a rectal temperature is taken with a low-reading thermometer.
On-going management

Once the person is able to eat and keep food down, subcutaneous insulin treatment should be resumed or initiated. A subcutaneous bolus insulin is given with the meal and for those whose long-acting basal insulin was continued during the DKA episode, the insulin infusion and fluids can be discontinued 30 minutes after the meal. If the long-acting insulin was stopped, the intravenous insulin infusion and fluids should be continued until some form of background insulin has been given. The inpatient stay provides an educational opportunity to assess why the DKA occurred and what steps are needed to prevent it from happening again.

Hyperosmolar hyperglycaemic state

Hyperosmolar hyperglycaemic state, in which severe hyperglycaemia develops without significant ketosis, is the characteristic metabolic emergency of uncontrolled type 2 diabetes. People present in middle or later life, often with previously undiagnosed diabetes. Common precipitating factors include consumption of glucose-rich fluids, concurrent medication such as thiazide diuretics or steroids, and intercurrent illness. The hyperosmolar hyperglycaemic state and ketoacidosis represent two ends of a spectrum rather than two distinct disorders (Box 23.20). The biochemical differences may partly be explained as follows:

- **Age.** Old people experience thirst less acutely and become dehydrated more readily. In addition, the mild renal impairment associated with age results in increased urinary losses of fluid and electrolytes.

- **The degree of insulin deficiency.** This is less severe in the hyperosmolar hyperglycaemic state. Endogenous insulin levels are sufficient to inhibit hepatic ketogenesis but insufficient to inhibit hepatic glucose production.

The normal range of osmolality is 285–300 mOsm/kg. It can be measured directly, or can be calculated approximately from the formula:

$$\text{Osmolality} = 2(\text{Na⁺} + \text{K⁺}) + \text{glucose} + \text{urea}.$$

For instance, in the example of severe ketoacidosis given above:

$$\text{Osmolality} = 2(140 + 5) + 30 + 8 = 328 \text{ mOsm/kg}.$$

and in the example of the hyperosmolar hyperglycaemic state:

$$\text{Osmolality} = 2(155 + 5) + 50 + 15 = 385 \text{ mOsm/kg}.$$

The normal anion gap is <17. It is calculated as:

$$\text{Anion gap} = (\text{Na⁺} + \text{K⁺}) - (\text{Cl⁻} + \text{HCO₃⁻})$$

In the example of ketoacidosis, the anion gap is 40, and in the example of the hyperosmolar hyperglycaemic state, the anion gap is 25. Mild hyperchloremic acidosis may develop in the course of therapy. This will be shown by a rising plasma chloride and persistence of a low bicarbonate, even though the anion gap has returned to normal.

#### Clinical features

The characteristic clinical features are dehydration, and stupor or coma. Impaired consciousness is directly related to the degree of hyperosmolality. Evidence of underlying illness, such as pneumonia or pyelonephritis, may be present, and the hyperosmolar state may predispose to stroke, myocardial infarction or lower limb arterial insufficiency.

#### Investigations and management

These are (with some exceptions) similar to the guidelines for ketoacidosis. The plasma osmolality is usually extremely high. It can be measured directly or calculated as $2(\text{Na⁺} + \text{K⁺}) + \text{glucose} + \text{urea}$, all in mmol/L. Again, the most important aspect of management is fluid replacement; 0.9% sodium chloride is the treatment of choice, but 0.45% sodium chloride may be considered if the osmolality is not declining despite adequate fluid balance. The rate of fall of plasma sodium should not exceed 10 mmol/L in 24 hours because the resultant change in osmolality may cause cerebral damage.

Fluid replacement is often enough to lower the glucose but insulin (0.05 units/kg per hour) should be used if the glucose is no longer falling with fluids alone or if the patient develops significant ketoacidemia, when the diagnosis should be reconsidered. Many patients are extremely sensitive to insulin and the glucose concentration may fall rapidly with the initiation of insulin. In order to prevent cerebral damage, the fall in blood glucose should be no more than 5 mmol/L per hour (90 mg/dL per hour).

Prophylactic low-molecular-weight heparin should be given.

#### Prognosis

The reported mortality ranges as high as 15–20%, mainly because of the more advanced age of the patients and the frequency of intercurrent illness. Unlike ketoacidosis, the hyperosmolar hyperglycaemic state is not an absolute indication for subsequent insulin therapy, and survivors may do well on diet and oral agents.

#### Lactic acidosis

The risk of lactic acidosis in people taking metformin is extremely low, provided that the therapeutic dose is not exceeded and the drug is withheld in people with advanced hepatic or renal dysfunction. Patients present in severe metabolic acidosis with a large anion gap (an anion gap is <17 mmol/L in health), usually without significant hyperglycaemia or ketosis. Treatment is by rehydration and infusion of isotonic 1.26% bicarbonate. The mortality is in excess of 50%.

### COMPLICATIONS OF DIABETES

Once effective treatment allowed people to survive the acute metabolic consequences of diabetes, it became apparent that long-term diabetes was associated with the development of a number of complications. These can be broadly divided into two groups: the microvascular complications that affect the capillaries and arterioles throughout the body but particularly involve the eyes (retinopathy), kidneys (nephropathy) and nerve (neuropathy), and macrovascular...
complications, which increase the risk of myocardial infarction, stroke and peripheral vascular disease. With improved treatment of diabetes, the incidence of diabetes complications has fallen for each individual but overall the prevalence has gone up as the number of people with diabetes has increased.

**Microvascular complications**

Microvascular complications are specific to diabetes and affect over 80% of individuals with diabetes. They are unusual in the first 10 years after the diagnosis of type 1 diabetes but are found in 20–50% of people with newly diagnosed type 2 diabetes as a result of the preceding undiagnosed hyperglycaemia. With the advent of screening for type 2 diabetes, the numbers with complications at presentation are falling.

**Pathology of microvascular complications**

Thickening of the capillary and arteriole basement membrane is the cardinal feature of microvascular complications. Although basement membrane thickening is seen in most people with diabetes, organ damage occurs much less frequently; however, with time, the small vessels become progressively narrower and eventually become blocked leading to ischaemia and tissue dysfunction. The tissues damaged by hyperglycaemia are those that have high blood flow and cannot down-regulate glucose uptake in the presence of hyperglycaemia.

The mechanisms leading to damage are ill-defined but likely to be multifactorial. There is no doubt that the duration and degree of hyperglycaemia play a major role in the production of complications. However, other factors also seem to play a role as some people are relatively protected against microvascular complications despite longstanding diabetes. Twin studies suggest that genetic polymorphisms may affect the risk of developing complications. There are also racial differences in the overall rates of nephropathy; in the USA, the prevalence is highest in Pima Native American people followed by Hispanic/Mexican-Americans then black Americans with the lowest rates in people of white Northern European ancestry.

The following are consequences of hyperglycaemia and likely contribute to the development of microvascular complications. The common feature of each stems from a single hyperglycaemia-induced process of overproduction of superoxide by the mitochondrial electron chain.

**Formation of advanced glycation end products (AGE)**

When a wide variety of proteins are exposed to increased glucose concentrations, glucose binds irreversibly to the protein to form advanced glycation end-products (AGE). These accumulate in proportion to hyperglycaemia and time; one example of this is HbA1c, which is used to diagnose diabetes and monitor treatment. AGEs cause tissue injury and inflammation via stimulation of pro-inflammatory factors, such as complement and cytokines.

**Increased flux of glucose through the sorbitol–polyol pathway**

When hyperglycaemia occurs, excess glucose is metabolized to sorbitol via the polyol pathway. This leads to accumulation of sorbitol and fructose, which cause changes in vascular permeability, cell proliferation and capillary structure via stimulation of protein kinase C and transforming growth factor-beta (TGF-β).

**Abnormal microvascular blood flow**

Hyperglycaemia swamps the normal autoregulatory mechanisms that limit tissue blood flow and the high flow rates damage the tissue, particularly when hypertension is present. Endothelial damage occurs and vasoconstrictors, such as endothelins and thrombogenesis, are released that can lead to microvascular occlusion. Nutrients and oxygen supply are impeded.

Blockage of the renin–angiotensin system slows the progression of microvascular complications to a greater extent than other blood pressure-lowering agents, suggesting the renin–angiotensin system may have a role in the development of microvascular complications.

**Growth factors and cytokines**

Through increased expression of protein kinase C β (PKCβ), a number of mitogenic cytokines and growth factors, including TGF-β, tumour necrosis factor and vascular endothelial growth factor (VEGF), are upregulated.

**Growth hormone–insulin-like growth factor axis**

The reduction in portal insulin concentrations impairs the ability of growth hormone to generate IGF-I in the liver, which in turn leads to growth hormone hypersecretion by the pituitary gland. Growth hormone excess has been implicated in the development of microvascular complications and, indeed, pituitary ablation was used to treat retinopathy before laser therapy became available.

**Diabetic retinopathy**

Diabetic retinopathy (damage to the retina) is the most commonly diagnosed diabetes-related complication (Fig. 23.14). Its prevalence increases with the duration of diabetes and affects around one-third of all people with diabetes (Fig. 23.15). Approximately 20% of people with type 1 diabetes will have retinal changes after 10 years, rising to 90% after 20 years (Box 23.21); 20–30% of people with type 2 diabetes have retinopathy at diagnosis, 10% of people with diabetes develop sight-threatening retinopathy, and worldwide diabetic retinopathy is the most common cause of blindness in people of working age. Approximately 30% of people with diabetes will require laser photocoagulation to prevent or limit progression to proliferative retinopathy.

**Early changes without vision loss**

The earliest changes in the retina are known as non-proliferative or background retinopathy (see Box 23.21). Damage to the wall of small vessels causes microaneurysms (small red dots) within the retina. When vessel walls are breached, superficial (blot) haemorrhages occur in the ganglion cell and outer plexiform layers. Damaged blood vessels leak fluid into the retina. The fluid is cleared into the retinal veins, leaving behind protein and lipid deposits, which are seen as hard exudates. These are eventually cleared by macrophages. Micro-infarcts within the retina due to occluded vessels cause cotton wool spots. The spot is swelling of the retinal nerve fibers because normal axoplasmic transport is disrupted leading to the accumulation of axoplasmic debris. This debris is removed by macrophages. As this occurs, there may be white dots at the site of the previous cotton wool spot (cytoid bodies).

Sequential retinal photographs have demonstrated that all these lesions can heal, and it is not uncommon for changes to be seen on one occasion but not the next.

**Transition to sight-threatening retinopathy**

The next stage of retinopathy is known as pre-proliferative retinopathy (see Box 23.21). Damage to the walls of veins causes their calibre to vary (venous beading) and elongation to occur, causing venous loops.
Fig. 23.14 Features of diabetic eye disease. (A) The normal macula (centre) and optic disc (to left). (B) Microaneurysms (small circles) and blot haemorrhage (larger circle) — early non-proliferative retinopathy. (C) Hard exudates (circled) and single cotton wool spot (arrowed) in addition to multiple blot haemorrhages in non-proliferative retinopathy. (D) Intraretinal microvascular abnormalities (IRMA) — pre-proliferative retinopathy (circled). (E) Venous loop (circled) also indicates pre-proliferative change. (F) Fronds of new vessels on the disc and elsewhere (proliferative; circled). (G) Pre-retinal haemorrhage in proliferative disease. (H) Hard exudates within a disc-width of the macula (maculopathy). (I) Cortical cataracts and (J) central cataracts can be seen against the red reflex with the ophthalmoscope.
Fig. 23.15 Prevalence of retinopathy. Prevalence is shown in relation to duration of the disease in people with type 1 diabetes mellitus diagnosed under the age of 33 years. Almost all eventually develop background change and 60% progress to proliferative retinopathy. (Data from Archives of Ophthalmology 1984; 102:520.)

4Hard exudates have a bright yellowish-white colour and are often irregular in outline with a sharply defined margin.
5Cotton-wool spots are greyish-white and have indistinct margins and a dull matt surface, unlike the glossy appearance of hard exudates.

**Sight-threatening retinopathy**

With further progression proliferative retinopathy develops (see Box 23.21). Blockage of blood vessels leads to areas of capillary non-perfusion. Ischaemia in these areas causes the release of vascular growth factors such as VEGF. These factors cause new blood vessels to grow in the retina (neovascularization).

Some of these new blood vessels are inside the retina and are helpful. These new intraretinal vessels, and other vessels whose walls are damaged and dilated, give the appearance of intraretinal microvascular abnormalities (IRMAs). IRMAs are a feature of pre-proliferative retinopathy.

Other new vessels emerge through the retina and lie on its surface, usually at the margin of an area of capillary closure. The normal shearing stresses that occur within the eye can cause these poorly supported new vessels to bleed. Small haemorrhages give rise to pre-retinal haemorrhages (boat-shaped haemorrhages). With further bleeding, vitreous haemorrhage may occur with sudden loss of vision. Later, collagen tissue grows along the margins of the new vessels and gives rise to fibrotic bands. These bands may contract and pull on the retina, causing further haemorrhage and retinal detachment. Sometimes, vessels may be induced to grow on the pupil margin (rubeosis) and in the angle of the anterior chamber of the eye, giving rise to a rapid increase in intraocular pressure (rubeotic glaucoma).

Fluorescein angiography (a fluorescent dye is injected into an arm vein and photographed in transit through the retinal vessels) may be needed to define the extent of the potentially sight-threatening diabetic retinopathy.

**Maculopathy**

Non-proliferative retinopathy may affect vision if it is situated within the macular area, which is responsible for fine vision (see Box 23.21). Fluid from leaking vessels is cleared poorly in this zone. Fluid from leaking vessels is cleared poorly in this zone.

Macular oedema occurs. This distorts and thickens the retina at the macula. If sustained, this distortion causes loss of central vision. Capillary occlusion in the macular area will also cause loss of central vision.

Macular oedema is not visible with the ophthalmoscope or with retinal photography. For this reason, ocular coherence tomography (OCT) is used to image the content of the layers of the macula and measure retinal thickness.

**Management of retinopathy**

Prevention is the best way of managing retinopathy; the Diabetes Chronic Complications Trial (DCCT) and United Kingdom Prospective Diabetes Study (UKPDS) showed conclusively that the risk of the development and progression of diabetic retinopathy can be reduced by tight control of both glucose and blood pressure. However, a short-term deterioration of retinopathy may occur following rapid improvement in glycaemic control and during pregnancy and by nephropathy. The lipid-lowering drug, fenofibrate, has been shown to slow the progression of retinopathy including macular oedema. Smoking cessation is recommended.

**Intravitreal injection**

Repeated injections of anti-VEGF drugs, such as bevacizumab, aflibercept and ranibizumab, can control proliferative diabetic retinopathy and sight-threatening maculopathy. Studies have shown benefit over laser phototherapy for this type of maculopathy, but
side-effects include infection, glaucoma, cataract and retinal detachment. The corticosteroid, triamcinolone, reduces macular oedema in the short term but may be useful while other treatments exert a more permanent effect.

Laser photoocoagulation

Laser photocoagulation therapy is used to treat the new vessels of proliferative retinopathy. New vessels on the disc carry the worst prognosis and warrant urgent laser therapy. The laser should be directed at the new vessels and, in addition, at the associated areas of capillary non-perfusion (ischaemia). If the proliferative retinopathy has progressed to development of new vessels on the optic disc, then a technique known as panretinal photoocoagulation is carried out. Rubeosis is also treated with panretinal photocoagulation. This involves multiple laser burns to the peripheral retina, especially in the areas of capillary non-perfusion. The principle is that by destroying the peripheral retina, the ischaemic stimulus for new vessel formation is diminished. Maculopathy may also be treated with localized laser photoocoagulation.

Although laser treatment prevents blindness, the main adverse effects result from the destruction of retinal tissue. The visual field becomes permanently smaller and there is reduced dark adaptation. In essence, peripheral vision is sacrificed to maintain central vision.

Vitreoretinal surgery

Vitreoretinal surgery is used if bleeding is recurrent and preventing laser therapy. It is also employed to try to salvage some vision if an intravitreal haemorrhage fails to clear and to treat fibrotic traction retinal detachment in advanced retinopathy.

Other ways in which diabetes can affect the eye

Cataract

Cataracts are caused by the denaturation of the protein and other components of the lens of the eye, which renders it opaque. Cataracts develop earlier in people with diabetes than in the general population. Sustained very poor diabetes control with a degree of ketosis can cause an acute cataract (snowflake cataract) to develop rapidly.

Extraction and intraocular lens implantation are indicated if the cataract is causing visual disability or an inability to view the retina adequately. Cataract extraction is straightforward if there is no retinopathy present. Pre-existing retinopathy may worsen after cataract extraction.

Refractory defects

The lens can also be affected by fluctuations in blood glucose concentration, which cause refractive variability, as a result of osmotic changes within the lens (the absorption of water into the lens causes temporary hypermetropia). This presents as fluctuating difficulty in reading but people should be reassured that this resolves with better metabolic control of the diabetes.

External ocular palsies

These most commonly affect the sixth and the third nerves and are described in the section on neuropathies (see p. 731). These nerve palsies usually recover spontaneously within a period of 3–6 months.

Glucoma

The prevalence of open-angle glaucoma is increased in people with diabetes.

Blindness

If sight loss occurs, individuals should be advised to register as blind and may require additional aids to help them to manage their diabetes. Less severe visual impairment is a bar to driving.

Clinical examination of the eye

Visual acuity should be checked using both a pinhole and distance spectacles if worn. The ocular movements are assessed to detect any ocular motor palsies. The iris is examined for rubeosis and then the pupils dilated with 1% tropicamide. About 5–10 minutes later, the eye is examined for the presence of a cataract by looking at the lens with a +10.00 lens in the ophthalmoscope and viewing the lens against the red reflex. All four quadrants of the retina and finally the macula are systematically examined. The macula is examined last because this induces the greatest discomfort, and pupillary constriction.

Eye screening

In the UK, the National Screening Committee has established universal digital photography-based screening across the country, based on a national set of standards. As a result of the early detection of retinopathy, diabetes is no longer the most common cause of blindness in those under 65 years of age in the UK. All people with diabetes over the age of 12 years are offered annual measurement of their acuity and retinal photographs. There are on-going discussions about whether the screening interval might be extended in those with no retinopathy while more frequent screening is required in some groups, for example pregnant women. Box 23.22 shows standardized criteria for screening schemes; these are regularly inspected.

Diabetic nephropathy

Diabetic nephropathy is characterized by gradually increasing urinary albumin excretion and blood pressure as the glomerular filtration rate falls insidiously towards end-stage renal disease. It is slowly progressive and diabetic nephropathy usually manifests 15–25 years after the diagnosis of diabetes but affects 25–35% of
people diagnosed under the age of 30 years. It is the leading cause of premature death in young people with diabetes.

The incidence of end-stage kidney disease has fallen in recent decades (2.5–7.8% after 30 years of type 1 diabetes), probably due to better control of blood glucose and blood pressure, but overall there are now more people with end-stage kidney disease because of the rising prevalence of both types of diabetes. Although the proportion of people with type 2 diabetes affected by end-stage kidney disease is lower, most people commencing renal replacement therapy have type 2 diabetes, because type 2 diabetes is so much commoner than type 1 diabetes. Diabetic nephropathy increases the risk of cardiovascular risk and most people with nephropathy die from cardiovascular disease before progressing to end-stage renal disease.

Pathophysiology

The earliest functional abnormality in the diabetic kidney is renal hypertrophy associated with a raised glomerular filtration rate. This appears soon after diagnosis and is related to hyperglycaemia. As the kidney becomes damaged by diabetes, the afferent arteriole (leading to the glomerulus) becomes vasodilated to a greater extent than the efferent glomerular arteriole. This increases the intraglomerular filtration pressure, further damaging the glomerular capillaries. This raised intraglomerular pressure also leads to increased local shearing forces, which likely contribute to mesangial cell hypertrophy and increased secretion of extracellular matrix material. This process eventually leads to glomerular sclerosis. The initial structural lesion in the glomerulus is thickening of the basement membrane. Associated changes result in disruption of the protein cross-linkages that normally make the membrane an effective filter. In consequence, there is a progressive leak of large molecules (particularly protein) into the urine.

Light-microscopic changes of both diffuse and nodular glomerulosclerosis become manifest; the latter is known as the Kimmelstiel–Wilson lesion. At the later stage of glomerulosclerosis, the glomerulus is replaced by hyaline material.

Albuminuria

Gradually increasing urinary albumin excretion is the hallmark of classical diabetic nephropathy. The earliest evidence of this is ‘microalbuminuria’, so called because the amounts of urinary albumin are too small as to be undetectable by standard dipsticks (see p. 1349). Microalbuminuria may, after some years, progress to intermittent albuminuria followed by persistent proteinuria (Fig. 23.16).

At the stage of persistent proteinuria, the plasma creatinine is normal but once this stage is reached, end-stage kidney disease ensues within 5–10 years, although the rate of progression varies widely between individuals. Rising plasma creatinine is a late feature.

The proteinuria may become so heavy as to induce a transient nephrotic syndrome, with peripheral oedema and hypoalbuminaemia. A small proportion of individuals with type 1 diabetes and up to 50% of those with type 2 diabetes have non-classical diabetic nephropathy. In this situation, the glomerular filtration rates falls progressively but with little or no albuminuria.

Other features of diabetic nephropathy

Diabetic nephropathy is typically associated with a normochromic normocytic anaemia and raised erythrocyte sedimentation rate and C-reactive protein. Hypertension is a common development and may itself damage the kidney still further.

**Screening for diabetic nephropathy**

The urine of all people with diabetes should be checked regularly (at least annually) for the presence of microalbuminuria. The albumin:creatinine ratio (ACR, tested on a midstream first morning urine sample) is less than 2.5 mg/mmol in healthy men and less than 3.5 mg/mmol in healthy women. If microalbuminuria is detected, the test should be repeated twice because false-positive readings are common.

**Investigation of microalbuminuria and proteinuria**

Once proteinuria is present, other possible causes should be considered, but once these are excluded, a presumptive diagnosis of diabetic nephropathy can be made. Clinical suspicion of a non-diabetic cause of nephropathy may be provoked by an atypical history, the absence of diabetic retinopathy (usually, but not invariably, present with diabetic nephropathy) and the presence of red-cell casts in the urine. Renal biopsy should be considered in such cases but is rarely necessary or helpful. Plasma creatinine level and eGFR should be measured regularly.

**Management of nephropathy**

The management of diabetic nephropathy is similar to that of other causes of chronic kidney disease, with a number of provisos. Although diabetic nephropathy is progressive, the time course can be markedly slowed by early aggressive antihypertensive therapy, particularly with ACE inhibitors and angiotensin receptor blockers, and meticulous glycaemic control. The target blood pressure should be <130/80 mmHg but renin–angiotensin system blockers should also be used in people with normal blood pressure and persistent microalbuminuria.

The development of nephropathy also has implications for glycaemic management. Oral antidiabetes agents, partially excreted via the kidney (e.g. glibenclamide and metformin), should be avoided. As insulin clearance is reduced in advanced renal disease, insulin dosage is usually reduced. Recent trials have demonstrated...
that SGLT2 inhibitors slow the progression of diabetic nephropathy and preserve renal function. Attention should also be paid to the management of cardiovascular risk factors (p. 734).

**Management of end-stage renal disease**
Managing end-stage renal disease is made more difficult by the fact that patients often have other complications of diabetes, such as blindness, autonomic neuropathy or peripheral vascular disease. Vascular shunts tend to calcify rapidly; hence, chronic ambulatory peritoneal dialysis may be preferable to haemodialysis. The failure rate of renal transplants is somewhat higher than in people without diabetes.

**Other ways that diabetes can damage the kidney**

**Ischaemic lesions**
Arteriolar lesions, with hypertrophy and hyalinization of the vessels, can occur in people with diabetes. The appearances are similar to those of hypertensive disease and lead to ischaemic damage to the kidneys.

**Urinary tract Infection**
Urinary tract infections are relatively more common in women with diabetes, but not in men. Ascending infection may occur because of bladder stasis resulting from autonomic neuropathy, and infections more easily become established in damaged renal tissue. Autopsy material frequently reveals interstitial changes suggestive of infection, but ischaemia may produce similar changes and the true frequency of pyelonephritis in diabetes is uncertain. Untreated infections in people with diabetes can result in renal papillary necrosis, in which renal papillae are shed in the urine, but this complication is now very rare.

**Diabetic neuropathy**
Diabetes can damage peripheral nervous tissue in several ways. The vascular hypothesis postulates occlusion of the vasa nervorum as the prime cause. This seems likely in isolated mononeuropathies but the diffuse symmetrical nature of the common forms of neuropathy implies a metabolic cause. Since hyperglycaemia leads to increased formation of sorbitol and fructose in Schwann cells, accumulation of these sugars may disrupt function and structure.

The earliest functional change in nerves of people with diabetes is delayed nerve conduction velocity; the earliest histological change is segmental demyelination, caused by damage to Schwann cells. In the early stages, axons are preserved, implying prospects of recovery; at a later stage, irreversible axonal degeneration develops. Diabetic neuropathy can manifest in a number of different ways (Fig. 23.17).

**Symmetrical distal polyneuropathy**
Peripheral neuropathy is often unrecognized by the person with diabetes in its early stages. Early clinical signs are mainly sensory and include loss of vibration sense, pain sensation (deep before superficial) and temperature sensation in the feet. At later stages, people may complain of a feeling of ‘walking on cotton wool’ and can lose their balance when washing the face or walking in the dark owing to impaired proprioception. Early involvement of the hands is less common and should prompt a search for non-diabetic causes. Complications include unrecognized trauma because of the loss of pain sensation.

Involvement of motor nerves to the small muscles of the feet gives rise to interosseous wasting. Unbalanced traction by the long flexor muscles leads to a characteristic shape of the foot, with a high arch and clawing of the toes, which in turn causes abnormal distribution of pressure on walking, resulting in callus formation under the first metatarsal head or on the tips of the toes. The hands...
show small-muscle wasting, as well as sensory changes, but these signs and symptoms must be differentiated from those of the carpal tunnel syndrome, which occurs with increased frequency in diabetes and may be amenable to treatment (p. 421).

**Acute painful neuropathy**

A diffuse, painful neuropathy is less common. The individual describes burning or crawling pains in the feet, shins and anterior thighs. These symptoms are typically worse at night and pressure from bedclothes may be intolerable. The condition may present at diagnosis or after sudden improvement in glycaemic control (e.g. when insulin is started). It usually remits spontaneously after 3–12 months if good glycaemic control is maintained. A more chronic form, developing later in the course of the disease, is sometimes resistant to almost all forms of therapy. Neurological assessment is difficult because of the hyperaesthesia experienced by the individual, but muscle wasting is not a feature and objective signs can be minimal.

It is important to explore non-diabetic causes (see p. 889). However, if no other cause is found, explanation and reassurance about the likelihood of remission within months may be all that is needed. Duloxetine, tricyclics, gabapentin or pregabalin (NICE recommends these as first-line therapies), mexiletine, valproate and carbamazepine all reduce the perception of neuritic pain, but usually not as much as patients hope for. Transepidermal nerve stimulation (TENS) benefits some people. Topical capsaicin-containing creams help occasionally. A few report that acupuncture has been of value.

**Mononeuritis and mononeuritis multiplex (multiple mononeuropathy)**

Any nerve in the body can be involved in diabetic mononeuritis; the onset is typically abrupt and sometimes painful. Radiculopathy (i.e. involvement of a spinal root) may also occur. Isolated palsies of nerves to the external eye muscles, especially the third and sixth nerves, are more common in diabetes. A characteristic feature of diabetic third nerve lesions is that they are painless and the pupillary reflexes are retained owing to sparing of pupillomotor fibres. Full spontaneous recovery is the rule for most episodes of mononeuritis over 3–6 months. Lesions are more likely to occur at common sites for external pressure palsies or nerve entrapment (e.g. the median nerve in the carpal tunnel).

**Diabetic amyotrophy**

This condition is usually seen in older men with diabetes. Presentation is with painful wasting, usually asymmetrical, of the quadriceps muscles. The wasting may be very marked and knee reflexes are diminished or absent. The affected area is often extremely tender. Extensor plantar responses sometimes develop and cerebrospinal fluid (CSF) protein content is elevated. Diabetic amyotrophy is usually associated with periods of more severe hyperglycaemia and may be present at diagnosis. It often resolves over time with improved glycaemic control.

**Autonomic neuropathy**

Asymptomatic autonomic disturbances can be demonstrated on testing in many people with diabetes (Box 23.23) but symptomatic autonomic neuropathy is rare. It affects both the sympathetic and parasympathetic nervous systems and can cause disabling postural hypotension.

**The cardiovascular system**

Vagal neuropathy results in tachycardia at rest and loss of sinus arrhythmia. At a later stage, the heart may become denervated (resembling a transplanted heart). Cardiovascular reflexes, such as the Valsalva manoeuvre, are impaired. Postural hypotension occurs owing to loss of sympathetic tone to peripheral arterioles. A warm foot with a bounding pulse is often seen in a polyneuropathy as a result of peripheral vasodilatation.

**Gastrointestinal tract**

Vagal damage can lead to gastroparesis, often asymptomatic but sometimes leading to intractable vomiting. Implantable devices that stimulate gastric emptying, and injections of botulinum toxin into the pylorus (to paralyse the sphincter partly), have each shown benefit in cases of this previously intractable problem.

Other symptoms resulting from altered gastrointestinal motility include dysphagia, dyspepsia, abdominal pain, constipation, diarrhoea and faecal incontinence. Autonomic diarrhoea characteristically occurs at night, accompanied by urgency and incontinence.

Small intestinal dysmotility predisposes to bacterial overgrowth, which can cause bile salt deconjugation, fat malabsorption and diarrhoea. Bacterial overgrowth may also lead to features such as anaemia and macrocytosis; treatment is with antibiotics such as tetracycline.

**Bladder involvement**

Loss of tone, incomplete emptying and stasis (predisposing to infection) can occur and may ultimately result in an atonic, painless, distended bladder. Treatment is with intermittent self-catheterization, permanent catheterization if that fails, and prophylactic antibiotic therapy for those prone to recurrent infection.

**Sexual dysfunction**

Sexual dysfunction is common in both men and women with diabetes. The overall prevalence in men is 35–40% but increases with age. Approximately 60% of men with diabetes aged 60 years or over are affected. The first manifestation is incomplete erection, which may, in time, progress to total failure; retrograde ejaculation also occurs in people with autonomic neuropathy.

The mechanisms involved in erectile dysfunction in diabetes are multifactorial and include inadequate vascular supply owing to athrombosis in pudendal arteries, primary or secondary gonadal failure, hypothyroidism, anxiety, depression, alcohol excess and drugs (e.g. thiazides and beta-blockers).

When a man presents with erectile dysfunction, a detailed history and examination is needed to search for these causes. Blood is taken for luteinizing hormone, follicle stimulating hormone, testosterone, prolactin and thyroid function.
Complications of diabetes

Treatment should ideally include sympathetic counselling of both partners. Phosphodiesterase type 5 inhibitors (sildenafil, tadalafil, vardenafil, avanafil), which enhance the effects of nitric oxide on smooth muscle and increase penile blood flow, are the first line treatment in those who do not take nitrates for angina. Although less effective in people with diabetes, approximately 60% of men benefit from this therapy.

Alternative treatments include:

- Apomorphine 2 mg or 3 mg sublingually 20 min before sexual activity.
- Alprostadil (prostaglandin E1 preparation), given as a small pellet inserted with a device into the urethra (125 μg initially to a maximum of 500 μg). If the partner is pregnant, barrier contraception must be used to prevent fetal exposure to the prostaglandin.
- Intracavernosal injection of alprostadil (2.5 μg initially to a maximum of 40 μg). Side-effects include priapism, which needs urgent treatment should erection last longer than 3h.
- Vacuum devices.
- Penile prostheses.

Women with diabetes may complain of vaginal dryness and impaired sexual arousal.

The diabetic foot

Up to 50% of older people with type 2 diabetes have risk factors for foot problems and 10–15% of people with diabetes develop foot ulcers at some stage in their lives. Diabetic foot problems (Fig. 23.18) are responsible for nearly 50% of all diabetes-related hospital admissions. Diabetes is the most common cause of non-traumatic lower limb amputation but many diabetic amputations could be delayed or prevented by more effective self-management education and medical supervision.

Ischaemia, resulting from peripheral vascular disease, neuropathy and infection, combine to produce tissue necrosis and ulceration. Peripheral vascular disease tends to affect more distal vessels and occurs at a younger age in people with diabetes. Ischaemia compromises the ability to heal after minor trauma or infection.

Pain is a protective mechanism and the diminished sensation that results from peripheral neuropathy means that the individual is less able to perceive trauma and may continue to walk on a wounded foot thereby worsening the injury. Autonomic neuropathy reduces sweating and alters blood flow resulting in dry skin that is prone to crack and fissure.

Although ischaemia and neuropathy may coexist, certain features allow an ischaemic to be distinguished from a predominantly neuropathic aetiology (Box 23.24).

Charcot neuroarthropathy

Charcot arthropathy is a complication of severe neuropathy. It occurs in a well-perfused foot and can be divided into three phases:

- Acute onset
- Bony destruction
- Radiological consolidation and stabilization.

Individuals present with an acutely swollen hot foot and about a third have pain. At this stage, it may be difficult to differentiate between Charcot arthropathy and cellulitis; if in doubt, both conditions should be treated. Acute gout and deep vein thrombosis may also masquerade as Charcot arthropathy. If treatment is delayed, the foot can become deformed as bone is destroyed, often very rapidly over a few weeks. After 6–12 months, the destructive process stabilizes. Rehabilitation is always necessary after a long period in a cast and reconstructive surgery may be needed.

The aim of treatment is to prevent or minimize bony destruction and deformity. Any resulting deformity can alter the pressure distribution across the foot and predisposes the foot to future ulceration. Immobilization in a non-weight bearing cast is the treatment of choice and should be continued until the swelling and temperature in the foot has resolved.

Management of the diabetic foot

The key to managing diabetic foot problems is prevention. Learning about the principles of foot care is essential (Box 23.25). Healthcare professionals should screen for foot problems at least once a year; this process should include questions about past or present ulceration, an examination of the foot to detect structural abnormalities or callus formation and an assessment of neuropathy and peripheral vascular disease. Although a clinical examination may

Fig. 23.18 Diabetic foot. (A) High arch and clawing of toes. (B) Typical neuropathic plantar ulceration. (C) Vascular pattern of ulceration.
reveal a distal loss of sensation, the use of monofilament, applied perpendicular to the foot and which buckles at a force of 10 g, has allowed reproducible assessments. Ability to feel that level of pressure provides protective sensation against foot ulceration. Doppler ultrasound is a useful addition to a clinical examination of the lower limb pulses. If neuropathy or impaired blood supply is detected, the individual can be warned that their foot is at increased risk of ulceration.

Foot ulceration
The key to healing an ulcer is to ensure that the foot is non-weight-bearing. Resting the affected leg may need to be supplemented with special shoes and insoles to move pressure away from critical sites, or by removable or non-removable leg casts. After healing, special shoes and insoles are likely to be needed in the long-term to protect the feet and prevent abnormal pressure repeating damage to a healed area. In neuropathic feet, particularly, sharp surgical debridement by a chiropodist is necessary to prevent callus distorting the local wound architecture and causing damage through abnormal pressure on normal skin nearby.

Ischaemia
Clinical signs of ischaemia may be confirmed by femoral angiography, which is used to localize areas of occlusion that may be amenable to bypass surgery or angioplasty.

Infection
Foot infections can take hold rapidly and should be treated as medical emergencies. Some people have termed this a ‘foot attack’ akin to heart attacks to emphasize the seriousness of this condition. Clinical signs may include purulent discharge, erythema, local warmth and swelling.

Early broad-spectrum antibiotics are essential, with therapy adjusted in the light of culture results. The organism grown from the skin surface may not be the organism causing deeper infection. Collections of pus are drained and excision of infected bone may be needed if osteomyelitis develops and does not respond to appropriate antibiotic therapy. Regular X-rays of the foot are needed to check on progress.

Wound environment
Dressings are used to absorb or remove exudate, maintain moisture, and protect the wound from contaminating agents; they should be easily removable. Various newer approaches to aid healing of diabetic foot ulcers have been tried in recent decades, including new dressings containing growth factors and other biologically active agents, hyperbaric oxygen, negative pressure wound therapy and bioengineered skin substitutes.

Multidisciplinary diabetic foot team
A multidisciplinary diabetic foot team, involving diabetologists working with podiatrists, orthopaedic and vascular surgeons, specialist nurses, orthotists and other healthcare professionals improves the outcome for people with diabetic foot ulcers. Rapid access to services is needed and people with diabetes should know how to contact the foot team if they develop problems.

Macrovascular complications

Atherosclerotic vascular disease
Diabetes is a risk factor for the development of atherosclerosis. Myocardial infarction, stroke, peripheral vascular disease and cardiovascular death are increased two- or threefold compared with the background population. This risk is increased up to tenfold in premenopausal women, who lose their normal protection against cardiovascular disease.

Pathogenesis
Atherosclerotic vascular disease in people with diabetes tends to occur at an earlier age, progress more rapidly and is more distal and diffuse than in people without diabetes. Although hyperglycaemia contributes to the development of macrovascular disease, unlike microvascular disease, other more important haemodynamic and metabolic mechanisms are involved. The relationship between glycaemic control and cardiovascular disease is less strong than microvascular disease but continues across the normal glucose range. The other factors include hypertension, dyslipidaemia, which is characterized by low HDL cholesterol and high triglyceride concentrations, obesity, hyperinsulinaemia and proteinuria including microalbuminuria.

Management of atherosclerotic cardiovascular risk
Addressing cardiovascular risk involves the aggressive and systematic management of each of the predisposing factors (Box 23.26). As discussed earlier, early tight glycaemic control reduces the long-term risk of cardiovascular disease. In people with type 2 diabetes with established cardiovascular disease, the use of SGLT2 inhibitors and GLP-1 receptor agonists is recommended because of their protective effect. Anti-hypertensive treatment produces a marked reduction in adverse cardiovascular outcomes as well as microvascular events. To achieve the target for blood pressure, most people with diabetes will need combination drug therapy. The use of ACE inhibitors or angiotensin receptor blockers may confer additional benefit. Treating people with diabetes and at least one other major cardiovascular risk factor with an ACE inhibitor produces a 25–35% lowering of the risk of heart attack, stroke, overt nephropathy or cardiovascular death. Angiotensin II receptor antagonists are sometimes preferred initially and are also used for those intolerant to ACE inhibitors.

Statins are recommended for those with diabetes over the age of 40 years or after a 10-year history of diabetes if microvascular complications are present as cardiovascular events are reduced by 20% for every 1 mmol/L reduction in LDL cholesterol. Other lipid lowering agents, such as ezetimibe or PCSK9 inhibitors, are indicated if statins are not tolerated or do not bring the cholesterol to target.

As in the general population, smoking cessation is important and help should be offered to those wishing to quit.

Low-dose aspirin reduces macrovascular risk but is associated with a morbidity and mortality from bleeding. The benefits of aspirin
through weight loss and exercise. Pioglitazone may also reduce intrahepatic fat.

Malabsorption secondary to gastrointestinal dysmotility is described earlier but people with diabetes may also develop malabsorption through chronic exocrine pancreatic insufficiency. This is unusual because only 10% of pancreatic function is sufficient for normal digestion. Treatment is with pancreatic enzymes. People with type 1 diabetes have a higher prevalence of coeliac disease.

### Infections

Although people with well-controlled diabetes are not more prone to infection, hyperglycaemia leads to more frequent infection through multiple disturbances in innate immunity; by contrast, humoral immunity appears relatively unaffected. Microvascular disease may further impede the immune system and likely contributes to the severity of certain infections, including malignant otitis externa, emphysematous pyelonephritis and necrotizing fasciitis. Some microorganisms, such as Klebsiella serotypes and Burkholderia pseudomallei, are more virulent in hyperglycaemic environments.

Urinary tract infections and asymptomatic bacteriuria are more common in people with diabetes, with autonomic neuropathy a common and important underlying factor. Mycotic genital infections are more common, particularly in women. Skin and soft tissue infections are more common. The risk of tuberculosis is increased in people with diabetes. Certain viral infections, such as hepatitis C, and treatment for HIV/AIDS increase the risk of diabetes.

### Cancer

Certain types of cancer are more common in type 2 diabetes. The risk of carcinoma of the uterus and of the pancreas is approximately doubled, and there is a 20–50% increase in the risk of colorectal and breast cancer. These associations appear to be mediated, at least in part, by obesity, which confers similar levels of risk in the absence of hyperglycaemia, although there is also an element of reverse causation with carcinoma of the pancreas, which can precipitate or cause diabetes. People treated with metformin have been reported to have a lower cancer risk than those on other therapies, and this agent is under investigation for possible anti-tumour properties.

### Skin and joints

Diabetic cheiroarthropathy refers to joint contractures in the hands as a result of long-standing diabetes. This may be diagnosed by asking the individual to join the hands as if in prayer; the metacarpophalangeal and interphalangeal joints cannot be opposed. Thickened, waxy skin can be noted on the backs of the fingers. These features may be due to glycation of collagen and are not progressive (p. 679). Frozen shoulder, Dupuytren’s contracture, trigger finger, and carpal tunnel syndrome all occur more commonly in diabetes.

Fracture risk is increased in both type 1 and type 2 diabetes. Although bone mineral density is decreased in type 1 diabetes, it is increased in type 2 diabetes and so other mechanisms are at play. Thiazolidinediones decrease bone formation and bone mineral density, and increase fracture risk in type 2 diabetes. Following a fracture, healing may be delayed in people with diabetes. The risk of gout is increased in people with type 2 diabetes.

PSYCHOSOCIAL IMPLICATIONS OF DIABETES

The interaction between mind and body is central to the management and outcome of all chronic diseases, but is particularly fascinating in the case of diabetes. People with diabetes have an increased risk of developing a number of psychological conditions, while a range of psychiatric disorders are associated with an increased risk of diabetes (Box 23.27). People who report chronic stress, low stress resilience, sleeping problems or depression are at increased risk of developing type 2 diabetes. Diabetes affects the quality of many aspects of life including emotional wellbeing, financial situation, leisure and work activities and relationships with friends and families.

Psychological problems associated with diagnosis

Most people show remarkable psychological resilience to a diagnosis of diabetes, despite the implications for self-management and long-term health. However, in some people, the diagnosis may lead to symptoms of anxiety and depression while others develop an ‘adjustment disorder’. Transient psychological symptoms begin within 3 months of the diagnosis of the diabetes but usually resolve within 6 months. These symptoms are seen as part of the normal ‘grieving process’ that often accompanies the development of any chronic illness and may also develop in the parents of children with newly diagnosed diabetes.

Diabetes-related distress

Living with diabetes is demanding; it is estimated that people with type 1 diabetes need to devote up to 2 hours a day to self-management while around half of people with diabetes report that taking medication interferes with their ability to live a normal life. There are no holidays from diabetes! Diabetes self-management is often frustrating when blood glucose levels remain stubbornly out-of-target despite the individual’s best efforts. More than 50% of people develop psychological symptoms, which are collectively known as diabetes distress, in response to living with the constant burden of diabetes. These include:

- experiencing worries about the future and the possibility of serious complications
- feeling guilty or anxious when the diabetes management goes awry
- feeling scared or depressed when thinking about living with diabetes
- feeling discouraged with diabetes regimen.

Fear of hypoglycaemia

Episodes of hypoglycaemia are frequently unpredictable and are associated with unpleasant, embarrassing symptoms associated with activation of the nervous system. It is perhaps unsurprising that many people worry about future occurrences of hypoglycaemia and some people develop significant fear of hypoglycaemia. This fear may also be experienced by other family members. Significant fear of hypoglycaemia is more common in people who have experienced loss of consciousness during a previous episode.

Depression

The prevalence of depression is increased two-fold in diabetes. Significant depressive symptoms affect approximately one in four adults with diabetes while a formal diagnosis of depressive disorders is made in 10–15% of people with diabetes. Depression is more common in women, those who are divorced and those who have experienced childhood adversity and social deprivation. In addition, there are a number of diabetes-specific risk factors associated with depression, including the development of complications and after initiation of insulin in type 2 diabetes.

Eating disorders

Eating disorders, such as anorexia nervosa and bulimia, are more common in people with diabetes. The drive to lose weight may lead to intentional insulin omission, which is reported by a third of young women aged 16–30.

Consequences of psychological and psychiatric disorders of diabetes

As well as affecting quality of life, the psychological sequelae of diabetes also impair the individual’s ability to manage their diabetes. They are less likely to follow a healthy diet and exercise, less likely to take medication as prescribed and it is therefore no wonder that psychological problems are associated with higher HbA1c, more frequent admissions with hypoglycaemia and diabetic ketoacidosis, a higher incidence of complications and shortened life expectancy.

Management of psychological issues

The key step to managing the psychological sequelae of diabetes is identifying the problem. It is important to ask the person with diabetes how they feel about their diabetes and whether they are experiencing difficulties with it. The diabetes specialist team will undertake much of the psychological management, but this should
include liaison with the mental health teams to ensure appropriate referral of those with more complex problems. Some diabetes teams now include a psychologist.

A range of psychological interventions, including cognitive behavioural therapy and problem solving, have been used successfully to improve the psychological wellbeing of people with diabetes.

For people with depression, antidepressants are effective as long as they are used in adequate doses.

**Social aspects of diabetes**

Diabetes affects many aspects of the daily lives of people with the condition but here we will consider driving and employment.

The main issues for drivers with diabetes are hypoglycaemia and visual impairment from either retinopathy or cataract. Disability from leg amputation or neuropathy may also affect the ability to drive safely. As hypoglycaemia is the most common cause of accidents in people with insulin-treated diabetes, drivers with diabetes must take precautions to avoid hypoglycaemia while driving. In most countries, a driver with diabetes will need to inform the relevant authorities and insurance companies of their diagnosis.

Diabetes should not prevent access to most occupations but certain occupations including the armed forces, emergency services, commercial pilots, prison and security services, and jobs in potentially dangerous areas (e.g. at heights, underwater and offshore) are barred or require special precautions. Shift work can make insulin management more complex but modern long-acting insulin analogues with duration of action longer than 24 hours have made life easier.

**Diabetes in special situations**

**Diabetes in childhood, adolescence and early adulthood**

More than 1 million children have diabetes worldwide with approximately 132,600 new cases diagnosed annually. The incidence has been steadily rising over the last 50 years. Most children with diabetes have type 1 diabetes, although type 2 diabetes is becoming more common in older children.

After diagnosis, the child should be managed as an outpatient by a team comprising a paediatrician specializing in diabetes, diabetes specialist nurse, dietitian, social worker and a psychologist trained in childhood diabetes. Support and education is needed for the parents and extended families as the diagnosis of diabetes can be devastating.

Insulin pump is the treatment of choice for children with type 1 diabetes although basal-bolus multiple daily injections are an acceptable alternative. As the doses of insulin are much smaller in children, even a one-unit change in dose can amount to a large percentage change. The insulin pump allows finer adjustment than multiple daily injections. Half unit pens are also available.

As the child grows up, the responsibility for managing the diabetes will shift from parent to child. Adolescence and young adulthood is characterized by complex biological, social and psychological changes, which poses unique challenges to those with diabetes. The pubertal increase in sex steroids and growth hormone increase insulin resistance by 25–30% and coupled with the increase in body size, insulin requirements can increase substantially. Insulin adjustment often lags behind these changes resulting in hyperglycaemia.

During adolescence, individuals develop a sense of self and identity and begin to establish control, autonomy and independence. This is often accompanied by anxiety as the adolescent seeks peer acceptance. Diabetes often singles out the adolescent and can leave them feeling isolated and different. Adolescents may prioritize their social network over diabetes management and studies have shown that HbA1c and admissions for diabetic ketoacidosis tend to rise during the teenage years. The diabetes team needs to support the adolescent and parents through this period; success relies on empowering the individual with the skills and confidence that they can manage their diabetes.

The period of transition between paediatric and adult services is challenging and many young adults with diabetes lose contact with healthcare professionals if this process is not managed effectively. The physical transfer between paediatric and adult services is only a small component of transition and the process can take a number of years as the paediatric team, working with the adult team, provides the young adult with the information and skills needs to negotiate an adult health service independently. Although many young adults move to adult services around the age of 18–19 years, the decision to transfer should be based on skills and competencies rather than chronological age.

Emerging adulthood is a new concept that describes the early years of adulthood when an individual may be entering the world of work and moving away from home for the first time, including going to university. As well as providing many new opportunities, it is often a time for risk-taking. Many centres have now developed young adult clinics to care for the specific needs of this age group.

**Diabetes in older people and at the end of life**

The prevalence of diabetes in older people is increasing dramatically because of an ageing population and age-related challenges in body composition and insulin resistance. The lifetime risk of developing diabetes is 22% for women and 19% for men from the age of 60 years. More than half of those with diabetes are aged over 65 years. Approximately 25% of older people living in care homes or nursing homes have diabetes.

Diabetes places an additional burden on older people, who frequently have other chronic conditions, with up to 40% having three or more other co-morbidities. Diabetes increases the risk of dementia and the cognitive decline compromises diabetes management. Frailty, which is characterized by weight loss, weakness, decreased physical activity, exhaustion and slow gait speed, is more common in older people.

The management of diabetes in the older individual should consider the health status and needs of the person with diabetes. A thorough assessment should identify co-morbidities. Older people with diabetes are a highly heterogeneous population ranging from someone living independently in the community to a frail individual...

Consensus is that the main priority is to avoid hypoglycaemia and diabetes treatments need to be adjusted accordingly.

As people with diabetes may be less able to self-manage their diabetes while in hospital, it is important the diagnosis of diabetes is clearly identified in the medical records and glucose and HbA1c measured on admission. Errors in insulin prescribing are common and one-third of all fatal inpatient medical errors that cause death within 48 hours of the error involve insulin administration. An emphasis on insulin safety, particularly when an intravenous insulin is being used, is essential. There is an increasing move for people with insulin-treated diabetes to self-manage once they are able to so themselves on the grounds that they know how to do so much better than many hospital staff.

Many hospitals have specialized diabetes inpatient teams who take responsibility for diabetes management but all staff caring for people with diabetes should be appropriately trained and competent in the management of inpatient diabetes (see Box 23.12).

Intravenous insulin is required for a number of specific conditions as this mode of administration provides the greatest flexibility to meet rapidly changing insulin requirements (Box 23.30). Intravenous insulin is usually administered as a variable rate infusion, but the insulin rate is fixed when treating diabetic ketoacidosis. Variable-rate or fixed-rate intravenous insulin infusion is preferred to the old but more ambiguous terminology ‘sliding scale’. In order to maintain patient safety, the glucose should be monitored frequently.

Management of diabetes during an admission for surgery

Both hyperglycaemia and hypoglycaemia in the postoperative period worsen surgical outcomes by increasing the risk of infection, myocardial infarction and death, and are associated with an increased duration of stay on the intensive care unit and in hospital.

The patient journey begins in primary care and general practitioners should help optimize glucose management in the preoperative period. This will reduce the likelihood of the surgery being cancelled or postponed owing to poor glycaemic control. The preoperative assessment provides a further opportunity to improve diabetes management and will allow the patient to be placed at the beginning of a morning list where possible to minimize the period of fasting and subsequent metabolic disturbance.

For people treated with insulin, unless the period of fasting is less than one missed meal, a variable-rate intravenous insulin infusion will be needed to control the glucose perioperatively. The long-acting insulin should be continued as this will prevent rebound...
hyperglycaemia when the intravenous insulin is stopped. Oral drugs that can cause hypoglycaemia should also be stopped for the dose immediately prior to surgery but can be resumed once the patient is eating and drinking normally. Metformin should be stopped if intravenous contrast is used.

Prior to discharge, a clear follow-up plan is needed, which should be communicated to the person with diabetes and their primary care team.

**Diabetes in pregnancy**

Diabetes is one of the most common medical conditions in pregnancy, affecting 2–5% of pregnant women. Approximately 85% of women with diabetes in pregnancy have gestational diabetes with the remainder having pre-existing diabetes. The epidemiology of pre-existing diabetes in pregnancy is changing as women are delaying pregnancy to an older age and the prevalence of obesity and type 2 diabetes is increasing in women of childbearing age. Whereas 25 years ago, type 2 diabetes was rare in pregnant women, the latest UK national audit has indicated that there are equal numbers of women with type 2 diabetes as type 1 diabetes.

**Adverse effects of diabetes in pregnancy**

Prior to the discovery of insulin, pregnancy was invariably fatal for both mother and fetus. Even in the era up to the 1960s, pregnancy remained a risky enterprise, with perinatal mortality rates of up to 40%. However, with an understanding that maternal hyperglycaemia was the major cause of fetal loss, management changed to ensure as near normoglycaemia as possible and outcomes began to improve. However, pregnancy outcomes in women with diabetes still remain worse than women without diabetes.

Diabetes in pregnancy is associated with risks to both the woman and to the developing fetus. Women with pre-existing diabetes may find it harder to conceive and in the first trimester have higher rates of miscarriage and congenital anomalies. The frequency of many developmental abnormalities, including cardiac and skeletal malformations, is increased. Although rare, the risk of caudal regression syndrome appears to be specifically increased in women with diabetes. Towards the end of pregnancy, women with either pre-existing diabetes or gestational diabetes have a higher risk of pre-term labour, hypertension and pre-eclampsia.

The risks to the fetus include higher rates of macrosomia and associated shoulder dystocia and birth injury, polyhydramnios, stillbirth and perinatal mortality, and impaired postnatal metabolic adaptation leading to higher rates of neonatal hypoglycaemia, jaundice and respiratory distress. After birth, neonatal hypoglycaemia may occur. Maternal glucose crosses the placenta but insulin does not; this leads the fetal islets to hypersecrete insulin in order to combat the rising hyperglycaemia, and rebound hypoglycaemia may occur when the umbilical cord is cut. In the longer term, offspring of mothers with diabetes have a higher risk of obesity and diabetes in adulthood.

Obesity itself adversely affects maternal and fetal outcomes. For the mother, obesity independently increases the risk of hypertension and pre-eclampsia, infections and venous thromboembolism. Through fetal overnutrition, obesity may also drive macrosomia and associated birth trauma.

**Management of diabetes during pregnancy**

As the adverse effects of diabetes are largely mediated by hyperglycaemia, the major aim of management in diabetic pregnancies is to maintain normoglycaemia by avoiding pre- and post-prandial hyperglycaemia without causing severe hypoglycaemia. This is a demanding process and so pregnant women with diabetes should be in contact with a specialist multidisciplinary team jointly led by a physician and obstetrician at least every 2 weeks.

**Pre-conception care**

Pregnancy management should begin well before conception; as pregnancy can only be diagnosed a minimum of 2 weeks after conception, it is important that optimal glycaemic control is achieved prior to conception. This requires planning on the part of both the woman with diabetes and the diabetes team. From puberty, girls with diabetes need to know about the importance of pregnancy planning and contraception until they are ready to start a family.

Once a woman expresses a desire for pregnancy, referral to a specialist diabetes preconception clinic improves the pregnancy outcomes. This provides an opportunity to review the diabetes management, discuss the need for high dose folic acid (5 mg daily) to reduce the risk of neural tube defects, ensure that microvascular screening is up-to-date and check that the woman has been immunized against rubella.

The optimal target pre-conception HbA1c is below 48 mmol/mol (6.5%) when this can be achieved safely but women should be advised not to become pregnant if their HbA1c is above 86 mmol/mol (10%). Target fasting plasma glucose levels 5–7 mmol/L (90–126 mg/dL) and 4–7 mmol/L (70–126 mg/dL) before meals at other times of the day are needed to achieve this level of glycaemic control. This is challenging for the women and they should be offered the opportunity to attend structured education if they have not done so already. Where necessary, insulin analogues should be used as these appear to convey advantages over human insulin. Metformin may be used while preparing for pregnancy but other oral anti-diabetes drugs and GLP-1 receptor agonists should be stopped. ACE inhibitors, angiotensin II receptor antagonists and statins should be stopped prior to conception.

**Antenatal management**

The need for tight glycaemic control continues once a woman becomes pregnant; the target glucose levels are less than 5.3 mmol/L fasting (95 mg/dL), less than 7.8 mmol/L (140 mg/dL) 1 hour after meals and less than 6.4 mmol/L (115 mg/dL) 2 hours after meals. Women need to monitor their glucose levels by capillary blood testing; where available, continuous glucose monitoring is preferred as this increases the time that women spend in the target glucose range and is associated with improved fetal outcomes.

These stringent glycaemic targets are made harder to achieve because pregnancy changes the insulin requirement; this tends to fall in the first trimester, partly as a result of the hormonal changes in pregnancy but also because pregnancy-associated nausea and vomiting can reduce appetite. This increases the risk and severity of hypoglycaemia; for reasons that are not entirely clear, early pregnancy is associated with impaired awareness of hypoglycaemia, further increasing the likelihood of hypoglycaemia. Women and their partners need to know about the risk and how to manage it. Interestingly, the fetus tolerates maternal hypoglycaemia relatively well.

During the second and third trimesters, pregnancy induces a state of insulin resistance, which typically increases insulin requirements by 50–100% in the latter half of pregnancy. Towards the end of pregnancy, insulin absorption is delayed and so women may need to increase the length of time between the short-acting insulin injection and eating in the third trimester.
Ketoacidosis in pregnancy carries a 50% fetal mortality and therefore if it occurs in pregnancy it should be diagnosed and managed rapidly. In order to expedite the diagnosis, women should be taught to monitor blood ketones at the outset of pregnancy.

As pregnancy can accelerate the progression of retinopathy, pregnant women should be screened in the first and third trimester and in the second trimester if any retinopathy is present at the outset.

Low-dose aspirin (150 mg daily) from the 12th week of pregnancy lowers the risk of hypertension and pre-eclampsia.

Enhanced fetal surveillance is needed and a detailed ultrasound scan for fetal anomalies including a four-chamber view of the fetal heart and outflow tracts should be offered at 18–20 weeks. Growth scans and other tests of fetal wellbeing should be performed during the third trimester.

Birth

Most babies of women with diabetes are born before term following an induction of labour or elective caesarean section to reduce the risk of stillbirth. Glycaemic control during labour is usually maintained by a variable rate intravenous insulin infusion but pumps are being increasingly used as an alternative in some centres.

Postnatal care

Following birth, maternal insulin requirements drop rapidly to pre-conception levels within hours of the birth and may even be lower if a woman chooses to breast-feed. As the neonate is at increased risk of hypoglycaemia, early feeding should be encouraged with breast-feeding being the preferred option and glucose checked regularly until it is clear that the pre-feeding glucose levels are being maintained in the normal range.

Gestational diabetes

Gestational diabetes is defined as diabetes occurring for the first time in pregnancy that is clearly not overt diabetes prior to pregnancy. It is usually diagnosed in the second and third trimester of pregnancy following a 75 g oral glucose tolerance test. Gestational diabetes occurs in women whose pancreatic β cells are unable to secrete sufficient insulin to meet the pregnancy-induced insulin resistance. The risk factors for gestational diabetes are the same as for type 2 diabetes and so gestational diabetes can be regarded as an early revelation of the metabolic abnormality brought on by the demands of pregnancy. Not all diabetes presenting in pregnancy is gestational. Screening may identify women with previously undiagnosed type 2 diabetes and, in a few cases, gestational diabetes may unmask pre-clinical type 1 diabetes.

Diagnosis of gestational diabetes

There is a lack of international agreement regarding the diagnosis with varying diagnostic cut-off values and number of abnormal values needed between recommendations (Box 23.31). Universal screening for diabetes is recommended in many countries but in the UK, NICE recommends screening only women with risk factors for gestational diabetes; the advantage of the latter approach is that many low-risk women do not need the screening test and it costs less but it risks missing gestational diabetes in a significant proportion of women (Box 23.32).

Management of gestational diabetes

The glucose targets are the same as for pre-existing diabetes but management begins with lifestyle modification, similar to the management of type 2 diabetes (pp. 712–713). If lifestyle modification does not achieve adequate maternal glycaemia within 1–2 weeks, pharmacological therapy is indicated. Although insulin is still widely used, studies have suggested that metformin or glibenclamide (a sulphonylurea) are acceptable alternatives.

Women with gestational diabetes have a 50% chance of developing diabetes within 10 years of the pregnancy. The diabetes antenatal team should discuss this risk and the measures needed to reduce the likelihood of developing diabetes prior to discharge after the birth. An annual HbA1c or glucose test is recommended to diagnose asymptomatic diabetes. At present, the uptake of postnatal interventions and screening is low, and more research is needed to find out how to manage this risk more effectively.

Further reading

The diabetes care team involves a multidisciplinary group of healthcare professionals who are available to support the person with diabetes (see Fig. 23.10). As the amount of time that each person with diabetes spends with a healthcare professional is small, on average less than 6 hours a year, it is important that every contact counts and provides appropriate medical and psychosocial support. To ensure that the person with diabetes derives the maximum benefit from the time spent with their diabetes team, whether in a hospital or community setting, the consultation should be collaborative, patient-centred, goal-focused and with clear aims. As well as traditional clinic visits, people with diabetes may access diabetes care virtually through phone, email or internet contact or through educational sessions.

Much of care is focused towards minimizing the long-term complications while avoiding adverse effects from treatment. Diabetes UK has described the 15 essentials of diabetes care (Box 23.33) that should be assessed and discussed at least once a year.

The majority of diabetes care takes place in a primary care setting but people with diabetes with complex medical or psychological needs will require management and support in a specialist setting for some or all of their care. A close collaboration between primary and secondary healthcare professionals and among specialists is essential to ensure that care is integrated and coordinated across the wide range of disciplines involved.

People with diabetes need to be involved in decisions about their care as this improves outcomes and the likelihood that a specific management plan will be followed. It is good practice to provide the person with diabetes with copies of any letters written about them so that all decisions are clear, and it is easier to review the management plans at subsequent contacts.

Lipid disorders are common, and of great public health importance. All doctors need to be comfortable with managing such patients in the context of their overall cardiovascular risk. Inherited metabolic diseases (IMDs) are individually much rarer, although as a group not altogether uncommon. Many patients with IMDs, including severe phenotypes of inherited lipid disorders, are diagnosed in childhood, and transition to the care of metabolic medicine specialists in tertiary referral centres in adulthood, supported by dieticians and other healthcare professionals. However, they may initially present as adults to general services, or require general or emergency management in non-specialist settings, meaning that all doctors need a basic awareness of these conditions.

Key skills in this area include:
- becoming familiar with the different drugs for lowering lipids and their role in reducing cardiovascular risk
- knowing when to suspect an inherited metabolic disease and understanding the principles of tailored therapy for rare diseases
- recognizing the acute presentations of such conditions and knowing core steps in management of these emergencies.

Opportunities for learning in this specialty include observing clinics in specialist metabolic medicine centres, and shadowing a dietician giving advice to patients on reducing cardiovascular risk.

INTRODUCTION

Lipid disorders are common, with 95% of Western populations having raised cholesterol levels compared with aboriginal/undeveloped societies. Cholesterol contributes up to half of population cardiovascular disease risk worldwide. A single genetic disorder of cholesterol metabolism – familial hypercholesterolaemia – is one of the commonest autosomal dominant disorders globally. Other disorders are less common but defects of the lipoprotein lipase pathway constitute a medical emergency as they can present as gross hypertriglyceridaemia associated with pancreatitis.

Inherited disorders of metabolism present in a variety of ways, often in childhood but sometimes in adults, as described in the second half of this chapter. Often disease will present with multi-system involvement, or in response to specific metabolic triggers such as starvation or dehydration. There may be a family history of similar symptoms or early death, or of consanguinity. It is important not to miss the diagnosis of an IMD because early institution of therapy or dietary modultation often significantly improves prognosis.

Approach to the patient

History

Significant factors relevant to lipid disorders include:
- demographics, including ethnicity.
- a cardiovascular risk factor history, including current and previous smoking, diabetes or pre-diabetes, family history of cardiovascular disease prior to age 60 (to second generation if available) and family history of hyperlipidaemia.
- a history of unexplained pancreatitis.

An IMD should be considered:
- in patients presenting with syndromes associated with particular IMDs, including encephalitis, rhabdomyolysis, acidosis, hypoglycaemia or stroke (see p. 752).
- where there is multisystem involvement.
- where there is a history of metabolic triggers (see p. 752).
- where there is a family history of similar symptoms, early death or of consanguinity.
- where an alternative more common diagnosis is not forthcoming.

It is important not to miss a diagnosis, as prognosis is often good following early institution of simply therapy or diet modulation. A confirmed diagnosis also has implications for the extended family who may benefit from early intervention and reproductive options.

Examination

Examination of a patient with a lipid disorder includes:
- noting signs of soft tissue lipid accumulation, such as tendon lumps (xanthomata), eyelid xanthelasma, and eruptive or planar xanthomata.
- measuring waist circumference and calculating body mass index (BMI).
- measuring blood pressure.
Patients with IMD may have signs relating to their clinical presentation, eg stroke or encephalitis. In some of the storage diseases, hepatosplenomegaly (sometimes massive) can be demonstrated.

Investigations
Patients with lipid disorders require a random or fasting lipid profile (see p. 745), and (at their first clinic visit) exclusion of secondary causes of proteinuria such as nephrotic syndrome (by measuring urine protein).

IMDs may require measurement of metabolites including ammonium, lactate, glucose, organic acids and amino acids in serum, urine and cerebrospinal fluid. Basic and additional tests, including the role of genetic testing, is described in Box 24.6.

DISORDERS OF LIPID METABOLISM

Physiology
Lipids are essential as fuel sources, structural components of membranes and as the basis for paracrine mediators. Lipid components can be synthesized from acetyl CoA derived from the tricarboxylic acid (Krebs) cycle pathway. Thus acetyl CoA can be made into linear chain fatty acids used mostly as fuel or the ring structures of cholesterol essential for membrane structure. The cholesterol synthesis pathway is regulated by its end-product through its rate-limiting initial enzyme, hydroxy-methyl-glutaryl coenzyme A reductase (HMG-CoAR), which is inhibited by ‘statins’, explaining their importance in the control of lipid disorders.

Lipids are insoluble in water and are transported in the bloodstream as macromolecular complexes. These complexes comprise a core of hydrophobic triglyceride, cholesterol and cholesterol esters surrounded by a phospholipid coat. Proteins (called apolipoproteins (apos)) on the surface of these ‘lipoprotein’ particles act as modulators of metabolism (e.g. enzyme cofactors) and ligands for receptors in the liver and the peripheral tissues. The structure of a chylomicron (one type of lipoprotein particle) is illustrated in Fig. 24.1.

Five principal types of lipoprotein particles are found in the blood (Fig. 24.2). They are structurally different and can be separated in the laboratory by their composition, density and electrophoretic mobility. The larger particles give postprandial plasma its cloudy appearance (lipaemia). The major apolipoproteins and most receptors have been isolated and sequenced, but the functions of some remains unclear. Plasma lipid levels are dependent on nutritional and environmental factors as well as genetic variants and contribute 55% of population-attributable risk for atherosclerotic disease. Genetic disorders of lipid metabolism are relatively common and contribute to highly increased risk of cardiovascular disease in some individuals. The pathways involved in lipid particle metabolism are concerned with exogenous lipid uptake and transport (chylomicrons), endogenous lipid synthesis and transport (apo B100-containing-particles) and reverse transport to the liver (apo A1-containing particles).

Chylomicrons
Chylomicrons (see Fig. 24.1) are synthesized in the small intestine post-prandially in response to the presence of gut fats (triglycerides) and cholesterol. They are secreted into the intestinal lymphatic drainage, and then pass along the thoracic duct into the bloodstream to be cleared eventually by the liver. They contain large quantities of triglycerides, some cholesterol and cholesterol esters. They are the main mechanism for transporting dietary fat, cholesterol and dietary-derived fat-soluble vitamins. Chylomicrons contain a ligand protein – apo B48 (one molecule), components of some future high-density lipoprotein (HDL) particles (apo A1 and apo A2), and acquire apoproteins C1-3 and apo-E by transfer from other particles in the bloodstream. Apo C2 binds to specific vascular surface (endothelial) receptors in adipose tissue, skeletal muscle and the liver, where the endothelial enzyme, lipoprotein lipase (LPL), hydrolyzes triglyceride into fatty acids for local uptake. The chylomicron remnant particle, containing most of the cholesterol, is taken up by the liver by a specific receptor and also by

![Fig. 24.1 A chylomicron particle (75–1200 nm) showing apoproteins lying in the surface membrane.](image-url)
the apo-E/B-100 receptor. Clearance is determined by the balance of apo-E promoting clearance and apo C3 delaying it.

**Very-low-density lipoprotein particles**

Very-low-density lipoprotein (VLDL) particles are synthesized conti

uous in the liver. They transport the body’s endogenously syn

thesized triglyceride and cholesterol. Apo B-100 is the signature protein component of VLDL and its metabolic derivatives, and present at one per particle. A small proportion of VLDL may complex with liver synthesized apo(a). As with chylomicrons, apo C1-3 and -E are incorporated later into VLDL by transfer from HDL particles and triglycerides are removed by LPL. This leaves a denser particle, due to partial depletion of triglyceride called an intermediate-density lipoprotein (IDL) particle.

**Intermediate-density lipoprotein particles**

IDL particles contain apo B-100 and apo C1-3 and apo-E molecules on the particle surface. Most IDL particles bind to liver low-density lipoprotein (LDL) (apo-E/B-100) receptors through the apo-E molecule and are catabolized. Further triglyceride removal leads to a denser remnant called LDL particles.

**Low-density lipoprotein particles**

LDL particles are the main carrier of cholesterol in fasting plasma, and deliver it both to the liver and to peripheral cells. The surface of the LDL particle contains apo B-100 and varying quantities of apo C-3 and apo-E. Apo B-100 is the principal ligand for the LDL (apo-E/B-100) receptor (LDLR). The LDLR binds LDL, forms coated pits on the surface of the hepatocyte, which invaginate and fuse with lysosomes and proteasomes, which destroy the LDL particle releasing its components (Fig. 24.3). This process is, in part, regulated by a serine protease, proprotein convertase subtilisin/kexin type 9 (PCSK9). PCSK9 binds to LDL–LDLR complexes increasing the rate of clearance of the complexes. If no PCSK9 is bound, then the LDLR can be recycled to the cell surface. The number of hepatic LDLR regulates the circulating LDL particle number and LDL cholesterol. LDL particles can deposit lipid into the walls of the peripheral vasculature through binding to elastin and other hyaline components, causing macrophage entry and atherosclerosis.

**Lipoprotein(a)**

The particles that comprise lipoprotein(a) are derived from VLDL by addition and covalent binding of apo(a). This protein contains multiple domain repeats (which control its plasma concentration) and an inactive plasminogen domain. Apo(a) binds in such a way to impede clearance of Lp(a) by the LDLR. High levels of Lp(a) are genetically co-dominantly inherited. Most Caucasians have little Lp(a) unlike West African populations. Lp(a) binds avidly to arterial glycans and acts to promote atherosclerosis. Patients with high levels of Lp(a) show increased rates of CVD even if they have only moderate levels of LDL-C.

**High-density lipoprotein particles**

Nascent high-density lipoprotein (HDL) particles are produced in both the liver and the intestine. They are initially disc-shaped and contain their signature protein apoprotein A1 (4 molecules), other apoprotein components and some phospholipid. The apoA1 molecules are arranged in an overlapping belt and can be replaced by the inflammation-associated protein serum amyloid A. HDL particles take up cholesterol from cells through the ATP-binding cassette transporter-A1 (ABC-A1). A concentration gradient for export is maintained by esterifying this cholesterol through the action of lecithin-cholesterol acyltransferase (LCAT). The particles acquire further cholesterol through ABC-G1 and also phospholipids, apo C1-3 and apo-E by transfer from chylomicrons and VLDL particles. The HDL particle transports excess cholesterol from the periphery and may transfer it to other particles, such as VLDL through the action of cholesterol ester transfer protein (CETP), or deliver cholesterol directly to the liver (reverse cholesterol transport) or to steroid-synthetic tissues (ovaries, testes, adrenal cortex). HDL particles are taken up by the liver scavenger-receptor B1 (SRB1). In contrast to apo B-100 particles, the apo A1 core is recycled and re-secreted. Highly depleted or modified HDL particles are eventually cleared by the kidney through megalin and cubilin receptors. Cholesterol in the liver can be oxidized to bile acids, which are secreted into the bile to promote cholesterol and triglyceride uptake in the gut. Excess bile salts are resorbed in the terminal ileum and recirculate in the enterohepatic circulation (see p. 1266). HDL particles also have multiple other actions including reducing inflammation, being anti-parasitic, modulating clotting factor activity, affecting bone marrow function and promoting endothelial health.

**Measurement of serum lipids**

In a fasting serum lipid profile, the majority of the total cholesterol concentration is present in LDL particles with about 20–30% in HDL particles. The triglyceride concentration largely reflects VLDL particles, as chylomicrons have normally been completely cleared by 8–12 hours of fasting. In non-fasting samples, the total triglyceride concentration will be raised, due to presence of triglyceride-rich chylomicrons. The laboratory will usually supply the non-HDL-cholesterol (difference of total and HDL-cholesterol) concentration as this is the strongest index of CVD risk. In patients with triglycerides below 4.5 mmol/L, and ideally fasting, the laboratory can calculate the LDL cholesterol (LDL-C) using the Friedewald formula: LDL-C = TC – HDL-C – (TG/2.2). Some laboratories measure concentrations of LDL-C directly, and also of lipoprotein(a), apo B-100 and apo A1.
Plasma lipids and cardiovascular risk

Population studies have repeatedly demonstrated a strong association between total, non-HDL cholesterol (the difference between total and HDL cholesterol; a surrogate for apo B-100-containing particles) and also LDL-cholesterol concentration, and CVD risk; the strongest association is with coronary heart disease. CVD risk rises progressively with total cholesterol, and with total cholesterol: HDL-C ratio (Fig. 24.4). Higher HDL concentrations (up to 1.8 mmol/L) protect against CVD. Triglycerides often move in opposition to HDL-C levels. There is a weak additional risk associated with triglyceride-rich VLDL or IDL particles and CVD risk. Chylomicrons do not confer an excess CVD risk but do raise the total plasma triglyceride concentrations. Raised triglyceride levels (>10 mmol/L), and especially those associated with continuing plasma persistence of chylomicrons, are associated with an increased risk of pancreatitis.

Hyperlipidaemia

Hyperlipidaemia results from genetic predispositions interacting with the environment, including nutritional factors.

Secondary hyperlipidaemia

Glucose and liver metabolism influence lipid levels. A clinical history, examination and simple investigations need to be performed to detect the causes of secondary hyperlipidaemia (Box 24.1), which may need specific treatment in their own right. Hypothyroidism, untreated diabetes, renal disease (especially nephrotic syndrome) and abnormal liver function can all raise plasma lipid levels.

Primary hyperlipidaemia

Lipid disorders can be grouped as follows:
- disorders of VLDL and chylomicrons – hypertriglyceridaemia
- disorders of LDL – hypercholesterolaemia alone
- disorders of HDL (rare)
- combined hyperlipidaemia.

Disorders of VLDL and chylomicrons: moderate and severe hypertriglyceridaemia

Most cases are caused by multiple gene variants acting together to produce a modest excess of circulating concentration of VLDL particles, such cases being termed polygenic hypertriglyceridaemia.

Lipoprotein lipase pathway deficiencies

These are rare orphan diseases that produce greatly elevated triglyceride concentrations (>20 mmol/L) owing to the persistence of chylomicrons (not VLDL particles), because their triglyceride cannot be metabolized. This may occur if the enzyme lipoprotein lipase (LPL) is defective (95% of cases), or sometimes because the normal enzyme cannot function, due to deficiencies of its apoprotein C2 co-factor (1%), a control protein affecting LPL secretion (apo-A5) (1%), a protein involved in particle maturation (lipid-maturation factor-1; LMF-1) or the cell surface receptor for LPL (glycerophosphoinositol-HDL-like binding-protein-1(GPI-HBP1). Patients with homozygous or dual deficiency present in childhood with eruptive xanthomas, lipoaemia retinalis (yellow lipid particles visible in retinal arteries), pancreatitis and hepatosplenomegaly. Heterozygotes can present as adults with gross hypertriglyceridaemia. Some cases are caused by severe polygenic hypertriglyceridaemia. The presence of chylomicrons floating like cream on top of fasting lipaemic plasma suggests this diagnosis. The aetiology can be implied by measurement of the triglyceride: apoB-100 ratio or ultracentrifugation but the diagnosis is confirmed by DNA sequencing.

Disorders of LDL: hypercholesterolaemia alone

Heterozygous familial hypercholesterolaemia

Heterozygous familial hypercholesterolaemia (HeFH) is an autosomal dominant monogenic disorder present in 1 in 350 of the population. Mutations affect the LDLR receptor (90%; more than 1500 mutations described), the apo-B100 LDLR ligand domain (5%; 1 principal mutation) and proteins such as PCSK9 that control LDLR expression (2%). The defect results in a reduction in LDLR function causing accumulation of LDL particles and LDL-C in plasma (Box 24.2). There is extensive phenotypic variation but more severe cases have a 50% CVD mortality rate by age 65. Genetic founder effects increase the prevalence in some groups (e.g. Afrikaner South Africans, Lebanese, French-Canadians). Patients often have no
physical signs, in which case, the diagnosis is made on the presence of very high plasma cholesterol concentrations that are unresponsive to dietary modification and are usually associated with a family history of early CVD before age 60. Diagnosis is easier if pathognomonic clinical features are present but these only occur in 10%. These signs include cholesterol deposition in extensor tendons such as the Achilles or those of the fingers. Lipid deposition in the skin around the eyes (xanthelasma) may be present but is not diagnostic of FH and is more typical of high triglyceride-low HDL disorders. The diagnosis of FH is confirmed by DNA sequencing. Given its autosomal dominant inheritance, mutation screening is simple to apply and children of affected individuals have a 50% chance of inheriting the defect.

**Homozygous familial hypercholesterolaemia**

Homozygous familial hypercholesterolaemia (HoFH) is an ultra-orphan disorder (affecting 1 in 250 000). Affected children have minimal LDLR function in the liver. They have a hugely elevated LDL-C (greater than 13 mmol/L), and massive deposition of lipid in arterial walls, the proximal aorta and in skin on extensor surfaces (tuberose xanthomata). Most die from ischaemic heart disease by age 35 if untreated. They have a limited response to drugs such as statins but PCSK9 inhibitors have been used with some success especially in patients with point mutations. Repeated fortnightly lipid-specific plasma extraction (apheresis) can be used to remove LDL-C in patients with null mutations. LDLR function can be restored by partial lobe liver transplantation which normalizes LDL-C levels and causes regression of xanthomata. Some orphan drug therapies are licensed for use in HoFH (Box 24.3).

**Mutations in the apoB and PCSK9 genes**

Mutations in the terminal part of apoB affect binding to the LDLR and cause another relatively common single-gene disorder resembling FH. The clinical picture resembles classical HeFH but is milder, with lower LDL-C levels as some LDLR functions are preserved. Activating mutations in PCSK9 cause downregulation of LDLR. In contrast, inactivating mutations in PCSK9 are associated with enhanced LDLR function and lower cholesterol levels. The two disorders can be distinguished clearly only by genetic tests. The approach to treatment is the same.

**Polygenic hypercholesterolaemia**

This is a term used to lump together the large group of patients without evidence of monogenic cholesterol disorders above, but with cholesterol in the upper part of the normal distribution. Panels for diagnosis of polygenic variants have been devised and include genes known to significantly affect cholesterol levels and CVD disease risk such as LDLR, apo5, apo(a), apo-E and PCSK9.

**Disorders of HDL**

Genetic disorders of HDL metabolism are rare and recessively inherited. They include those causing low HDL-C levels including mutations in apo-A1, ABC-A1 and LCAT. Apo-A1 mutations cause low HDL-C, which are associated with amyloid deposition, and either atherosclerosis or protection from atherosclerosis depending on the exact site affected. Very high HDL-C levels are caused by mutations in cholesterol ester transfer protein (CETP) or endothelial lipase, which affect metabolism of HDL particles.

**Tangier disease**

Macrophages are involved in uptake of excess cholesterol in arterial walls, and donate this to HDL particles. If a defect occurs in cholesterol transport, e.g. the ABC-A1 transporter, then they accumulate cholesterol (see Box 24.2). In Tangier disease, cholesterol accumulates in reticuloendothelial tissue and arteries, causing enlarged, orange-coloured tonsils and hepatosplenomegaly, corneal opacities and polynuropathy, as well as CVD.

**Combined hyperlipidaemia**

The most common patient group with abnormalities of serum lipid concentrations have a polygenic combined hyperlipidaemia. Patients have an increased CVD risk due to high non-HDL-C concentrations, abundant pro-atherogenic triglyceride-rich particles, high LDL-C and suppression of HDL concentrations by the hypertriglyceridaemia (low LPL, excess CETP activity).

**Familial combined hyperlipidaemia (FCHL)**

This is relatively common, affecting 1 in 200 of the general population. Its lipid phenotype includes hypertriglyceridaemia, hypercholesterolaemia or both, associated with premature CVD. The genetic basis for the disorder is not clear though current studies suggest the primary defect lies in excess adipose tissue fatty acid release. It is diagnosed by finding raised cholesterol and triglyceride concentrations in association with a typical family history. There are no typical physical signs.

**Remnant hyperlipidaemia**

This is a rare (1 in 5000) cause of combined hyperlipidaemia. It is due to accumulation of IDL remnant particles and is associated with an extremely high risk of CVD. It may be suspected in a patient with

Disorders of lipid metabolism

almost equal cholesterol and triglyceride concentrations and by finding lipid deposition in the dermis visible at palmar creases (palmar xanthomata, which is diagnostic) and in the skin over the knees and elbows (tuberose xanthomata) (Fig. 24.5). Remnant hyperlipidaemia is commonly associated with inheritance of apo-E variant alleles (e.g. homozygosity for apoprotein E2 that has reduced LDLR binding), together with aggravating factor such as another primary hyperlipidaemia. The diagnosis can be confirmed using the triglyceride: apoB-100 ratio, by genotyping apo-E or by ultracentrifugation.

Management of hyperlipidaemia

Lipid-lowering diet

The main elements of a lipid-lowering diet are similar to those for people with diabetes or hypertension (see Box 23.10). Additional specific measures are to:

- reduce alcohol consumption, since this may worsen primary lipid disorders at doses that would not affect normal individuals
- include foods capable of binding cholesterol such as bran or soya protein.

Aboriginal or undeveloped societies typically have a total cholesterol 3.5–4.0 mmol/L with LDL-C 1.5–2.0 mmol/L. A vegan diet can reduce cholesterol and LDL-C by 2 mmol/L and a vegetarian diet by 1 mmol/L compared to the usual western diet. Several ‘nutraceutical’ or alternative health products are available that can reduce LDL cholesterol levels. Plant stanols are analogues of cholesterol that bind to gut cholesterol transporters and reduce the absorption of cholesterol. Products containing sitostanol or sitosterol reduce cholesterol by approximately 0.35–0.5 mmol/L, but with wide inter-individual variation. Red yeast rice is a Chinese medicine that contains a homologue of a statin (monacolin A) capable of reducing LDL-C by 10–20%.

Exercise, weight loss and smoking

Regular exercise, weight loss and stopping smoking all reduce CVD risk, irrespective of lipid levels.

Drugs

See Box 24.3 for the classes of drugs used to treat hyperlipidaemia and Box 24.4 for principles of use.

Statins

Statins block HMG-CoA reductase, the rate-limiting step in cholesterol synthesis, leading to compensating effects that increase the expression of LDL receptors and hence a reduction in plasma cholesterol concentrations of 20–50%. Statins reduce CVD events by 21% per 1 mmol/L LDL-C reduction. Their adverse effects are uncommon, reversible and occur in 1–2% of individuals, generally within weeks of starting the drug. Generalized muscular aches (myalgia) are the most common, occasionally representing myositis if creatine kinase (CK) is raised and extending rarely to rhabdomyolysis in severe cases (CK >5000IU/L). A pharmacogenetic effect exists for some statins due to
variants in the SLCO1B1 transporter, which increase gut uptake of the statin resulting in higher levels in plasma and increased toxicity.

Gut-acting cholesterol-lowering drugs
Ezetimibe is a gut-acting drug binding to the Niemann–Pick C1-Like protein 1 (NPC1L1) duodenal cholesterol transporter. This molecule is also the binding site for sitosterol. It reduces plasma cholesterol by 20% and has been shown to reduce CVD events when added to statin therapy.

Bile acid sequestrants (e.g. colesevelam) are drugs that bind bile acids preventing micelle formation and thus reducing gut cholesterol uptake. They reduce cholesterol by 15–20% and have some CVD outcome evidence from previous trials with monotherapy, but lack data on CVD outcomes in the era of statins. They are commonly associated with excess gastrointestinal side-effects and are now rarely used outside the context of liver disorders associated with raised cholesterol.

PCSK9 inhibitors
PCSK9 is involved in downregulating LDLR expression. Antibodies to PCSK9 (e.g. alirocumab) reduce LDL-C by 40–60% and have been shown to reduce CVD events. These drugs are used as third-line agents in familial hypercholesterolaemia, severe progressing CVD or in patients intolerant to multiple statins.

Fibrates
Fibrates are gene regulators affecting peroxisomal-proliferator activating receptors-alpha subtype (PPAR-α). They reduce triglycerides by increasing synthesis of LPL, reducing synthesis of apoC3 to promote clearance of triglyceride-rich particles (e.g. VLDL), and can increase apo-A1. They have a moderate effect in reducing CVD events.

Omega-3 fatty acids
These preparations (often termed fish oils) include the essential fatty acids docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA). They bind to specific free fatty acid receptors (FFAR-4) to affect lipid and inflammation pathways. They exert dose-proportional effects in reducing triglycerides by 20–50%. Their effects in prevention of CVD are controversial with conflicting results. Low doses in low-risk patients seem to do little but high doses of EPA in high-risk patients seem to reduce CVD events.

New classes of lipid-lowering drugs in development are listed in Box 28.5.

Screening
Cardiovascular disease (CVD) secondary to atherosclerosis is common. Most patients with hyperlipidaemia are asymptomatic and have no clinical signs. Screening practices for CVD vary between countries ranging from opportunistic measurements to systematic programmes targeting individuals aged greater than 40 years. Opportunistic measurement of lipids is justified for:
- a family history of coronary heart disease (especially below 60 years of age)
- a family history of lipid disorders
- the presence of physical signs, e.g. xanthoma or xanthelasma at any age; or corneal arcus before the age of 40 years
- diabetes mellitus
- hypertension
- obesity
- acute pancreatitis
- patients undergoing renal replacement therapy.

Where one family member is known to have a monogenic disorder, such as FH, siblings and children must have their plasma lipid concentrations measured.

Acute severe illnesses, such as myocardial infarction, reduce plasma lipid concentrations for up to 3 months. Lipid profiles should be measured either within 48 hours of an acute myocardial infarction (before derangement has had time to occur) or 3 months later. Cholesterol and HDL-C concentrations do not change significantly after a meal so screening is performed using random blood samples for cholesterol, triglycerides and HDL-C. Patients with moderate hypertriglyceridaemia should have a repeat fasting profile performed.

Management of hypertriglyceridaemia
A serum triglyceride concentration below 2.0 mmol/L is normal. In the range 2.0–6.0 mmol/L, no specific intervention will be needed unless there are coincident CVD risk factors, and in particular a strong family history of early CVD or an increased calculated CVD risk. Patients should be told they have a minor lipid problem; and offered advice on lifestyle improvement including weight reduction if obese. The commonest causes are associated with a fatty liver (moderately raised transaminases, raised gamma-glutamyl transferase (GGT) and high triglyceride:HDL-C ratio). Some individuals have livers that respond to even moderate degrees of alcohol intake by increased production of VLDL, so a trial of abstinence is advised. Other drugs, including high-dose thiazides, oestrogens and glucocorticoids, can have similar effects in susceptible patients.

If the triglyceride concentration remains above 6.0 mmol/L despite lifestyle measures, drug therapy is warranted (see Box 28.3 and 28.4). The severe hypertriglyceridaemia associated with disorders of the LPL pathway may require restriction of dietary fat to 10–20% of total energy intake, the use of orphan disease drugs, and the use of special preparations of medium-chain triglycerides in cooking in place of oil or fat as these are not absorbed via chylo-microns (see p. 744).

Management of hypercholesterolaemia
(without hypertriglyceridaemia)
Familial hypercholesterolaemia
Individuals often require treatment with dietary measures and more than one cholesterol-lowering drug from teenage years. Ezetimibe is often added to a statin therapy (Box 28.3 and 28.4) and PCSK9 inhibitors are used in severe refractory cases.
Primary prevention for people with type 2 diabetes
Lipid-lowering therapy with a moderate dose statin, or alternatives as above, is used routinely in asymptomatic individuals with type 2 diabetes alone aged over 40 years, unless the LDL-C is particularly low (<1.8 mmol/L). Calculated CVD risk usually exceeds 10% per decade in these individuals.

Primary prevention for people without diabetes
Lipid-lowering with a moderate dose statin in the first instance is offered to people after an unsuccessful trial of lifestyle intervention whose calculated CVD risk exceeds 10% over the next decade.

Secondary prevention
Statin treatment with high-dose high potency agents is warranted for any patient with known macrovascular disease (coronary artery disease, transient ischaemic attack or stroke, peripheral arterial disease), irrespective of the total or LDL-C level. The treatment target is total cholesterol below 4.0 mmol/L and LDL-C below 2 mmol/L; or alternatively, the maximum tolerated statin dose can be used. If a statin is not tolerated, combinations of other agents are tried (see Box 28.4).

Risk prediction tables
CVD risk is typically multifactorial. An isolated high level of a risk factor may not justify treatment unless levels are extreme (e.g. 95th centile). Epidemiological studies consistently identify age, gender, smoking, presence of type 2 diabetes, hypertension and the ratio of total cholesterol: HDL cholesterol as primary risk factors. Ancillary risk factors such as family history of premature CVD may add to predictive efficiency in some cases. CVD risk calculators rely on population studies to predict risk in individuals (see p. 1080). This is always an approximate process. The commonest tools calculate either CVD mortality (Europe) or events (USA ASCVD, UK NICE), based on 10-year, 30-year or lifetime horizons. They are unreliable in populations aged less than 40 years or greater than 75 years as CVD risk is driven principally by age. Generally, a 20% risk is considered mandatory for drug treatment while discussion should be had with patients above 10% risk on lifestyle intervention and then risks and benefits of drug treatment if no significant improvement is observed. In young individuals, treatment decisions are often based on excess relative risk driven by family history while in older patients, co-morbidities and life expectancy are significant factors to consider. In some countries imaging techniques such as coronary artery calcium scores are used to refine CVD risk predictions in borderline cases.

Management of combined hyperlipidaemia
Hypertriglyceridaemia increases CVD risk for any cholesterol concentration. Therapy is with diet in the first instance and then with drugs if required. Statins are first-line in patients with triglycerides less than 8 mmol/L while fibrates are used first-line for higher levels. Combination therapy is often required (see Box 28.4).

Other lipid disorders

**Hypolipidaemia**
Low lipid levels can be found in severe protein–energy malnutrition. They are also seen occasionally with severe malabsorption and in intestinal lymphangiectasia.

Hypobetalipoproteinaemia (see Box 28.2) is a benign familial condition with cholesterol levels in the range 1–3.5 mmol/L. Rare causes include mutations in apo-B, PCSK9 and apo3.

**INHERITED METABOLIC DISEASES**
IMDs, previously known as inborn errors of metabolism, are a heterogeneous group of complex monogenic disorders that occur due to an impairment in the activity of an enzyme involved in one or more metabolic pathways. Hundreds of disorders exist, with the number of known disorders increasing yearly. Although individually rare, collectively they are not that uncommon, with reported prevalence ranging from 1 in 800 to 1/2500 live births. IMDs are more common in populations where consanguinity occurs. Specific founder mutations are found in societies derived from small original ancestral populations, where inter-marriage and genetic drift further increase the prevalence of specific IMDs, especially in geographically or culturally isolated populations.

Clinical signs and symptoms occur due to accumulation of substrates precursors or due to deficiencies of enzyme products. The majority of IMDs present in childhood but there is increasing recognition of adult presentations that may differ from those seen in paediatric cases. Patients may present to the emergency department with acute metabolic decompensation, or to any specialist outpatient clinic with problems related either to a previously diagnosed IMD or an as-yet undiagnosed IMD.

Patients in IMD services include those who:
- transition into adult services, having been diagnosed in childhood (newborn screening, early diagnosis and specific therapies have improved prognosis and life spans, albeit with sequelae needing ongoing medical attention; their risk of more common age-related conditions is at least as high as in the general population)
- present for the first time in adulthood (up to 40% of patients managed in dedicated Adult IMD centres as per survey in 2006).

This section will discuss acute presentations where an IMD should form part of the differential diagnosis. A few common, mostly treatable, IMDs will also be discussed separately in more detail. Wherever possible the estimated incidence is given (as lifespans improve, the prevalence of these conditions will be significantly higher than the incidence).

**Abetalipoproteinaemia**
This is described on page 1196.

**Further reading**

Special considerations

Patients with IMDs may have specific risks related to pregnancy, surgery or anaesthesia. Hence any pregnancy or surgery should be discussed with a specialist metabolic physician well in advance, to enable a personalized birth/surgical treatment plan to be drawn up.

Genetic testing, including multigene panels, whole exome and whole genome sequencing are becoming almost first-line diagnostic tools, and are likely to widen the spectrum of IMDs both in terms of phenotypic presentations and new diseases.

Acute presentations of IMDs

Patients with known IMDs or undiagnosed IMDs can present acutely to the emergency department as a result of metabolic decompensation precipitated by some metabolic triggers, including:

- catabolic states such as inter-current illness or an inability to tolerate oral food and drinks
- labour and the postpartum period
- non-compliance with IMD treatment
- drugs (therapeutic or recreational), including alcohol
- change in diet.

Management of acute presentations of inborn errors

Known IMD

Patients at risk of decompensation will often carry with them an emergency management plan provided by their specialist metabolic centre. They would, if appropriate for their condition, have been prescribed a basic oral emergency regime (ER) to use when unwell. The advice on the oral ER is usually to take 200 mL of 25% glucose polymer drink every 2 hours, with instructions to attend hospital for i.v. treatment and further management if unable to tolerate oral ER, if getting worse despite oral ER or if they fail to improve. Intravenous ER is usually an infusion of 10% glucose i.v. at 2 mL/kg per hour.

Emergency departments should ensure these patients are triaged at least as ‘very urgent’ and treatment and investigations instituted without delay as per plan. While prompt treatment is often associated with good prognosis, a delay can lead to permanent neurological damage or death. Patients should also be investigated and treated for metabolic triggers of acute decompensation. ERs for common metabolic conditions are available online, for example, on the British Inherited Metabolic Disease Group (BIMDG) website (see Further reading and Significant websites). Every effort should be made to contact the patient’s metabolic centre for advice as soon as possible, ideally within the first hour (many metabolic centres, including in the UK, offer 24/7 on-call advice).

Suspected IMD

A diagnosis of IMD should be considered in patients presenting with encephalopathy, psychiatric presentations, acid–base disturbance, rhabdomyolysis, atypical seizure or stroke if a more common alternative diagnosis is not forthcoming. A suggestive personal and/or family history, the presence of one or more metabolic triggers, a history of aversion to certain food groups such as proteins or recent history of exclusion diets (low carbohydrate/high fat and protein diets) should alert physicians to an IMD aetiology. A basic metabolic screen should be sent off. Abnormalities in biochemistry may only be apparent during an acute episode. Therefore, samples for a basic acute metabolic screen (Box 24.6) should be taken at presentation. Specialist advice sought and treatment initiated as soon as possible if an IMD is suspected.

Clinical presentations where an IMD should be suspected include the disorders described here.

Encephalopathy

IMDs should be considered in all adults presenting with encephalopathy.

Both patients with known IMD and those with an as-yet undiagnosed IMD can present for the first time in adulthood with encephalopathy. Metabolic encephalopathy most commonly occurs secondary to hyperammonaemia. This must therefore be excluded urgently.

Disorders of ammonia metabolism

Ammonia is a by-product of protein catabolism. It is detoxified by conversion to urea via the urea cycle in the liver, and subsequently excreted by the kidneys. A diagnosis of IMD, most often a urea cycle defect, should be sought in patients where other more common causes of hyperammonaemia such as decompensated liver disease and drugs have been excluded. Prolonged hyperammonaemia is associated with permanent neurological deficit and death. Since prompt diagnosis and treatment can reverse progression, ammonia should be included in the first-line screening investigations for any patient presenting with encephalopathic symptoms. Ammonia samples are unstable and should be collected on ice and despatched promptly to the laboratory. If hyperammonaemia is confirmed, treatment can and should be started before the precise IMD causing hyperammonaemia is known.

The main principles of treatment are to:

- prevent catabolism by giving i.v. ER (this can be done before ammonia levels are known if index of suspicion high)
- lower plasma ammonia levels as quickly as possible – most effectively done using haemofiltration/haemodialysis in symptomatic patients
- decrease protein load by temporarily stopping all external natural protein intake (this can be done before ammonia levels are known if index of suspicion high); total protein restriction should not continue beyond 48 hours
- use ammonia scavengers like sodium benzoate/phenylbutyrate as soon as available.

Published guidelines ‘Urea cycle defects – acute emergency management’ are available on the BIMDG website (see Significant websites). Advice from a specialist IMD centre should be sought for ongoing management and further investigations.

Rhabdomyolysis

While trauma and drugs are the commonest causes of rhabdomyolysis, IMDs such as glycogen storage disease type 5 (see Box 24.11) or disorders of fatty acid metabolism (see Box 24.12) should be considered in patients with recurrent episodes or a suggestive history. Send samples for an acute metabolic screen including creatine kinase. In addition to standard treatment for rhabdomyolysis, patients with IMD related rhabdomyolysis will benefit from i.v. ER.

Stroke

Thrombotic strokes in younger adults or a cerebral sinus thrombosis should prompt measurement of plasma homocysteine levels to exclude homocysteine/folate metabolism disorders, particularly as they are treatable.

IMDs such as mitochondrial disorders and Fabry’s disease should also be considered in patients with strokes where symptoms or imaging is inconsistent with a defined vascular territory.
Hypoglycaemia

While hypoglycaemia is a common neonatal/childhood presentation of glycogen storage disorders (GSDs) (see Box 24.11) and fatty acid oxidation disorders (FAOD) (see Box 24.12), presentations among adults are rare. Nevertheless, there are isolated reports of patients with IMDs such as glucokinase-activating mutations presenting for the first time in adulthood with hypoglycaemia. As it is eminently treatable, diagnosis should be considered and excluded. Insulin/C-peptide measurements and an acute metabolic screen at the time of hypoglycaemia will provide important diagnostic clues.

Acidosis

A raised unexplained anion gap may be suggestive of an IMD. Hyperlactataemia, hyperammonaemia, or ketosis without hyperglycaemia may all be diagnostic clues. Clinicians should send samples for an acute metabolic screen, including blood gases, bicarbonate, glucose and lactate at presentation if an IMD is suspected.

Mitochondrial diseases

Mitochondrial function is regulated by the interplay between nuclear genes that code for nearly 1500 mitochondrial proteins and the 37 mitochondrial genes (see p. 19). Thus, mitochondrial diseases can be caused by maternally inherited defects in the mitochondrial genome or by Mendelian inherited nuclear genome defects. De novo mutations are also known to occur.

Every nucleated cell in the body contains between 100 and 10,000 mitochondria that are responsible for ATP generation through oxidative phosphorylation. Hence mitochondrial dysfunction leads to clinical manifestations secondary to cellular dysfunction and premature cell death as a result of energy deficit. MDs are not that uncommon, with a reported incidence of 1 in 4300 in the UK. MDs presenting in adulthood were traditionally thought to be caused by mutations in the mitochondrial genome; however, it is now increasingly apparent that roughly 25% of mitochondrial diseases presenting for the first time in adulthood may be secondary to mutations in the nuclear genome.

Patients can present with a variable phenotype with one or more clinical features associated with mitochondrial disease, varying in severity and chronology (Box 24.7). Patients may sometimes present with well-defined clinical syndromes that are associated with a particular nuclear or mitochondrial mutation (Box 24.8). General physicians should be aware of and consider mitochondrial disease in patients with a suggestive family history, and multisystem disease where more common causes have been excluded. Investigation profiles should include glucose, lactate, acyl-carnitines and creatine kinase.

Diagnosis

While biochemistry may be indicative, confirmatory diagnosis requires specialist investigations including tissue (most often muscle) biopsy and genetic testing.
**Disorders of protein metabolism**

**Phenylketonuria**

Phenylketonuria (PKU; incidence 1:20,000 globally) is an autosomal recessive amino acid metabolism disorder caused by a bi-allelic mutation in the phenylalanine hydroxylase gene. It is the most common IMD encountered in specialist metabolic centres in Europe, where the incidence is highest (1 in 5000 to 15,000 in white babies of European descent). It is characterized by elevated levels of phenylalanine in the blood, and if treatment is delayed, can result in severe intellectual disability. Early treatment within the first few days of life results in normal development. Many countries including the UK offer newborn screening for PKU, with an aim to start therapy within the first 2 weeks of life. The aim of treatment is to maintain phenylalanine levels below therapeutic targets which may vary slightly between countries. The therapeutic targets in the UK are broadly aligned to European consensus guidelines, which also advocate phenylalanine restriction for life. The mainstay of treatment is a diet restricted in natural proteins, combined with supplements (phenylalanine-free protein, vitamins and minerals) and specialist low-protein foods available on prescription. High phenylalanine levels during pregnancy can result in microcephaly, significant intellectual disability, cardiac defects and growth retardation in the baby. Women are therefore advised against unplanned pregnancy. Therapeutic targets for preconception and pregnancy are significantly lower than baseline adult targets and require close monitoring/management by specialist centres. Unplanned pregnancy in a woman with PKU is a medical emergency and should be referred to a metabolic centre to enable treatment to be started/options discussed within 24 hours. GP practices across the UK can expect to have one or more patients with PKU on their register. The oldest patients diagnosed on newborn screening in the UK are nearing 50 years of age. Clinicians can therefore expect to occasionally encounter them in their routine practice, presenting with other common age-related illness not directly linked to PKU.

Some other common protein metabolism IMDs are listed in Box 24.9.

**Lysosomal storage disorders**

Lysosomes play an important role in cell turnover. Their main function is to break down complex macromolecules to simple monomers, and to transport these monomers out of the lysosome into the cytosol for recycling. Any disruption to this process results in lysosomal storage disease (LSD). Genetically inherited LSDs are one of the commonest IMDs encountered in metabolic centres treating adult patients, with Gaucher’s and Fabry’s disease being the most common amongst these. A number of these conditions can present for the first time in adulthood. Prognosis is variable, dependent on residual enzyme activity. Specific therapies are now available for a number of LSDs, and hence it is important that clinicians consider LSDs in patients presenting with suggestive symptoms. A few common LSDs with specific therapies are listed in Box 24.10.
Disorders of carbohydrate metabolism

Glycogen storage disorders

Glycogen storage disorders (GSDs) refers to a group of IMDs where either glucose utilization (glycolysis) or glycogen mobilization (glycogenolysis or glycogen transport) is impaired. Glycogen is a glucose polymer stored most abundantly in the muscle and liver. Patients present with symptoms related to decreased availability of glucose for ATP generation and/or abnormal glycogen accumulation and impairment in other linked metabolic pathways. Effective treatments for a number of GSDs exist, and early treatment significantly improves prognosis. GSDs can be classified broadly based on the most affected organs. Some of the principal GSDs are listed in Box 24.11. A few other treatable IMDs of carbohydrate metabolism are listed in Box 24.12.

Disorders of fatty acid oxidation defects

The fatty acid oxidation pathway provides important an alternative fuel source, by using fats in situations such as fasting, exercise or illness where glucose supply may be inadequate. A detailed description of the process is beyond the scope of this book. Briefly, it involves:

- conversion of fatty acids to fatty acetyl CoA on entry through the plasma membrane
- entry of fatty acetyl CoAs into the mitochondria via the carnitine shuttle
- beta-oxidation of fatty acetyl CoAs to acetyl CoA by dehydrogenases in the mitochondria
- transfer of electrons by dehydrogenases to the respiratory chain via electron carriers.

Acetyl CoA is used either to generate ketone bodies (an alternate fuel for the brain), or for direct ATP production via Krebs cycle (e.g. in skeletal muscle). Defects in any step in the pathway results in a fatty acid oxidation disorder. Characteristic features of FAODs include hypoketotic hypoglycaemia, cardiomyopathy and myopathy with or without rhabdomyolysis. While most present in childhood, some can present for the first time in adulthood (Box 24.13) with myopathy and/or rhabdomyolysis. Unlike in GSD5, symptoms usually occur after prolonged exercise, a prolonged fast or during an inter-current illness, that results in a catabolic state. Once diagnosis is known, management to avoid crisis is relatively simple (see Box 24.13). As with all other IMDs, symptoms may be unmasked (with catastrophic consequences) by a recent change in diet, for example a ketogenic diet, in addition to all the other metabolic triggers described above. Baseline investigations to exclude these conditions and close monitoring on initiation of a therapeutic ketogenic diet for conditions such as epilepsy is mandatory.

Porphyrias

Porphyrias are a group of disorders caused by defects in the haem synthesis pathway. Detailed descriptions of the different porphyrias is beyond the scope of this book. Briefly, symptoms occur due to accumulation of toxic metabolites. A block in the early stages of synthesis leads to accumulation of porphyrin precursors including porphobilinogen (PBG) and α-aminolevulinic acid (ALA), while a block in the late stages results mainly in accumulation of porphyrins. Porphyrin precursors are neurotoxic while porphyrins themselves induce a photosensitive blistering rash. Thus, presentations may be acute neurovisceral crisis (block in the early stages of haem synthesis – acute intermittent porphyria) or non-acute cutaneous (block in the late stages – porphyria cutanea tarda; commonest, incidence 1:5000 to 1:70000, erythropoietic protoporphyrin and congenital erythropoietic porphyria). A block in the intermediate stages causes cutaneous and neurovisceral symptoms (variegate porphyria and hereditary coproporphyria).

Acute porphyrias have an autosomal dominant inheritance and almost always present in late childhood/adulthood. Prevalence is 5 : 1 000 000 in Europe, with a much higher prevalence in South Africa (3 : 1000). Clinical features include abdominal pain, vomiting, neuropsychiatric symptoms, hypertension, seizures, hyponatraemia and fever. In addition to the usual triggers for metabolic decompensation in IMDs, anaesthesia and drugs (including cytochrome P450 enzyme inducers), can precipitate an acute attack. Porphyria occurs more often in women, particularly in the luteal phase of the menstrual cycle and pregnancy. Symptoms may mimic an acute abdomen, and anaesthesia during an acute attack can be catastrophic. It is treatable and hence a diagnosis of porphyria should be considered and sought early in the emergency department if symptoms are suggestive. Diagnosis is made by measuring ALA and PBG in a fresh urine sample (plain bottle, with no preservatives and always protected from light). Normal levels exclude acute porphyria and an alternative diagnosis for symptoms should be sought.

If porphyria is confirmed/likely, management should be initiated immediately.

- Remove all precipitating causes, including any triggering drugs (www.drugs-porphyria.org).
- Give supportive therapy for symptoms, and an i.v. infusion for hydration and correction of electrolyte imbalance.
- Ensure a high carbohydrate intake of at least 600mg per day.
- Administer heme arginate (i.v.).
- Contact a porphyria reference centre for further advice. Published emergency management guidelines are available on the BIMDG website. Recurrent severe attacks may merit consideration for liver transplantation.

For details confirmatory tests of diagnosis, pathophysiology and presentations of other porphyrrias see Further reading.

Peroxisomal diseases

X-Adrenoleukodystrophy

Being X-linked, presentation is more severe in males who present with the cerebral form. Symptoms usually begin between 4 and 10 years with behavioural/neuropsychiatric problems, cognitive decline and variable progressive neurological decline, which is fatal. Presentation may be delayed into adulthood, and even into the third or fourth decade. Patients also often develop adrenal insufficiency, which may precede development neurological symptoms. While no treatment exists for symptomatic patients, pre-symptomatic patients may be amenable to treatment with bone marrow transplant (BMT) or a clinical trial of gene therapy. Therefore, X-adrenoleukodystrophy (ALD) should be excluded in all patients with adrenal insufficiency where no other cause is found. Female carriers and adult males may also present with adrenomyeloneuropathy, resulting in spastic paraparesis of the lower limbs and bladder disturbances. Cerebral ALD and adrenal insufficiency almost never occur in female carriers. Adult physicians should exclude ALD in patients with suggestive symptoms, as a positive diagnosis will initiate cascade testing to find any pre-symptomatic relatives, who may be eligible for BMT, and female carriers who may benefit from prenatal counselling.
Adult Refsum’s disease
Adult Refsum’s (AR) is a recessive disease that results in phytanic acid accumulation in tissues and plasma secondary to mutations in the PHYH or PEX7 gene. Diagnosis should be excluded in patients presenting with retinitis pigmentosa, which along with anosmia is present in almost all patients with AR. These two features often precede development of other features like ataxia, peripheral neuropathy and cataract by several years. A third of patients may have bony abnormalities such as shortened fourth metatarsals. Cardiac arrhythmias may occur, particularly when phytanic acid levels are high. Treatment includes a phytanic acid restricted diet and avoidance of fasting or rapid weight loss. Plasmapheresis may be needed. Without treatment there is gradual progressive deterioration. Elevated plasma phytanic acid levels with low pristanic acid levels is diagnostic.

<tr>
<td><strong>Urea cycle defects</strong></td>
<td>Mutations in one of six urea cycle enzymes, most commonly OTC deficiency</td>
<td>AR</td>
<td>OTC is X-linked 1 : 8000–1 : 45000</td>
<td>Yes, including as first presentation in adulthood May be unmasked in adulthood by a change in diet for e.g. low-carbohydrate, high-protein diets</td>
<td>Progressive encephalopathy Cyclical vomiting/non-specific neuropsychiatric symptoms</td>
<td>When unwell: hyperammonaemia, characteristic abnormalities in AA/OA May also have: alkalosis consistently very low urea</td>
<td>As for hyperammonaemia in acute setting Life-long protein restriction, ammonia scavengers, arginine, citrulline</td>
<td>Good if treated promptly Fatal if diagnosis/treatment delayed</td>
</tr>
<tr>
<td><strong>Tyrosinaemia Type 1</strong></td>
<td>Fumaryl-acetoacetate hydroxylase deficiency</td>
<td>AR</td>
<td>1 : 100 000 More common in Quebec, Canada, due to founder mutations</td>
<td>Yes, first presentation in adulthood reported</td>
<td>Liver failure Gastrointestinal bleeding Fanconi’s syndrome, tubulopathy Renal rickets, acute porphyria Guillain–Barré syndrome - like acute neurogenic crisis Hepatocellular carcinoma</td>
<td>Raised tyrosine in serum AA and raised succinylacetone in urine OA</td>
<td>Nitisinone (NTBC) Tyrosine restriction Tyrosine-free amino acid supplementation Liver transplantation may be considered</td>
<td>Good if treated early If patient not compliant with medication or untreated, can present in adulthood with any of clinical features described</td>
</tr>
<tr>
<td><strong>Alkaptonuria</strong></td>
<td>Homogentisate 1,2-dioxygenase deficiency</td>
<td>AR</td>
<td>1 : 250 000 AR</td>
<td>Presents more often in adulthood (3rd–5th decades)</td>
<td>Large joint arthritis Ochronotic pigmentation (sclera/ears) Valvular heart disease Urine turns black on standing Black nappies in children</td>
<td>Raised homogentisic acid on urine OA</td>
<td>Nitisinone (NTBC) improves biochemical profile</td>
<td>Chronic progressive disease with variable prognosis</td>
</tr>
<tr>
<td><strong>Classical homocystinuria</strong></td>
<td>Cystathionine β-synthase deficiency</td>
<td>AR</td>
<td>1 : 40 000 to 250 000</td>
<td>Yes, including first presentation in adulthood</td>
<td>Thromboembolic events (stroke/artrial or venous occlusive disease) Acute lens dislocation/visual loss Neuropsychiatric symptoms Developmental delay Seizures Acute/subacute/chronic neurological deterioration Marfanoid habitus Osteoporosis</td>
<td>Raised plasma homocysteine (partly/early if &gt;50 μmol/L) Raised plasma methionine Reduced plasma cysteine Genetic analysis may be useful in predicting response to pyridoxine in addition to confirming diagnosis Note: folate/vitamin B12 deficiencies and metabolism defects can also cause mild to moderate rise in homocysteine levels – these must be excluded</td>
<td>Pyridoxine Betaine Vitamin B12 Folate Methionine-restricted diet in pyridoxine-non-responsive homocystinuria with added vitamin supplements</td>
<td>Variable depending on severity Early treatment (in neonatal/early childhood) results in normal IQ and decreased risk of long-term morbidity</td>
</tr>
<tr>
<td><strong>Defects in metabolism of branched chain amino acids</strong></td>
<td>MSUD – branch chain α-ketoacid dehydrogenase deficiency PA – propionyl coA carboxylase deficiency MMA – genetically heterogenous disorder</td>
<td>AR</td>
<td>MSUD 1 : 185 000. 1 : 380 in Old Order Mennonite population (PA) 1 : 10 0000, more common in Saudi Arabsians 1 : 10 0000</td>
<td>Yes, first presentation in adults very unusual</td>
<td>Acute decompensation: encephalopathy, acidosis, hyperammonaemia Developmental delay Abnormal neurology Cardiomyopathy (PA) Pancreatitis (MMA/PA) Renal failure (occasionally adults with milder forms of MMA may present with just renal impairment)</td>
<td>Metabolic acidosis with high anion gap. Hyperammonaemia during acute decompensation Characteristic abnormalities on AA/OA and AC profiles</td>
<td>Natural protein restriction Avoid catabolism Liver transplantation (MSUD, PA) Renal/combined liver and renal transplantation (MMA) Carnitine supplementation (PA/MMA) BCAA free supplements (MSUD)</td>
<td>Variable depending on severity Acute decompensations can be fatal</td>

| Gaucher          | Beta-glucocerebrosidase (GBA) deficiency            | AR          | Panethnic, 1:75,000, 1:850 in AJ population                                         | 94% of patients have non-neuronal disease (type 1) characterized by hepatosplenomegaly, bone marrow involvement, cytopenia and skeletal symptoms such as severe bone pain and avascular necrosis  
Presentation can occur in adulthood  
Neuropathic form is much rarer (6% of patients)  
Acute (1%) (type 2) – presentation almost always at <1 year of age – severe progressive neurological deficit leading to early death  
Chronic (5%) (type 3) – mild to severe neurological and skeletal symptoms and organomegaly  
Intermediate forms occur, as can late neurological presentations in adulthood with neurological symptoms including a supranuclear horizontal gaze palsy  
Acute complications: avascular necrosis of bone and splenic infarcts  
Heterozygous mutations may increase risk of Parkinson's syndrome | Deficient GBA activity in leukocytes or fibroblasts  
‘Gaucher cells’ on biopsy  
Genetics                                                                 | Supportive Enzyme replacement therapy (ERT) using recombinant GBA |
| Fabry            | Alpha-galactosidase A (α-GLA) deficiency            | X-linked    | 1:40,000.  
Late onset milder forms much more common                                                                 | Acroparesthesia, cornea verticillata, angiokeratomas  
Gastrointestinal symptoms (classical phenotype, most common presenting symptoms in paediatric population)  
Adults more often present with end organ disease  
Arrhythmia, cardiac fibrosis, hypertrophic cardiomyopathy  
Proteinuria, renal impairment  
Stroke  
Decreased exercise tolerance, fatigue, depression  
Females can also be symptomatic due to lyonization of X chromosome. End organ symptoms usually a decade later than men  
Wide phenotypic spectrum in both males and females based on residual enzyme activity levels | Deficient (α-GLA) activity in white cells. Activity can be normal in 60% of affected females – genetic confirmation therefore needed                                                                 | Supportive  
ERT  
Cascade testing for family members at risk |
| Niemann–Pick B   | Acid sphingomyelinase deficiency                    | AR          | 1:250,000, 1:40,000 in AJ                                                          | Age of presentation and severity variable. Can present for the first time in adulthood  
Splenomegaly, hypersplenism  
Hepatomegaly, hepatic fibrosis, cirrhosis  
Dyslipidaemia (high LDL-C and triglycerides)  
Osteoporosis  
Storage facies  
Cherry-red macular spot (25%)  
Lung fibrosis causing restrictive lung disease | Deficient enzyme activity in leukocytes  
Genetic confirmation                                                                 | Supportive  
Clinical trial for ERT ongoing |
| Tay–Sachs        | Beta-hexosaminidase (isoform A) deficiency          | AR          | 1:250,000.  
However, 1:25 (versus 1:250 in the general population) carrier frequency in AJ  
Actual incidence in Jewish populations now significantly decreased in many countries due to effective counselling | Childhood disease is fatal with rapidly progressive neurology, visceromegaly, dysmorphism and increased startle response  
Late onset adult disease – age of onset and severity varies  
Cerebellar and motor neurone dysfunction causing tremor, dysarthria, chorea, dystonia | Deficient enzyme activity in leukocytes  
Genetic confirmation                                                                 | Supportive |
| Pompe's (GSD type 2) | Acid alpha-glucosidase (acid maltase) deficiency | AR          | 1:40,000                                                                 | Adult with Pompe’s usually symptomatic in 3rd–4th decade with: limb girdle muscle weakness  
respiratory insufficiency secondary to diaphragm weakness, which is often major cause of death  
acute decompensation related to respiratory failure  
Classical infantile form – more severe presentation in the first few months of life | Deficient enzyme activity in leukocytes  
Genetics  
Vacuolated lymphocytes  
Vacuolar myopathy on muscle biopsy  
Pulmonary function test (>20% change in VC between sitting and supine position) | Supportive ERT |

AJ, Ashkenazi Jewish population; AR, autosomal recessive; VC, vital capacity.

Liaison psychiatry is a subspecialty within psychiatry that primarily concerns itself with the interface between psychiatry and other medical specialties. It is a vital component of hospital medicine, supporting every medical specialty to some degree, from the most acute of presentations to more chronic problems.

Inpatient medical teams may seek the advice of a liaison psychiatrist when a patient with known psychiatric co-morbidity is admitted to hospital; when patients that develop new onset psychopathology, often in the absence of a past history; or where psychopathology arises as a clinical sign within a given medical diagnosis – for example in neurological or some endocrine disorders.

Key skills in psychological medicine include:

- assessing risk in the potentially suicidal patient
- understanding functional somatic syndromes found in different medical specialties
- assessing mental capacity: a vital requirement for informed consent
- understanding the roles of psychoactive medications including antidepressants, antipsychotics and sedatives in patient care; and their patterns of toxicity.

Acute aspects of psychological medicine can be learned by shadowing a liaison psychiatrist or liaison psychiatry mental health nurse in assessing psychiatric morbidity and on-going risk in patients presenting to the emergency department, including after instances of self-harm or suicide attempts. On an outpatient basis, important experience will be gained by assessing patients with functional disorders. Developing skills in psychiatric history-taking and mental state examination allows the complex biopsychosocial understanding of any condition to be unpicked.

Provision of psychiatric care in the general hospital

The structure of psychiatric services varies between countries but in broad terms, they tend to be located in three settings: in the community, in psychiatric hospitals and in general hospitals. General hospital psychiatry is referred to as liaison psychiatry. This subspecialty is increasingly recognized as an essential component of effective care in acute hospitals, reducing length of hospital stay and improving outcome measures. In the UK, 79% of hospitals now have a liaison psychiatry service; the provision may be limited to the emergency department, or in other places extend to the general wards and even the outpatient department.

Epidemiology and vulnerable patient groups

The point prevalence of psychiatric disorders in adults in the UK is about 20%, mostly composed of depressive and anxiety disorders...
and substance misuse (mainly alcohol) (Box 25.1). The prevalence is about twice as high in patients attending the general hospital, with the highest rates in the emergency department and medical wards. The most prevalent disorders among general hospital inpatients are organic brain disorders (e.g. delirium), depressive illnesses and alcohol dependence or harmful use. In more than half of such cases, a psychiatric intervention is required. Particularly vulnerable groups include those admitted to the wards with neurological disorder, including acquired brain injury, patients on the intensive care unit (where post-traumatic stress disorder (PTSD) is especially common) and older patients, who are at greater risk of organic brain disorders such as delirium. A further patient group of importance is those with a pre-existing psychiatric diagnosis.

Culture and ethnicity

These can alter the presentation and prevalence of psychiatric ill-health. Biological factors in mental illness are similar across cultures but may vary between ethnicities, whereas psychological and social factors will vary across culture. For example, the prevalence and presentation of schizophrenia vary little between countries, suggesting that biological factors operate independently of cultural ones. In contrast, disorders in which social factors play a greater role vary between cultures, so that anorexia nervosa is more common in Western-influenced cultures. Culture can also influence the presentation of illnesses, such that physical symptoms are more common presentations of depressive illness in Asia than in Europe. Culture also influences the healthcare that is sought and provided for the same condition.

### CLINICAL APPROACH TO THE PATIENT WITH A PSYCHIATRIC DISORDER

#### Psychiatric history

The history is essential in making a diagnosis and is similar to that used in all specialties, but tailored to help to make a psychiatric diagnosis, determine possible aetiology and estimate prognosis. The interview also enables a doctor to establish a therapeutic relationship with the patient. Box 25.2 gives essential guidance on how to conduct such an interview safely, although it is rare for a patient to harm a healthcare professional.

Components of the history are summarized in Box 25.3.

### Box 25.1 Approximate prevalence of psychiatric disorders in different UK populations

*Total in the community (general population) is 20% due to co-morbidity. An underestimate.*

### Box 25.2 Essentials of a safe psychiatric interview

- **Beforehand**: Ask someone with experience who knows the patient whether it is safe to interview the patient alone.
- **Access to others**: If in doubt, interview in the view or hearing of others, or accompanied by another member of staff.
- **Setting**: If safe, conduct the interview in a quiet room alone for confidentiality, not by the bed.
- **Seating**: Place yourself between the door and the patient.
- **Alarm**: If one is available, find out where the alarm is and how to use it.

### Box 25.3 Summary of the components of the psychiatric history

<table>
<thead>
<tr>
<th>Component</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Reason for referral</td>
<td>Why and how the patient came to the attention of the doctor</td>
</tr>
<tr>
<td>Present illness</td>
<td>How the illness progressed, from the earliest time at which a change was noted until the patient came to the attention of the doctor</td>
</tr>
<tr>
<td>Past psychiatric history</td>
<td>Prior episodes of illness, and where and how they were treated. Prior self-harm</td>
</tr>
<tr>
<td>Past medical history</td>
<td>This should include emotional reactions to illness and procedures</td>
</tr>
<tr>
<td>Family history</td>
<td>History of psychiatric illnesses and relationships within the family</td>
</tr>
<tr>
<td>Personal (biographical)</td>
<td><strong>Childhood</strong>: mother’s pregnancy and patient’s birth (complications, nature of delivery), early development and attainment of developmental milestones (e.g. learning to crawl, walk, talk). <strong>School history</strong>: age started and finished; truancy, bullying, reprimands; qualifications. <strong>Adulthood</strong>: employment (age at first job, total number of jobs, reasons for leaving, problems at work), relationships (sexual orientation, age at first relationship, total number of relationships, reasons for ending them), children and dependants.</td>
</tr>
<tr>
<td>Reproductive history</td>
<td><strong>Women</strong>: menstrual problems, pregnancies, terminations, miscarriages, contraception and menopause</td>
</tr>
<tr>
<td>Social history</td>
<td>Current employment, benefits, housing, current stressors</td>
</tr>
<tr>
<td>Personality</td>
<td>This may help to determine prognosis. How do they normally cope with stress? Do they trust others and make friends easily? Irritable? Moody? A loner? This list is not exhaustive</td>
</tr>
<tr>
<td>Drug history</td>
<td>Prescribed and over-the-counter medication, units and type of alcohol/week, tobacco, caffeine and illicit drugs</td>
</tr>
<tr>
<td>Forensic history</td>
<td>Explain that you need to ask about this, since ill-health can sometimes lead to problems with the law. Note any violent or sexual offences. This is part of a risk assessment. Worst harm they have ever inflicted on someone else? Under what circumstances? Would they do the same again, were the situation to recur?</td>
</tr>
<tr>
<td>Systematic review</td>
<td>Psychiatric illness is not exclusive of physical illness! The two may not only coexist but also have a common aetiology</td>
</tr>
</tbody>
</table>
Mental state examination

The history will already have assessed several aspects of the mental state examination (MSE), but several of these will need to be expanded on and specific areas, such as cognition, tested. The MSE is typically followed by a physical examination, and concluded with an assessment of insight and risk, and a formulation that takes into account a differential diagnosis and aetiology. Each domain of the MSE is given below; abnormalities that might be detected are summarized in Box 25.4.

Aspects of the MSE

Appearance and general behaviour
The clothes (state, colour, style), facial appearance, eye contact, posture and movement provide information about a patient’s affect. Agitation and anxiety cause an easy startle response, sweating, tremor, restlessness, fidgeting and visual scanning (for perceived danger).

Speech
The rate, rhythm, volume and content of the patient’s speech should be examined for abnormalities. Speech is the only way that you can examine thought form and so this is typically observed in this section. The content of the patient’s thoughts is dealt with separately (see below). Neurological abnormalities (e.g. dysarthria, dysphasia) should also be assessed.

Mood and affect
Precise terminology is used in psychiatry: the patient has an emotion or feeling, tells you about their mood, and what you observe is the patient’s affect. Mood can demonstrate persistent change, fluctuations and incongruity.

Thoughts
Abnormalities of thought content and thought possession are recorded here. Delusions (see Box 25.4) can be further categorized as primary or secondary, depending on whether they arise de novo or secondary to other abnormalities of the mental state.

Abnormal perceptions
Assessing perceptions involves observation and questioning of the patient. Patients experiencing auditory hallucinations may appear startled by voices that you cannot hear, or may interact with them, for example by engaging in conversation when nobody else is in the room. Hallucinations can affect any sensory modality and specific types of hallucination and the disorders in which they are seen will be addressed later in the chapter.

Cognitive state
A cognitive examination is necessary to diagnose organic brain disorders, such as delirium and dementia. Poor concentration, confusion and memory problems are the most common subjective complaints. Screening of cognitive functions may suggest the need for more formal psychometry. Simple questioning detects about 90% of people with cognitive impairment, with about 10% false positives. Testing can be divided into tests of diffuse and focal brain functions, summarized in Box 25.5.

Insight and illness beliefs
Insight is the degree to which a person recognizes that they are unwell, and is minimal in people with a psychosis. Illness beliefs are the patient’s own explanations of their ill-health, including diagnosis and causes. These beliefs may be important in determining prognosis and adherence to treatment.

Defence mechanisms
Defence mechanisms are unconscious mental processes. Although not part of the MSE examination, they help understand aspects of behaviour. Common defence mechanisms are described in Box 25.6.

Risk assessment
Risk assessment may sound daunting but is common to all clinical practice: for instance, when determining whether a patient with chest pain should be reviewed in the resuscitation room of the emergency department rather than a normal cubicle. Risk must be assessed in people with a psychiatric diagnosis, although the nature of ‘risk’ is different, comprising the risk that the patient poses to themselves and that which they pose to others (Box 25.7). An appraisal of risk will have started with the initial preparations for seeing a patient (see Box 25.2) and in checking ‘forensic history’ (see Box 25.3). Additional information from family, friends or professionals who know the patient may prove invaluable.

Severe behavioural disturbance
Patients who are aggressive or violent cause understandable apprehension in all staff, and are most commonly seen in the accident and emergency department. Information from anyone accompanying the patient, including police or carers, can help considerably. Box 25.8 lists the main causes of disturbed behaviour.

Management of the severely disturbed patient
The primary aims of management are the control of dangerous behaviour and the establishment of a provisional diagnosis. Four specific strategies may be necessary when dealing with the violent patient (Box 25.9):

- reassurance and explanation
- medication
- physical restraint
- monitoring.

Remember that the behaviour exhibited is normally a reflection of an underlying disorder and so portrays suffering and often fear. The approach to the agitated or violent patient must take this into account and the steps listed intend to alleviate this suffering while maintaining the safety of the individual, other patients and staff.

Relevant physical examination
This should be guided by the history and mental state examination. Particular attention should be paid to the neurological and endocrinological examinations when organic brain syndromes and affective illnesses are suspected.

Summary or formulation
When the full history and mental state have been assessed, you should make a concise assessment or ‘formulation’ of the case.

</table>
**Box 25.5 Cognitive examination**

<table>
<thead>
<tr>
<th>Cognitive domain</th>
<th>Assessment</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Diffuse functions</strong></td>
<td></td>
</tr>
<tr>
<td>Pre-morbid intelligence</td>
<td>An estimate is helpful in assessing changes in cognitive abilities: ask the patient about the final year and level of their education, and the highest qualifications or skills they achieved</td>
</tr>
<tr>
<td>Orientation</td>
<td>Assess orientation to time, place and person. Consciousness can be defined as the awareness of the self and the environment. Clustering of consciousness is more accurately a fluctuating level of awareness and is commonly seen in delirium</td>
</tr>
<tr>
<td>Attention</td>
<td>Ask the patient to say the months of the year or days of the week backwards</td>
</tr>
<tr>
<td>Verbal memory</td>
<td>Immediate recall or registration: ask the patient to repeat a name and address with ten or so items, noting how many times it takes to recall it with 100% accuracy (normal is 1 or 2). Short-term memory: ask the patient to try to remember the address and then ask it of them again after 5 min (0 or 1 error is normal).</td>
</tr>
<tr>
<td>Long-term memory</td>
<td>Ask the patient to recall the news from that morning or recently. If they are not interested in the news, find out their interests (football team, favourite soap opera) and ask relevant questions. Amnesia is literally an absence of memory; dysnesia indicates a dysfunctioning memory</td>
</tr>
<tr>
<td><strong>Focal functions</strong></td>
<td></td>
</tr>
<tr>
<td>Frontal, temporal and parietal lobe function</td>
<td>These are covered in detail on pages 806–808</td>
</tr>
<tr>
<td>Behaviour</td>
<td>Disinhibited behaviour that cannot be explained by a psychiatric illness is suggestive of frontal lobe lesions</td>
</tr>
<tr>
<td>Sequential tasks</td>
<td>Ask the patient to alternate making a fist with one hand at the same time as a flat hand with the other. Ask the patient to tap a table once if you tap twice, and vice versa. Note any motor perseveration whereby the patient cannot change the movement once established. Observe for verbal perseveration, in which the patient repeats the same answer as given previously for a different question</td>
</tr>
<tr>
<td>Abstract thinking</td>
<td>Ask the patient the meaning of common proverbs: a literal meaning may suggest frontal lobe dysfunction, assuming reasonable pre-morbid intelligence</td>
</tr>
</tbody>
</table>

*This correlates well with more time-consuming intelligence quotient (IQ) tests, but it will not pick up cognitive problems caused by focal brain lesions as easily.*

**Box 25.6 Common defence mechanisms**

<table>
<thead>
<tr>
<th>Defence mechanism</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Repression</td>
<td>Avoiding thinking about memories, emotions and/or impulses that would cause anxiety or distress if allowed to enter consciousness</td>
</tr>
<tr>
<td>Denial</td>
<td>Similar to repression and occurs when patients behave as though unaware of something that they might be expected to know, e.g. a patient who, despite being told that a close relative has died, continues to behave as though the relative were still alive</td>
</tr>
<tr>
<td>Displacement</td>
<td>Transferring of emotion from a situation or object with which it is properly associated to another that gives less distress</td>
</tr>
<tr>
<td>Identification</td>
<td>Unconscious process of taking on some of the characteristics or behaviours of another person, often to reduce the pain of separation or loss</td>
</tr>
<tr>
<td>Projection</td>
<td>Attribution to another person of thoughts or feelings that are in fact one's own</td>
</tr>
<tr>
<td>Regression</td>
<td>Adoption of primitive patterns of behaviour appropriate to an earlier stage of development. It can be seen in ill people who become child-like and highly dependent</td>
</tr>
<tr>
<td>Sublimation</td>
<td>Unconscious diversion of unacceptable behaviours into acceptable ones</td>
</tr>
</tbody>
</table>

Box 25.10 International Classification of Psychiatric Disorders (ICD-10)

- Organic disorders
- Mental and behavioural disorders due to psychoactive substance use
- Schizophrenia and delusional disorders
- Mood (affective) disorders
- Neurotic, stress-related and somatoform disorders
- Behavioural syndromes
- Disorders of adult personality and behaviour
- Mental retardation

AETIOLOGY OF PSYCHIATRIC DISORDERS

A psychiatric disorder may result from several causes, which may interact. It can be helpful to divide causes into the three ‘Ps’— predisposing, precipitating and perpetuating factors:

- **Predisposing factors** often stem from early life and include genetic factors, pregnancy- and delivery-related factors, previous emotional traumas and personality factors.

- **Precipitating factors** are ‘triggers’ that may be physical, psychological or social. Whether or not they produce a disorder depends on their nature and severity, and the presence of predisposing factors.

- **Perpetuating factors** maintain the disorder once it has been triggered and may be physical, psychological or social. There may be more than one and these may interact.

PSYCHIATRIC ASPECTS OF PHYSICAL DISEASES

People with non-psychiatric, ‘physical’ diseases are more likely to suffer from psychiatric disorders than those who are well. The most common examples are mood and acute organic brain disorders (delirium). The relationship between mental and physical conditions may be understood in one of four ways:

- Psychological distress and disorders can precipitate physical diseases (e.g. the cardiac risk associated with depressive disorders, or hypokalaemia causing arrhythmias in anorexia nervosa).

- Physical diseases and their treatments can cause mental symptoms or ill-health (Box 25.11).
FUNCTIONAL SOMATIC SYNDROMES

So-called functional (in contrast to ‘organic’) somatic syndromes are illnesses in which no obvious pathology is found and there is an assumed dysfunction of an organ or system. Examples are given in Box 25.13. The psychiatric classification of these disorders might be somatoform disorders but they do not fit easily within either medical or psychiatric classification systems, since they occupy the borderland between them. This classification also implies a dualistic ‘mind or body’ dichotomy, which is not supported by evidence. Since current classifications still support this outmoded understanding, this chapter will address these conditions in this way.

The word psychosomatic has had several colloquial meanings, including ‘all in the mind’, but the modern concept is that psychosomatic disorders are syndromes in which both physical and psychological factors are likely to be causative. So-called medically unexplained symptoms and syndromes are very common in both primary care and the general hospital. Because orthodox medicine has not been particularly effective in treating or understanding these disorders, many patients perceive their doctors as unsympathetic

SICK ROLE AND ILLNESS BEHAVIOUR

The sick role describes the behaviour usually adopted by ill people. Such people are not expected to fulfil their normal social obligations. They are treated with sympathy by others and are only obliged to see their doctor and take medical advice or treatments.

Illness behaviour is the way in which given symptoms may be differentially perceived, evaluated and acted (or not acted) upon. We all have illness behaviour when we choose what to do about a symptom. Going to see a doctor is generally more likely with more severe, disabling and numerous symptoms and in introspective individuals who focus on their health.

Abnormal illness behaviour occurs when there is a discrepancy between the objective pathology present and the patient’s response to it, in spite of adequate medical investigation and explanation.
and seek out complementary or even alternative treatments of uncertain efficacy.

Because epidemiological studies suggest that having one of these syndromes significantly increases the risk of having another, some doctors believe that these conditions represent different manifestations of a single ‘functional syndrome’, indicating a global somatization process, particularly since they are also associated with depressive and anxiety disorders. However, the majority of primary care patients with one of these disorders do not have a mood or other functional disorder. It also seems that it requires a major stress or the development of a co-morbid psychiatric disorder in order for such sufferers to see their doctor, which might explain why doctors are overly impressed with the associations with both stress and psychiatric disorders. Doctors have historically tended to diagnose ‘stress’ or ‘psychosomatic disorders’ in people with symptoms that they cannot explain. History is full of such disorders being reclassified as research clarifies the pathology. An example is writer’s cramp (see p. 863), which most neurologists agree is a dystonia rather than a neurosis.

The likelihood is that these functional disorders will be reclassified as their causes and pathophysiology are revealed. Functional brain scans and peripheral sensory testing suggest that central nervous system sensitization is found in a number of these disorders, which might help to explain their clustering together.

**Chronic fatigue syndrome**

There has probably been more controversy over the existence and causes of chronic fatigue syndrome (CFS) than any other functional somatic syndrome in recent decades. There is good evidence for the independent existence of this syndrome, although the diagnosis is made clinically and by exclusion of other fatiguing disorders. Its prevalence is 0.5–2.5% worldwide, mainly depending on how it is defined. It occurs most commonly in women between the ages of 20 and 50 years.

**Clinical features**

The cardinal symptom is chronic fatigue made worse by minimal exertion. The fatigue is usually both physical and mental, and is most commonly associated with:

- poor concentration
- impaired registration of memory
- alteration in sleep pattern (either insomnia or hypersomnia)
- muscular pain.

Mood disorders are present in a significant minority of patients, and can cause problems in diagnosis because of the overlap in symptoms. These mood disorders may be secondary, independent (co-morbid) or primary (with a misdiagnosis of CFS).

**Aetiology**

Functional disorders often have some aetiological factors in common with each other (Box 25.14), as well as more specific aetiologies. For instance, CFS can be triggered by certain infections, such as infectious mononucleosis and viral hepatitis. About 12% of patients who have infectious mononucleosis have CFS 6 months after the onset of infection, yet there is no evidence of persistent infection in these patients. Those fatigue states that clearly do follow on from a viral infection can also be classified as post-viral fatigue syndromes.

Other aetiological factors are uncertain. Immune and endocrine abnormalities noted in CFS may be secondary to the inactivity or sleep disturbance commonly seen. The role of stress is uncertain, with some indication that the influence of stress is mediated through consequent psychiatric disorders exacerbating fatigue, rather than any direct effect.

**Management**

The general principles of the management of functional disorders are given in Box 25.15. Specific management of CFS should include a mutually agreed and supervised programme of gradually increasing activity. However, only about a quarter of patients recover after treatment. It is sometimes difficult to persuade a patient to accept what are inappropriately perceived as ‘psychological therapies’ for such a physically manifested condition.
Antidepressants do not work in the absence of a mood disorder, pain or insomnia.

**Prognosis**

Prognosis is poor without treatment, with less than 10% of hospital attenders recovered after 1 year. Outcomes are worse with greater severity, increasing age, co-morbid mood disorders, and the conviction that the illness is entirely physical. A large trial showed that about 60% improve with active rehabilitative treatments, such as graded exercise therapy and cognitive behaviour therapy, when added to specialist medical care.

**Fibromyalgia (chronic widespread pain)**

Fibromyalgia is characterized by widespread muscle and joint pain but is also associated with chronic fatigue and sleep disturbance. The ‘tender points’, previously used diagnostically (see p. 430), are no longer used but their importance is still argued by some. It is commonest in women aged 40–65 years, and has a prevalence in the community of 1–11%, varying by definition. There are associations with depressive and anxiety disorders, other functional disorders, physical deconditioning and a possibly characteristic sleep disturbance (see Box 25.14). Functional brain scans and peripheral sensory testing support the idea of an underlying abnormal sensory processing that may be related to abnormal regulation of central opioidergic mechanisms.

**Management**

Apart from the general principles set out in Box 25.15, management consists of:

- centrally acting analgesia
- reversal of the sleep disturbance
- a physically orientated rehabilitation programme.

A meta-analysis suggests that tricyclic antidepressants such as amitriptyline and dosulepin that inhibit reuptake of both serotonin (5-hydroxytryptamine, 5-HT) and noradrenaline (norepinephrine) have the greatest effect on sleep and pain. The doses used are too low to exert an antidepressant effect and the drugs may work primarily through their hypnotic effects. Other centrally acting anti-nociceptive agents that are also antidepressants include duloxetine and milnacipran (not available in the UK), used at full doses and the gabapentinoids, pregabalin and gabapentin.

**Other chronic pain syndromes**

A chronic pain syndrome is a condition of chronic disabling pain for which no medical cause can be found. The psychiatric classification would be a persistent somatoform pain disorder; this is unsatisfactory since the criteria stipulate that emotional factors must be the main cause, of which it is difficult to be clinically certain.

The most commonly affected sites are the lower back, abdomen, genitalia, head, face, neck or all over (fibromyalgia). ‘Functional’ low back pain is the most common ‘physical’ reason for being off sick long term in the UK (see p. 421). Quite often, minor abnormalities are found on investigation but are not severe enough to explain the severity of the pain and resultant disability. These pains are often unremitting and respond poorly to analgesics. Sleep disturbance is almost universal and co-morbid psychiatric disorders are commonly found.

**Aetiology**

The perception of pain involves sensory (nociceptive), emotional and cognitive processing in the brain. Functional brain scans suggest that the brain responds abnormally to pain in these conditions, with increased activation in response to chronic pain. Alongside this, the brain’s ability to inhibit pain through descending mechanisms in the spinal cord is impaired. The brain may then adapt to the prolonged stimulus of the pain by changing its central processing. The insula, striatum, thalamus and cingulate gyrus seem to be particularly affected, all of which are involved in the experience of pain in general. Thus, it is possible to start to understand how interactions between physiology, cognitions, emotions and behaviour might influence the perception of chronic pain.

**Management**

Management involves the same principles as are applied in other functional syndromes (see Box 25.15). Since analgesics are rarely effective and can cause long-term harm, patients should be encouraged to reduce their use gradually. It is often helpful to involve the patient’s immediate family or partner, to ensure that the partner is also supported and not unconsciously discouraging progress.

Specific drug treatments are few:

- **Nerve blocks** are not usually effective.
- **Gabapentinoids**: gabapentin and pregabalin (see p. 825).
- **Dual-acting antidepressants** (serotonin and noradrenaline reuptake inhibitors, SNRIs, e.g. duloxetine) affect both serotonin and noradrenaline (norepinephrine) reuptake; these demonstrate the greatest efficacy. Low-dose tricyclic antidepressants that affect both of these neurotransmitters (e.g. amitriptyline, dosulepin) are also effective, although this may be primarily through an improvement in sleep. Selective serotonin reuptake inhibitors, SSRIs, are less effective, except in the presence of co-morbid anxiety and depressive disorders.

**Irritable bowel syndrome**

This is one of the most common functional somatic syndromes, affecting some 10–30% of the population worldwide. The clinical features and management of irritable bowel syndrome (IBS) and related functional bowel disorders are described in more detail in on page 1187. Although the majority of people with IBS do not have a psychiatric disorder, depressive illness should be excluded in those with constipation and a poor appetite. Anxiety disorders should be excluded in individuals with nausea and diarrhoea. Persistent abdominal pain or a feeling of emptiness may occasionally be the presenting symptom of a severe depressive illness, particularly in the elderly, with a nihilistic delusion that the body is empty or dead inside (see p. 776).

**Management**

This is dealt with in more detail in Box 25.15. Seeing a physician who provides specific education addressing individual illness beliefs and concerns can provide lasting benefit.

Antidepressants are frequently indicated in moderate to severe cases and the choice of agent will depend on the presence of pain, sleep disturbance and psychiatric co-morbidity, as well as the effect of drug families on bowel transit times (e.g. this is reduced with SSRIs). Milder cases will often respond well to low doses of amitriptyline, although this may be poorly tolerated. Non-pharmacological treatments are also important considerations, most commonly cognitive behaviour therapy.
Multiple chemical sensitivity, Candida hypersensitivity and food allergies

Some complementary health practitioners, doctors and patients themselves make diagnoses of multiple chemical sensitivities (MCS) (e.g. to foods, smoking, perfumes, petrol), Candida hypersensitivity and allergies (to food, tap water and even electricity). Symptoms and syndromes attributed to these putative disorders are numerous and variable, and include all the functional disorders, mood disorders and arthritis. Scientific support for the existence of these disorders is weak, particularly when double-blind methodologies have been used.

**Type 1 hypersensitivities** to foods such as nuts certainly exist, although they are fortunately uncommon (approximately 3/1000) (see p. 62). Direct specific food intolerances also occur (e.g. chocolate with migraine, caffeine with IBS).

Candidiasis can occur in the gastrointestinal tract in immunocompromised individuals, such as those with the acquired immunodeficiency syndrome (AIDS). Vaginal candidiasis can follow antibiotic treatment in otherwise healthy women. A double-blind and controlled study of nystatin in women diagnosed as having candidiasis hypersensitivity syndrome showed that vaginitis was the only condition relieved more by nystatin than placebo. There is little evidence of Candida having a systemic role in other symptoms. In spite of this evidence, the patient is often convinced of the legitimacy and usefulness of these diagnoses and their treatments.

**Aetiology**

Surveys of patients diagnosed with MCS or food allergies have shown high rates of current and previous mood and anxiety disorders (see Box 25.14). Eating disorders (see p. 797) are effective. A prospective study has shown that PMDD, considered as a dysphoric disorder, is more common in women with eating disorders (see p. 797). Eating disorders are effective treatments for PMDD.

**Management**

The general principles in Box 25.15 apply. Treatments with vitamin B₆ (see p. 1241), diuretics, progesterone, oral contraceptives, oil of evening primrose, and oestrogen implants or patches (balanced by cyclical norethisterone) remain empirical. Psychotherapies aimed at enhancing the patient’s coping skills can reduce disability. Two trials suggest that graded exercise therapy improves symptoms. Several studies have demonstrated that SSRIs (see p. 780) are effective treatments for PMDD.

**Menopause**

The clinical features and management of the menopause are described on page 1468. A prospective study has shown that there is no increased incidence of depressive disorders at this time. Menopausal vasomotor symptoms are associated with sleep disturbance that may give rise to mood disturbance. Such a significant bodily change, sometimes occurring at the same time as children leave home, is naturally accompanied by an emotional adjustment that does not normally amount to a pathological state.

White PD, Goldsmith KA, Johnson AL et al. Comparison of adaptive pacing therapy, cognitive behaviour therapy, graded exercise therapy, and specialist medical care for chronic fatigue syndrome (PACE): a randomised trial. Lancet 2011; 377:823–836.

**Somatoform disorders**

As explained in the section on functional disorders (see p. 769), the classification of somatoform disorders is unsatisfactory because of their uncertain nature and aetiology. However, there are certain disorders, beyond those described above, that present frequently and coherently enough to be usefuly recognized.

**Somatization disorder**

One in ten patients presenting with a functional disorder will fulfil the criteria of a chronic somatization disorder. The condition is composed of multiple, recurrent, medically unexplained physical symptoms, usually starting early in adult life. Symptoms may be referred to almost any part or bodily system. The patient has often had multiple medical opinions and repeated negative investigations. Medical reassurance fails to reassure the patient, who will continue to ‘doctor-shop’ and is usually reluctant to accept that psychological and/or social factors may play a role. Abnormal
illness behaviour is evident and patients may become increasingly dependent on doctors.

The aetiology is unknown, but both mood and personality disorders are often also present. Somatization disorder is frequently associated with dependence upon or overuse of prescribed medication, usually sedatives and analgesics. There is often a history of significant childhood traumas, or chronic ill-health in the child or parent, which may play an aetiological role or help to explain difficult therapeutic relationships. The condition is probably the somatic presentation of psychological distress, although iatrogenic damage (from postoperative and drug-related problems) soon complicates the clinical picture. It is a chronic and disabling disorder, with longstanding family, relationship and/or occupational problems.

**Hypochondriasis**

The conspicuous feature is a preoccupation with an assumed serious disease and its consequences. Patients commonly believe that they suffer from cancer or some other serious condition. Characteristically, such patients repeatedly request investigations either to prove they are ill or to reassure themselves that they are well. Such reassurance rarely lasts long before another cycle of worry and requests begins. The symptom of hypochondriasis may be secondary to or associated with a variety of psychiatric disorders, particularly depressive and anxiety disorders. Occasionally, the hypochondriasis is delusional, secondary to schizophrenia or a depressive psychosis. Hypochondriasis may coexist with physical disease but the diagnostic point is that the patient’s concern is disproportionate and unjustified.

**Management of somatoform disorders**

The principles outlined in Box 25.15 apply to these disorders. Given their poor prognosis, the aim is to minimize disability. It is vital that all members of staff and close family members adopt the same approach to the patient’s problems as the patient will often, consciously or unconsciously, split both medical staff and family members into ‘good’ and ‘bad’ (or caring and uncaring) people, as a way of projecting their distress.

Patients appreciate a discussion and explanation of their symptoms. You should sensitively explore possible psychological and social difficulties, if possible by asking about or demonstrating links between symptoms and stresses. Such discussion usually gives information that can be used to formulate an agreed plan of management. A contract of mutually agreed care, involving the appropriate professionals (general practitioner, and a choice of psychotherapist, physician or psychiatrist), with agreed frequency of visits and a review date, can be helpful in managing the condition. Management also includes cessation of reassurance that no serious disease has been uncovered, since this simply reinforces dependence on the doctor. Repeated investigations should be discouraged. Cognitive behaviour therapy has been shown to provide effective rehabilitation in significant numbers of patients suffering from a somatoform disorder.

### DISASSOCIATIVE/CONVERSION DISORDERS

Increasingly, these disorders are referred to as ‘functional neurological disorders’.

A **dissociative disorder** is a condition in which there is a profound loss of awareness or cognitive ability without medical explanation. The term dissociative indicates the disintegration of different mental activities, and covers such phenomena as amnesia, fugues and non-epileptic attacks.

**Conversion disorder** occurs when an unresolved conflict is converted into, usually symbolic, physical symptoms as a defence against it. Such symptoms commonly include paralysis, abnormal movements, sensory loss, aphonia, disorders of gait and pseudocyesis (false pregnancy). The lifetime prevalence has been estimated at 3–6 per 1000 in women, with a lower prevalence in men. Most cases begin before the age of 35 years and are unusual in the elderly.

**Clinical features**

The various symptoms are usually divided into dissociative and conversion categories (Box 25.16). Dissociative disorders have the following three characteristics that are necessary in order to make the diagnosis:

- They occur in the absence of physical pathology that would fully explain the symptoms.
- They are produced unconsciously.
- Symptoms are not caused by overactivity of the sympathetic nervous system.

Other characteristics include:

- Symptoms and signs often reflect a patient’s ideas about illness.
- There is usually abnormal illness behaviour, with exaggeration of disability.
- There may have been significant childhood traumas.
- **Primary gain** is the immediate relief from the emotional conflict.
- **Secondary gain** refers to the social advantage gained by the patient by being ill and disabled (sympathy of family and friends, time off work, disability pension).
- Physical disease is, not uncommonly, also present (e.g. pseudo-seizures are more common in someone with epilepsy). **Dissociative amnesia** commences suddenly. Patients are unable to recall long periods of their lives and may even deny any knowledge of their previous life or personal identity. In a **dissociative fugue**, patients not only lose their memory but also wander away from their usual surroundings; when found, they have no memory of their whereabouts during this wandering. The differential diagnosis of a fugue state includes post-epileptic automatism, depressive illness and alcohol misuse.

**Multiple personality disorder** is rare but dramatic, and may be triggered by suggestion on the part of a psychotherapist. There are rapid alterations between two or more ‘personalities’ in the same

---

**Box 25.16 Common dissociative/conversion symptoms**

**Dissociative (mental)**

- Amnesia
- Fugue
- Pseudodementia
- Dissociative identity disorder

**Conversion (physical)**

- Paralysis
- Disorders of gait
- Tremor
- Aphonia
- Mutism
- Sensory symptoms
- Globus
- Pseudoseizures
- Blindness
The psychoanalytical theory of dissociation is that it is the result of emotionally charged memories that are repressed into the unconscious at some point in the past. Symptoms are explained as the combined effects of repression and the symbolic conversion of this emotional energy into physical symptoms. This hypothesis is difficult to test, although there is some evidence that people with dissociative disorders are more likely to have suffered childhood abuse. Caution should be taken when such a history is obtained by therapies that recover childhood memories previously completely unknown to the patient.

Management
The treatment of dissociation is similar to the treatment of somatoform disorders (see Box 25.15). The first task is to engage the patient and their family with an acceptable explanation of the illness that makes sense to them and leads to the appropriate management (Box 25.17). Such an explanation would be modified by mutual discussion until an agreed understanding was achieved, which would serve as a working model for the illness. Provision of a rehabilitation programme that addresses both the physical and the psychological needs of the patient would then be planned.

- **A graded and mutually agreed plan for a return to normal function** can usually be led by the appropriate therapist (e.g. speech therapist for dysphonia, physiotherapist for paralysis).
- **A psychotherapeutic assessment** should be made at the same time, in order to determine the most appropriate psychotherapy. For instance, couple therapy will address a significant relationship difficulty; individual psychotherapy could ease an unresolved conflict from childhood (see p. 788).

Abreaction brought about by hypnosis or by intravenous injections of small amounts of midazolam may produce a dramatic, if sometimes short-lived, recovery. In the abreactive state, the patient is encouraged to relive the stressful events that provoked the disorder and to express the accompanying emotions: that is, to abreact. It should only be contemplated in the presence of an anaesthetist with suitable resuscitation equipment to hand. Hypnotherapy is psychotherapy applied while the patient is in a hypnotic trance, the idea being that therapy is more easily possible because the patient is relaxed and not using repression. This may allow the therapist access to the previously unconscious emotional conflicts or memories. There are no published trials of this technique in dissociation. Care should be taken to avoid a catastrophic emotional reaction when the patient is suddenly faced with the previously repressed memories.

Prognosis
Most cases of recent onset recover quickly with treatment, while chronicity predicts a worse outcome (with the exception of non-epileptic attack disorder where it has no impact), emphasizing the importance of early diagnosis. One study found that 83% were still unwell at 12 years’ follow-up.
SLEEP DIFFICULTIES

Sleep is divided into rapid eye movement (REM) and non-REM sleep:
- As drowsiness begins, the alpha rhythm on an electroencephalogram (EEG) disappears and is replaced by deepening slow-wave activity (non-REM).
- After 60–90 minutes, this slow-wave pattern is replaced by low-amplitude waves, on which are superimposed rapid eye movements lasting a few minutes.
- This cycle is repeated during the duration of sleep, with the REM periods becoming longer and the slow-wave periods shorter and less deep (Fig. 25.2).
- REM sleep is accompanied by dreaming and physiological arousal.
- Slow-wave sleep is associated with release of anabolic hormones and cytokines, with an increased cellular mitotic rate. It helps to maintain host defences, metabolism and repair of cells. For this reason, slow-wave sleep is increased in those conditions where growth or conservation is required (e.g. adolescence, pregnancy, thyrotoxicosis).

Insomnia

Insomnia is difficulty in sleeping; a third of adults complain of insomnia, and in a third of these it can be severe.

Sleep disorders secondary to another medical diagnosis will not be discussed here.

Primary sleep disorders

These include sleep apnoea (see p. 960), narcolepsy (p. 858), the restless legs syndrome (Wittmaack–Ekbom's syndrome, also known as Willis–Ekbom disease; see p. 858) and the related periodic leg movement disorder, in which the legs (and sometimes the arms) jerk while asleep.

Delayed sleep phase syndrome

This occurs when the circadian pattern of sleep is delayed, so that the patient sleeps from the early hours until midday or later; it is most common in young people.

Parasomnias

Night terrors, sleep-walking and sleep-talking are non-REM phenomena, called parasomnias; they are most commonly found in children, but can recur in adults when under stress or suffering from a mood disorder.

Psychophysiological insomnia

This is commonly secondary to functional, mood and substance misuse disorders, and is frequently present in individuals under stress. It can often be triggered by one of these factors before becoming a habit on its own, driven by anticipation of insomnia and daytime naps.

Clinical Features

Insomnia causes daytime sleepiness and fatigue, with consequences such as road traffic accidents. Assessment should focus on mood, life difficulties and drug intake (especially alcohol, nicotine and caffeine). The timing of the insomnia should be ascertained:
- Initial insomnia (trouble going off to sleep) is common in mania, anxiety, depressive disorders and substance misuse.
- Middle insomnia (waking up in the middle of the night) occurs with medical conditions such as sleep apnoea and prostatism.
- Late insomnia (early morning wakening) is caused by depressive illness and malnutrition (anorexia nervosa).

Habitual alcohol consumption should be estimated, since even a small excess can be a potent cause of insomnia, as well as recent withdrawal. The effects of caffeine are easily under-estimated. Six cups of coffee a day are likely to cause insomnia in the average healthy adult. Caffeine is found not only in tea and coffee, but also in chocolate, cola drinks and some analgesics.

Prescription drugs that can either disturb sleep or cause vivid dreams include appetite suppressants, glucocorticoids, dopamine agonists, lipid-soluble beta-blockers (e.g. propranolol) and certain psychotropic drugs (especially on initiation, e.g. fluoxetine, risperidone).

Hypersomnia

This is not uncommon in adolescents with depressive illness. It occurs in narcolepsy, and may temporarily follow infections such as infectious mononucleosis.

Management of insomnia

This is determined by diagnosis. Where none is immediately apparent, it is worth educating the patient about sleep hygiene. In addition:
- Simple measures, such as decreasing alcohol intake, having supper earlier, exercising daily, having a hot bath prior to going to bed and establishing a routine of going to bed at a consistent time, should all be tried.
- Relaxation techniques and cognitive behaviour therapy have a role in those with intractable insomnia.
- Short-half-life benzodiazepines can be useful for acute insomnia, but should not be used for more than 2 weeks continuously to avoid dependence.

Fig. 25.2 Sleep architecture. Cycles of slow-wave sleep are interspersed with rapid eye movement (REM) sleep. Sleep is ‘staged’ by the electroencephalogram (EEG). Deeper sleep (stages 3 and 4) is demonstrated by slow waves on the EEG. Sleep occurs in cycles, light sleep (accompanied by REM sleep and dreaming) to deep sleep and back again, and these cycles last about 90 minutes.
MOOD (AFFECTIVE) DISORDERS

The central feature of these disorders is an abnormality of mood. Mood is best described in terms of a continuum ranging from severe depression at one extreme to severe mania at the other, with normal, stable mood in the middle. Mood disorders are divided into unipolar and bipolar affective disorders.

Unipolar affective disorders

Patients suffer from depressive episodes alone, which are commonly recurrent.

Bipolar affective disorder

Patients suffer bouts of both depression and mania. Although mania can occur by itself without depressive episodes, it is far more commonly found in association with them, although it can take several years for the first depressive illness to appear.

- **Bipolar I** disorder is defined as one or more manic or mixed (signs of mania and depression) episodes.
- **Bipolar II** is defined as a depressive episode with at least one episode of hypomania (this is shorter-lived than mania and is not accompanied by psychotic symptoms). Hypomania is noticeably abnormal but does not result in functional impairment or hospitalization.
- **Bipolar III** disorder is less well established and describes depressive episodes, with hypomania occurring only when taking an antidepressant.

About 10% of patients who have depressive illness are eventually found to have a bipolar illness.

Depressive disorders

Depressive disorders or ‘episodes’ are classified by the ICD-10 as mild, moderate or severe, with or without somatic symptoms. Severe depressive episodes are divided according to the presence or absence of psychotic symptoms.

Clinical features of depressive disorder

Whereas everyone will, at some time or other, feel ‘fed up’ or ‘down in the dumps’, it is when such symptoms become qualitatively different and pervasive or interfere with normal functioning that a depressive illness has occurred. Depressive disorder, clinical or ‘major’ depression, is characterized by disturbances of mood, speech, energy and ideas (Box 25.19). Patients often describe their symptoms in physical terms. Marked fatigue and headache are the two most common physical symptoms in depressive illness and may be the first symptoms to appear. Patients describe the world as looking grey, and themselves as lacking a zest for living, and being devoid of pleasure and interest in life (anhedonia). Anxiety and panic attacks are common; secondary obsessional and phobic symptoms may emerge. Symptoms should last for at least 2 weeks and cause significant incapacity (e.g. trouble working or relating to others) in order to be considered an illness.

In the more severe forms, diurnal variation in mood can occur, patients feeling worse in the morning, after waking in the early hours with apprehension. Suicidal ideas are more frequent, intrusive and prolonged. Delusions of guilt, persecution and bodily disease are not uncommon, along with second-person auditory hallucinations insulting the patient or suggesting suicide. In severe depressive illness, particularly in the elderly, concentration and memory can be so badly affected that the patient appears to have dementia (pseudodementia). Delusions of poverty and non-existence (nihilism) occur particularly in this age group. Suicide is a real risk; lifetime risk is approximately 6% in all patients, but higher in those with depressive illness severe enough to warrant admission to hospital, those with bipolar affective disorder and those with co-morbid substance misuse.

Epidemiology

About a third of the population will feel unhappy at any one time but this is not the same as depressive illness; the middle-aged feel least happy compared with the young and elderly. The point prevalence of depressive illness is 5% in the community, with a further 3% having dysthymia (see below). It is more common in women, but there is no increase with age, and no difference by ethnic or socioeconomic group (apart from a clear association with unemployment). Married and never-married people have similar prevalence.
rates, with separated and divorced people having two to three times the prevalence. Depressive illnesses are becoming more common and are more frequently found in the presence of:

- physical diseases, particularly if chronic, stigmatizing or painful
- excessive and chronic alcohol use
- social stresses, particularly loss events, such as separation, redundancy and bereavement
- interpersonal difficulties with those close to the patient, especially when socially humiliated
- lack of social support, with no confiding relationship

Depressed people with another physical disorder view themselves as more sick and disabled, visit their doctors almost four times as often, stay in hospital longer, adhere less to medical advice and medication, and undergo more medical and surgical procedures. Depressive illness may be associated with increased mortality (excluding suicide) in people with physical illness, such as myocardial infarct.

**Dysthymia**

Dysthymia is a mild or moderate depressive illness that lasts intermittently for 2 years or more and is characterized by tiredness and low mood, lack of pleasure and low self-esteem. The mood relapses and remits, with several weeks of feeling well, soon followed by longer periods of being unwell. It can be punctuated by depressive episodes of greater severity, so-called ‘double depression’.

**Seasonal affective disorder**

Seasonal affective disorder is characterized by recurrent episodes of depressive illness occurring during the winter months in the northern hemisphere. Symptoms are similar to an atypical depressive illness, with hypersomnia, increased appetite (with carbohydrate craving) and weight gain, and profound fatigue. Such patients have a higher prevalence of bipolar affective disorder, and some doctors are uncertain whether the condition is different from normal depressive illness, with the accentuation of mood that naturally occurs by season. However, there is evidence that seasonal depressive illness can be successfully treated with bright light therapy given in the early morning, which causes a phase advance in the circadian rhythm of melatonin. By contrast, the same treatment given in the evening has less antidepressant effect. Selective serotonin reuptake inhibitors (SSRIs) are alternative treatments.

**Puerperal affective disorders**

Affective illnesses and distress are common in women soon after they have given birth.

*’Baby blues’* describe the brief episodes of emotional lability, irritability and tearfulness arising in about 50% of women 2–3 days postpartum and resolving spontaneously in a few days.

*Postpartum psychosis* occurs once in every 500–1000 births. Over 80% of cases are an affective psychosis and the onset is usually within the first 2 weeks following delivery. Disorientation and confusion are often noted. Severely depressed patients may have delusional ideas that the child is deformed, evil or otherwise affected in some way, and such false ideas may lead to either attempts to kill the child or attempts at suicide. The response to speedy treatment is generally good. The recurrence rate for a psychosis in a subsequent puerperium is 20–30%.

*Non-psychotic postnatal depressive disorders* occur during the first postpartum year in 10% of mothers, especially in the first 3 months, with a higher prevalence in developing countries. Risk factors are first pregnancy, poor relationship with the partner, ambivalence about the pregnancy, and emotional personality traits.

A lack of emotional bonding with the baby is a common consequence. The Edinburgh Postnatal Depression Scale (EPDS) is a ten-item questionnaire that can be used as an effective screening tool.

**Differential diagnosis of depressive disorders**

See Box 25.21. Other psychiatric disorders are the most common misdiagnoses. Some 90% of patients presenting with a depressive illness while misusing alcohol will no longer be depressed 2 weeks after their last drink.

Pathological (abnormal) grief and normal grief are described on page 788. Pathological grief is closely associated with depressive illness.

**Investigation of depressive disorders**

A corroborative history can be valuable in helping to exclude differential diagnoses such as alcohol misuse, and in elucidating perpetuating factors such as a poor relationship with a partner. Investigations should be guided by the history and examination, but those commonly performed are:

- full blood count, urea and electrolytes, serum creatinine, estimated glomerular filtration rate (eGFR)
- liver biochemistry (including glutamyl transpeptidase)
- serum calcium
- erythrocyte sedimentation rate/C-reactive protein (ESR/CRP)
- thyroid function tests (free T₄, thyroid-stimulating hormone (TSH))

Other tests include:

- serum cortisol (morning and evening)
- antinuclear antibody
- chest X-ray
- EEG or brain scan, as indicated.

**Aetiology of unipolar depressive disorders**

The aetiology of unipolar depressive disorders is multifactorial and is composed of a mixture of genetic and environmental factors.

**Genetic factors**

Unipolar depression is probably polygenic but no linkage has been firmly identified. The risk of unipolar depression in a first-degree relative of a patient is approximately three times that in the non-affected. The concordance of unipolar depression in monozygotic twins is between 30% and 60%, increasing with more recurrent illnesses.

**Unipolar depressive disorders**

Affective (mood) disorders include major depressive disorder (recurrent major depression) and dysthymia. Other diagnoses include the following:

- **Major depression (recurrent)**
  - mood (affective) disorders
  - postpartum depressive disorder
  - premenstrual dysphoric disorder

- **Dysthymia**
  - mood (affective) disorders
  - non-psychotic affective disorders

- **Postpartum depressive disorder**
  - mood (affective) disorders
  - non-psychotic affective disorders
  - postpartum psychosis

- **Premenstrual dysphoric disorder**
  - mood (affective) disorders
  - premenstrual syndrome

**Major depression**

- mood (affective) disorders
- postpartum depressive disorder
- premenstrual dysphoric disorder

**Postpartum depression**

- mood (affective) disorders
- non-psychotic affective disorders
- postpartum psychosis

**Premenstrual dysphoric disorder**

- mood (affective) disorders
- premenstrual syndrome

**Investigation of depressive disorders**

A corroborative history can be valuable in helping to exclude differential diagnoses such as alcohol misuse, and in elucidating perpetuating factors such as a poor relationship with a partner. Investigations should be guided by the history and examination, but those commonly performed are:

- full blood count, urea and electrolytes, serum creatinine, estimated glomerular filtration rate (eGFR)
- liver biochemistry (including glutamyl transpeptidase)
- serum calcium
- erythrocyte sedimentation rate/C-reactive protein (ESR/CRP)
- thyroid function tests (free T₄, thyroid-stimulating hormone (TSH))

Other tests include:

- serum cortisol (morning and evening)
- antinuclear antibody
- chest X-ray
- EEG or brain scan, as indicated.

**Aetiology of unipolar depressive disorders**

The aetiology of unipolar depressive disorders is multifactorial and is composed of a mixture of genetic and environmental factors.

**Genetic factors**

Unipolar depression is probably polygenic but no linkage has been firmly identified. The risk of unipolar depression in a first-degree relative of a patient is approximately three times that in the non-affected. The concordance of unipolar depression in monozygotic twins is between 30% and 60%, increasing with more recurrent illnesses.
Polymorphisms that increase the risk of depression involve monoamines and their receptors, but studies are inconclusive. Recent research suggests a possible role for epigenetic changes. The issue is complicated by genetic influences on sleep, emotional personality and even life events, which are all involved in the genesis of depressive illness.

Biochemical changes

Monoamines

The monoamine deficiency theory of depressive illness is supported by the efficacy of monoamine reuptake inhibitors and the depressive effect of dietary tryptophan depletion. There is, however, a discrepancy between the timing of changes in neurotransmitter metabolism and clinical improvement.

Neuroimaging studies have revealed a raised density of monoamine oxidase A (MAO-A) receptors. Depression is proposed to be related to a chronic and on-going depletion of these neurotransmitters as a result of increased MAO-A activity and its interaction with region-specific monoamine transporter densities. Together, these are then thought to determine the particular expression of the depressive illness and the predominance of particular symptoms.

Neuroendocrine tests suggest that the serotonin neurotransmitter system is downregulated. 5-HT1A and 5-HT2 receptor subtypes are thought most likely to be involved. Receptor-labelled functional brain scans suggest that dopamine underactivity relates to anhedonia and psychomotor retardation.

Hypothalamo–pituitary–adrenal axis

Exogenous steroids are associated with the onset of depressive symptoms and people with Cushing’s syndrome often demonstrate depressive episodes. Acute stress, whether physical or psychological, is associated with a rise in glucocorticoids. Severe depressive episodes have been linked with hypercortisolae mia (although cortisol is low in ‘atypical’ depression), but whether this is aetiological or secondary to sleep disturbance and weight loss is unknown. This cortisol dysregulation has been associated with impaired glucocorticoid negative feedback, adrenal hyperresponsiveness to adrenocorticotropic hormone (ACTH) and hypersecretion of cortisol-releasing hormone (CRH).

Exposure to the high levels of cortisol is thought to have a direct effect on neuronal plasticity and to lower resistance to neuronal damage. The hippocampus seems especially susceptible, resulting in atrophic changes. This, in turn, has further deleterious effects on wider neuroendocrine function, leading to a self-perpetuating dysregulation that may serve to maintain and/or worsen the illness.

The interplay at this level becomes more complicated, with reduced central and peripheral glucocorticoid receptor sensitivity, hypothalamo-pituitary-adrenal (HPA) axis upregulation, and the release of pro-inflammatory cytokines that may, in turn, explain changes in mood, fatigue, appetite, sensitivity to pain and reduced libido (note that depression is a side-effect of interferon treatment). At the cellular level, this affects monoamine transport and causes neuronal apoptosis and dysfunction of glial cells, normally responsible for maintaining neuronal homeostasis.

Brain-derived neurotrophic factor

Healthy interactions between neurones and glial cells are maintained by brain-derived neurotrophic factor (BDNF), which is found in its greatest concentration in the hippocampus and cerebral cortex. It promotes cell growth and long-term potentiation (the enhancement of synchronous firing between two neurones). Pro-BDNF, its precursor, promotes the reduction of dendritic spines and apoptosis. BDNF is then involved in the growth and activity of neural networks.

• Animal studies suggest that BDNF is reduced by stress.

• Adult humans with untreated depressive illness have lower serum concentrations of BDNF when compared with both healthy controls and those that have received antidepressant treatment.

• Low levels normalize with antidepressant treatment.

BDNF therefore has potential as an objective marker of depression and its response to treatment, and as a pharmacological target for drug development.

Neuroimaging changes

The use of functional magnetic resonance imaging (fMRI) and positron emission tomography (PET) has revealed a number of abnormalities in the brains of people with major depression. These changes are non-specific but involve regions that are associated with both the emotional and the cognitive abnormalities seen in depression. Increased brain ventricle volume, and orbitofrontal, dorsolateral frontal and anterior cingulate cortex altered activation have been implicated. The hippocampus is smaller in several stress-related neuropsychiatric disorders, including recurrent depression.

Sleep

A reduced time between onset of sleep and REM sleep (shortened REM latency), and reduced slow-wave sleep both occur in depressive illness. These abnormalities persist in some patients when they are not depressed. Families with several sufferers of depressive illness can share these traits, suggesting that sleep patterns may be inherited and may predispose to depression.

Childhood traumas and personality

Physical, sexual and emotional abuse and neglect in childhood predispose adults to depressive illness but the effect is non-specific. Both ‘neurtic’ (emotional) and perfectionist personality traits are risks for depressive illness, and these may be determined as much by genetic factors as childhood environment.

Social factors

Some 30% of women will develop a depressive illness after a severe life event or difficulty, such as a divorce, and this is compounded by low self-esteem and a lack of a confiding relationship. Unemployment is a significant risk factor in men.

An integrated model of aetiology

Stress is more likely to trigger depressive illness in a person predisposed by lack of social support and/or certain personality traits. Stress triggers various changes in both neurohormones (e.g. CRH) and neurotransmitters (e.g. serotonin) known to be altered in depressive illness. This suggests an integrated biopsychosocial model of depressive illness and challenges dualistic ideas that depressive illnesses are either psychological or physical rather than being both.

Management of depressive illness

The patient needs to know the diagnosis to provide understanding and rationalization of the overwhelming distress inherent in depressive illness and this in itself may have an ‘antidepressant’ effect. The treatment of depressive disorders involves physical, psychological and social interventions (Box 25.22).

Patients who are actively suicidal or severely depressed (with or without psychotic symptoms) should be admitted to hospital. Admission is necessary for perhaps 1 in 1000 people with clinical depression in primary care. This allows support, listening,
Moderate clinical depression. The therapist focuses on those things that cannot be changed, and committing oneself to doing depression. These commonly include catastrophizing (e.g. ‘I failed an exam; therefore I am a failure as a person’) and categorical (‘all-or-none’) thinking (e.g. ‘My work is either perfect or abysmal’). CBT then involves identifying the links between these thoughts, consequent behaviour and feeling low, and then testing their logic. This is done by looking at the evidence either in the therapy sessions (e.g. Q: ‘Did you pass the other exams you took?’; A: ‘Yes; I guess I did’) or in behavioural ‘experiments’ (e.g. showing the ‘abysmal’ work to a colleague and asking their opinion).

There is good evidence that individual CBT is as effective as antidepressant drugs for mild and moderate depressive illness, and should be offered as first-choice treatment. It is also effective in preventing a relapse of clinical depression after therapy has ceased. Individual CBT is more effective than group-delivered therapy, and computer-delivered CBT programmes are also helpful when used to supplement therapist involvement. Third-wave CBT therapies, such as mindfulness-based CBT, centred on the use of meditation, can prevent recurrence. Acceptance and commitment therapy (accepting the things that cannot be changed, and committing oneself to things that can be) shows promise.

Interpersonal psychotherapy
This psychotherapy is probably as effective as CBT in mild and moderate clinical depression. The therapist focuses on those interpersonal relationships involved in, or affected by, the patient’s illness, using problem-solving techniques to help the individual to find solutions.

Other psychotherapies

Couple therapy is effective when a patient is in a problematic relationship that may be contributing to the depressive illness; both the patient and partner attend therapy.

Family therapy is effective not only to treat a family with problems, but also to assist the family to help a patient get better. It may involve understanding one family member’s ‘depression’ as a systemic ‘solution’ for a wider problem within the family.

Physical treatments

Exercise and other self-help
There is good evidence that regular exercise, particularly involving other people, can help relieve depressive illness of mild severity. The benefit is independent of a physical training effect. The role of exercise is unclear but recent evidence suggests that kynurenine is prevented from crossing the blood–brain barrier, thereby reducing neuroactive metabolites. Other self-help and psycho-educational advice (e.g. reduction of alcohol consumption, regular meals and sleep–wake cycle) may be helpful, particularly if supported by bibliotherapy.

Use of drugs in the treatment of clinical depression

Moderate and severe depressive episodes can be effectively treated using medication. Antidepressants are designed to provide an acute increase in monoamine activity. They do this through either prevention of reuptake or enzymatic degradation. This occurs acutely and, although an equally rapid depletion of monoamines has an acute mood-lowering effect, the mood-elevating benefits of these drugs require weeks of continuous administration. The benefits are therefore unlikely to be due to this mechanism alone.

The effects of chronic administration of monoamine reuptake inhibitors are various. Examples include an increase in the synthesis of binding proteins necessary for serotonin receptor activity and increases in cyclic adenosine monophosphate activation, in turn increasing BDNF synthesis, enhancing glucocorticoid receptor sensitivity and inhibiting cytokine signalling. These effects may be secondary to the acute restoration of monoamine levels but rely upon transcriptional and translational changes that alter neuronal plasticity. It is this protein synthesis-dependent process that is thought to be the final pathway responsible for the clinical effect of the drugs.

As the neurobiology for depressive illness becomes clearer, so too are novel approaches to its treatment; some of the novel targets under active investigation are listed in Box 25.23. A general approach to the prescription of antidepressants is outlined in Box 25.24.

Drug choices in specific circumstances

- Recurrent episodes. Maintenance treatment with the antidepressant at the dose that obtained remission should be continued for at least 2 years. Maintenance treatment beyond this point should be re-evaluated, considering age, co-morbidities and risk factors.

- Refractory depressive illness. While 50% may show a response, as few as 30% of individuals (outpatients) experience complete remission with the first choice of drug. Strategies available at this point are switching drug classes or augmenting with other agents. This should be overseen by a specialist.
Brain-derived neurotrophic factor (BDNF)
- Tumour necrosis factor-alpha (TNF-α)
- Interleukin-1 beta (IL-1β)
- Glucocorticoid receptors
- Corticotrophin-releasing hormone
- Melatonin-concentrating hormone
- Alpha-melanocyte stimulating hormone
- Ghrelin
- Leptin
- Orexins
- Neuropeptide Y
- Nesfatin-1

**Box 25.24 A general approach to the prescription of antidepressants**

- Any drugs that may contribute to or exacerbate depression, e.g. corticosteroids, should be stopped
- An ECG should be performed prior to institution of antidepressants
- Patient education should be provided (e.g. 80% of the UK public wrongly believe that antidepressants are addictive)
- Regular follow-up (especially weeks 1–6) should accompany the prescription of antidepressants to increase adherence
- All antidepressants have similar efficacy and speed of onset
- Selective serotonin reuptake inhibitors (SSRIs) are considered first-line agents
- Choice of agent will depend on safety and adverse effects, which can be used to positive effect (sedating drugs given at night to enhance sleep)
- The rate of improvement is greatest in weeks 1–2
- An alternative agent should be considered week 4 in the absence of any response
- With resolution of symptoms, antidepressants should be continued for 6–9 months after a single episode but for at least 2 years in the case of multiple prior episodes
- Some 50% of patients who stop antidepressants immediately on recovery relapse in the next 6 months

**Psychotic depression.** This needs either a combination of an antidepressant and an antipsychotic drug, or electroconvulsive therapy.

**Depressive episodes in bipolar affective disorder.** Monotherapy with quetiapine has been proposed as the treatment of choice. Other drugs include mood stabilizers or olanzapine, either alone or in combination with an SSRI antidepressant (see p. 783).

### Selective serotonin reuptake inhibitors

Selective serotonin reuptake inhibitors (SSRIs) selectively inhibit the reuptake of the monoamine serotonin (5-HT) within the synapse (Fig. 25.3). Citalopram and its levo-isomer escitalopram, as well as fluoxetine, paroxetine and sertraline have the advantage of causing less serious adverse effects than tricyclic antidepressants and do not usually cause significant weight gain. Because of their long half-lives, they can also be given just once daily, normally in the morning after breakfast. For these reasons, patients adhere better to treatment and therefore SSRIs are first-line treatments for depressive disorders.

The most common adverse effects of SSRIs resemble a ‘hangover’ and include nausea, vomiting, headache, diarrhoea and dry mouth. Insomnia and paradoxical agitation can occur when first starting the drugs. Adolescents, in particular, may develop suicidal thoughts with SSRIs and only fluoxetine is licensed in the UK for adolescents. Further studies suggest that this risk is small, if present, and no study has shown a significant increased risk of suicide itself. One in five patients also has sexual adverse effects, including erectile dysfunction and loss of libido. Uncommon adverse effects include restless legs syndrome (see p. 858) and hyponatraemia.

A **risk of bleeding** is associated with SSRIs and is thought to be due to the inhibition of serotonin uptake by platelets as part of normal aggregation in response to vascular injury. To date, much of
the reported incidence relates to gastrointestinal bleeding, and any patient with one or more risk factors for upper gastrointestinal bleeding, such as taking an NSAID, should be given gastro-protection with a proton pump inhibitor or advised to stop the NSAID. A risk of intra- and postoperative bleeding has also been reported. While antidepressants are certainly not a reason to withhold a surgical intervention, there is certainly an added risk, of which the surgeon and anaesthetist should be aware.

**‘Serotonin syndrome’** is a toxic hyper-serotonergic state, which can be caused by the ingestion of two or more drugs that increase serotonin levels, e.g. an SSRI combined with a monoamine oxidase inhibitor, a dopaminergic drug (e.g. selegiline) or a tricyclic antidepressant. Symptoms include hyperthermia, agitation, confusion, tremor, diarrhoea, tachycardia and hypertension. This is a medical emergency and requires admission to hospital.

**Discontinuation syndrome**, a specific withdrawal syndrome, has been reported with some SSRIs, and may occur with any antidepressant if stopped suddenly. The syndrome is characterized by shivering, anxiety, dizziness, ‘electric shocks’, headache and nausea. Patients should be warned not to omit a dose and to reduce SSRIs gradually when stopping them.

A **prolonged QTc interval** has been noted, particularly with high doses of citalopram and escitalopram.

### Tricyclic antidepressants

Tricyclic antidepressants (TCAs) potentiate the action of the monoamines, noradrenaline (norepinephrine) and serotonin, by inhibiting their reuptake into nerve terminals (see Fig. 25.3). Dosulepin, imipramine, nortriptyline and amitriptyline are the most commonly used TCAs in the UK, but with the exception of modern compounds that are safer in overdose (e.g. lofepramine), their use as antidepressants is unusual and they are more commonly prescribed in low dose as hypnotics and in the management of chronic pain. They are toxic in overdose and should be avoided in the actively suicidal patient (Box 25.25).

#### Serotonergic and noradrenergic antidepressants

These antidepressants block a number of different neurotransmitter receptors both at the synapse and elsewhere. Their different receptor profiles cause different adverse effects.

- **Dual-acting agents** (*serotonin and noradrenaline reuptake inhibitors, SNRIs*). Duloxetine is the most potent blocker of both serotonin and noradrenaline (norepinephrine) reuptake and at higher doses is equipotent for both neurotransmitters.

### Monoamine oxidase inhibitors

Monoamine oxidase inhibitors (MAOIs) act by irreversibly inhibiting the intracellular enzymes monoamine oxidase A and B, leading to an increase of noradrenaline (norepinephrine), dopamine and 5-HT in the brain (see Fig. 25.3). MAOIs produce a dangerous hypertensive reaction with foods containing tyramine or dopamine and therefore a restricted diet is prescribed. Tyramine is present in cheese, pickled herrings, yeast extracts, certain red wines, and any food, such as game, that has undergone partial decomposition. Dopamine is present in broad beans. MAOIs interact with drugs such as pethidine and can also cause liver damage occasionally. They are less frequently prescribed because of these restrictions.

### Reversible inhibitors of monoamine oxidase A

An example of a reversible inhibitor of monoamine oxidase A (RIMA) is moclobemide. These drugs appear to have fewer adverse effects than the MAOIs (insomnia and headache, but some sexual problems) and constitute a low risk in overdose. Patients prescribed such antidepressants can eat a normal diet, but should be careful to avoid excessive amounts of food rich in tyramine (see above).

### Selective irreversible inhibitors of monoamine oxidase B

Selegiline is a selective irreversible inhibitor of MAO-B. At higher doses it loses its specificity and also inhibits MAO-A. It is more frequently used in the treatment of Parkinson’s disease (see p. 861) than in depression, as it prolongs the activity of levodopa because dopamine is a substrate of MAO-B.

### Melatonin receptor agonist and serotonin receptor antagonist

Agomelatine is the only class member. It is an agonist at melatonin MT₁ and MT₂ receptors and a weak antagonist at 5-HT₂C receptors but does not affect the uptake of serotonin, noradrenaline (norepinephrine) or dopamine. Agomelatine has the same antidepressant efficacy as the SSRIs. It is contraindicated in hepatic impairment.
Antidepressant augmentation
If two trials of antidepressants have failed, adding a second anti-
depressant or drugs such as lithium or an atypical antipsychotic
can be helpful.

Antidepressant use in general medicine
- **Cardiac disease.** In people with cardiac disease, SSRIs, 
  lofotenamine and trazodone are preferred over more quinidine-
  like compounds which may have arrhythmogenic effects.
- **Epilepsy.** SSRIs are typically first-line. Interactions with anticon-
  vulsants should be checked.
- **Drug interactions.** Most antidepressants are metabolized by the 
  cytochrome P450 system but relatively few inhibit cytochrome 
  enzymes, with paroxetine and the TCAs being the exception.
- **Herbal medicine.** Antidepressants should be avoided in pa-
  tients taking the herbal antidepressant St John’s wort, which 
  interacts with serotonergic drugs in particular.
- **Elderly.** Doses of antidepressants should initially be halved in 
  the elderly and in people with renal or hepatic failure.
- **Pregnancy.** Antidepressants should be avoided if possible 
  in pregnancy and breast-feeding. If other treatments are inef-
  fective, the risks of drug therapy should be balanced against 
  those of taking no treatment, since depression can affect fetal 
  progress and future mother–child bonding. TCAs are generally 
  believed to be safe in pregnancy, with no significant increase in 
  congenital malformations in fetuses exposed to them. Howev-
  er, occasionally, their antimuscarinic adverse effects produce 
  jitteriness, sucking problems and hyperexcitability in the new-
  born. Postpartum plasma levels of babies breast-fed by treated 
  mothers are negligible. SSRIs do not seem to be teratogenic 
  but manufacturers advise against their use in pregnancy until 
  more data are available. Pulmonary hypertension in the new-
  born is a rare complication. MAOIs should be avoided during 
  pregnancy.

Combining antidepressants with psychotherapy
Historically, the understanding has been that combining psycho-
therapy with antidepressants provided no additive benefit. Recently, 
however, a well-designed randomized controlled trial has suggested 
that an additive effect can be achieved with this approach (spe-
ifically, with CBT). However, this is both a modest and a specific 
effect. Patients with more severe and non-chronic episodes attain 
this benefit, while those with milder forms of the disorder, chronic 
depression and co-morbid personality disorders do not, when 
compared with antidepressants alone. Individuals who obtained ben-
efit from the combined treatment also experienced fewer adverse 
effects from the antidepressants prescribed.

Electroconvulsive therapy
Electroconvulsive therapy (ECT) is the treatment of choice in severe, 
life-threatening depressive illness, particularly when psychotic 
symptoms are present. It is sometimes essential treatment when 
the patient is dangerously suicidal or refusing to eat and drink, and 
when a rapid resolution is required, such as in postpartum depres-
sive illness, when returning baby to mother as soon as it is safe to 
do so forms part of the treatment.

ECT is performed under general anaesthetic and involves the 
passage of an electric current across two electrodes applied to the 
anterior temporal areas of the scalp, in order to induce a seizure. 
The motoric seizure is less significant than its electrophysiological 
evidence (spike-and-wave activity on an EEG). Treatments are nor-

Mania, hypomania and bipolar disorder

ECT is a controversial treatment, yet it is free of serious adverse 
effects. Most adverse effects are due to the general anaesthetic. 
Post-ictal confusion and headache are not uncommon, while tran-
sient and short-term retrograde amnesia and a temporary defect in 
new learning can occur during the weeks of treatment, but these are 
typically short-lived. Autobiographical memory loss is a more com-
mon adverse effect than previously thought. This is often discrete 
and, in most instances, not recognized by the patient, unless the 
partial memory is actively sought. Patients should be forewarned 
of this during the consenting process.

Uncommonly used physical treatments
**Transcranial magnetic stimulation (TMS)** shows moderate effi-
cacy, but is uncommonly used. **Psychosurgery** is very occasion-
ally considered in people with severe intractable depressive illness, 
when all other treatments have failed (see p. 789). A third improve-
remarkably, while a further third improve somewhat.

**Deep brain stimulation** may represent major advances in the 
management of chronic and treatment-refractory depressive disor-
ders, but definitive trials are not available.

Social treatments

Many people with clinical depression have associated social prob-
lems (see Box 25.22). Assistance with these can make a significant 
contribution to clinical recovery. Interventions include the provision 
of group support, social clubs, occupational therapy and refer-
ral to a social worker. Educational programmes, self-help groups 
and informed and supportive family members can help improve 
outcome.

Prognosis

Depression is one of the leading causes of disease burden world-
wide. People with major depressive illness are between 1.5 and 
2 times more likely to die than non-depressed people in the next 
16 years, and the risks encompass not only suicide, but also car-

diovascular disorders. Depression produces greater disability than 
angina, arthritis, asthma and diabetes, which makes effective treat-
ment and prevention imperative.

Most patients have recovered by 6 months in primary care and 
12 months in secondary care. About a quarter of patients attend-
ing hospital with depressive illnesses will have a recurrence within 
1 year, and three-quarters will have a recurrence within 10 years. 
People with recurrent depressive illnesses should be offered pre-
vention. This may involve CBT that concentrates on relapse pre-
vention, other forms of psychotherapy, prolonged antidepressant 
use, and advice on lifestyle activities such as regular exercise. Full-
dose antidepressants are the most effective prophylaxis in recurrent 
depressive disorders.
Disturbance of registration of memories

Physical Insomnia, mild to moderate weight loss, increased libido
Behaviour Disinhibition, increased sexual activity, excessive drinking or spending
Hallucinations Fleeting auditory

relationships (from promiscuity or irritability), social ostracism and lost employment (from reckless or disinhibited behaviour).

Some patients have a rapid-cycling illness, with frequent swings from one mood state to another. A mixed affective state occurs when features of mania and depressive illness are seen in the same episode. Cyclothymia is a personality trait with spontaneous swings in mood that are not sufficiently severe or persistent to warrant another diagnosis.

Differential diagnosis
Acute intoxication with recreational drugs such as amphetamines, amphetamine derivatives (MDMA: Ecstasy) and cocaine can mimic mania. Up to a quarter of people with Cushing’s syndrome develop mania. Similarly, corticosteroids can induce mania less commonly than depressive illness. Dopamine agonists (e.g. bromocriptine) are also known to induce mania sometimes.

Epidemiology
The lifetime prevalence of bipolar affective disorder is 1% across the world. Unlike unipolar depressive illness, it is equally common in men and women, supporting its different aetiology. There is no variation by socioeconomic class or race. The mean age of onset is 21, earlier than unipolar depression. The higher prevalence found in divorced people is probably a consequence of the condition.

Aetiology
Genetic factors
There is strong evidence for a genetic aetiology in this disorder, with a 60–80% concordance rate in monozygotic twins, compared to 15% in dizygotic twins, suggesting a high rate of heritability. Studies in adoptive twins show similar rates, so this high rate is probably genetic and not due to the family environment. Linkage studies have so far proved disappointing, with several polymorphism associations being found, similar to polymorphisms associated with schizophrenia.

Biochemical changes
Brain monoamines, such as serotonin, are increased in mania. Dexamethasone tends not to suppress cortisol levels in people with mania, suggesting a similar pattern of non-suppression to that seen in severe depressive illness.

Psychological factors
The effect of life events is weaker in bipolar compared with unipolar illnesses, most effects being apparent at first onset. Similarly, personality does not seem to be a major influence, in contrast to unipolar depression, although there is some evidence of a link with creativity and divergent thinking that may be an advantage in the right occupation.

Management
Acute mania or hypomania
Treatment is summarized in Box 25.27. Acute mania is treated with an atypical antipsychotic, sodium valproate or lithium.

• Lithium is a mood-stabilizing drug that prevents mania and depression. The mean age of onset is 21, earlier than unipolar depression. The higher prevalence found in divorced people is probably a consequence of the condition.

Prevention of relapses
Since bipolar illnesses tend to be relapsing and remitting, prevention of recurrence is the major therapeutic challenge. A patient who has experienced more than two episodes of affective disorder within a 5-year period is likely to benefit from preventive treatments. Recommendations include lithium, olanzapine and valproic acid (avoided in women of childbearing age).

Lithium
Lithium (carbonate or citrate) is one of the two main agents used for prophylaxis in people with repeated episodes of bipolar illness (the other being valproic acid). It is rapidly absorbed from the gastrointestinal tract and more than 95% is excreted by the kidneys; small amounts are found in the saliva, sweat and breast milk. Renal clearance of lithium correlates with renal creatinine clearance. Lithium is a mood-stabilizing drug that prevents mania and depression. It lowers the frequency and severity of relapses by half and significantly reduces the likelihood of suicide. Its mode of action is
Box 25.28 Lithium

Adverse effects
- Nausea
- Diarrhoea
- Fine tremor
- Weight gain, mainly through increased appetite
- Polyuria
- Polydipsia

Toxicity (>1.5 mmol/L, more likely with dehydration and drug interactions)
- Drowsiness
- Nausea
- Vomiting
- Blurred vision
- Coarse tremor
- Ataxia
- Dysarthria
- Delirium
- Convulsions
- Coma
- Death

unknown, but lithium is known to act on the serotonergic system. Poor response to lithium is associated with a negative family history, an unstable pre-morbid personality and a rapid-cycling illness. Pharmacogenetic work suggests that certain polymorphisms may predict response.

Plasma levels
These should be monitored weekly, with blood drawn 12 h after the last dose (a ‘trough’ level) until a steady state is reached and at 3-monthly intervals thereafter. The minimum level for prophylaxis is 0.4 mmol/L, with an optimum range of between 0.6 and 0.75 mmol/L. Levels higher than this may afford further protection against manic episodes but the relationship with depression is less clear. For this reason, the therapeutic range is typically quoted as 0.5–1.0 mmol/L. Fluctuations in plasma levels increase the risk of relapse.

Screening prior to starting lithium and at 6-monthly intervals thereafter includes:
- Thyroid function (free T4, TSH and thyroid autoantibodies). Lithium interferes with thyroid function and can produce frank hypothyroidism. The presence of thyroid autoantibodies increases the risk.
- Parathyroid function. Serum calcium and parathyroid hormone levels are higher in 10% of patients.
- Renal function (serum urea and creatinine, eGFR and 24-h urinary volume). Long-term treatment with lithium causes two renal problems: nephrogenic diabetes insipidus (p. 643) and reduced glomerular function. The best screen for diabetes insipidus is to ask the patient about polyuria and polydipsia.

Toxicity
Patients should always carry a lithium card with them, be advised to avoid dehydration, and be warned of drug interactions, such as with NSAIDs and diuretics. As with all medications, it is vital to discuss adverse effects and signs of toxicity (Box 25.28).

Pregnancy
As a rule, lithium is not advised during pregnancy, particularly in the first trimester, because of an increased risk of fetal malformation (Ebstein’s anomaly). About 25% of women with a history of bipolar disorder relapse within 2 weeks of delivery. Restarting lithium within 24 h of delivery (if the mother is prepared to forgo breast-feeding) markedly reduces the risk of relapse.

Other mood stabilizers
Valproic acid (as the semisodium salt) is recommended in both prophylaxis and treatment of manic states. Second-line treatments include lamotrigine. Carbamazepine is less frequently used and more effective in mania than depressive states. Some patients who do not respond to lithium may respond to these anticonvulsants or a combination of both. People with rapid-cycling illnesses show a better response to anticonvulsants than to lithium.

Other drugs that appear to exert a prophylactic mood-stabilizing effect include olanzapine and risperidone.

Both valproate and carbamazepine are associated with neural tube defects and should be avoided in all women of childbearing age. See page 857 for other adverse effects of these drugs.

Prognosis
The mean duration of a manic episode is 2 months, with 95% making a full recovery in time. Recurrence is the rule in bipolar disorders, up to 90% relapsing within 10 years.

SUICIDE AND SELF-HARM

(See also p. 260.) There are 800 000 suicide deaths worldwide per year. Suicide accounts for 2% of male and 1% of female deaths in England and Wales each year, equivalent to a rate of 10 per 100 000. The rate increases with age, peaking for women in their sixties and for men in their seventies. Suicide is the second most common cause of mortality in 15- to 34-year-olds. Meta-analyses of relevant studies suggest that the lifetime risk of suicide is 7% in alcohol dependence, 6% in affective disorders and 4% in schizophrenia.

The highest rates of suicide have been reported in Guyana, Lesotho and Russia, while the lowest are found in the Caribbean. Such variations may reflect differences in reporting, which may be related to religion, as much as genuine differences. The provision of mental health care to suicidal individuals varies greatly around the world; a World Health Organization (WHO) study suggests that most receive no treatment at all. Factors that increase the risk of suicide are indicated in Box 25.29.

A distinction must be drawn between those who attempt suicide – self-harm (SH) – and those who succeed (suicide):
Box 25.29 Factors that increase the risk of suicide

- Male sex
- Older age
- Living alone
- Immigrant status
- Recent bereavement, separation or divorce
- Unemployment or retirement
- Living in a socially disorganized area
- Family history of affective disorder, suicide or alcohol misuse
- Previous history of affective disorder, alcohol or drug misuse
- Previous suicide attempt
- Addiction to alcohol or drugs
- Severe depression or early dementia
- Incapacitating painful physical illness

Box 25.30 Guidelines for the assessment of patients who harm themselves

Questions to ask: of concern if positive answer
- Was there a clear precipitant/cause for the attempt?
- Did the patient leave a suicide note?
- Had the patient taken pains not to be discovered?
- Did the patient make the attempt in strange surroundings (i.e., away from home)?
- Would the patient do it again?

Other relevant factors
- Has the precipitant or crisis resolved?
- Was the act premeditated or impulsive?
- Is there a continuing suicidal intent?
- Does the patient have any psychiatric symptoms?
- What is the patient’s social support system?
- Has the patient inflicted self-harm before?
- Has anyone in the family ever taken their life?
- Does the patient have a physical illness?

Indications for referral to a psychiatrist

Absolute indications
- Clinical depression
- Psychotic illness of any kind
- Clearly pre-planned suicidal attempt that was not intended to be discovered
- Persistent suicidal intent (the more detailed the plans, the more serious the risk)
- A violent method used

Other common indications
- Alcohol and drug misuse
- Patients over 45 years, especially if male, and young adolescents
- Those with a family history of suicide in first-degree relatives
- Those with serious (especially incurable) physical disease
- Those living alone or otherwise unsupported
- Those in whom there is a major unresolved crisis
- Persistent suicide attempts
- Any patients who give you cause for concern

There is, however, an overlap between SH and suicide. Between 1% and 2% of people who attempt suicide will kill themselves in the year following SH. The risk of suicide stays elevated in those with SH, with 0.5% per annum committing suicide in the following 20 years. Following the guidelines for the assessment of such patients (Box 25.30) will help in the identification of risk factors and the need for a psychiatric referral.

In general, it is worth trying to interview a family member or close friend and checking these points with them. Requests for immediate re-prescription on discharge should be denied, only 3 days’ supply of essential medication should be given, and the patient should be requested to report to their general practitioner or to their psychiatric outpatient clinic for further supplies. Occasionally, involuntary admission to hospital may be required (see p. 800).

ANXIETY DISORDERS

These are conditions in which anxiety dominates the clinical symptoms. They are classified according to whether the anxiety is persistent (general anxiety) or episodic, with the episodic conditions classified according to whether the episodes are regularly triggered by a cue (phobia) or not (panic disorder). The differential diagnoses of anxiety disorders are given in Box 25.31. A patient with one anxiety disorder may develop others in time.

Box 25.31 Anxiety disorders: differential diagnosis

Psychiatric disorders
- Depressive illness
- Obsessive–compulsive disorder
- Pre-senile dementia
- Alcohol dependence
- Drug dependence
- Benzodiazepine withdrawal

Endocrine disorders
- Hyperthyroidism
- Hypoglycaemia
- Phaeochromocytoma

Generalized anxiety disorder

Generalized anxiety disorder (GAD) occurs in 4–6% of the population and is more common in women. Symptoms are persistent and often chronic. GAD and the related panic disorder are differential diagnoses for functional somatic syndromes, owing to the many physical symptoms that are caused by these conditions.

Clinical features

See Box 25.32 for physical and psychological symptoms. The patient looks worried, and has a tense posture, restless behaviour, a pale and sweaty skin, or intermittent flushing. The patient takes time to go to sleep and wakes intermittently with worry dreams.
Box 25.32 Physical and psychological symptoms of anxiety

**Physical symptoms**

*Gastrointestinal*
- Dry mouth
- Difficulty in swallowing
- Epigastric discomfort
- Aerophagy (swallowing air)
- Diarrhoea (usually frequency)

*Respiratory*
- Feeling of chest constriction
- Difficulty in inhaling
- Over-breathing
- Choking

*Cardiovascular*
- Palpitations
- Awareness of missed beats
- Chest pain

*Genitourinary*
- Increased frequency
- Failure of erection
- Lack of libido

*Nervous system*
- Fatigue
- Blurred vision
- Dizziness
- Sensitivity to noise and/or light
- Headache
- Sleep disturbance
- Trembling

**Psychological symptoms**

- Apprehension and fear
- Irritability
- Difficulty in concentrating
- Distractibility
- Restlessness
- Depersonalization
- Derealization

Associated conditions include hyperventilation, which is even more common in panic disorders (Box 25.33). The patient will either breathe rapidly and shallowly or sigh deeply, particularly when talking about the stresses in their life.

**Mixed anxiety and depressive disorder**

This disorder is the most common mood disorder in primary care (7% point prevalence). There are equal elements of anxiety and depression, showing how closely associated these two abnormal mood states are.

**Panic disorder**

Panic disorder is diagnosed when the patient has repeated, sudden attacks of overwhelming anxiety, accompanied by severe physical symptoms, usually related to both hyperventilation (see Box 25.33) and sympathetic nervous system overactivity (palpitations, tremor, restlessness and sweating). The lifetime prevalence is 5%. People with a panic disorder often have catastrophic illness beliefs during the panic attack, such as the conviction that they are about to die from a stroke or heart attack. The fear of a stroke is related to dizziness and headache. Fear of a heart attack accompanies chest pain (atypical chest pain). The occasional patient with longstanding attacks may no longer feel anxious and simply notices the physical symptoms.

Box 25.33 Hyperventilation syndrome

**Clinical features**

- Panic attacks – fear, terror and impending doom – accompanied by some or all of the following:
  - Dyspnoea (trouble getting a good breath in)
  - Palpitations
  - Chest pain or discomfort
  - Suffocating sensation
  - Dizziness
  - Paraesthesiae in hands and feet
  - Perioral paraesthesiae
  - Sweating
  - Carpopedal spasms

**Aetiology**

- Over-breathing leading to a decrease in $P_{2CO_2}$ and an increase in arterial pH, causing relative hypocalcaemia

**Diagnosis**

- A provocation test – voluntary over-breathing for 1 minute – provokes similar symptoms; rebreathing from a large paper bag relieves them

**Management**

- Explanation and reassurance is given
- The patient is trained in relaxation techniques and slow, controlled breathing
- The patient is asked to breathe into a closed paper bag

Box 25.34 Phobias

- A phobia is an abnormal fear and avoidance of an object or situation
- Phobias are common (the incidence varies from 3.5% to 12.8% worldwide), disabling and treatable with behaviour therapy

**Aetiology**

Generalized anxiety and panic disorders occur four times more commonly in first-degree relatives of affected patients. Sympathetic nervous system overactivity, increased muscle tension and hyperventilation are the common pathophysiological associations. Anxiety is the emotional response to the threat of a loss, whereas depression is the response to the loss itself. There is some evidence that being bullied leads to anxiety disorders in adolescents.

**Phobic (anxiety) disorders**

Phobias are common conditions in which intense fear is triggered by a stimulus, or group of stimuli, that are predictable and normally cause no particular concern to others (e.g. agoraphobia, claustrophobia, social phobia). This leads to avoidance of the stimulus (Box 25.34). The patient knows that the fear is irrational but cannot control it. The prevalence of all phobias is 8%, with many patients having more than one. Phobias of ‘medical’ stimuli exist (e.g. of doctors, dentists, hospitals, blood and injections), which affect the patient’s ability to receive adequate healthcare.

**Aetiology**

Phobias may be caused by classical conditioning, in which a response (fear and avoidance) becomes conditioned to a previously benign stimulus (e.g. a lift), often after an initiating emotional shock (e.g. being stuck in a lift). In children, phobias can arise through imagined threats (e.g. ghost stories). Women have twice the prevalence of phobias than men. Phobias aggregate in families, indicating the importance of genetic factors.
Agoraphobia
Translated as ‘fear of the marketplace’, this common phobia (4% prevalence) presents as a fear of being away from home, with travelling, walking down a road and going to supermarkets being common cues. At its most disabling, the patient avoids leaving home, particularly when unaccompanied. It is often associated with clausrophobia, a fear of enclosed spaces.

Social phobia
This is the fear and avoidance of social situations: crowds, strangers, parties and meetings. Public speaking would be the sufferer’s worst nightmare. It is suffered by 2% of the population.

Simple phobias
The phobia of spiders (arachnophobia) is the most common, particularly in women. The prevalence of simple phobias is 7% in the general population. Other common phobias include insects, bats, dogs, snakes, heights, thunderstorms and the dark. Children are particularly phobic about the dark, ghosts and burglars, but the large majority grow out of these fears.

Management of anxiety disorders

Psychological management
For many people with brief episodes, discussion with a doctor concerning the nature of anxiety and its precipitants is sufficient.

- **Relaxation techniques** can be effective in mild/moderate anxiety. Relaxation can be achieved in many ways, including complementary techniques such as meditation and yoga. Conventional relaxation training involves a slowing down of the rate of breathing, muscle relaxation and mental imagery.

- **Anxiety management** training involves two stages. In the first stage, verbal cues and mental imagery are used to arouse anxiety to demonstrate the link with symptoms. In the second stage, the patient is trained to reduce this anxiety by relaxation, distraction and reassuring self-statements.

- **Biofeedback** is useful for showing patients that they are not relaxed, even when they fail to recognize it, having become so used to anxiety. Biofeedback involves feeding back to the patient a physiological measure that is abnormal in anxiety. These measures may include electrical resistance of the skin of the palm, heart rate, muscle electromyography or breathing pattern. The effect tends not to generalize to everyday life away from the feedback.

- **Behaviour therapies** are treatments that are intended to change behaviour and thus symptoms. The most common and successful behaviour therapy (with 80% success in some phobias) is graded exposure or ‘systematic desensitization’. First, the patient rates the phobia into a hierarchy of worsening fears (e.g. in agoraphobia: walking to the front door with a coat on; walking out into the garden; walking to the end of the road). Second, the patient practises exposure to the least fearful stimulus until no fear is felt. Each sequentially greater fear is then addressed in order, in the same manner.

- **Cognitive behaviour therapy** (CBT; see p. 779) is the treatment of choice for panic disorder and generalized anxiety disorder because the therapist and patient need to identify the mental cues (thoughts and memories) that may subtly provoke exacerbations of anxiety or panic attacks. CBT also allows identification and alteration of the patient’s ‘schema’, or way of looking at themselves and their situation, which feeds anxiety.

Box 25.35 Withdrawal syndrome with benzodiazepines
- Insomnia
- Anxiety
- Tremulousness
- Muscle twitching
- Perceptual distortions
- Hallucinations (which may be visual)
- Hypersensitivities (light, sound, touch)
- Convulsions

Drug treatments
Initial ‘drug’ treatment should involve advice for gradual cessation of anxiogenic substances such as caffeine and alcohol (which can cause a rebound anxiety). Prescribed drugs used in the treatment of anxiety can be divided into two groups: those that act primarily on the central nervous system, and those that block peripheral autonomic receptors.

- **Benzodiazepines** are centrally acting anxiolytic drugs. They are agonists of the inhibitory transmitter γ-aminobutyric acid (GABA). Diazepam and chloridiazepoxide have relatively long half-lives (20–40 h) and are used as anti-anxiety drugs in the short term. Adverse effects include sedation and memory problems, and patients should be advised not to drive while on treatment. They can cause dependence and tolerance within 4–6 weeks, particularly in those with dependent personalities. A withdrawal syndrome (Box 25.35) can occur after only 3 weeks of continuous use and is particularly severe when high doses have been given for a longer time. Thus, if a benzodiazepine drug is prescribed for anxiety, it should be given in as low a dose as possible and for not more than 2–4 weeks.

- **Most SSRIs** (e.g. fluoxetine, paroxetine, sertraline, escitalopram, citalopram) are useful symptomatic treatments for generalized anxiety and panic disorders, as well as some phobias (social phobia), although doses higher than those used in depression are often required. Duloxetine, mirtazapine, venlafaxine and pregabalin are alternative treatments for GADs, with the added benefit of possibly preventing the subsequent development of depression. Treatment response is often delayed several weeks; a trial of treatment should last 3 months.

- **Antipsychotics**, such as quetiapine or olanzapine, can be effective for more severe or refractory cases.

- **Beta-blockers** are effective in reducing peripheral symptoms, as many of the symptoms of anxiety are due to an increased or sustained release of adrenaline (epinephrine) and noradrenaline (norepinephrine) from the adrenal medulla and sympathetic nerves. Beta-blockers, such as propranolol (20–40 mg two or three times daily), can reduce peripheral symptoms such as palpitations, tremor and tachycardia, but they do not help central symptoms such as anxiety.

Acute stress reactions and adjustment disorders

Acute stress reaction
This occurs in response to exceptional physical and/or psychological stress. While severe, such a reaction usually subsides within days. The stress may be an overwhelming traumatic experience (e.g. accident, battle, physical assault, rape) or a sudden change in the social circumstances, such as a bereavement. Individual vulnerability and coping capacity play a role in the occurrence and severity of an acute stress reaction, as evidenced by the fact that not all people exposed to exceptional stress develop symptoms.
Symptoms usually include an initial state of feeling ‘dazed’ or numb, with inability to comprehend the situation. This may be followed either by further withdrawal from the situation, or by anxiety and overactivity. No treatments beyond reassurance and support are normally necessary.

Adjustment disorder
This disorder can follow an acute stress reaction and is common in the general hospital. It is a more prolonged (up to 6 months) emotional reaction to a significant life event, with low mood joining the initial shock and consequent anxiety, but not of sufficient severity or persistence to fulfill a diagnosis of a depressive or anxiety disorder. Supportive counselling is usually a successful treatment, allowing facilitation of unexpressed feelings and fears, and education about the likely future.

Normal grief
Normal grief immediately follows bereavement, is expressed openly, and allows a person to go through the social ceremonies and personal processes of bereavement. The three stages are, first, shock and disbelief; second, the emotional phase (anger, guilt and sadness); and, third, acceptance and resolution. This normal adjustment process may take up to a year, with movement between all three stages occurring in a sometimes haphazard fashion.

Pathological (abnormal) grief
This is a particular kind of adjustment disorder. It can be characterized as excessive and/or prolonged grief, or even absent grieving with abnormal denial of the bereavement. Usually, a relative will be stuck in grief, with insomnia and repeated dreams of the dead person, anger at doctors or even the patient for dying, consequent guilt in equal measure, and an inability to ‘say goodbye’ to the loved person by dealing with their effects. Guided mourning uses cognitive and behavioural techniques to allow the relative to stop grieving and move on in life.

Post-traumatic stress disorder
PTSD is a protracted response to a stressful event or situation of an exceptionally threatening nature, likely to cause pervasive distress in almost anyone. Causes include natural or human disasters, war, serious accidents, witnessing the violent death of others, and being the victim of sexual abuse, rape, torture or terrorism. Pre-disposing factors, such as personality, previously unresolved traumas or a history of psychiatric illness, may prolong the course of the syndrome. These factors are neither necessary nor sufficient to explain its occurrence, which is mostly related to the intensity of the trauma, proximity to the traumatic event, and its prolonged or repeated nature.

Clinical features
The typical symptoms of PTSD include:
- ‘flashbacks’, repeated vivid reliving of the trauma in the form of intrusive memories, often triggered by a reminder of the trauma
- insomnia, usually accompanied by nightmares, the nocturnal equivalent of flashbacks
- emotional blunting, emptiness or ‘numbness’, alternating with intense anxiety on exposure to events that resemble an aspect of the traumatic event, including anniversaries of the trauma
- avoidance of activities and situations reminiscent of the trauma
- emotional detachment from other people
- hypervigilance, with autonomic hyperarousal and an enhanced startle reaction.

Guided mourning uses cognitive and behavioural techniques to allow the relative to stop grieving and move on in life.

Management
Psychodynamic psychotherapy
Psychodynamic psychotherapy is derived from psychoanalysis and is based on several key analytical concepts. These include Freud’s ideas about psychosexual development, defence mechanisms, free association as the method of recall, and the therapeutic techniques of interpretation, including that of transference, defences and dreams. Such therapy usually involves once-weekly sessions, the length of treatment varying between 3 months and 2 years. The long-term aim is symptom relief and personality change. Psychodynamic psychotherapy is classically indicated in the treatment of unresolved conflicts in early life, as might be found in non-psychotic and personality disorders. There is no convincing evidence concerning its superiority over alternative forms of treatment.

Cognitive analytical therapy
Cognitive analytical therapy is an integration of CBT and psychodynamic therapy. It is a short-term therapy involving the patient and therapist recognizing the origins of a recurrent problem, reformulating how it continues to occur, and revising other ways of coping and internalizing it, using both the transference of the patient-therapist relationship and behavioural experiments.
Obsessive–compulsive disorder

Obsessive–compulsive disorder (OCD) is characterized by obsessional ruminations and compulsive rituals. It is particularly associated with both depressive illness and Tourette’s syndrome (see p. 863). The prevalence is between 1% and 2% in the general population, and patients uncommonly seek help. There is an equal distribution by gender, and the mean age of onset ranges from 20 to 40 years.

Clinical features

The obsessions and compulsions are time-consuming and intrusive, so that they affect functioning and cause considerable distress. Obsessions are often unpleasant repetitive thoughts, out of character, such as being dirty or violent. This can lead to a compulsive need to check that everything and everyone is all right and that things have been done correctly, and reassurance cannot remove the doubt that persists. Some rituals are derived from superstitions, such as actions repeated a fixed number of times, with the need to start again if interrupted. When severe and primary, OCD can last for many years and may be resistant to treatment. However, obsessional symptoms commonly occur in other disorders, most notably depressive illness, and remit with the resolution of the primary disorder.

Minor degrees of obsessional symptoms and compulsive rituals or superstitions are common in the healthy population and do not require treatment, particularly in times of stress and in children, who usually grow out of it. The mildest grade is that of obsessional personality traits, such as over-conscientiousness, tidiness, punctuality, and other indicators of a strong tendency towards conformity and inflexibility. Such individuals are perfectionists who are intolerant of shortcomings in themselves and others, and take pride in their high standards. When such traits are so marked that they dominate other aspects of personality, in the absence of clear-cut OCD, the diagnosis is obsessional (anankastic) personality (see p. 799).

Aetiology

Genetic factors

OCD is found in 5–7% of the first-degree relatives. Twin studies showed 80–90% concordance in monozygotic twins and about 50% in dizygotic twins. Genetic factors account for more of the variance in childhood-onset versus adult-onset cases.

Biological model

Neuroimaging studies suggest dysfunction in the orbito-striatal area (including the caudate nucleus) and dorsolateral prefrontal cortex, combined with abnormalities in serotonergic (underactive) and glutamatergic (overactive) neurotransmission. Further support for this model comes from an association with neurological disorders involving dysfunction of the striatum, including Parkinson’s disease, Huntington’s disease, Tourette’s syndrome and Sydenham’s chorea. The latter has also been associated with OCD and tic disorders in the paediatric autoimmune neuropsychiatric disorder associated with streptococcal infection (PANDAS). This is a rare condition in children that follows group A haemolytic streptococcal infection. OCD also can follow brain injury.

Cognitive behavioural model

Most people have occasional intrusive thoughts, but would ordinarily dismiss these as meaningless and not focus upon them further. These develop into an obsession when they assume great significance to the individual, causing greater anxiety. This anxiety motivates suppression of these thoughts, and ritual behaviours are developed to reduce anxiety further.

Management

Psychological management

CBT focusing on exposure and response prevention is reasonably effective. This involves confronting the anxiety-provoking stimulus in a controlled environment and not performing the associated ritual. The aim is for the individual to habituate to the stimulus, thus reducing anxiety. Since it provokes anxiety, the dropout rate is often high.

Physical management

Tricyclic antidepressants (TCAs) and serotonin reuptake inhibitors (SSRIs)

Clomipramine (a TCA) and the SSRIs are the mainstay of drug treatment. Their efficacy is independent of their antidepressant action but the doses required are usually some 50–100% higher than those effective in depression. Although many sufferers respond, relapse rates on discontinuation are high. Three months’ treatment with maximum tolerated doses may be necessary for a positive response; in those who fail to respond, the addition of an antipsychotic significantly improves outcome, especially when tics occur co-morbidly. Positive correlations between reduced severity of OCD and decreased orbitofrontal and caudate metabolism following behavioural and SSRI treatments have been demonstrated in a number of studies.

Deep brain stimulation

This is a non-ablative, and therefore potentially reversible, surgical technique that involves the electrical stimulation of the basal ganglia by implanted electrodes, creating a ‘functional lesion’ (Fig. 25.4). Although this has had success, often impressively so in intractable cases, issues still remain regarding subject selection and the optimum anatomical targets.

Psychosurgery

This is very occasionally recommended in cases of chronic and severe OCD refractory to other treatments. The development of stereotactic techniques has led to the replacement of the earlier, crude leucotomies with more precise surgical interventions such as subcaudate tractotomy and cingulotomy, with small yttrium radioactive implants, which induce lesions in the cingulate area or the ventromedial quadrant of the frontal lobe.
**Prognosis**

Two-thirds of cases improve within a year; the remainder run a fluctuating or persistent course. The prognosis is worse with primary and severe OCD or with an anankastic pre-morbid personality when the personality is obsessionial or anankastic.

---

**ALCOHOL MISUSE AND DEPENDENCE**

A wide range of physical, social and psychiatric problems are associated with excessive drinking. Alcohol misuse occurs when a patient is drinking in a way that regularly causes problems to the patient or others.

- **The problem drinker** is one who causes or experiences physical, psychological and/or social harm as a consequence of drinking alcohol. Many problem drinkers, while heavy drinkers, are not physically addicted to alcohol.

- **Heavy drinkers** are those who drink significantly more in terms of quantity and/or frequency than is safe in the long term.

- **Binge drinkers** are those who drink excessively in short bouts, separated by often lengthy periods of abstinence. Their overall monthly or weekly alcohol intake may be relatively modest.

- **Alcohol dependence** is defined by a physical dependence on or addiction to alcohol. The term ‘alcoholism’ is a confusing one and has off-putting connotations of vagrancy, ‘mehs’ drinking and social disintegration. It has been replaced by the term ‘alcohol dependence syndrome’.

**Epidemiology**

A total of 20% of men and 10% of women drink more than double the recommended limit of 14 units per week in the UK. The amount of alcohol consumed in the UK has doubled over the last 50 years. Some 4% of men and 2% of women report alcohol withdrawal symptoms, suggesting dependence. Approximately 1 in 5 male admissions to acute medical wards is directly or indirectly due to alcohol. People with serious drinking problems have a 2–3 times increased risk of dying compared with the general population of the same age and sex.

**Box 25.36** provides an estimate of what behavioural impairment can be expected in an average individual with a particular blood alcohol level. The amount of alcohol is measured for convenience in units that contain about 8 g of absolute alcohol and raise the blood alcohol concentration by 15–20 mg/dL, the amount that is metabolized in 1 h. One unit of alcohol is found in half a pint of ordinary beer (3.5% alcohol by volume, ABV) and in 125 mL of 9% wine. Note that most lagers are 5% ABV (3 units per pint) and wine is often 13% ABV and sold in 175 mL glasses (2–3 units per glass).

  - Homelessness

**Diagnosis**

Alcohol misuse should be suspected in any patient presenting with one or more of the physical problems commonly associated with excessive drinking (see p. 1258). Alcohol misuse may also be associated with a number of psychiatric symptoms/disorders and social problems (Box 25.37).

**Guidelines**

The patient’s frequency of drinking and the quantity drunk during a typical week should be established. Although previous guidelines proposed different weekly limits for men and women as representing ‘safe drinking’, this has now been abandoned.

- 14 units per week has now been set for both sexes as ‘low risk’ rather than ‘safe’, with the declaration that there is no safe drinking level.
- 10–20 years of regularly drinking more than 14 units per week is associated with adverse health consequences, including malignancies and diseases of the cardiovascular, gastrointestinal and nervous systems.

**Diagnostic markers of alcohol misuse**

Laboratory parameters indicating alcohol misuse in recent weeks include elevated γ-glutamyl transpeptidase (γ-GT) and mean corpuscular volume (MCV). Blood or breath alcohol tests are useful in anyone suspected of very recent drinking.

**Alcohol dependence syndrome**

Dependence is a pattern of repeated self-administration that causes tolerance, withdrawal and compulsive substance use, the essential
Alcohol misuse and dependence

Environmental factors
Adverse childhood experience increases the risk of subsequent alcohol dependence and this rises if there is also a history of parental alcohol dependence or other substance misuse.

Neurobiological factors
Similar to many drugs of addiction, there is substantial empirical evidence for the involvement of dopaminergic and opioidergic neural circuitry within the striatum and ventral tegmentum. Sites where these converge, ‘hedonic hotspots’, underpin ‘motivational salience’: what we are most likely to respond to in our environment and the likelihood of the same response recurring under the same circumstances in the future. Corticotrophin-releasing hormone may have a bearing on what is potentially addictive to one individual and not to another by altering the valency of the given stimulus (good versus bad), which potentially ties continued abuse to dysregulation of the stress axis. This is not specific to alcohol and may imply that addictive behaviour is a consequence of stress but also a cause of it. Specific neurobiological causal factors have not been reliably identified.

Psychiatric illness
Psychotic, depressed, anxious and phobic patients frequently self-medicate with alcohol but this is an uncommon cause of dependency.

Excess consumption in society
The prevalence of alcohol dependence correlates with the general level of alcohol use in a society. This, in turn, is determined by price, licensing laws, availability and the societal norms concerning alcohol consumption.

Management
Psychological management of problem drinking
Successful identification at an early stage can be a helpful intervention in its own right. It should lead to:
- the provision of information concerning low-risk drinking levels
- a recommendation to cut down where indicated
- simple support and advice concerning associated problems.
This alone may prove effective. Successful alcohol misuse treatment involves motivational enhancement (motivational therapy), feedback, education about the adverse effects of alcohol, and agreed drinking goals. A motivational approach is based on five stages of change: pre-contemplation, contemplation, determination, action and maintenance. The therapist uses motivational interviewing and reflective listening to allow the patient to persuade himself along the five stages to change. This technique, CBT and 12-step facilitation (as used by Alcoholics Anonymous, AA) have all been shown to reduce harmful drinking. With addictive drinking, self-help group therapy, involving long-term support by fellow members of the group (e.g. AA), is helpful in maintaining abstinence. Family and marital therapy involving both the alcohol misuser and partner may also help. Families of drinkers find meeting others in a similar situation helpful (Al-Anon).

Drug treatments for problem drinking
Alcohol withdrawal and delirium tremens
Addicted drinkers often experience considerable difficulty when they attempt to reduce or stop drinking. Withdrawal symptoms are a particular problem and delirium tremens (DTs) needs urgent treatment (Box 25.40). In the absence of DTs, alcohol withdrawal can be treated on an outpatient basis (see Box 25.40), so long as the patient attends daily for medication and monitoring, and has good

---

Box 25.38 Symptoms of alcohol dependence
- Inability to keep to a drink limit
- Difficulty in avoiding getting drunk
- Spending a considerable amount of time drinking
- Missing meals
- Memory lapses, blackouts
- Restlessness without drink
- Organizing the day around drink
- Trembling after drinking the day before
- Morning retching and vomiting
- Sweating excessively at night
- Withdrawal fits
- Morning drinking
- Increased tolerance
- Hallucinations, frank delirium tremens

---

Box 25.39 Diagnostic criteria for alcohol withdrawal syndrome

Any three of the following:
- Tremor of outstretched hands, tongue or eyelids
- Sweating
- Nausea, retching or vomiting
- Tachycardia or hypertension
- Anxiety
- Psychomotor agitation
- Headache
- Insomnia
- Malaise or weakness
- Transient visual, tactile or auditory hallucinations or illusions
- Grand mal convulsions

---

Coping with alcohol misuse

**Aetiology of alcohol dependence**

**Genetic factors**
Sons of alcohol-dependent people who are adopted by other families are four times more likely to develop drinking problems than are the adopted sons of non-alcohol misusers. Genetic markers include the serotonin transporter gene, dopamine-2 receptor allele A1, alcohol dehydrogenase subtypes and monoamine oxidase B activity, but they are not specific.
Liaison psychiatry

Box 25.40 Management of delirium tremens (DTs)

**General measures**
- Admit the patient to a medical bed
- Correct electrolyte abnormalities and dehydration
- Treat any co-morbid disorder (e.g. infection)
- Give parenteral thiamine slowly (250 mg daily for 3–5 days) in the absence of Wernicke–Korsakoff’s syndrome
- Give parenteral thiamine slowly (500 mg daily for 3–5 days) with Wernicke–Korsakoff’s encephalopathy. Note: Beware anaphylaxis
- Give prophylactic phenytoin or carbamazepine, if there is a previous history of withdrawal fits

**Specific drug treatment**
- Give one of the following orally:
  - Diazepam 10–20 mg
  - Chlordiazepoxide 30–60 mg
- Repeat 1 h after the last dose, depending on response

**Fixed-schedule regimens**
- Diazepam 10 mg every 6 h for 4 doses, then 5 mg 6-hourly for 8 doses OR
- Chlordiazepoxide 30 mg every 6 h for 4 doses, then 15 mg 6-hourly for 8 doses
- Provide additional benzodiazepine when symptoms and signs are not controlled

**Social support.** Outpatient schedules are sometimes given over 5 days. Long-term treatment with benzodiazepines should not be prescribed in those patients who continue to misuse alcohol.

**Drugs for prevention of alcohol dependence**

**Naltrexone**, the opioid antagonist (50 mg per day), reduces the risk of relapse into heavy drinking and the frequency of drinking. **Acamprosate** (1–2 g/day) acts on several receptors, including those for GABA, noradrenaline (norepinephrine) and serotonin and reduces drinking frequency. Neither drug seems particularly helpful in maintaining abstinence. The effects of both are enhanced by combining them with counselling, but their moderate efficacy precludes regular use.

**Disulfiram** reacts with alcohol to cause unpleasant acetaldehyde intoxication and histamine release. There is mixed evidence of efficacy.

Oral thiamine (300 mg/day) can prevent Wernicke–Korsakoff’s syndrome (see p. 891) in heavy drinkers and should always be prescribed.

**Prognosis**

Research suggests that 30–50% of alcohol-dependent drinkers are abstinent or drinking very much less up to 2 years following traditional intervention. The long-term outcome of patients treated with the latest psychological and pharmacological therapies remains uncertain.

**Hallucinogens**
- Cannabis preparations
- Solvents
- Lysergic acid diethylamide (LSD)
- Mescaline

**Narcotics**
- Morphine
- Heroin
- Codeine
- Pethidine
- Methadone
- Tranquillizers
- Barbiturates
- Benzodiazepines

Box 25.41 Commonly used drugs of misuse and dependence

**Drugs of misuse and their effects**

**Inhaled substances**

Some 1% of adolescents in the UK sniff solvents such as glue for their intoxicating effects. Tolerance develops over weeks or months. Intoxication is characterized by euphoria, excitement, a floating sensation, dizziness, slurred speech and ataxia. Acute intoxication can cause amnesia and visual hallucinations.

Nitrous oxide (laughing gas) is increasingly popular in the UK and is associated with the functional deactivation of vitamin B₁₂ and potentially disabling neurological sequelae.

**Amphetamines and related substances**

These have temporary stimulant and euphoriant effects that are followed by fatigue and depression, the latter sometimes prolonged for weeks. Psychological rather than true physical dependence occurs with amphetamine sulphate (‘speed’). Methyl amphetamine, also known as ‘crystal meth’, is another amphetamine psychostimulant. The high potential for abuse is associated with the activation of neural reward mechanisms involving nucleus accumbens dopamine release.

In addition to a manic-like presentation, amphetamines can produce a schizophrenia-like paranoid psychosis.

‘Ecstasy’ is the street name for 3,4-methylenedioxymethamphetamine (MDMA), a psychoactive phenylisopropylamine, synthesized as an amphetamine derivative. It has a brief duration of action (4–6 h). Deaths have been reported from malignant hyperpyrexia and dehydration. Acute renal and liver failure can occur.

**Cocaine**

Cocaine (see p. 267) is a central nervous system stimulant (with similar effects to amphetamines), derived from *Erythroxylon coca* trees grown in the Andes. In purified form, it may be taken orally, snorted or injected. If cocaine hydrochloride is converted to its base (‘crack’), it can be smoked. Dependent users take large doses and alternate between withdrawal phenomena of depression, tremor and muscle pains, and the hyperarousal produced by increasing
doses. Prolonged use of high doses produces irritability, restlessness, paranoid ideation and, occasionally, convulsions. Persistent sniffing of the drug can cause perforation of the nasal septum. Overdoses cause death through myocardial infarction, cerebrovascular disease, hyperthermia and arrhythmias (see p. 268).

Hallucinogenic drugs

Hallucinogenic drugs, such as lysergic acid diethylamide (LSD) and mescaline, produce distortions and intensifications of sensory perceptions, as well as frank hallucinations in acute intoxication. Psychosis is a long-term complication.

Cannabis

Cannabis is a widely used drug in some subcultures. It is derived from the dried leaves and flowers of the plant Cannabis sativa. It can cause tolerance and dependence. Hashish is the dried resin from the flower tops, while marijuana refers to any part of the plant. The drug, when smoked, seems to exaggerate the pre-existing mood, be it depression, euphoria or anxiety. It has specific analgesic properties. Cannabis use, especially of the more potent ‘skunk’, has increased in the UK. An amotivational syndrome with apathy and memory problems has been reported with chronic daily use. Cannabis may, of itself, sometimes cause psychosis in the right circumstances (see later).

Tranquilizers

Drugs that cause dependence include barbiturates and benzodiazepines. Benzodiazepine dependence is common and may be iatrogenic, when the drugs are prescribed and not discontinued. Discontinuing treatment with benzodiazepines may cause withdrawal symptoms (see Box 25.35). For this reason, withdrawal should be supervised and gradual.

Opiates

Physical dependence occurs with morphine, heroin and codeine, as well as with synthetic and semi-synthetic opiates such as methadone, pethidine and fentanyl. These substances display cross-tolerance – the withdrawal effects of one are reduced by administration of another. The psychological effects of opiates are a calm, slightly euphoric mood associated with freedom from physical discomfort and a flattening of emotional response. This is believed to be due to the attachment of morphine and its analogues to endorphin receptors in the central nervous system. Tolerance to this group of drugs is rapidly developed and marked, but is quickly lost following abstinence. The opiate withdrawal syndrome consists of a constellation of signs and symptoms (Box 25.42) that reaches peak intensity on the second or third day after the last dose of the opiate. These rapidly subside over the next 7 days. Withdrawal is dangerous in people with heart disease or other chronic debilitating conditions.

Opiate addicts have a relatively high mortality rate, owing to both the ease of accidental overdose and the blood-borne infections associated with shared needles. Heart disease (including infective endocarditis), tuberculosis and AIDS are common causes of death, while the complications of hepatitis B and C are also common. Some illegal supplies of heroin used by addicts contain fentanyl which increases the toxicity, leading to a high mortality, particularly in the United States.

Management of chronic misuse

Blood and urine screening for drugs is required in circumstances where drug misuse is suspected. When a patient with an opiate addiction is admitted to hospital for another health problem, advice should be sought from a psychiatrist or drug misuse clinic regarding management of their addiction while an inpatient.

The treatment of chronic dependence aims to help the patient either to live without drugs, or to regularize and control use, and to prevent secondary ill-health. Patients need help and advice in order to avoid a withdrawal syndrome. An overdose should be treated immediately with the opioid antagonist naloxone.

Drug-induced psychosis

Drug-induced psychosis has been reported with amphetamine and its derivatives, and with cocaine and hallucinogens. It can occur acutely after drug use but is more usually associated with chronic misuse. Psychoses are characterized by vivid hallucinations (usually auditory, but often occurring in more than one sensory modality), misidentifications, delusions and/or ideas of reference (often of a persecutory nature), psychomotor disturbances (excitement or stupor) and an abnormal affect. For diagnosis, ICD-10 requires the condition to occur within 2 weeks and usually within 48 hours of drug use, and to persist for more than 48 hours but not more than 6 months.

Cannabis use can result in anxiety, depression or hallucinations. Manic-like psychoses occurring after long-term cannabis use have been described but seem more likely to be related to the toxic effects of heavy ingestion. Evidence suggests that the risk of psychosis is significantly raised in those using cannabis at an early age (before, as compared to after, 15 years) and on a daily basis. High-potency cannabis (‘skunk’) is associated with an increased risk. A meta-analysis suggests that daily cannabis use doubles the risk of psychosis, and that 14% of schizophrenia in the UK would be prevented if cannabis use ceased.

Liaison psychiatry

SCHIZOPHRENIA

The group of illnesses conventionally referred to as ‘schizophrenia’ is diverse in nature and covers a broad range of perceptual, cognitive and behavioural disturbances. The point prevalence of the condition is 0.5% throughout the world, with equal gender distribution. A non-psychiatrist primarily needs to know how to recognize schizophrenia, what problems it might present with in the general hospital and how it is treated.

Aetiology

No single cause has been identified. Schizophrenia is likely to be a disease of neurodevelopmental disconnection caused by an interaction of genetic and environmental factors that affect brain development. The genetic aetiology is likely to be polygenic and non-mendelian; a recent very large study suggests there are about 100 single nucleotide polymorphisms that are associated. Schizophrenia has a heritability of about 60%. Functional neuroimaging studies and histology point towards alterations in prefrontal and, less consistently, temporal lobe function, with enlarged lateral ventricles and disorganized cytoarchitecture in the hippocampus, supporting neurodevelopmental models. Dopamine excess (D2) is the oldest and most widely accepted neurochemical hypothesis, although this may explain only one group of symptoms (the positive ones). The cognitive impairments in schizophrenia may be related to dopamine D1 abnormalities. The interaction between serotonergic and dopaminergic systems is likely to play a role. Glutamate and glycine have been recent pharmacological targets with promising preclinical data that has not been realized in subsequent trials.

Clinical features

The peak age of onset is the early twenties but it may start at any time. The characteristic symptoms of the condition have been termed first-rank symptoms. They consist of:

- **auditory hallucinations** in the third person and/or voices commenting on the patient’s behaviour
- **thought withdrawal**, insertion and broadcast
- **primary delusion** (arising out of nothing)
- **delusional perception**
- **somatic passivity and feelings** – patients believe that their thoughts, feelings or acts are controlled by others.

The more of these symptoms a patient has, the more likely it is that the diagnosis is schizophrenia, but they also occur in other psychoses.

Other symptoms of acute schizophrenia include behavioural disturbances, other hallucinations, secondary (usually persecutory) delusions and blunting of mood. Schizophrenia is sometimes divided into ‘positive’ and ‘negative’ symptom clusters:

- **Positive schizophrenia** is characterized by acute onset, prominent delusions and hallucinations, normal brain structure, a biochemical disorder involving dopaminergic transmission, a good response to neuroleptics, and a better outcome.
- **Negative schizophrenia** is characterized by a slow, insidious onset, a relative absence of acute symptoms, the presence of apathy, social withdrawal, lack of motivation, underlying brain structure abnormalities and poor antipsychotic response.

**Chronic schizophrenia** is characterized by its long duration and by the ‘negative’ symptoms of underactivity, lack of drive, social withdrawal and emotional emptiness.

Differential diagnosis

Schizophrenia should be distinguished from:

- organic mental disorders (e.g. partial complex epilepsy)

- mood (affective) disorders (e.g. mania)
- drug psychoses (e.g. amphetamine psychosis)
- personality disorders (schizotypal).

In older patients, any acute or chronic brain syndrome can present in a schizophrenia-like manner. A helpful diagnostic point is the fact that altered consciousness and disturbances of memory do not occur in schizophrenia, and visual hallucinations are unusual.

A schizoaffective psychosis describes a clinical presentation in which clear-cut affective and schizophrenic symptoms coexist in the same episode.

Management

The best results are obtained by combining drug and social treatments.

Antipsychotic drugs

These act by blocking the D1 and D2 groups of dopamine receptors and are most effective against acute, positive symptoms and are least effective in the management of chronic, negative symptoms. Complete control of positive symptoms can take up to 3 months, and premature discontinuation of treatment can result in relapse.

As antipsychotic drugs block both D1 and D2 dopamine receptors, they usually produce extrapyramidal adverse effects. This limits their use in the maintenance therapy of many patients. They also block adrenergic and muscarinic receptors and thereby cause a number of other unwanted effects (Box 25.43).

Neuroleptic malignant syndrome

This is an infrequent but potentially dangerous adverse effect. Neuroleptic malignant syndrome is a medical emergency and should be managed by medical admission. It occurs in 0.2% of patients on antipsychotic drugs, particularly the potent dopaminergic antagonists.

*The frequency and type of side-effects will depend upon the choice of antipsychotic agent and its dose.*
such as haloperidol. Symptoms occur a few days to a few weeks after starting treatment and consist of hyperthermia, muscle rigidity, autonomic instability (tachycardia, labile blood pressure, pallor) and a fluctuating level of consciousness. Investigations show a raised creatine kinase, raised white cell count and abnormal liver biochemistry. The more severe consequences include acute renal injury, pulmonary embolus and death. Treatment consists of stopping the drug and general resuscitation measures, such as temperature reduction. Bromocriptine enhances dopaminergic activity and dantrolene will reduce muscle tone but no treatment has proven benefit.

Pregnancy
Data on the potential teratogenicity of antipsychotic medications are still limited. The disadvantages of not treating during pregnancy have to be balanced against possible developmental risks to the fetus. The butyrophenones (e.g. haloperidol) are probably safer than the phenothiazines, such as chlorpromazine. Subsequent management decisions relating to dosage will depend primarily on the ability to avoid adverse effects, since the antiparkinsonian agents are still believed to be teratogenic and should be avoided.

Typical or first-generation antipsychotics
Phenothiazines were the first group of antipsychotics to be developed but are used less frequently now. Chlorpromazine (100–1000mg daily) is the drug of choice when a more sedating drug is required. Tri-fluoperazine is used when sedation is undesirable. Fluphenazine decanoate is used as a long-term prophylactic to prevent relapse, as a depot injection (25–100mg i.m. every 1–4 weeks). Butyrophenones (e.g. haloperidol 2–15mg daily) are also powerful antipsychotics, and are used in the treatment of acute schizophrenia and mania. They are likely to cause a dystonia and/or extrapyramidal adverse effects, but are much less sedating than the phenothiazines.

Atypical antipsychotics or serotonin dopamine antagonists
Atypical, second-generation antipsychotics or serotonin dopamine antagonists (SDAs), are ‘atypical’ in that they block D₃ receptors less than D₁, and thus cause fewer extrapyramidal adverse effects and less tardive dyskinesia. They are now recommended as first-line drugs for newly diagnosed schizophrenia.

Risperidone is a benzisoxazole derivative with combined dopamine D₂ receptor and 5-HT₂₃-receptor blocking properties. The drug is not markedly sedative and the overall incidence and severity of extrapyramidal adverse effects is lower than with more conventional antipsychotics. Hyperprolactinaemia can be problematic and prolactin levels should be monitored. Paliperidone is an active metabolite of risperidone. Both are available in oral and depot preparations.

Olanzapine has affinity for 5-HT₂, D₁, D₂, D₄ and muscarinic receptor sites. Clinical studies indicate that it has a lower incidence of extrapyramidal adverse effects. The apparent better compliance with the drug may be related to its lower side-effect profile and its once-daily dosage. Weight gain is a problem with long-term treatment and there is an increased risk of type 2 diabetes mellitus with this and other atypical drugs.

Other atypical antipsychotics include amisulpride, lurasidone, sulpiride, zotepine, ziprasidone and quetiapine, the latter causing less hyperprolactinaemia. Those taking atypical antipsychotics should have regular monitoring of their body mass index, cholesterol levels, blood sugar and QTC interval on ECG. No more than one antipsychotic should be prescribed routinely.

Clozapine is used in patients who have intractable schizophrenia refractory to at least two conventional antipsychotic drugs; alternatively, it may be used as first-line therapy. This drug is a dibenzodiazepine with a relative high affinity for D₃ dopamine receptors, as compared with D₁, D₂, D₃ and D₄, in addition to muscarinic and α-adrenergic receptors. It acts additionally as a partial agonist at 5-HT₁₆ receptors, which may be of benefit in treating the ‘negative’ symptoms of psychosis. Functional brain scans have shown that clozapine selectively blocks limbic dopamine receptors more than striatal ones, which is probably why it causes considerably fewer extrapyramidal adverse effects. Clozapine exercises a strong therapeutic effect on both intractable positive and negative symptoms. However, it is expensive and produces severe agranulocytosis in 1–2% of patients. Therefore, in the UK, for example, it can only be prescribed to registered patients by doctors and pharmacists registered with a patient-monitoring service. White cell counts should be monitored weekly for 18 weeks and then 2-weekly for the length of treatment. In addition to its antipsychotic actions, clozapine may also help reduce aggressive and hostile behaviour and the risk of suicide. It can cause considerable weight gain and sialorrhoea. There is an increased risk of diabetes mellitus, and gastrointestinal hypomotility resulting in a functional obstruction has also been reported.

Psychological management
This consists of reassurance, support and a good doctor–patient relationship. Psychotherapy of an intensive or exploratory kind is contraindicated. In contrast, individual CBT may have some efficacy, particularly in those who decline drug treatment.

Social management
Social treatment involves attention being paid to the patient’s environment and social functioning. Family education can help relatives and partners to provide the optimal amount of emotional and social stimulation, so that not too much emotion is expressed (a risk for relapse). Over 90% of patients are unemployed but sheltered employment can be helpful. Assertive outreach mental health teams will follow up those adhering poorly to treatment.

Medical presentations related to treatment
The motor adverse effects of neuroleptics are the most common reason for a patient with schizophrenia to present to a physician, followed by self-harm. Acute dystonia normally arises in patients newly started on neuroleptics, causing torticollis. Extrapyramidal adverse effects are common and present in the same way as Parkinson’s disease. They remit once the drug is stopped and on use of antimuscarinic drugs, such as procyclidine. Akathisia is motor restlessness, most commonly affecting the legs. It is similar to the restless legs syndrome but is apparent during the day. Amenorrhoea and galactorrhoea can be caused by dopamine antagonists. Postural hypotension can affect the elderly, and neuroleptics can be the cause of delirium in this age group, if their antimuscarinic effects are prominent.

Long-term benefits outweigh the risks in most cases, and long-term treatment is associated with a lower mortality rate when compared with no treatment. In this respect, the atypical antipsychotics are preferable to the typical antipsychotics and clozapine is the class leader.

Prognosis
The prognosis of schizophrenia is variable: 15–25% of people with schizophrenia recover completely, about 70% will have relapses and may develop mild to moderate negative symptoms, and about 20% will remain seriously disabled. There is some evidence that early drug treatment improves prognosis.
Further reading

ORGANIC MENTAL DISORDERS
Organic brain disorders result from structural pathology, as in dementia (see p. 880), or from disturbed central nervous system function, as in fever-induced delirium.

Delirium
Delirium, also termed toxic confusional state and acute organic psychosis, is an acute or subacute brain failure in which impairment of attention is accompanied by abnormalities of perception and mood. It is the most common psychosis seen in the general hospital setting, where it occurs in 14–24% of patients. This figure rises in specialist populations such as intensive care patients. Agitation is usually worse at night, with consequent sleep reversal, so that the patient is asleep in the day and awake all night. In addition to an agitated, ‘hyperactive’ presentation, a hypoactive variant is also recognized and is thought to represent a worse prognosis in the elderly. Most cases will demonstrate a fluctuation between these two psychomotor forms. During the acute phase, thought and speech are incoherent, memory is impaired and misperceptions occur. Episodic visual hallucinations (or illusions) and persecutory delusions occur. As a consequence, the patient may be frightened, suspicious, restless and uncooperative.

A developing, deteriorating or damaged brain predisposes a patient to develop delirium (Box 25.44). A large number of diseases may cause delirium, particularly in elderly patients, such that it is wise to assess for delirium in patients over 65 years who are admitted to hospital. Some causes of delirium are listed in Box 25.45. Delirium tremens should be considered in the differential diagnosis (see p. 791), as well as Lewy body dementia (p. 883). Diagnostic criteria are given in Box 25.46.

Management
History should be taken from a witness. Examination may reveal the cause. Investigation and treatment of the underlying physical disease should be undertaken (see Box 25.45). The patient should be carefully nursed and rehydrated in a quiet single room with a window that does not allow exits. If a high fever is present, the patient’s temperature should be reduced. All current drug therapy should be reviewed and, where possible, stopped. If they are needed, ensure that patients have hearing aids, glasses and dentures. Psychoactive drugs should be avoided if possible (because of their own risk of exacerbating delirium). In severe delirium, haloperidol is an effective choice, the daily dose usually ranging between 1.5 mg (in the elderly) and 20 mg per day. Benzodiazepines should not be used as first-line medication and may prolong confusion. If necessary, the first dose can be administered intramuscularly. Olanzapine is an effective alternative, especially if given at night for insomnia.

Prognosis
Delirium usually clears within a week or two, but brain recovery usually lags behind recovery from the causative physical illness. The prognosis depends not only on the successful treatment of the causative disease, but also on the underlying state of the brain. Some 25% of the elderly with delirium will have an underlying dementia; 15% of patients do not survive their underlying illness; 40% are in institutional care at 6 months. Mortality rates are raised in patients with delirium in the 18 months after admission and this is greatest in those who present to emergency departments with the diagnosis.

Box 25.45 Some common causes of delirium
- Systemic infection:
  - Any infection, particularly with high fever (e.g. malaria, septicaemia)
- Metabolic disturbance:
  - Hepatic failure
  - Chronic kidney disease
  - Disorders of electrolyte balance, dehydration
  - Hypoxia
- Vitamin deficiency:
  - Thiamine (Wernicke–Korsakoff's syndrome, beriberi)
  - Nicotinic acid (pellagra)
  - Vitamin B₁₂
  - Endocrine disease:
    - Hypothyroidism
    - Cushing's syndrome
  - Intracranial causes:
    - Trauma
    - Tumour
    - Abscess
    - Subarachnoid haemorrhage
    - Epilepsy
  - Drug intoxication:
    - Anticonvulsants
    - Antimuscarinics
    - Anxiolytics/hypnotics
    - Tricyclic antidepressants
    - Dopamine agonists
    - Digoxin
    - Drug/alcohol withdrawal
    - Postoperative states

Box 25.46 Delirium: diagnostic criteria
- Disturbance of consciousness:
  1. Clarity of awareness of environment
  2. Ability to focus, sustain or shift attention
- Change in cognition:
  - Memory deficit, disorientation, language disturbance, perceptual disturbance
  - Disturbance develops over a short period (hours or days)
  - Fluctuation over the course of a day

EATING DISORDERS

Obesity
Obesity is the most common eating disorder (see p. 1247) and has become epidemic in many developed countries. It is usually caused by a combination of constitutional and social factors, but a binge-eating disorder and psychological determinants of ‘comfort eating’ should be excluded.

Anorexia nervosa
Case register data suggest an incidence rate of 19/100 000 females aged between 15 and 34 years. Surveys have suggested a prevalence rate of approximately 1% among schoolgirls and university students. However, many more young women have amenorrhoea accompanied by less weight loss than the 15% required for the diagnosis of anorexia nervosa. The condition is much less common among men (ratio of 1 : 10).

Clinical features
The main clinical criteria for diagnosis are shown in Box 25.47. Clinical features include the following:
• Onset is usually in adolescence.
• There is a previous history of faddish eating.
• The patient generally eats little, yet is obsessed by food.
• Exercising is excessive.
• Amenorrhoea in women.

Aetiology
Biological factors
Genetic
Some 6–10% of female siblings of affected women suffer from anorexia nervosa. There is an increased concordance amongst monozygotic twins, suggesting a genetic predisposition.

Hormonal
The reductions in sex hormones and downregulation of the hypothalamic–pituitary–adrenal axis are secondary to malnutrition and usually reversed by refeeding.

Psychological factors
Individual
Anorexia nervosa has often been seen as an escape from the emotional problems of adolescence and a regression into childhood. Patients commonly have had dietary problems in early life. Perfectionism and low self-esteem are common antecedents. Studies suggest that survivors of abuse are at greater risk of developing an eating disorder, usually anorexia nervosa, in adolescence.

Family
Family problems are most commonly secondary to the stress of coping with a family member with the illness.

Social and cultural factors
There is a higher prevalence in higher social classes, Westernized families, certain occupational groups (e.g. ballet dancers and nurses) and societies where cultural value is placed on thinness.

Management
Treatment can be conducted on an outpatient basis, unless the weight loss is severe and accompanied by marked cardiovascular signs and/or electrolyte and vitamin disturbances. Hospital admission may then be unavoidable and may need to be on a medical ward initially. Uncommonly, the patient’s weight loss may be so severe as to be life-threatening. If the patient cannot be persuaded to enter hospital, compulsory admission may have to be used. Inpatient treatment goals include:
• establishing a therapeutic relationship with both the patient and their family
• restoring the weight to a level between the ideal body weight and the patient’s ideal weight
• providing a balanced diet, aimed at gaining 0.5–1 kg weight per week
• eliminating purgative and/or laxative use and vomiting.

Outpatient treatment should include cognitive behavioural or interpersonal psychotherapies. Family therapy is more effective than individual psychotherapy in adolescents and those still at home, and less effective in those who have left home. Motivational enhancement techniques are used with some success.

Drug treatment has met with limited success, and those drugs that increase the QTc interval should be avoided. Vitamins and minerals may need replacement.

Prognosis
The condition runs a fluctuating course, with exacerbations and partial remissions. Long-term follow-up suggests that about two-thirds of patients maintain normal weight and that the remaining one-third are split between those who are moderately underweight and those who are seriously underweight. Indicators of a poor outcome include:
• a long initial illness
• severe weight loss
• older age at onset
• bingeing and purging
• personality difficulties
• difficulties in relationships

Box 25.47 Clinical criteria for anorexia nervosa
- Body weight >15% below the standard weight or a body mass index <17.5 kg/m² (ICD-10)
- Self-induced weight loss: avoidance of fattening foods, vomiting, purging, exercise or appetite suppressants
- Distortion of body image, i.e. patients regard themselves as fat when they are thin
- Morbid fear of fatness
- Amenorrhoea in women

(From World Health Organization. The ICD-10 Classification of Mental and Behavioural Disorders, 10th edn. Geneva: WHO, 2016.)
Suicide has been reported in 2–5% of people with chronic anorexia nervosa. The mortality rate per year is 0.5% from all causes. The illness can quickly cause osteopenia, and later osteoporosis. More than one-third have recurrent affective illness, and various family, genetic and endocrine studies have found associations between eating disorders and depression.

**Bulimia nervosa**
This refers to episodes of uncontrolled excessive eating, which are also termed ‘binges’, accompanied by means to lose weight. There is a preoccupation with food and habitual behaviours to avoid the fattening effects of periodic binges. These behaviours include:
- self-induced vomiting
- misuse of drugs – laxatives, diuretics, thyroid extract or anorectics.

Additional clinical features are shown in Box 25.48.

The lifetime prevalence of bulimia ranges between 3% and 7% for women. Bulimia is sometimes associated with anorexia nervosa. A pre-morbid history of dieting is common. The prognosis for bulimia nervosa is better than that for anorexia nervosa.

**Management**
Individual CBT is more effective than both interpersonal psychotherapy and drug treatments. SSRIs (e.g. fluoxetine) are also an effective treatment, even in the absence of a depressive illness, but may require high doses.

**Atypical eating disorders**
These include eating disorders that do not conform clinically to the diagnostic criteria for anorexia nervosa or bulimia nervosa. Binge-eating disorders (BEDs) consist of bulimia without the vomiting and other weight-reducing strategies. The new DSM-5 considers binge-eating disorder as a separate diagnosis, characterized by discrete episodes of significant overeating combined with a sense of having no control over eating during these episodes. Periods of bingeing need to be present at least once a week over a period of 3 months or more. ICD-10 continues to consider the diagnosis as an otherwise undefined eating disorder. Management strategies include self-help programmes and CBT, which are often combined with an SSRI.

### SEXUAL DISORDERS

Sexual disorders can be divided into sexual dysfunctions and deviations, and gender role disorders (Box 25.49).

**Sexual dysfunction**
Sexual dysfunction in men refers to the repeated inability to achieve normal sexual intercourse, whereas in women it refers to a repeatedly unsatisfactory quality of sexual satisfaction. Problems of sexual dysfunction can usefully be classified into those affecting sexual desire, arousal and orgasm.

Among men presenting for treatment of sexual dysfunction, erectile dysfunction is the most frequent complaint. The prevalence of premature ejaculation is low, except in young men, while ejaculatory failure is rare. Common female problems include reduced libido, vaginismus and anorgasmia.

Sexual drive is affected by constitutional factors, ignorance of sexual technique, anxiety about sexual performance, medical and psychiatric conditions, and certain drugs (Boxes 25.50 and 25.51).

The treatment of sexual dysfunction involves careful assessment of both physical and psychosocial factors, the participation (where appropriate) of the patient’s partner, sex education, and specific therapeutic techniques, including relaxation, behavioural therapy and couple therapy. The introduction of phosphodiesterase type 5 inhibitors (e.g. sildenafil) has provided an effective therapy for the treatment of erectile dysfunction (see p. 1485).

**Sexual deviation**
Sexual deviations are regarded as unusual forms of behaviour rather than as an illness. Doctors are only likely to be involved when the behaviour involves breaking the law (e.g. paedophilia) and when there is a question of an associated mental or physical disorder. Men are more likely than women to have sexual deviations.

**Box 25.49 Classification of sexual disorders**

**Sexual dysfunction**
- Affecting sexual desire
  - Low libido
- Impaired sexual arousal
- Erectile dysfunction
- Failure of arousal in women

**Affecting orgasm**
- Premature ejaculation
- Retarded ejaculation
- Orgasmic dysfunction in women

**Sexual deviations**
- Variations of the sexual ‘object’
  - Fetishism
  - Transvestism
  - Paedophilia
  - Bestiality
  - Necrophilia
- Variations of the sexual act
  - Exhibitionism
  - Voyeurism
  - Sadism
  - Masochism
  - Frotteurism

**Disorders of the gender role**
- Transsexualism

**Box 25.48 Clinical features of bulimia nervosa**

- Physical complications of vomiting:
  - Cardiac arrhythmias
  - Renal impairment
  - Muscular paralysis
  - Tetany – from hypokalaemic alkalosis
  - Swollen salivary glands – from vomiting
  - Eroded dental enamel
  - Associated psychiatric disorders:
    - Depressive illness
    - Alcohol misuse
  - Fluctuations in body weight within normal limits
  - Menstrual function – periods irregular but amenorrhea is rare
  - Personality – perfectionism and/or low self-esteem present premorbidly
Gender role disorders

Transsexualism involves a disturbance in gender identity in which the patient is convinced that their body is the wrong gender. A person’s gender identity refers to the individual’s sense of masculinity or femininity, as distinct from sex. There is increasing evidence that transsexualism is biologically determined, perhaps by prenatal endocrine influences, and functional brain imaging shows specific differences from normal controls.

For males, treatment includes oestrogen administration and, if surgery is to be recommended, a period of living as a woman as a trial beforehand. In the case of female transsexuals, treatment involves surgery and the use of methyltestosterone.

**PERSONALITY DISORDERS**

These disorders comprise enduring patterns of behaviour that manifest themselves as inflexible responses to a broad range of personal and social situations. Personality disorders are developmental conditions that appear in childhood or adolescence and continue into adult life. Their prevalence is about 15% in the population. They are not secondary to another psychiatric disorder or brain disease, although they may precede or coexist with other disorders. In contrast, personality change is acquired, usually in adult life, following severe or prolonged stress, extreme environmental deprivation, serious psychiatric disorder or brain injury or disease.

Personality disorders are usually subdivided according to clusters of traits that correspond to the most frequent or obvious behavioural manifestations, but many will show the characteristics of more than one category. The main categories of personality disorder are described in Box 25.52.
Mental capacity is the ability to make decisions about all aspects of one’s life, including, but not exclusively, healthcare. All doctors need to be able to assess mental capacity. In England and Wales, a new act was passed in 2005, which, for the first time, formally protects patients who lack capacity. Some 3% of people in the UK are thought to lack capacity due to conditions affecting brain function, such as dementia. However, the assessment of capacity is specific to an individual decision, so it is possible to have capacity to make one decision but not another. The assessment of capacity is outlined in Box 25.54. Capacity is assumed unless there is evidence to the contrary. In the absence of capacity, it is best to act in the best interests of the patient and provide the least restrictive management, after consulting the nearest relative or an independent advocate.

**Box 25.54 Assessment of mental capacity to make a decision**

The patient lacks decision-making capacity if they have a demonstrated impairment or disturbance of their mind/brain, alongside a demonstrated inability to do any one of the following:

- Understand relevant information
- Retain that information for sufficient time to make the decision
- Use or weigh that information
- Communicate their decision

Neurology is a large and diverse subject that covers many conditions requiring long-term coordinated care and having serious effects on the daily lives of patients and their families. Neurology includes conditions as diverse as cognitive disorders involving higher-level mental functioning, and disorders of peripheral nerve and skeletal muscle.

In recent years a focus on ‘acute neurology’ has seen many hospitals employ neurologists supporting general medical admissions units to deal with neurological emergencies that present via the hospital emergency department (for instance meningococcal or Guillain–Barré syndrome). Other neurological conditions are managed primarily in outpatients (such as epilepsy and migraine), and those causing significant disability require close cooperation with allied health professionals, primary care and community services. Neurological subspecialties include stroke, movement disorders, muscle disease and epilepsy.

Key skills in neurology include:
- distilling information gathered during a careful history and physical examination into a well-defined clinical syndrome, suggesting likely diagnoses and a rational approach to investigation
- managing neurological emergencies including stroke, coma, central nervous system infection, spinal cord compression and myasthenic crisis
- managing disability, working with other health professionals to help patients achieve a maximum level of functional independence despite advanced or progressive disease.

Opportunities for learning neurology include attending ward rounds on a stroke unit or with acute neurology teams, practising neurological examination with consenting patients, attending a range of general and specialist neurology clinics, and observing specialist neurologist investigations such as electrophysiology or lumbar puncture.
History

There are many different clinical presentations of neurological disease, and specific diagnostic approaches are covered in greater depth in relevant sections of this chapter. However, patterns emerge from a properly conducted history and examination that can suggest the likely causes, site and extent of disease; this section focuses on developing a diagnostic clinical approach to patients that is relevant in all areas of the specialty. An approach to history-taking in neurology is shown in (Box 26.1).

Box 26.1 Taking a history in neurology

Presenting symptoms
- Duration of symptoms, and any previous episodes
- Pattern – constant, intermittent, progressive
- Onset – sequence of events when symptoms first began, or each time they recur
- Triggers – warm baths may worsen symptoms caused by demyelination; sensory stimuli can trigger epilepsy; dietary stimuli, tiredness or stress can trigger migraines

Screening questions for other relevant features
- Systemic symptoms – fever (may suggest infection), weight loss and anorexia (may suggest malignancy with paraneoplastic neurological phenomena)
- Raised intracranial pressure symptoms – headaches worse on waking and on lying flat, vomiting, diplopia
- Visual symptoms – blurring, diplopia, flashing lights
- Bulbar symptoms – changes in speech and difficulties swallowing
- Motor symptoms – weakness, stiffness, abnormal gait
- Sensory symptoms – loss of sensation, neuropathic (“tingling” or “electric”) pain
- Loss of coordination – dizziness, staggering gait, loss of fine motor control, altered speech
- Autonomic symptoms – postural dizziness, faecal incontinence, urinary retention
- Loss of consciousness – features suggesting a neurological cause include aura, muscle jerking, tongue biting, incontinence and a drowsy post-ictal phase.
- Disturbance of higher functions – personality change, cognitive decline, loss of executive control, disinhibition, psychiatric symptoms

Past medical history
- Atherosclerotic risk factors – hypertension, diabetes, other cardiovascular disease
- Risk factors for embolic disease – atrial fibrillation, patent foramen ovale
- Diabetes – time since diagnosis, degree of glycaemic control, presence of other complications
- Malignancies, systemic inflammatory disorders, immunosuppressive conditions, e.g. HIV

Medication history
- Use of neuroactive medications, for instance antipsychotics

Family history
- History of inherited neurological disorders such as Huntington’s chorea, myotonic dystrophy and Charcot–Marie–Tooth disease in close relatives

Risk factors for functional disease
- Employment status, job security, stress at work, relationships with colleagues
- Family circumstances, relationship status, conflict, bereavements

Disability and effect on lifestyle
- Mobility
- Ability to perform activities of daily living
- Current provision of carers

Lifestyle factors
- Smoking, alcohol consumption, use of illegal drugs

Safety
- Do they drive?
- What is their employment? Might their illness pose a risk to themselves or others?
- Do they take baths or go swimming alone? Any other potentially risky leisure activities?
Examination

If the neurological history focuses primarily on the likely cause of the neurological disease, the examination focuses on the likely anatomical location of the lesion. The diagram above illustrates key a basic approach to focused examination of the nervous system with key signs to elicit or exclude.

Putting it all together

Information from the history and examination should be used together in order to answer the questions in Box 26.2, which will direct likely diagnoses and investigations that are likely to be helpful.

Box 26.2 Formulating a diagnosis in neurology

Is the lesion global or focal?
- Global lesions affect all (or most) brain functions, and typically affect cognition and consciousness
- Focal lesions affect one region of the body and resultant signs may be asymmetric

What is the timescale?
- Immediate onset symptoms are usually vascular (ischaemia or haemorrhage), or electrical (epilepsy) in aetiology
- Rapidly progressive symptoms (over days) may represent infective (e.g. meningitis) or inflammatory (e.g. demyelinating) disease
- Slowly progressive symptoms tend to be caused by degenerative diseases

Do motor lesions affect the upper or the lower motor neurone?
- Upper motor neurone (UMN) signs include increased tone (spasticity), weakness, increased reflexes and upgoing plantars – a ‘pyramidal’ pattern of weakness where stronger muscles (upper limb flexors, lower limb extensors) overwhelm weaker ones
- Lower motor neurone (LMN) signs include flaccid weakness, decreased or absent reflexes, wasting and fasciculations

Where is the lesion?
- Cerebral cortex/internal capsule: contralateral UMN signs
- Cerebellum: nystagmus, impaired balance/co-ordination
- Brainstem: impaired consciousness, global signs, cranial nerve abnormalities
- Spinal cord: UMN paraplegia/quadruplegia with sensory level
- Nerve root: LMN myotomal signs; dermal sensory loss
- Single peripheral nerve: LMN signs and sensory loss according to distribution of nerve
- All peripheral nerves: ‘length dependent’ LMN signs (worst in hands/feet), ‘glove and stocking’ sensory loss
- Neuromuscular junction/muscle: Only motor signs present. Fatiguability common, wasting and fasciculations

Is there a functional component?
- Are there elements that don’t fit within standard neuroanatomical patterns of disease?
- Are there risk factors for functional disease (see history section opposite)?
- Functional elements commonly exist alongside organic disease
INTRODUCTION

Neurology is a broad clinical specialty that requires good clinical skills and a rational diagnostic approach to link underlying pathophysiological processes with a diverse range of clinical syndromes that affect patients’ lives. The skills required cannot be replaced with investigations or imaging alone.

Some 17% of general practitioner consultations and 10% of emergency department visits are for neurological symptoms; 19% of all hospital admissions are for neurological disorders and 25% of chronic disability in adults below the age of 64 is due to neurological disease (Box 26.3).

CLINICAL APPROACH TO THE PATIENT WITH NEUROLOGICAL DISEASE

Clinical features of neurological disease

Pattern recognition in neurology – interpretation of history, symptoms and examination – is very reliable. Practical experience is vital. There are three critical questions in formulating a clinical diagnosis:

- What is/are the site(s) of the lesion(s)?
- What is the likely pathology?
- Does a recognizable disease fit this pattern?

Difficulty walking and falls

Change in walking pattern is a common complaint (Box 26.4). Arthritis and muscle pain make walking painful and slow (antalgic gait). The pattern of gait is valuable diagnostically.

Spasticity and hemiparesis

Spasticity (see p. 819), more pronounced in extensor muscles and with or without weakness, causes stiff, effortful and slow walking. Toes of shoes become scuffed, catching level ground. Pace shortens; a narrow base is maintained. Clonus – involuntary extensor rhythmic leg jerking – may occur.

In a hemiparesis, when spasticity is unilateral and weakness marked, the stiff, weak leg is circumscribed and drags.

Parkinson’s disease: shuffling gait

Stride length shortens and, in advanced forms, the gait slows to a shuffle. Posture is stooped and arm swing reduced (initially, unilaterally). Gait becomes festinant (hurried) with short, rapid steps. There is difficulty turning quickly (count the number of steps to turn around). Eventually, gait initiation difficulty and freezing episodes (sudden involuntary halts, such as when passing through a doorway) may develop. Falls are uncommon, except in late-stage disease, and may indicate a ‘Parkinson’s plus’ syndrome.

Cerebellar ataxia: broad-based gait

In lateral cerebellar lobe disease (see p. 820), stance becomes broad-based, unstable and tremulous. Ataxia describes this incoordination. When walking, the person tends to veer to the side of the affected cerebellar lobe.

In disease of midline structures (cerebellar vermis), the trunk becomes unsteady without limb ataxia, and there is a tendency to fall backwards or sideways – truncal ataxia.

Sensory ataxia: stamping gait

Peripheral sensory loss (e.g. polyneuropathy; see p. 889) causes ataxia because of loss of proprioception (position sense). A broad-based, high-stepping, ‘stamping’ gait develops as feet are placed clumsily, relying in part on vision, so balance is worse in the dark. Romberg’s test, first described in sensory ataxia of tabes dorsalis (see p. 872), becomes positive.

Lower limb weakness: high-stepping and waddling gaits

When weakness is distal, affecting ankle dorsiflexors, such as in a common peroneal nerve palsy (see p. 889), gait becomes high-stepping to avoid tripping. The sole returns to the ground with an audible slap.

Weakness of proximal leg muscles (e.g. polymyositis, muscular dystrophy) causes difficulty rising from sitting. Walking becomes a waddle, the pelvis being poorly supported by each leg.

Gait apraxia

With frontal lobe disease (e.g. diffuse cerebrovascular disease, normal-pressure hydrocephalus), walking skills become disorganized, despite normal motor and sensory function when examined on the couch. The gait is shuffling with small steps...
(marche à petits pas), gait ignition failure and hesitancy with fear of falling. Unlike in the gait of Parkinson’s disease, arm swing and posture are normal. Urinary incontinence and dementia are often present.

**Falls**

Falls are a major health problem in elderly people, often leading to hospital admission; they are frequently a reason for requiring residential care. A third of people over the age of 65 will fall each year and 10% sustain serious injury, such as hip fracture or head injury. Falls are the leading cause of injury-related death in elderly people.

The cause of falls is usually multifactorial and a multidisciplinary approach to assessment and prevention is essential, considering both intrinsic medical risk factors and external environmental factors, such as rugs, stairs, footwear, poor lighting and so on. Medical risk factors for falls (Box 26.5) are additive, with multiple factors substantially increasing the risk of falling. A fuller discussion of falls prevention and risk factor modification is given in chapter 15.

**Dizziness, vertigo and blackouts**

Dizziness covers many complaints, from a vague feeling of unsteadiness to severe, acute vertigo. It is frequently used to describe light-headedness (e.g. due to hypotension), panic, anxiety, palpitations and chronic ill-health. The real nature of this symptom must be determined.

Vertigo (see p. 816) means the illusion of movement, a sensation of rotation or tipping. The patient feels the surroundings are spinning or moving. This is distressing and often accompanied by nausea or vomiting.

Blackout, like dizziness, is simply descriptive, implying either altered consciousness (see epilepsy, p. 852, and syncope, p. 857), transient visual disturbance as part of pre-syncope or falling, or hypoglycaemia in a diabetic patient. A good history is essential.

Collapse is a vague term but often used. It should be avoided.

Fatigue is common. When it is an isolated symptom, it rarely indicates neurological disease, although it may be a symptom of many neurological disorders. General medical causes, such as anaemia and endocrine disorders, should be excluded. No serious disease is found in many (>20%) patients referred with symptoms suggestive of possible neurological conditions.

**Examination and formulation**

Following a short or detailed examination, relevant findings are summarized in a brief formulation, which becomes the basis for investigation, transfer of information and management (Boxes 26.6–26.8).

**Box 26.5 Medical risk factors for falls in the elderly**

- Cognitive impairment (dementia and delirium)
- Arthritis, muscle weakness
- Disorders of balance and gait, e.g. parkinsonism, ataxia, stroke
- Visual impairment
- Postural hypotension and syncope
- Vestibular disorders
- Polypharmacy, especially with sedative drugs, neuroleptics, antihypertensives and anticonvulsants
- Alcohol excess
- Peripheral neuropathy
- Effects of ageing on strength (sarcopenia), postural stability and reaction time
- Use of walking aid

**Further reading**

**Box 26.6 Five-part short neurological examination**

1. **Look at patient**
   - General demeanour
   - Speech
   - Gait
   - Arm swinging

2. **Head**
   - Fundi
   - Pupils
   - Eye movements
   - Facial movements
   - Tongue

3. **Upper limbs**
   - Posture of outstretched arms
   - Wasting, fasciculation
   - Power, tone
   - Coordination
   - Reflexes

4. **Lower limbs**
   - Wasting, fasciculation
   - Power, tone
   - Reflexes
   - Plantar responses

5. **Sensation**
   - Ask the patient

**Box 26.7 Ten-part neurological examination**

1. **State of consciousness, arousal, appearance**
2. **Mental state, attitude, insight**
3. **Cognitive function** – orientation, recall, level of intellect, language, other cortical problems, e.g. apraxia
4. **Gait and balance tests**, including tandem walking and Romberg’s test
5. **Neck** – stiffness, palpation and auscultation of carotids
6. **Cranial nerves** (see Box 26.10)
7. **Motor system**
   - Upper limbs:
     - Wasting and fasciculation
     - Posture of arms: drift, rebound, tremor
     - Tone: spasticity, clonus, extrapyramidal rigidity
     - Power: 0–5 scale (see Box 26.8)
     - Tendon reflexes: + or ++ normal; +++ pathological; 0 = absent with reinforcement
   - Thorax and abdomen:
     - Respiration
     - Thoracic and abdominal muscles
     - Abdominal reflexes
   - Lower limbs:
     - Wasting and fasciculation
     - Tone, power and tendon reflexes
     - Plantar responses
8. **Coordination and fine movements**
9. **Sensory system**
   - Chart area of sensory loss; start in area with abnormal sensation and move stimulus towards normal area to demarcate boundaries
   - Posterior columns:
     - Vibration (128Hz tuning fork)
     - Joint position – small movements of distal interphalangeal joints in toes and fingers
     - Light touch – use cotton wool
     - Two-point discrimination (normal: 2–4mm fingertips, 2 cm soles)
   - Spinohalamic tracts:
     - Pain: use a split orange-stick or a sterile pin (never a hypodermic needle)
   - Temperature: warm and cold objects
   - Cortical sensory loss – dysgrafahesia and astereognosis
10. **Specialized tests** as required e.g. Hallpike for vertigo, Phalen’s test and so on
**FUNCTIONAL NEUROANATOMY**

**Neurone and synapse**

The neurone is the functional unit of the entire nervous system (Fig. 26.1). Its cell body and axon terminate in a synapse. The size and type of each group of neurones vary. A thoracic spinal cord α-motor neurone has an axonal length of more than 1 metre and innervates between several hundred and 2000 muscle fibres in one leg – a motor unit. By contrast, some spinal or intracerebral interneurones have axons shorter than 100 μm, terminating on one neuronal cell body.

**Neurotransmitters**

Neurotransmitters are excitatory (acetylcholine, noradrenaline (norepinephrine), adrenaline (epinephrine), 5-hydroxytryptamine (5-HT, serotonin), dopamine, glutamate and aspartate) or inhibitory (γ-aminobutyric acid (GABA), histamine and glycine). Neuropeptides, such as vasopressin, adrenocorticotrophic hormone (ACTH), substance P and opioid peptides, as well as the purines adenosine triphosphate (ATP) and adenosine monophosphate (AMP) are both excitatory and inhibitory.

Synaptic transmission is mediated by neurotransmitters released by action potentials passing down an axon. Neurotransmitters activate postsynaptic receptors and are removed by transporter proteins. The neurotransmitter–receptor reaction increases ionic permeability and propagates a further action potential. Axonal electrical activity and synaptic chemical release are the basis of neurological function.

**Clinical features of focal brain lesions: general mechanisms**

The symptoms and signs suggest the area of the brain that is malfunctioning (e.g. aphasia – dominant frontal lobe, hemiparesis – the internal capsule, or a Bell’s palsy – VIIth cranial (facial) nerve).

Focal lesions of the cortex, and lesions throughout the nervous system, cause symptoms and signs by two processes:

- **Suppression or destruction of neurones** and surrounding structures (Fig. 26.2). This is the most common process: part of the system simply fails to work.

- **Synchronous discharge of neurones** by irritative lesions (Fig. 26.3), e.g. cortical lesions, causes epilepsy, either focal or generalized.

**Localization within the cerebral cortex**

Work on neuronal networks, functional imaging and plasticity questions the traditional views of highly specific localization of cortical function. The following paragraphs summarize areas of clinical relevance.

**Dominant hemisphere (usually left)**

The concept of cerebral dominance arose from a simple observation: right-handed stroke patients with acquired language disorders had destructive lesions within the left hemisphere. Right-handed (and 70% of left-handed) people have language function on the left.

More specifically, destructive lesions within the left frontotemporal-parietal region cause disorders of communication:

- spoken language – **aphasia**, also called **dysphasia**
- writing – **agraphia**
- reading – acquired **alexia**.
Functional neuroanatomy

Developmental dyslexia describes delayed, disorganized reading and writing ability in children, usually with normal intelligence.

Aphasia

Aphasia is loss of, or defective language from damage to, the speech centres within the left hemisphere. Numerous varieties have been described.

Broca’s (expressive, anterior) aphasia

Damage in the left frontal lobe causes reduced speech fluency with relatively preserved comprehension. The patient makes great efforts to initiate language, which becomes reduced to a few disjointed words with failure to construct sentences (sometimes described as *telegrammatic*). Patients who recover say they knew what they wanted to say but could not get the words out.

Wernicke’s (receptive, posterior) aphasia

Left temporo-parietal damage leaves fluency of language unaffected but words are muddled. This varies from insertion of a few incorrect or unnecessary words into speech to a profuse outpouring of jargon (non-existent words). Severe jargon aphasia is bizarre and often mistaken for psychotic behaviour.

Patients who recover from Wernicke’s aphasia say that they found speech, both their own and others’, like an unintelligible foreign language – that is, incomprehensible – but they could neither stop speaking nor understand speech.

Nominal (anomic) aphasia

This means difficulty in naming objects. Naming difficulty is an early feature in all types of aphasia. This is often tested in practice by asking patient to name parts of a watch; a more sensitive test utilizes pictures to test low-frequency words, such as rhinoceros, violin, tricycle or ladybird.

Global (central) aphasia

This means the combination of the expressive problems of Broca’s aphasia and the loss of comprehension of Wernicke’s, with loss of both language production and understanding. It is due to widespread damage to speech areas and is the most common aphasia after a severe left hemisphere infarct. Writing and reading are also affected.

Dysarthria

Dysarthria is disordered articulation – slurred speech. Language is intact. Paralysis, slowing or incoordination of the muscles of
articulation, causes various patterns of dysarthria. Examples are the **gravelly** speech of pseudobulbar palsy (see p. 817), the **jerky** ataxic speech of cerebellar lesions, the hypophonic **monotone** of Parkinson’s, and speech in myasthenia that **fatigues** and dies away. Many aphasic patients are also dysarthric.

**Non-dominant hemisphere**

Disorders in right-handed patients with right hemisphere lesions are often difficult to recognize. There are abnormalities of perception of internal and external space. Examples are loss of the way in familiar surroundings, failure to put on clothing correctly (dressing apraxia), or inability to draw simple shapes – constructional apraxia.

**Memory and its disorders**

Like most brain functions, memory has a modular organization, with different aspects of memory dependent on functionally and anatomically distinct brain networks. Three distinct processes are required: learning, storage and subsequent retrieval of learned information. There is a fundamental distinction between **explicit** memory, which can be consciously accessed, such as long-term memory for events (**episodic** memory) and knowledge of word meaning (**semantic** memory) on the one hand, and **implicit** memory, which is not conscious: for example, how to ride a bike (Fig. 26.4). Short-term memory is frequently misunderstood and refers to **working** memory lasting seconds only: for example, phone numbers.

Disorders of memory can result from damage to the medial structures of the temporal lobes and their brainstem connections – the hippocampi, fornices and mammillary bodies, as well as from damage to the thalamus and frontal lobe. The distributed anatomical basis of memory means that bilateral lesions are necessary to cause **amnesia**. Impairment of episodic memory usually results in a temporal memory gradient: recent and new memories are mainly affected, with relative preservation of distant memories.

**Box 26.9 Causes of an amnestic syndrome**

- Dementia (note: multiple cognitive domains affected, not memory in isolation)
- Amnestic mild cognitive impairment (see p. 881)
- Alcohol – thiamine deficiency (Wernicke–Korsakoff’s syndrome)
- Head injury (severe)
- Anoxic brain damage and that following carbon monoxide poisoning
- Stroke, including bilateral thalamic infarction, subarachnoid haemorrhage, diffuse small-vessel disease, and post cardiac surgery
- Viral, paraneoplastic and autoimmune encephalitis
- Drugs – psychotropics, anticholinergics and solvent abuse
- Bilateral invasive tumours
- Temporal lobe epilepsy and temporal lobectomy
- Following hypoglycaemia
- Temporary amnesia: transient global amnesia, transient epileptic amnesia, post-traumatic amnesia
- Dissociative (functional/psychogenic)

Amnesia must be distinguished from delirium.

Memory loss (the amnestic syndrome) is frequently a symptom of dementia, especially Alzheimer’s disease (see p. 881), but also occurs as an isolated entity (Box 26.9).

**Essential elements of neuroanatomy**

For clinical purposes, the complexity of neuroanatomy must be reduced to its core elements:

- cranial nerves
- three systems of motor control:
  - corticospinal or pyramidal system
  - extrapyramidal system
  - cerebellum
- motor unit
- reflex arc
• sensory pathways and pain
• control of the bladder and sexual function.

CRANIAL NERVES

See Box 26.10.

I: Olfactory nerve

This sensory nerve arises from olfactory (smell) receptors within nasal mucosa. Branches pierce the cribriform plate and synapse in the olfactory bulb. The olfactory tract passes to the olfactory cortex.

Anosmia (loss of the sense of smell) is caused by head injury (shearing of olfactory neurones as they pass through the cribriform plate at the skull base) or tumours of the olfactory groove (e.g. meningioma). Olfaction is temporarily (or permanently, on occasion) lost or diminished after upper respiratory infections and with local disorders of the nose. Many patients with gradual-onset anosmia over many years may be unaware of the deficit: for example, in Parkinson’s disease, where anosmia precedes motor symptoms by many years but is often not noticed by the patient.

Detailed smell testing is difficult in routine clinical practice and rarely performed. Adequate testing requires use of commercially available kits, such as scratch and sniff cards or odour-filled pens with forced multiple-choice identification.

II: Optic nerve and visual system

Light regulated by the pupillary aperture is converted into action potentials by retinal rod, cone and ganglion cells (see p. 912). The lens, under control of the ciliary muscle, produces the image (inverted) on the retina. Axons in the optic nerve (1 on Fig. 26.5) decussate at the optic chiasm (2), and fibres from the nasal retina cross and join with uncrossed fibres originating in the temporal retina to form the optic tract (3). Each optic tract thus carries information from the contralateral visual hemifield.

From the lateral geniculate body, fibres pass in the optic radiation through the parietal and temporal lobes (4 and 5) to reach the visual cortex of the occipital lobe (6 and 7), which is somatotopically organized with macular vision located at the occipital pole.

Beyond the visual cortex, visual information is further processed by neighbouring visual association areas to detect lines, orientation, shapes, movement, colour and depth; there is even a distinct area responsible for face recognition.

Visual acuity

Visual acuity (see p. 914) is assessed in each eye with a Snellen chart and/or Near Vision Reading Types, corrected for refractive errors with lenses or a pinhole. The patient should stand 6 metres from a well-lit chart. Acuity is recorded as distance in metres from the chart over distance at which the line should be legible, e.g. 6/6 indicates ‘normal’ acuity and 6/60 very poor acuity.

Visual field defects

Visual fields are assessed at the bedside by confrontation – comparing the examiner’s and patient’s fields, one eye at a time and quadrant by quadrant. Patience and good technique are required to produce reliable results. White and red targets (traditionally, hatpins) are used to assess peripheral and central fields, respectively, although in practice a fingertip is often substituted as a cruder screening test. More detailed quantification of fields may

be obtained using Goldmann (manual) or Humphrey (automated) perimetry testing.

Field defects are described as hemianopic when half the field is affected and quadrantanopic when a quadrant is affected. Lesions posterior to the optic chiasm produce homonymous field defects, indicating involvement of the same part of the visual field in both eyes, as information from the two visual hemifields is separated beyond this point. Lesions damaging decussating nasal fibres at the optic chiasm cause bitemporal defects.

**Retinal and local eye lesions**

See pages 923–924.

**Optic nerve lesions**

Unilateral visual loss, commencing with a central or paracentral (off-centre) scotoma, is the hallmark of an optic nerve lesion. Because most fibres in the optic nerve subserve macular vision, lesions within the nerve disproportionately affect central vision and colour vision. A total optic nerve lesion causes unilateral blindness with loss of pupillary light reflex. Examination findings in optic neuropathy are:

- reduced acuity in the affected eye
- a scotoma (usually central)
- impaired colour vision (assess with Ishihara plates)
- an afferent pupillary defect (see below)
- optic atrophy – pale disc (develops late).

Causes are listed in Box 26.11.

**Papilloedema**

Papilloedema means swelling of the optic disc. Causes are shown in Box 26.12. The earliest signs of swelling are disc pinkness, with blurring and heaping up of disc margins, nasal first. There is loss of spontaneous pulsation of retinal veins within the disc. The physiological cup becomes obliterated, and the disc is engorged with dilated vessels. Small haemorrhages often surround the disc.

Various conditions simulate true disc swelling. Marked hypermetropic (long-sighted) refractive errors make a disc appear pink, distant and ill defined. Myelinated nerve fibres at disc margins and hyaline bodies (drusen; see p. 923) can be mistaken for disc swelling. **Disc infiltration** also causes a swollen disc with raised margins (e.g. in leukaemia).

When there is doubt about disc oedema, intravenous fluorescein angiography is diagnostic; retinal leakage is seen with papilloedema. Papilloedema produces few, if any, visual symptoms other than momentary visual obscurations with changes in posture. The underlying disease is the source of the patient’s symptoms. The blind spot is enlarged but this is not noticed by the patient. However, over time, progressive and permanent constriction of visual fields occurs, ultimately culminating in optic atrophy.

**Inflammatory optic neuropathy (optic neuritis)**

Optic neuritis is one of the most common causes of subacute visual loss. Symptoms may vary from a mild fogging of central vision with colour desaturation to a dense central scotoma, but very rarely complete blindness. Pain on eye movements is almost universal. The optic disc usually appears normal, despite severe visual loss (unless the inflammation is at the optic nerve head, in which case the disc may appear swollen in the acute phase).

A plaque of demyelination within the optic nerve is the most common cause in Western populations. Dedicated magnetic resonance imaging (MRI) of the optic nerves may show the inflammatory plaque, and imaging of the brain may show additional inflammatory lesions, which confer a higher risk of developing multiple sclerosis (MS). Approximately 50% of patients go on to develop MS with prolonged follow-up (see p. 864). Recovery of visual acuity to 6/9 or better occurs in 95% of cases over months; recovery time is improved by high-dose intravenous or oral steroids given acutely.

Optic neuritis may be caused by infective or other inflammatory disorders, such as sarcoidosis or vasculitides (see Box 26.11).

**Anterior ischaemic optic neuropathy**

The anterior part of the optic nerve is supplied by the posterior ciliary arteries, occlusion or hypoperfusion of which leads to infarction of all or part of the optic nerve head. There is sudden or stuttering altitudinal visual loss (typically, the lower half of the visual field) with disc swelling, later replaced by optic atrophy. The other eye is affected later in one-third of cases.

Individuals with small hypermetropic discs seem to be predisposed, and often there are relatively few vascular risk factors. Less commonly, arteritis is the cause (see p. 985).

**Optic atrophy**

Optic atrophy means disc pallor, from loss of axons, glial proliferation and decreased vascularity. This may eventually develop following any type of optic neuropathy of sufficient severity to damage axons extensively within the nerve, including chronic papilloedema.

**Optic chiasm**

**Bitemporal hemianopia or quadrantanopia** occurs with compression of the chiasm from above or below. Common causes are:

- pituitary tumours (see p. 591)
- meningioma
- craniopharyngioma.
Optic tract and optic radiation

Optic tract lesions (rare) cause a homonymous hemianopia (loss of the contralateral visual field in both eyes). Optic radiation lesions cause homonymous quadrantanopic defects. Temporal lobe lesions (e.g., tumour, infarction) cause upper quadrantanopic defects, and parietal lobe lesions cause lower quadrantanopic defects.

Occipital cortex

Homonymous hemianopic defects are produced by unilateral posterior cerebral artery infarction (see p. 840). The macular cortex (at each occipital pole) supplied by the middle cerebral artery may be spared.

Widespread bilateral occipital lobe damage by infarction (‘top of the basilar’ syndrome, occlusion of the rostral basilar artery), trauma or coning causes cortical blindness (Anton syndrome). The patient cannot see but characteristically lacks insight into this; he or she may even deny it. Pupillary responses remain normal (see p. 840).

Pupils

A slight difference between the size of each pupil (up to 1 mm) is common (physiological anisocoria) and does not vary with differing light levels. The pupil tends to become smaller and irregular in old age (senile miosis); anisocoria is more pronounced. Convergence becomes sluggish with ageing.

Pupillary reactions to light and accommodation may be tested (Fig. 26.6). A bright torch (not an ophthalmoscope light!) should be used to test the pupillary light reaction.

Afferent pupillary defect (APD). A complete optic nerve lesion causes a dilated pupil and an APD. For a left APD:
- The pupil is unresponsive to light (i.e. the direct reflex is absent).
- The consensual reflex (constriction of the right pupil when the left is illuminated) is absent. Conversely, the left pupil constricts when light is shone in the intact right eye: that is, the consensual reflex of the right eye remains intact.

Relative afferent pupillary defect (RAPD). This occurs with incomplete damage to one optic nerve relative to the other. An RAPD is a sensitive sign of optic nerve pathology and can provide evidence of an optic nerve lesion, even after recovery of vision. For a left RAPD:
- Direct and indirect reflexes are intact in each eye but differ in relative strength.
- When the light is swung from one eye to the other, the left pupil dilates slightly when illuminated and constricts slightly when the right eye is illuminated (the consensual reflex is stronger than the direct).

Horner’s syndrome

The sympathetic nervous supply to the eye is a three-neurone pathway originating in the hypothalamus and descending by way of the brainstem and cervical cord to the T1 nerve root, paravertebral sympathetic chain and, on via the carotid artery wall, to the eye. Damage to any part of the pathway results in Horner syndrome (Box 26.13). This is significant not only because it affects vision but also because it may indicate serious underlying pathology.

The clinical features of Horner’s syndrome are:
- unilateral miosis (constricted pupil)
- partial ptosis
- loss of sweating on the same side (extent depending on the level of the lesion)
- possible subtle conjunctival injection and enophthalmos.

The miosis is most easily seen in low light, as the pupil cannot dilate, and may not be apparent in bright light.

Myotonic pupil (Holmes–Adie pupil)

This is a dilated, often irregular, pupil, and is more frequent in women; it is common and usually unilateral. There is no (or very slow) reaction to bright light and also incomplete constriction to convergence. This is due to denervation in the ciliary ganglion, of unknown cause, and has no other pathological significance. A myotonic pupil is sometimes associated with diminished or absent tendon reflexes.

Argyll Robertson pupil

Now rarely seen in clinical practice, an Argyll Robertson pupil is small and irregular; it is fixed to light but constrits on convergence. The lesion is in the brainstem surrounding the aqueduct of Sylvius. Once considered diagnostic of neurosyphilis, it is now only occasionally seen in diabetes or MS.
III, IV, VI: Oculomotor, trochlear and abducens nerves

These cranial nerves supply the extraocular muscles and disorders commonly result in abnormal eye movements and diplopia (double vision) due to breakdown of conjugate eye movements. Diplopia may also occur with local orbital lesions or myasthenia gravis.

Examination of eye movements

Pursuit (slow) eye movements and saccadic (fast) eye movements are tested separately. The examiner assesses the range of eye movements in all directions and asks the patient to report double vision. Jerky pursuit movements with saccadic intrusion (i.e. brief, fast saccades interspersed with slower pursuit movements), overshoot on saccadic movements, and nystagmus may indicate cerebellar or brainstem pathology.

Control of eye movements

Fast voluntary eye movements originate in the frontal lobes. Fibres descend and cross in the pons to end in the centre for lateral gaze (paramedian pontine reticular formation, PPRF), close to the VIth nerve nucleus. Each PPRF also receives input from:

- the ipsilateral occipital cortex – pathway concerned with tracking objects
- the vestibular nuclei – pathways linking eye movements with position of the head and neck (vestibulo-ocular reflex).

Conjugate lateral eye movements are coordinated from each PPRF via the medial longitudinal fasciculus (MLF; Fig. 26.7). Fibres from the PPRF pass both to the ipsilateral VIth nerve nucleus (lateral rectus) and, having crossed the midline, to the opposite IIIrd nerve nucleus (medial rectus and other muscles) via the MLF, thus linking the eyes for lateral gaze.

Abnormalities of conjugate lateral gaze

A destructive lesion on one side allows the eyes to be driven by the intact opposite pathway. A left frontal destructive lesion (e.g. an infarct) leads to failure of conjugate lateral gaze to the right. In an acute lesion, the eyes are often deviated to the side of the lesion, past the midline, and therefore look towards the left (normal) limbs; there is usually a contralateral (i.e. right) hemiparesis. In the brainstem, a unilateral destructive lesion involving the PPRF leads to failure of conjugate lateral gaze towards that side. There is usually a contralateral hemiparesis, and lateral gaze is deviated towards the side of the paralysed limbs.

Internuclear ophthalmoplegia

Damage to one MLF causes internuclear ophthalmoplegia (INO), a common complex brainstem eye movement disorder seen frequently in MS. In a right INO, there is a lesion of the right MLF (see Fig. 26.7). On attempted left lateral gaze, the right eye fails to adduct or does so slowly in comparison to the abducting eye. The left eye develops nystagmus in abduction. The side of the lesion is on the side of impaired adduction, not on the side of the (obvious, unilateral) nystagmus. Bilateral INO is almost pathognomonic of MS.

One and a half syndrome

Pontine infarction involving the PPRF, VIth nerve nucleus and MLF on one side results in an ipsilateral horizontal gaze palsy and an INO, so that abduction of the opposite eye (with nystagmus) is the only horizontal eye movement possible. Vertical gaze and convergence are preserved, as they have distinct neural control mechanisms.

Vestibulo-ocular (doll’s eye) reflexes

Examination is of diagnostic value in coma (see p. 236) and assessment of vertigo (see p. 816).

Abnormalities of vertical gaze

Failure of upgaze may be caused by dorsal midbrain lesions, such as pinealoma or infarct. When the pupillary light reflex fails in addition, this is called Parinaud’s syndrome. Defective upgaze also develops in certain degenerative disorders (e.g. progressive supranuclear palsy). Some impairment of upgaze occurs as part of normal ageing.

Nystagmus

Nystagmus is rhythmic oscillation of eye movement; it is a sign of disease of the retina, cerebellum and/or vestibular systems and their connections. Nystagmus is either jerk or pendular. Nystagmus must be sustained within binocular gaze to be of diagnostic value; a few beats at the extremes of gaze are normal.

Jerk nystagmus

Jerk nystagmus (usual in neurological disease) is a fast/slow oscillation. This is seen in vestibular, VIIth nerve, brainstem and cerebellar lesions. The direction of nystagmus is decided by the fast component, a reflex attempt to correct the slower, primary movement.

- **Horizontal or rotary jerk nystagmus** may be either of peripheral (vestibular) or central origin (VIIth nerve, brainstem, cerebellum and connections).
• In peripheral lesions, nystagmus is usually acute and transient (minutes or hours) and associated with severe prostrating vertigo.
• In central lesions, nystagmus tends to be long-lasting (weeks, months or more). Vertigo caused by central lesions tends to wane after days or weeks, the nystagmus outlasting it.
• Vertical jerk nystagmus is typically caused by central lesions.
• Down-beat jerk nystagmus is a rarity caused by lesions around the foramen magnum (e.g. menigioma, cerebellar e ctopia).

**Pendular nystagmus**

Pendular describes movements to and fro, similar in velocity and amplitude. Pendular nystagmus is usually vertical and present in all directions of gaze. The causes are generally ocular (e.g. poor visual fixation from longstanding, severe visual impairment) or congenital.

**III: Oculomotor nerve lesions**

The nucleus of the IIIrd nerve lies ventral to the aqueduct in the midbrain. It supplies four external ocular muscles (superior, inferior and medial recti, and inferior oblique) and levator palpebrae superioris (which lifts the eyelid), and effects parasympathetic constriction of the pupil. Causes of a IIIrd nerve lesion are listed in Box 26.14.

Signs of a complete IIIrd nerve palsy include:
- unilateral complete ptosis (levator weakness)
- deviation of the eye down and out (unopposed lateral rectus and superior oblique)
- a fixed and dilated pupil.

Patients do not complain of diplopia as the ptosis effectively covers the eye. *Sparring of the pupil* indicates that parasympathetic fibres are undamaged; these run in a discrete bundle on the surface of the nerve, and so the pupil is of normal size and reacts normally. Diabetic IIIrd nerve infarction is usually painless and pupil-sparing, unlike compression by a posterior communicating artery aneurysm.

**IV: Trochlear nerve lesions**

The trochlear nerve supplies the superior oblique muscle. The patient complains of torsional diplopia (two objects at an angle) when attempting to look down (e.g. descending stairs); the head is tilted away from that side. The most common cause is head injury, often with bilateral trochlear nerve palsies occurring.

**VI: Abducens nerve lesions**

The abducens nerve supplies the lateral rectus muscle (abduction). Lesions cause horizontal diplopia when looking into the distance, which is maximal when looking to the side of the lesion. The eye cannot be fully abducted and an esotropia (inward eye deviation) may be visible in the primary position.

The VIth nerve has a long intracranial course. It can be damaged in the brainstem (e.g. by MS or infarction). In raised intracranial pressure, it is compressed against the tip of the petrous temporal bone (this may be bilateral). The nerve sheath may be infiltrated by tumours, particularly nasopharyngeal carcinoma. Microvascular ischaemia of the nerve may occur in diabetes with acute onset, followed by recovery within 3 months in most cases.

**Complete external ophthalmoplegia**

Complete external ophthalmoplegia describes an immobile eye when IIIrd, IVth and VIth nerves are paralysed at the orbital apex (e.g. by metastasis) or within the cavernous sinus (e.g. by sinus thrombosis or menigioma).

Wernicke’s encephalopathy due to thiamine deficiency (see p. 891) may cause a complex eye movement disorder or complete ophthalmoplegia, as may neuromuscular junction disorders such as myasthenia, botulism and some myopathies or metabolic disorders.

**V: Trigeminal nerve**

The trigeminal is the largest cranial nerve; it is mainly sensory with a motor component to the muscles of mastication.

Sensory fibres (Fig. 26.8; see also Figs 26.13 and 26.14) of the three divisions – ophthalmic (V₁), maxillary (V₂) and mandibular (V₃) – pass to the trigeminal (Gasserian) ganglion at the apex of the petrous temporal bone. Ascending fibres transmitting light touch enter the fifth nucleus in the pons. Descending central fibres carrying pain and temperature form the spinal tract of V, to end in the spinal fifth nucleus that extends from the medulla into the cervical cord.

**Clinical features of a Vth nerve lesion**

A complete Vth nerve lesion causes unilateral sensory loss on the face, scalp anterior to the vertex, and the anterior two-thirds of the tongue and buccal mucosa; the jaw deviates to that side as the mouth opens (motor fibres). Diminution of the corneal reflex is an early and sometimes isolated sign of a Vth nerve lesion.

**Aetiology**

- Brainstem pathology (infarction, demyelination or tumour) may damage the nucleus, with light touch and spinothalamic pathways sometimes being differentially involved.

**Box 26.14 Some causes of a IIIrd nerve lesion**

- Aneurysm of the posterior communicating artery
- Infarction of IIIrd nerve, e.g. diabetes, atheroma
- Coning of the temporal lobe
- Midbrain infarction
- Midbrain tumour (primary or secondary)

**Fig. 26.8 Sensory input of fifth nerve (red) and motor output of the VIth nerve (blue).** FO, foramen ovale; FR, foramen rotundum; GG, Gasserian ganglion; SF, stylomastoid foramen; SOF, superior orbital fissure.
• **Cerebellopontine angle tumours** (acoustic neuroma or meningoima) may compress the nerve and also affect the VIIth and VIIIth nerves, producing facial weakness and deafness.

• **Cavernous sinus and skull base pathology** (tumour or infection) may affect the ganglion and proximal branches.

• **Peripheral branches** may be picked off individually, e.g. the ‘numb chin syndrome’ seen with a breast cancer metastasis in the mandible.

### Trigeminal neuralgia

Trigeminal neuralgia is discussed with facial pain (see p. 852).

### Trigeminal sensory neuropathy

This causes gradually progressive, unilateral, facial sensory loss and tingling with normal imaging. The condition is probably heterogeneous in aetiology but may have an autoimmune basis, with inflammation of the trigeminal ganglion, occurring mainly in association with mixed and undifferentiated connective tissue disease and primary Sjögren’s syndrome.

### VII: Facial nerve

The VIIth nerve is largely motor, supplying muscles of facial expression. It carries sensory taste fibres from the anterior two-thirds of the tongue via the chorda tympani and supplies motor fibres to the stapedius muscle. The VIIth nerve (see Fig. 26.8) arises from its nucleus in the pons and leaves the skull through the stylomastoid foramen. Neurones in each VIIth nucleus supplying the upper face (principally frontalis) receive bilateral supranuclear innervation.

### Unilateral facial weakness

#### Upper motor neurone (UMN) lesions

These cause weakness of the lower part of the face on the opposite side. Frontalis is spared; normal furrowing of the brow is preserved; eye closure and blinking are largely unaffected. The first sign is slowing of one side of the face: for example, on bar ing the teeth. There is sometimes relative preservation of spontaneous emotional movement (e.g. smiling) compared with voluntary movement.

#### Lower motor neurone (LMN) lesions

A complete unilateral LMN VIIth lesion causes weakness (ipsilateral) of all facial expression muscles. The angle of the mouth falls; unilateral dribbling develops. Frowning (frontalis) and eye closure are weak. Corneal exposure and ulceration occur if the eye does not close during sleep. Taste sensation is frequently also impaired.

### Causes of facial weakness

The most common cause of a UMN lesion is hemispheric stroke with hemiparesis on the opposite side. At lower levels, lesion sites are recognized by LMN weakness with additional signs.

• **Pons.** Here the VIIth nerve loops around the Vth (abducens) nucleus (see Fig. 26.8), leading to a lateral rectus palsy (see p. 813) with unilateral LMN facial weakness. When the neighbouring PPRF and corticospinal tract are involved, there is the combination of:
  - LMN facial weakness
  - failure of conjugate lateral gaze (towards lesion)
  - contralateral hemiparesis.

Causes include pontine tumours (e.g. glioma), MS and infarction.

#### Cerebellopontine angle (CPA)

The neighbouring Vth, VIIth and VIIIth nerves are compressed with VII in the CPA; for example, by acoustic neuroma, meningoima or metastasis.

**Petrous temporal bone.** The nerve may be damaged within the bony facial canal, within which lies the sensory geniculate ganglion (receiving taste fibres from the anterior two-thirds of the tongue via the chorda tympani). As well as LMN facial weakness, lesions in this region cause:

- loss of taste on the anterior two-thirds of the tongue
- hyperacusis (loud noise distortion – paralysis of stapedius).

Causes include:

- Bell’s palsy
- trauma
- middle ear infection
- herpes zoster (Ramsay Hunt syndrome; see p. 815).

#### Skull base, parotid gland and within the face

The facial nerve can be compressed by skull base tumours and in Paget’s disease of bone. Branches of VII may be damaged by parotid gland tumours as the nerve traverses the parotid, and by sarcoidosis (see p. 985) and trauma.

### Bell’s palsy

This common (37 per 100,000 incidence), acute facial palsy is thought to be due to viral infection/reactivation (often herpes simplex) causing swelling of nerve within the tight petrous bone facial canal. Unilateral LMN facial weakness develops over 24–48 hours, sometimes with lost or altered taste on the tongue, and hyperacusis. Pain behind the ear is common at onset. Patients often suspect a stroke and may be very distressed. Vague altered facial sensation is often reported, although examination of facial sensation is normal.

Diagnosis is made on clinical grounds and tests are usually not required. The ear (and palate) should be examined for vesicles (see Ramsay Hunt syndrome later), hearing loss or evidence of local pathology such as cholesteatoma or malignant otitis externa; parotid tumours should be excluded. Involvement of other cranial nerves means facial weakness is not due to Bell’s palsy. Lyme disease may account for one-quarter of cases of facial palsy in endemic areas and HIV seroconversion is the most common cause in parts of Africa.

**Bell’s phenomenon** is the upward conjugate eye movement that occurs normally when the eyes are closed but is accentuated when the orbicularis oculi muscle is weak.

### Management and prognosis

Complete, or almost complete, recovery over 4–12 weeks occurs in at least 85% of patients, even without specific treatment. Patients should be reassured that the prognosis is good and that the condition is unlikely to recur.

Inability to blink in severe facial weakness may lead to exposure keratitis. Use of lubricating eye ointment is often required and patients should be advised to tape the eye closed carefully at night. For more severe facial weakness with complete inability to close the eye, early ophthalmological assessment is necessary and lateral tarsorrhaphy and/or insertion of a gold weight into the upper lid may be required until recovery occurs.

Early treatment with corticosteroids (prednisolone 50 mg for 10 days) improves outcome if started within 72 hours of onset. The latest evidence does not support use of antiviral agents.

Recovery sometimes takes up to a year if axons have to regrow rather than just remyelinate, in which case aberrant re-innervation of facial muscles (e.g. mouth twitching with blinking) is a frequent late complication. Plastic surgery may be helpful where recovery is not complete. Bell’s palsy rarely recurs; if it does, this should prompt a search for an alternative cause.
Ramsay Hunt syndrome
This is herpes zoster (shingles) of the geniculate ganglion. There is a facial palsy (identical to Bell’s) with vesicles around the external auditory meatus and/or the soft palate (sensory twigs from VII). Deafness and vertigo/unsteadiness may occur. Complete recovery is less likely than in Bell’s. Antiviral treatment (aciclovir/valaciclovir) is usually given with steroids.

Bilateral facial weakness
Bilateral facial palsy is rare, accounting for less than 1% of cases of facial palsy, but is more likely than unilateral palsies to have an identifiable underlying cause. Paradoxically, bilateral weakness is often less obviously apparent than unilateral weakness, as there is no facial asymmetry.

Causes include:
- infections:
  - Lyme disease (bilateral in 25% – Bannwarth’s syndrome)
  - viral: human immunodeficiency virus (HIV) seroconversion, Epstein–Barr virus
  - mastoiditis (bilateral)
  - diphtheria and botulism (rare)
- sarcoidosis
- skull-base trauma and tumours
- pontine lesions, e.g. gliomas
- neuromuscular disorders as part of more generalized weakness:
  - Guillain–Barré syndrome
  - myasthenia
  - myotonic dystrophy and facioscapulohumeral dystrophy
- congenital and genetic causes (Gelsolin gene mutations).

Hemifacial spasm
Hemifacial spasm (HFS) is an irregular, painless unilateral spasm of facial muscles, usually occurring after middle age. It starts in the orbicularis oculi and usually progresses gradually over the years to involve other facial muscles on the same side. It varies from a mild to a severe, disfiguring spasm.

HFS is usually caused by compression of the root entry zone of the facial nerve, generally by vascular structures such as the vertebral or basilar arteries or their branches (a mechanism similar to that of trigeminal neuralgia; see p. 852). Other mass lesions in the cerebellopontine angle, including tumours, are the cause in approximately 1% of cases.

Occasionally, HFS may occur with ipsilateral trigeminal neuralgia, one symptom usually preceding the other: a combination called tic convulsif. The paroxysms of pain and spasm occur independently. A compressive cause, such as a vascular loop or other structural lesion, is usually identified.

Management
Mild cases require no treatment. Botulinum toxin injection into affected muscles every 3–4 months is now the standard treatment. Drugs (e.g. carbamazepine) are of little value. Decompression of the VIIth nerve in the CPA is sometimes helpful. Surgical decompression of the facial nerve in the posterior fossa involves interposing a non-resorbable sponge between the nerve and any adjacent vascular loop identified at operation. The procedure results in complete resolution of symptoms in up to 90% of cases but is associated with a risk of facial weakness or deafness.

Other involuntary facial movements
Myokymia of orbicularis oculi is an irritating twitch, usually of the lower eyelid. It is a normal phenomenon but sometimes a cause of anxiety. More extensive facial myokymia may result from intrinsic brainstem pathology.

Tics and tardive dyskinesia frequently involve facial or perioral muscles (see p. 863).

Blepharospasm is a form of focal dystonia affecting orbicularis oculi (see p. 863).

VIII: Vestibulocochlear nerve
Auditory fibres from the spiral organ of Corti within the cochlea pass to the cochlear nuclei in the pons. Fibres from these nuclei cross the midline and pass upwards via the medial lemnisci to the medial geniculate bodies and then to the temporal cortex.

Symptoms of a cochlear nerve lesion are deafness and tinnitus (see p. 907). Sensorineural and conductive deafness can be distinguished with tuning fork tests, e.g. Rinne’s and Weber’s (using a 256 Hz, not 128 Hz, tuning fork; see p. 903).

Basic investigations of cochlear lesions
- Pure tone audiometry and auditory thresholds.
- Auditory evoked potentials (recording responses from repetitive clicks via scalp electrodes; lesion levels are determined from the response pattern).

Causes of deafness
These are listed in Box 26.15 and Box 27.2.

Vertigo and the vestibular system
The vestibular system of the inner ear detects head movements and has three primary functions:
- to stabilize gaze during head movements, e.g. looking ahead while running (the vestibulo-ocular reflex)
- to control posture and balance
- to facilitate perception of orientation and motion.

D, hearing loss; V, vertigo.
Nerve impulses generated by movement of hair cells within the three semicircular canals detect head motion in the three planes (yaw/pitch/roll). Balance is maintained by integrating information from:

- the vestibular system
- the visual system
- the somatosensory system – proprioception from limbs, trunk and neck.

The main symptoms of vestibular lesions are vertigo and loss of balance.

### Vertigo

Vertigo is the illusion of movement of the subject or surroundings, typically rotatory, and should be distinguished from other causes of non-specific dizziness. It can be described to patients as being similar to the sensation one feels after getting off a child’s roundabout or after spinning on the spot and suddenly stopping.

Vertigo frequently accompanies acute vertigo of any cause. Vertigo is always made worse by head movements and patients prefer to remain still and maintain visual fixation. Walking is unsteady. Nystagmus (see p. 812) is the principal sign.

### Causes of vertigo

Vertigo indicates a disturbance of the vestibular apparatus or brainstem and associated neural pathways (see Box 26.15). Causes:

- **Peripheral causes** (vestibular system) are common. Deafness and tinnitus accompanying vertigo indicate involvement of the ear or cochlear nerve (see p. 903).
- **Central causes** (brainstem and connections) are rarer. Other clinical features, such as diplopia, weakness, cerebellar signs or cranial nerve palsies, may help localize the lesion.

### Peripheral (vestibular) disorders

Vestibular disorders are fully discussed elsewhere (see p. 907). Attack duration and frequency, as well as trigger factors, help the clinician distinguish on history between different pathological causes. The ability to perform a Hallpike test, head impulse test and Epley particle repositioning manoeuvre are invaluable skills for all clinicians (see p. 906; Fig. 26.9 and see Fig. 27.9).

The most commonly encountered vestibular disorders presenting with vertigo are:

- **benign paroxysmal positional vertigo** (BPPV) – frequent attacks lasting seconds only (see p. 906).
- **vestibular neuritis** – acute onset lasting days or weeks; non-recurrent
- **Ménière’s disease** – recurrent attacks lasting minutes or hours, usually accompanied by hearing loss, tinnitus and a feeling of fullness in the ear
- **trauma** – vestibular disruption following head injury.

Central causes of vertigo

Vertigo may be a manifestation of brainstem pathology, including:

- **infarcts involving the vestibular nuclei** in the medulla (e.g. the lateral medullary syndrome)
- **demyelination** involving the brainstem
- **posterior fossa mass lesions** – e.g. tumours, haemorrhage or vascular malformations
- **migrainous vertigo** (see p. 850) – lasts hours, occurring every few weeks or months
- **CPA mass lesions** and tumours compressing the vestibular nerve (technically, these should be classified as ‘peripheral’ disorders, but are distinct from disorders of the vestibular apparatus)
- **drugs** – e.g. anticonvulsant toxicity and alcohol.

Although vertigo occasionally occurs in isolation with brainstem pathology, it is more typically a single component of a more complex clinical picture, associated with other symptoms or examination findings. The brainstem nuclei and tracts are tightly packed into a small space and most pathological processes affect multiple contiguous neural pathways, resulting, for example, in diplopia, eye movement disorders, cranial nerve palsies, cerebellar signs or hemiparesis.

Slowly growing CPA tumours, such as vestibular nerve schwannomas, may cause vertigo but rarely do so in the absence of unilateral deafness and tinnitus.

Basic investigations for vestibular problems

Bedside assessment is usually sufficient to make a diagnosis in the majority of patients:

- examination of eye movements for nystagmus (see p. 812)
- assessment of hearing andotoscopic examination of the ear (see p. 815)
- head impulse (thrust) test – to assess the vestibulo-ocular reflex (VOR) and identify a unilateral vestibulopathy
- Hallpike manoeuvre – a positioning test to stimulate the posterior semicircular canal and trigger an attack in BPPV (see Fig. 27.9).

Specialist testing is occasionally required to assess vestibular function and hearing. This includes:

- caloric testing – irrigation of the external auditory meatus with cold and then warm water to stimulate the horizontal semicircular canal and induce nystagmus; labyrinthine function is tested in each ear separately
• electro-nystagmography – to quantify and characterize nystagmus under different conditions, e.g. in a rotating chair
• posturography – assesses body sway on a moving platform
• pure-tone audiograms
• high-definition MRI – provides the best structural imaging of the brainstem and CPA, and is useful where a central cause of vertigo is suspected.

Vestibular neuronitis
Vestibular neuronitis is a common but poorly understood problem. It is an acute attack of isolated vertigo with nystagmus, often with vomiting, and is believed to follow viral infections. The disturbance lasts for several days or weeks, is self-limiting and rarely recurs. Vestibular neuronitis is sometimes followed by BPPV (see p. 906). Deafness is absent. Acute treatment is with vestibular sedatives. Similar symptoms can be caused by MS or brainstem vascular lesions. Other signs are usually apparent.

Lower cranial nerves IX, X, XI, XII
The glossopharyngeal (IX), vagus (X) and accessory (XI) nerves arise in the medulla and leave the skull through the jugular foramen. The hypoglossal (XII) arises in the medulla, to leave the skull base via the hypoglossal foramen. Outside the skull, the four cranial nerves lie together, close to the carotid artery and sympathetic trunk.

Glossopharyngeal (IX)
This nerve is largely sensory, supplying sensation and taste from the posterior third of the tongue and the pharynx (afferent pathway of gag reflex). Motor fibres supply some pharyngeal muscles, and parasympathetic fibres supply the parotid.

Vagus (X)
The vagus is a mixed nerve, largely motor, which supplies striated muscle of the pharynx (afferent pathway via recurrent laryngeal nerves) and larynx (including vocal cords via recurrent laryngeal nerves) and upper oesophagus. There are sensory fibres from the larynx. Parasympathetic fibres supply the heart and abdominal viscera.

Accessory (XI)
The accessory nerve, a complex motor nerve, supplies the trapezius and sternomastoid muscles.

Hypoglossal (XII)
The hypoglossal nerve is a motor nerve to tongue muscles.

IXth and Xth nerve lesions
Principal causes of IXth, Xth, XIth and XIIth nerve lesions are listed in Box 26.16.

Isolated lesions of IXth and Xth nerves are unusual, since disease at the jugular foramen affects both nerves and sometimes XI.

A unilateral IXth nerve lesion causes diminished sensation on the same side of the pharynx and is hard to recognize in isolation. A Xth nerve palsy produces ipsilateral failure of voluntary and reflex elevation of the soft palate (which is drawn to the opposite side) and ipsilateral vocal cords.

Bilateral lesions of IXth and Xth nerves cause palatal weakness, reduced palatal sensation, an absent gag reflex, dysphonia and choking with nasal regurgitation. Bulbar palsy is a general term describing palatal, pharyngeal and tongue weakness of LMN or muscle origin.

Recurrent laryngeal nerve lesions
Paralysis of this branch of each vagus causes hoarseness (dysphonia) and failure of the forceful, explosive part of coughing (“bovine cough”). There is no visible palatal weakness; vocal cord paralysis is seen endoscopically. Bilateral acute lesions (e.g. postoperatively) cause respiratory obstruction – an emergency.

The left recurrent laryngeal nerve (looping beneath the aorta) is damaged more commonly than the right.

Causes of recurrent laryngeal nerve lesions include:
• mediastinal primary tumours (e.g. thymoma)
• secondary spread from bronchial carcinoma
• aortic aneurysm
• trauma or surgery of neck or thorax.

XIth nerve lesions
XIth nerve lesions cause weakness of sternomastoid (rotation of the head and neck to the opposite side) and trapezius (shoulder shrugging). Nerve section (e.g. following lymph node biopsy in the neck posterior triangle) is followed by persistent neuralgic pain.

XIIth nerve lesions
LMN lesions of XII lead to unilateral tongue weakness, wasting and fasciculation. The protruded tongue deviates towards the weaker side. Bilateral supranuclear (UMN) lesions produce slow, limited tongue movements and a stiff tongue that cannot be protruded far. Fasciculation is absent.

Bulbar and pseudobulbar palsy
Bulbar palsy
This is a motor nerve to tongue muscles.

Bulbar palsy
This is LMN weakness of muscles whose cranial nerve nuclei lie in the medulla (the bulb). Paralysis of bulbar muscles is caused by disease of lower cranial nerve nuclei, lesions of IXth, Xth and XIth nerves (see Box 26.16), malfunction of their neuromuscular junctions (e.g. myasthenia gravis, botulism) or disease of muscles themselves (e.g. dystrophies).

Pseudobulbar palsy
Describes bilateral supranuclear (UMN) lesions of lower cranial nerves producing weakness of the tongue and pharyngeal muscles. This resembles, superficially, a bulbar palsy: hence pseudobulbar. Findings are a stiff, slow, spastic tongue (not wasted), dysarthria and dysphagia. Gag and palatal reflexes are preserved and the jaw jerk exaggerated. Emotional lability (inappropriate laughing or crying) often accompanies pseudobulbar palsy. Principal causes are:
• motor neurone disease, often both UMN and LMN lesions (i.e. elements of both pseudobulbar and bulbar palsy)
• cerebrovascular disease, typically following multiple infarcts
• neurodegenerative disorders such as progressive supranuclear palsy (see p. 861)
• severe traumatic brain injury
• MS, mainly as a late event.

Difficulty swallowing, dysarthria and drooling also develop in later stages of Parkinson’s disease.

**Dropped head syndrome**

As the name suggests, weakness of neck extensors causes neck flexion and inability to hold the head up. Seen mainly in the elderly, it is often due to isolated neck extensor myopathy of uncertain cause but may be a presenting feature of motor neurone disease, myasthenia or various myopathic disorders.

---

**MOTOR CONTROL SYSTEMS**

There are three systems, each of which interacts by feedback loops with the other two, with sensory input from the reticular formation:

- **The corticospinal (or pyramidal) system** enables purposive, skilled, intricate, strong and organized movements. Defective function is recognized by a distinct pattern of signs – loss of skilled voluntary movement, spasticity and reflex change – seen, for example, in a hemiparesis, hemiplegia or paralysis.

- **The extrapyramidal system** facilitates fast, fluid movements that the corticospinal system has generated. Defective function produces slowness (bradykinesia), stiffness (rigidity) and/or disorders of movement (rest tremor, chorea and other dyskinesias). One feature (e.g. stiffness, tremor or chorea) will often predominate.

- **The cerebellum** and its connections have a role coordinating smooth and learned movement, initiated by the pyramidal system, and in posture and balance control. Cerebellar disease leads to unsteady and jerky movements (ataxia), with characteristic limb signs of past-pointing, action tremor and incoordination, gait ataxia and/or truncal ataxia.

---

**Corticospinal (pyramidal) system**

The corticospinal tracts originate in neurones of the cortex and terminate at motor nuclei of cranial nerves and spinal cord anterior horn cells. The pathways of particular clinical significance (*Fig. 26.10*) congregate in the internal capsule and cross in the medulla (decussation of the pyramids), passing to the contralateral cord as the lateral corticospinal tracts. This is the pyramidal system, disease of which causes UMN lesions. ‘Pyramidal’ is simply a descriptive term that draws together anatomy and characteristic physical signs; it is used interchangeably with the term UMN.

A proportion of the corticospinal outflow is uncrossed (anterior corticospinal tracts). This is of no relevance in practice.

**Characteristics of pyramidal lesions**

Signs of an early pyramidal lesion may be minimal (*Box 26.17*). Weakness, spasticity or changes in reflexes can predominate, or be present in isolation.

**Pyramidal drift of an upper limb**

Normally, the outstretched upper limbs are held symmetrically, when the eyes are closed. With a pyramidal lesion, when both upper limbs are held outstretched, palms uppermost, the affected limb drifts downwards and pronates. This sign, with slowing of fast finger movements, is an early one, sometimes occurring before weakness and/or reflex changes become apparent.

**Weakness and loss of skilled movement**

A unilateral pyramidal lesion above the decussation in the medulla causes weakness of the opposite limbs. When acute and complete, this weakness will be immediate and total: a hemiplegia – for example, following an internal capsule infarct. With slowly progressive
lesions (e.g. a hemisphere glioma), a characteristic pattern of weakness emerges: a hemiparesis.

In the upper limb, flexors are stronger than extensors, whereas in the lower limb, extensors are stronger than flexors. In the upper arm, weaker movements are thus shoulder abduction and elbow extension; in the forearm and hand, wrist and finger extensors and abductors are weaker than their antagonists. In the lower limb, weaker movements are hip flexion, knee flexion, ankle dorsiflexion and eversion. There is also loss of skilled movement; fine finger and toe control diminishes. Wasting (except from disuse) is not a feature. When a UMN lesion is below the decussation of the pyramids – in the cervical cord, for example – hemiparesis is on the same side as the lesion; this is an unusual situation.

Changes in tone and tendon reflexes
An acute lesion of one pyramidal tract (e.g. internal capsule stroke) causes initially flaccid paralysis with loss of tendon reflexes. Increase in tone follows, usually within several days, due to loss of inhibitory effects of the corticospinal pathways and an increase in spinal reflex activity. This increase in tone (spasticity) is most easily detectable in stronger muscles. Spasticity is characterized by sudden changing resistance to rapid passive movement – the clasp-knife effect. Relevant tendon reflexes become exaggerated; clonus may emerge.

Changes in superficial reflexes
The normal flexor plantar response becomes extensor. In a severe acute lesion, this extensor response can be elicited from a wide area of the foot. As recovery progresses, the receptive area diminishes until the lateral posterior third of the sole remains receptive to an orange-stick stimulus (the appropriate instrument). An extensor plantar response is certain when great toe dorsiflexion is accompanied by abduction of adjacent toes. Abdominal reflexes are abolished on the affected side.

Patterns of UMN disorders
There are three main patterns:

- **Hemiparesis** means weakness of the limbs on one side; it is usually caused by a lesion in the brain and occasionally in the cord.
- **Paraparesis** means weakness of both lower limbs and is usually diagnostic of a cord lesion; bilateral medial brain lesions (e.g. parasagittal meningioma) occasionally cause paraparesis.
- **Tetraparesis** (also called quadriparesis) means weakness of four limbs.

Hemiplegia, paraplegia and tetraplegia (strictly) indicate total paralysis but are often used to describe severe weakness.

Hemiparesis
The level within the corticospinal system is recognized from particular features.

**Motor cortex.** Weakness and/or loss of skilled movement confined to one contralateral limb (an arm or a leg – monoparesis) or part of a limb (e.g. a clumsy hand) is typical of an isolated motor cortex lesion (e.g. an infarct or secondary neoplasm). A defect in cognitive function (e.g. aphasia) and focal epilepsy may occur.

**Internal capsule.** Corticospinal fibres are tightly packed in the internal capsule (about 1 cm²); thus a small lesion causes a large deficit. A middle cerebral artery branch infarction (see p. 840) produces a sudden, dense, contralateral hemiplegia.

**Pons.** A pontine lesion (e.g. an MS plaque) is rarely confined to the corticospinal tract. Adjacent structures, e.g. VIth and VIIth nuclei, MLF and PPRF (see p. 812) are involved. Diplopia, facial weakness, internuclear ophthalmoplegia (INO) and/or a lateral gaze palsy occur with contralateral hemiparesis.

**Spinal cord.** An isolated lesion of one lateral corticospinal tract (e.g. a cervical cord injury) causes an ipsilateral UMN lesion, the level being indicated by changes in reflexes (e.g. absent biceps, C5/6), features of a Brown–Séquard syndrome (see p. 865) and muscle wasting at the level of the lesion (p. 824).

Spastic paraparesis
Paraparesis indicates bilateral damage to corticospinal pathways, causing weakness and spasticity (or flaccid weakness in the initial phase of spinal shock after an acute cord insult). Cord compression (see p. 878) or cord diseases are the usual causes; cerebral lesions occasionally produce paraparesis. Paraparesis is a feature of many neurological conditions; finding the cause is crucial (see p. 879).

Extrapyramidal system
The extrapyramidal system is a general term for basal ganglia motor systems: that is, corpus striatum (caudate nucleus + globus pallidus + putamen), subthalamic nucleus, substantia nigra and parts of the thalamus. In basal ganglia/extrapyramidal disorders, two features (either or both) become apparent, in limbs and axial muscles:

- reduction in speed of movement (bradykinesia) or akinesia (no movement), with muscle rigidity
- involuntary hyperkinetic movements (tremor, chorea, dystonia, tics, myoclonus).

Extrapyramidal disorders are classified broadly into akinetorigid syndromes (see p. 861) where poverty of movement predominates, and hyperkinetic movement disorders where there are abnormal involuntary movements (see p. 862).

The most common extrapyramidal disorder is Parkinson’s disease.

Essential anatomy
The corpus striatum lies close to the substantia nigra, thalami and subthalamic nuclei, lateral to the internal capsule (Fig. 26.11; see Fig. 26.10).

Function and dysfunction
Overall function of this system is modulation of cortical motor activity by a series of loops between cortex and basal ganglia (see Fig. 26.11). In involuntary movement disorders, there are specific changes in neurotransmitters (Box 26.18) rather than focal lesions seen on imaging or at postmortem.

**Proposed model of principal pathways**

1. Direct pathway from striatum to medial globus pallidus (GPM) and substantia nigra pars reticulata (SNr). Inhibitory synapse F. GABA and substance P.
2. Indirect pathway from striatum to globus pallidus, via lateral globus pallidus (GPi; inhibitory synapse C, GABA, enkephalin) and subthalamic nucleus (inhibitory synapse D, GABA). Terminates in GPM–SNr (in excitatory synapse E, glutamate).
3. Direct pathways, both inhibitory and excitatory, from substantia nigra pars compacta (SNc) to striatum. Synapse A, dopamine, D₁, excitatory; and synapse B, D₂, inhibitory.
4. GPM and SNr to thalamus. Inhibitory synapse G, GABA.
5. Thalamus to cortex. Excitatory, synapse H.
The model helps explain how basal ganglia disease can either reduce excitatory thalamo-cortical activity at synapse H – that is, movement – causing bradykinesia, or increase it, causing hyperkinetic disorders.

**Parkinson’s disease (PD).** This is characterized by slowness, stiffness and rest tremor (see p. 859). Degeneration in SNc causes loss of dopamine activity in the striatum. Dopamine is excitatory for synapse A and inhibitory for synapse B. Through the direct pathway there is reduced activity at synapse F, leading to increased inhibitory output (G) and decreased cortical activity (H).

Also in PD, in the indirect pathway, dopamine deficiency results in disinhibition of neurones synapsing at C. This leads to reduced activity at D, and to increased activity of neurones in the subthalamic nucleus. There is excess stimulation at synapse E, enhancing further inhibitory output of GPm-SNr.

The net effect via both pathways is to inhibit the ventral anterior (VA) and ventrolateral (VL) nuclei of the thalamus at synapse G. Cortical (motor) activity at H is thus reduced.

Levodopa helps slowness and tremor in PD (see p. 860) but induces unwanted dyskinesias by increasing dopamine activity at synapses A and B; it is thought to do this by reversing sequences in both direct and indirect pathways.

**Hemiballismus** (see p. 862). Wild, flinging (ballistic) limb movements are caused by a lesion in the subthalamic nucleus, typically an infarct. This reduces excitatory activity at synapse E, reduces inhibition at G, with increased thalamo-cortical neuronal activity, and increases activity at H.

---

**Cerebellum**

The third system of motor control modulates coordination and learned movement patterns, rather than speed. Ataxia, i.e. unsteadiness, is characteristic.

The cerebellum receives afferents from:
- proprioceptive receptors (joints and muscles)
- vestibular nuclei
- basal ganglia
- the corticospinal system
- olivary nuclei.

Efferents pass from the cerebellum to:
- each red nucleus
- vestibular nuclei
- basal ganglia
- the corticospinal system.

Each lateral cerebellar lobe coordinates movement of the ipsilateral limbs. The vermis (a midline structure) is concerned with maintenance of axial (midline) posture and balance.

**Cerebellar lesions**

**Box 26.19** summarizes the main causes of cerebellar disease. Expanding lesions obstruct the aqueduct to cause hydrocephalus, with severe pressure headaches, vomiting and papilloedema. Coning of the cerebellar tonsils (see p. 875) through the foramen magnum leads to respiratory arrest, sometimes within minutes/hours. Rarely, tonic seizures (attacks of limb stiffness) occur.

**Lateral cerebellar hemisphere lesions**

A lesion within one cerebellar lobe (e.g. tumour or infarction) causes disruption of the normal sequence of movements (dyssynergia) on the same side.

**Posture and gait.** The outstretched arm is held still in the early stages of a cerebellar lobar lesion (cf. the drift of pyramidal lesions) but there is rebound upward overshoot when the limb is pressed downwards and released. Gait becomes broad and ataxic, faltering towards the side of the lesion.

**Tremor and ataxia.** Movement is imprecise in direction, force and distance (dysmetria). Rapid alternating movements (tapping, clapping or rotary hand movements) become disorganized (dysdiadochokinesia). Intention tremor (action tremor with past-pointing) is seen, but speed of fine movement is preserved (cf. extrapyramidal and pyramidal lesions).
**Nystagmus.** Coarse horizontal nystagmus (see p. 812) develops with a lateral cerebellar lobe lesion. The fast component is always towards the side of the lesion.

**Dysarthria.** Halting, jerking speech (scanning speech) develops.

**Other signs.** Titubation – rhythmic head tremor as either forward and back (yes–yes) movements or rotary (no–no) movements – can occur, mainly when cerebellar connections are involved (e.g. in essential tremor and MS; see p. 862). Hypotonia (floppy limbs) and depression of reflexes (with slow, pendular reflexes) are also sometimes seen.

**Midline cerebellar lesions**

Cerebellar vermis lesions have dramatic effects on trunk and axial muscles. There is difficulty standing and sitting unsupported (truncal ataxia), with a broad-based, ataxic gait. Lesions of the flocculonodular region cause vertigo and vomiting with gait ataxia if they extend to the roof of the IVth ventricle.

**Tremor**

Tremor means a regular and sinusoidal oscillation of the limbs, head or trunk.

**Postural tremor**

Everyone has a physiological tremor (often barely perceptible) of the outstretched hands at 8–12 Hz. This is increased with anxiety, caffeine, hyperthyroidism and drugs (e.g. sympathomimetics, sodium valproate, lamotrigine, lithium) and occurs in mercury poisoning. A higher-amplitude, postural tremor is seen in benign essential tremor (usually quite fast at 5–12 Hz).

**Intention tremor**

Tremor exacerbated by action, with past-pointing and accompanying incoordination of rapid alternating movement (dysdiadochokinesia), occurs in cerebellar lobe disease and with lesions of cerebellar connections. Titubation (head tremor) and nystagmus may be present.

**Rest tremor**

Seen typically in Parkinson’s disease, this tremor is noticeably worse at rest, usually 4–7 Hz (often pill-rolling, between thumb and forefinger). Unlike essential tremor, parkinsonian tremor is generally unilateral for the first few years.

**Other tremors**

Dystonic tremor occurs after the age of 50 and is a manifestation of dystonia that is often seen without dystonic posturing. It is generally unilateral (or asymmetric), affecting hand/arm or head, and worse with posture and certain tasks such as drinking, pouring liquids, or using cutlery or a pen. It is often mistaken for parkinsonian tremor. Holmes tremor (present at rest, action and posture) is seen following lesions of the red nucleus (e.g. infarction, multiple sclerosis).

**LOWER MOTOR NEURONE LESIONS**

The lower motor neurone (LMN) is the pathway from anterior horn cell (or cranial nerve nucleus) via a peripheral nerve to muscle motor end-plates. The motor unit consists of one anterior horn cell, its single fast-conducting axon that leaves the cord via the anterior root, and the group of muscle fibres (100–2000) supplied via the nerve. Anterior horn cell activity is modulated by impulses from:

- corticospinal tracts
- the extrapyramidal system
- the cerebellum
- afferents via posterior roots.

**Clinical features of lower motor neurone lesions**

These are seen in voluntary muscles that depend on an intact nerve supply for both contraction and metabolic integrity. Signs follow rapidly if the LMN is interrupted (Box 26.20).

**Aetiology**

Examples of LMN lesions at various levels include:

- cranial nerve nuclei (Bell’s palsy) and anterior horn cell (motor neurone disease)
- spinal root – radiculopathy, e.g. cervical and lumbar disc protrusion (see p. 892)
- peripheral (or cranial) nerve – trauma, entrapment (see p. 888) and polyneuropathy (p. 889).

**Spinal reflex arc**

Components are illustrated in Fig. 26.12. The stretch reflex is the physiological basis for all tendon reflexes. In the knee jerk, a tap on the patellar tendon activates stretch receptors in the quadriceps. Impulses in first-order sensory neurones pass directly to LMNs (L3 and L4) that contract quadriceps. Loss of a tendon reflex is caused by a lesion anywhere along the spinal reflex path. The reflex lost indicates its level (Box 26.21).

**Reinforcement.** Distraction of the patient’s attention, clenching teeth or pulling interlocked fingers enhances reflex activity.

SENSORY PATHWAYS AND PAIN

Peripheral nerves and spinal roots
Peripheral nerves carry all modalities of sensation from either free or specialized nerve endings to dorsal roots and thence to the cord. Sensory distribution of spinal roots (dermatomes) is shown in Fig. 26.13.

Spinal cord
Posterior columns
Axons in the posterior columns whose cell bodies are in the ipsilateral gracile and cuneate nuclei in the medulla carry sensory modalities of vibration, joint position (proprioception), light touch and two-point discrimination. Axons from second-order neurones then cross in the brainstem to form the medial lemniscus, passing to the thalamus (Fig. 26.14).

Spinothalamic tracts
Axons carrying pain and temperature sensation synapse in the dorsal horn of the cord, cross within the cord, and pass in the spinothalamic tracts to the thalamus and reticular formation.

Sensory cortex
Fibres from the thalamus pass to the parietal region sensory cortex (see Fig. 26.14). Connections exist between the thalamus, sensory cortex and motor cortex.

Lesions of the sensory pathways
Altered sensation, tingling (paraesthesia), clumsiness, numbness and pain are the principal symptoms of sensory lesions. The pattern and distribution point to the site of pathology (Fig. 26.15).

Peripheral nerve lesions
Symptoms are felt within the distribution of a peripheral nerve. Section of a sensory nerve is followed by complete sensory loss. Nerve entrapment (see p. 888) causes numbness, pain and tingling. Tapping the site of compression sometimes causes a sharp, electric shock-like pain in the distribution of the nerve, known as Tinel’s sign, such as in carpal tunnel syndrome (see p. 888).
Neuralgia

Neuralgia refers to pain, usually of great severity, in the distribution of a damaged nerve. Examples are:
- trigeminal neuralgia (see p. 852)
- postherpetic neuralgia (see p. 872)
- complex regional pain syndrome type II (causalgia) – chronic burning pain that occasionally follows peripheral nerve damage.

Spinal root lesions

Root pain

Pain of root compression is felt in the myotome supplied by the root, and there is also a tingling discomfort in the dermatome. The pain is worsened by manoeuvres that either stretch the root (e.g. straight-leg raising in lumbar disc prolapse) or increase pressure in the spinal subarachnoid space (coughing and straining). Cervical and lumbar disc protrusions (see p. 892) are common causes of root lesions.

Dorsal spinal root lesions

Section of a dorsal root causes loss of all modalities of sensation within a dermatome (see Fig. 26.13). However, overlap between adjacent dermatomes makes it difficult to detect anaesthesia when a single root is destroyed.

Spinal cord lesions

Posterior column lesions

These cause:
- tingling
- electric shock-like sensations
- clumsiness

- numbness
- tight band-like sensations.

These symptoms, though lateralized, are often felt vaguely without a clear sensory level. Position sense, vibration sense, light touch and two-point discrimination are diminished below the lesion. Position sense loss produces a stamping gait (sensory ataxia; see p. 804).

Lhermitte’s phenomenon

Electric shock-like sensations radiate down the trunk and limbs on neck flexion. This points to a cervical cord lesion. Lhermitte’s is common in acute exacerbations of MS (see p. 865), and also occurs in cervical myelopathy (p. 892), subacute combined degeneration of the cord (p. 891), radiation myelopathy (p. 893) and cord compression.

Spinothalamic tract lesions

Pure spinothalamic spinal lesions cause contralateral loss of pain and temperature sensation with a clear level below the lesion. This is called dissociated sensory loss – pain and temperature are dissociated from light touch, which remains preserved. This is seen typically in syringomyelia where a cavity occupies the central cord (see p. 879).

The spinal level is modified by lamination of fibres within the spinothalamic tracts. Fibres from lower spinal roots lie superficially and are damaged first by compressive lesions from outside the cord. As an external compressive lesion (e.g. a mid-thoracic extradural meningioma; Fig. 26.16) enlarges, the spinal sensory level ascends as deeper fibres become involved. Conversely, a central cord lesion (e.g. a syrinx; see p. 879) affects deeper fibres first. Spinothalamic tract lesions cause loss of pain and temperature perception (e.g. painless burns). Perforating ulcers and neuropathic (Charcot) joints develop.

Spinal cord compression

Cord compression (see Fig. 26.16) causes progressive spastic paraparesis (or tetraparesis/quadruparesis) with sensory loss below the level of compression. Sphincter disturbance is common. Root pain is frequent but not invariable, felt characteristically at the level of compression. With thoracic cord compression (e.g. an extradural meningioma), pain radiates around the chest and is exacerbated by coughing and straining, as meningeal root sheaths are stretched.

Damage to one spinothalamic tract (contralateral loss of pain and temperature) with the ipsilateral corticospinal tract is known as the Brown–Séquard syndrome (originally, cord hemisection). The patient complains of numbness on one side and weakness on the other. Paraparesis/spinal cord lesions are discussed on page 865.

Pontine lesions

Since lesions (e.g. an MS plaque) lie above the decussation of the posterior columns, and both medial lemniscus and spinothalamic tracts are close together, there is loss of all forms of sensation on the side opposite the lesion. Combinations of IIIrd, IVth, Vth and VIth cranial nerve nuclei are seen, and may indicate a level (see Fig. 26.14).

Thalamic lesions

Thalamic pain (also called central post-stroke pain or thalamic syndrome) follows a small thalamic infarct. The patient has a stroke (hemiparesis and sensory loss). Weakness improves but deep-seated constant pain in the parietic limbs develops. Choreo-athetotic movements occur. Secondary depression may lead to
self-harm. Thalamic lesions can also cause diminished sensation alone, on the opposite side; this is less usual.

Parietal cortex lesions
Sensory loss, neglect of one side, apraxia (see p. 804) and subtle disorders of sensation occur. Pain is not a feature of destructive cortical lesions. Irritative phenomena (e.g. focal sensory seizures from a parietal cortex glioma) cause tingling sensations in a limb or elsewhere.

Pain
Pain is an unpleasant, complex sensory and emotional experience. Acute pain serves a biological purpose (e.g. withdrawal) and is typically self-limiting, ceasing as healing ensues. Some forms of chronic pain (e.g. causalgia) outlast the period required for healing and may be permanent.

Essential physiology of pain
Pain perception is mediated by small-diameter myelinated A-delta and non-myelinated C fibres. Chemicals released following injury produce pain either by direct stimulation or by sensitization of nerve endings. A-delta fibres give rise to perception of sharp, immediate pain; slower-onset, more diffuse and prolonged pain is mediated by slower-conducting C fibres.

Noxious (pain) impulses enter the cord via dorsal spinal roots forming synapses in the spinal cord dorsal horn (substance P and glutamate neurotransmitters). Second-order neurones then decussate to the contralateral side and ascend in the spinal cord via two main pathways: the spinothalamic tract (for pain localization) and the spino-reticular tract (mediation of the emotional component of pain; Fig. 26.17). Both pathways project via synapses in the thalamus to the sensory cortex and limbic system. There are projections to brainstem structures: the reticular formation (spino-reticular tract) and periaqueductal grey matter (spinothalamic tract), which modulates pain transmission via descending
monoaminergic pathways to the spinal cord dorsal horn. The emotional and affective components of pain, mediated through cortical and limbic networks, are now recognized to be fundamental to pain perception.

**Gate theory of pain**

Gate theory proposes that transmission of afferent nociceptive (pain) impulses is regulated (‘gated’) in the spinal cord dorsal horn synapses by afferent impulses from non-nociceptive, large-diameter sensory fibres and descending pathways from the periaqueductal grey (PAG) and other brainstem structures. It explains the phenomenon of rubbing a painful area to ease the pain and is also the basis of transcutaneous electrical nerve stimulation (TENS) therapy. Similar gating and modulation of afferent pain signals occur in the brainstem under the influence of connections from the thalamus and limbic system.

**Peripheral and central sensitization**

Sensitization is an increase in the excitability of peripheral nociceptors and central pain pathways, causing normal sensory inputs such as light touch to produce abnormal responses: that is, pain (termed allodynia). For example, warm water in a shower feels painfully burning on sunburnt skin and touching the scalp is painful during a migraine. This is an adaptive protective response to ensure that contact with an injured area is minimized. However, maladaptive responses to pain via this mechanism at the central or peripheral level may be the basis for chronic pain when it becomes permanent and out of proportion to the initial painful stimulus.

**Plasticity and receptor changes**

Pain results in neural plasticity changes and reorganization in pain pathways at spinal cord and cortical/brainstem level. These modulate pain and may be maladaptive in some cases, leading to maintenance of chronic pain. Molecular changes also occur in response to painful stimuli, including upregulation of sodium channels and receptor changes.

**Neuropathic pain**

Pain results directly from damage to, or dysfunction of, the pain/sensory pathways, such as in peripheral nerve damage, radiculopathy, post-stroke pain and post-herpetic neuralgia (Box 26.22). It is common, affecting 6–8% of people. Clinically, the pain usually has an unpleasant burning, electrical or stabbing quality, with allodynia being a frequent feature. It often becomes chronic due to peripheral and central sensitization processes.

**Neurotransmitters and receptors involved in pain**

These are involved in pain processing, explaining why a wide range of drug classes are helpful in treating pain.

- **Excitatory neurotransmitters** include substance P, glutamate and calcitonin gene-related peptide (CGRP) in the dorsal horn of the spinal cord and peripherally.
- **Gamma-aminobutyric acid** (GABA) is a key inhibitory neurotransmitter.
- **Opioid receptors**, activated by endogenous endorphins or opiate medications, are widely distributed in pain pathways, including in the spinal cord, peri-aqueductal grey matter and other brainstem structures.
- **Noradrenaline** (norepinephrine) and 5-HT (serotonin) are distributed in descending regulatory pathways.
- **The vanilloid receptor** (TRPV1 – transient receptor potential cation channel VI) on peripheral nociceptors is activated by capsaicin, the active constituent of chilli peppers.

**Management of chronic pain**

Chronic pain is gravely disabling, distressing and difficult to treat (see p. 429). Multidisciplinary pain clinics provide the best setting for long-term management.

Management plans for intractable pain have a number of components.

**Diagnostic**

Rigorous attention must be paid to the diagnosis, reviewing the entire history and investigations. A specific surgical approach may become apparent (e.g. nerve root or peripheral nerve compression or trigeminal neuralgia).

**Psychological**

Chronic pain influences quality of life. Depression (see p. 776) is commonly associated with pain; antidepressants can help. Psychology-based pain management programmes and cognitive behavioural therapy are now a cornerstone of chronic pain management, helping people to control symptoms and the response to pain.

**Analgesics**

These include aspirin, paracetamol, non-steroidal anti-inflammatory drugs (NSAIDs) and opiates. Some opiates, such as tramadol and tapentadol, also have a monoamine reuptake inhibition mechanism of action. The World Health Organization (WHO) analgesic ladder (see p. 140) is useful.

**Co-analgesics**

Co-analgesics have a primary use other than for pain, and help when used alone or added to analgesics. They may have a synergistic effect when used in combination. Examples are:

- tricyclic antidepressants, e.g. amitriptyline
- duloxetine – a serotonin (5-HT)–noradrenaline (norepinephrine) reuptake blocker (SNRI)
- anticonvulsants, e.g. carbamazepine, gabapentin, pregabalin and lamotrigine (see Box 7.9)
calcium-channel blockers, e.g. ziconotide used intrathecally
muscle relaxants, e.g. baclofen
capsaicin topical preparations – extracts from capsicum plants (chilli peppers), which bind to vanilloid receptors (see above)
N-methyl-D-aspartate (NMDA) antagonists, e.g. ketamine
cannabinoids – administered via oral spray in MS and resistant cancer pain
botulinum toxin – licensed for chronic migraine; increasing evidence supports a role in modulating pain neurotransmitters.

Stimulation
Acupuncture, ice, heat, ultrasound, massage, TENS and spinal cord stimulation all achieve analgesia by gating effects on large myelinated nerve fibres.

Nerve blocks
Pain pathways can be blocked, either temporarily by local anaesthetic (by injection or with topical patches) or permanently with phenol or with radiofrequency lesions:
somatic blocks:
- peripheral nerve and plexus injections
- epidural and spinal analgesia
sympathetic blocks:
- sympathetic ganglia injections
- central epidural and spinal sympathetic blockade.

Neurosurgery
Highly specialized techniques have a place alongside drugs. Examples are dorsal rhizotomy, sympathectomy, cordotomy and neurostimulation.
Box 26.22 Causes of neuropathic pain

**Peripheral nerve injury**
- Peripheral neuropathy – especially if small (pain) fibres are affected, e.g. diabetes, AL amyloid, HIV, chemotherapy (e.g. carboplatin neuropathy), vitamin deficiency, alcohol, Fabry’s
- Vasculitic nerve lesions – e.g. diabetic femoral neuropathy (neuropathic amyotrophy)
- Nerve compression – carpal tunnel syndrome, meralgia paraesthetica
- Postherpetic neuralgia
- Nerve trauma or section – e.g. phantom limb pain
- Trigeminal neuralgia

**Nerve root and plexus**
- Radiculopathy due to intervertebral disc prolapse
- Plexopathy – e.g. inflammatory (brachial neuritis) or neoplastic infiltrative (e.g. breast cancer)

**Central nervous system disorders**
- Multiple sclerosis (pain is common in progressive forms)
- Post-stroke pain – e.g. thalamic strokes
- Spinal cord lesions – intrinsic cord lesions, inflammatory or vascular (infarcts) especially
- Parkinson’s disease

### BLADDER CONTROL AND SEXUAL DYSFUNCTION

Changes in micturition and failure of normal sexual activity due to neurological conditions are seen in sacral, spinal cord and cortical disease.

**Essential functions and anatomy**
The bladder has two functions: storage and voiding. Afferent pathways (T12–S4) respond to pressure within the bladder and sensation from the genitalia. As the bladder distends, continence is maintained by suppression of parasympathetic outflow and reciprocal activation of sympathetic outflow. Both are under some voluntary control. Voiding takes place by parasympathetic activation of the detrusor, and relaxation of the internal sphincter (Box 26.23).

Cortical awareness of bladder fullness is located in the post-central gyrus, parasagittally, while initiation of micturition is in the pre-central gyrus. Voluntary control of micturition is located in the frontal cortex, parasagittally.

**Neurological disorders of micturition**
Urogenital tract disease is dealt with largely by urologists. Incontinence is common and easy to recognize; neurological causes are sometimes not obvious. These are:

- **Cortical:** Post-central lesions cause loss of the sense of bladder fullness.
- Pre-central lesions cause difficulty in initiating micturition.
- Frontal lesions cause socially inappropriate micturition.

- **Spinal cord:** Bilateral UMN lesions (pyramidal tracts) cause urinary frequency and incontinence. The bladder is small and hypertonic: that is, sensitive to small changes in intravesical pressure. Frontal lesions can also cause a hypertonic bladder.

**LMN.** Sacral lesions (conus medullaris, sacral root and pelvic nerve – **bilateral**) cause a flaccid, atonic bladder that overflows (cauda equina; see p. 893), often unexpectedly.

**Management.** Assessment of both urological causes (e.g. calculi, prostatism, gynaecological problems) and potential neurological causes of incontinence is necessary. Intermittent self-catheterization is used by many patients who have, for example, spinal cord lesions.

**Male erectile dysfunction**
Failure of penile erection often has mixed organic and psychological causes. Depression is common. Erectile dysfunction is described on page 1485.

### INVESTIGATION OF NEUROLOGICAL DISEASE

Neurological investigations, such as brain scans, should not be a substitute for clinical evaluation through history-taking and examination. An experienced clinician will be able to make an accurate diagnosis in most patients without recourse to investigations: for example, in most individuals presenting with headache. However, cross-sectional imaging will allow confirmation of the anatomical localization of lesions and may reveal the presence of other clinically ‘silent’ lesions. Imaging does not always indicate the pathological nature of a visualized lesion (careful history-taking is essential in this regard) and therefore needs to be carefully interpreted in the clinical context. Neurophysiological investigations provide information about nervous system function and are more diagnostically helpful than imaging in some situations: for example, in patients with primary generalized epilepsies or peripheral nerve disorders.

Unnecessary or inappropriate use of investigations, particularly brain imaging, exposes patients to risk, such as radiation; is an inefficient use of resources; and may lead to identification of incidental findings that cause considerable anxiety (there is a 3% incidental abnormality rate for brain MRI scans). Clinicians should also be familiar with the range of normal in the population; for example, the high prevalence of white-matter hyperintensities on brain MRI in older people and the range of common non-specific electroencephalogram (EEG) changes.

**Skull and spinal X-rays**
**Skull X-rays** have now been largely superseded by computed tomography (CT) and MRI. They show fractures, bone metastases, osteomyelitis, Paget’s disease, sinus disease and intracranial calcification.

**Spinal X-rays** show fractures, congenital and destructive lesions (bone cysts, infection, metastases), and degenerative spondylosis.
Brain computed tomography

In brain CT, an X-ray beam and detectors revolve rapidly as the patient is moved slowly through the scanner, producing a spiral set of "slices". The digital data are converted to cross-sectional images. Differences in attenuation (density, expressed as Hounsfield units) between different tissues allow accurate recognition of, for example, fresh blood, bone or calcification (Fig. 26.18). Enhancement with intravenous iodinated contrast delineates areas of vascular leak, such as with tumours and inflammation (Box 26.24).

CT angiography

Spiral CT after intravenous injection of contrast produces high-quality arterial angiograms (or venograms), which are now considered the gold standard for non-invasive angiography.

Spinal CT and CT myelography

Spinal CT is useful for assessing the bone architecture of the spine but provides little information about soft tissues, such as nerve roots, and for this purpose spinal cord MRI is required. CT myelography (spinal CT after intrathecal injection of contrast) is used for identification of spinal fluid leaks/blockage or for situations where MRI is contraindicated.

Magnetic resonance imaging

A hydrogen nucleus is a proton whose electrical charge creates a local electrical field. In MRI, protons are aligned by sudden, strong magnetic impulses and then imaged with radiofrequency waves at right angles to their alignment. The protons resonate and spin, then revert to their normal alignment. As they do so, images are made at different phases of relaxation, known as T₁, T₂, T₂ STIR, FLAIR, diffusion-weighted imaging (DWI) and other sequences. The combination of these sequences increases the diagnostic sensitivity and specificity of MRI. Gadolinium is used as intravenous contrast to show areas of increased vascularity.

The superior spatial resolution and soft tissue contrast of MRI, as compared to CT, makes MRI of the brain and spine generally preferable in the non-emergency situation. It can image pathology not easily visualized on CT, such as small lesions, white-matter disease such as MS plaques and spinal cord lesions or compression, and demonstrate anatomy more accurately.

Doppler studies

Ultrasound is a safe, low-cost and rapid method for detecting and quantifying carotid stenosis and assessing carotid plaque burden. It is operator-dependent and less reproducible than other imaging modalities.

Catheter angiography

Contrast is injected intra-arterially in selected vessels via a catheter inserted in the femoral artery. Angiography carries a mortality and stroke risk (<1%). Images of aorta, carotid, vertebral and brain arteries demonstrate occlusion, stenoses, aneurysms and arteriovenous...
malformations (AVMs). Spinal angiography is complex and is used to identify spinal AVMs and dural fistulas. Aneurysms and AVMs may be treated by endovascular means (embolization with glue or platinum coils) during the procedure.

**Positron emission tomography, single proton emission computed tomography, dopamine transporter imaging and functional MRI**

These functional imaging techniques track uptake of radio-isotopes and/or metabolites. Fluorodeoxyglucose positron emission tomography (FDG-PET) is used principally to detect occult neoplasms or tumour recurrence, outside the central nervous system (CNS), or to identify large-vessel vasculitis. Dopamine transporter imaging (DAT) is used to identify reduced nigrostriatal dopaminergic terminals in parkinsonian disorders, mainly in patients with atypical tremor where the clinical diagnosis is uncertain. Functional MRI (fMRI) is largely a research tool for mapping brain function, in health and disease. New techniques using radionuclide tracers to image brain amyloid deposits in Alzheimer’s disease are currently available in the research domain and limited clinical centres.

**Isotope bone scanning**

The radio-isotope $^{99m}$Tc-pertechnetate is given intravenously. The technique is used principally in detection of vertebral, skull and bone metastases.

---

**Neurophysiological investigations**

**Electroencephalography**

Brain electrical activity (Fig. 26.19) is recorded from scalp electrodes (20 channels simultaneously). Its main use is to characterize epilepsy syndromes. Recordings are usually made between seizures (inter-ictal). Sleep-deprived EEG and 24-hour ambulatory EEG increase diagnostic sensitivity. Videotelemetry (VT) combines continuous EEG with video over several days to record the semiology and electrical characteristics of seizures. VT is invaluable diagnostically to identify seizure type where there is clinical uncertainty, and to pinpoint the seizure focus in focal epilepsies.

**Epilepsy**

Spikes, or spike-and-wave abnormalities, are hallmarks of epilepsy, but it is important to emphasize that patients with epilepsy often have a normal EEG between seizures (see p. 855).

**Diffuse brain disorders**

Slow-wave EEG abnormalities appear in encephalopathy (e.g. hepatic coma), encephalitis and prion (Creutzfeldt–Jakob) diseases.

**Brain death**

The EEG is isoelectric (flat); EEG is not necessary to confirm brain death in many countries (see p. 833).

**Electromyography and nerve conduction studies**

Electromyography (EMG) and nerve conduction studies (NCS) are skilled investigations of nerve function that are essential for investigation of peripheral nerve, anterior horn cell, neuromuscular junction (NMJ) and, to a lesser extent, muscle disorders. NCS are highly sensitive in identification of peripheral neuropathy, and assessment of the nerves affected and the type of pathology (axonal loss versus demyelinating). In mononeuropathies, the anatomical site of the lesion may be identified with considerable accuracy and prognostic information obtained.

**Electromyography**

A concentric needle electrode is inserted into voluntary muscle. Amplified recordings, on an oscilloscope, are also heard through a speaker. The main EMG features include:

- normal interference pattern
- denervation and re-innervation changes
- myopathic and myotonic features (see p. 893).

Single-fibre EMG is used for disorders of NMJ transmission.

**Peripheral nerve conduction**

Electrical stimulation of a peripheral nerve generates a nerve impulse that may be recorded (Fig. 26.20). Four measurements are of principal value in neuropathies and nerve entrapment:

- nerve conduction velocity
- distal motor latency
sensory action potentials (SAPs)
• compound muscle action potentials (CMAPs).

Small action potential size (SAP and CMAP) indicates loss of axons. Conduction block and slowing of conduction velocity indicate demyelinating neuropathy, as saltatory conduction is lost with damage to the myelin sheath. Repetitive nerve stimulation is used to identify NMJ conduction disorders (myasthenia).

Cerebral-evoked potentials
Visual-evoked potentials (VEPs) record the interval visual stimuli take to reach the occipital cortex, and the amplitude of response. VEPs are used to confirm previous optic neuritis (see p. 810); this leaves a delayed latency despite clinical recovery.

Similar techniques for auditory and somatosensory potentials (from a limb) are also used.

Lumbar puncture and cerebrospinal fluid examination
See Boxes 26.25 and 26.26. Indications for lumbar puncture (LP) include:
• diagnosis of meningitis and encephalitis
• diagnosis of subarachnoid haemorrhage (in a patient with a normal CT)
• measurement of CSF pressure, e.g. idiopathic intracranial hypertension (see p. 851)
• removal of CSF therapeutically, e.g. idiopathic intracranial hypertension
• diagnosis of various conditions, e.g. MS, neurosyphilis, sarcoidosis, Behçet’s, malignant meningitis, polyneuropathies
• intrathecal injection/drugs.

In suspected CNS infection, close liaison between clinician and microbiologist is essential. Specific techniques (e.g. polymerase chain reaction to identify specific pathogens) are invaluable.

CSF, cerebrospinal fluid.

Box 26.26 Lumbar puncture

Explain the procedure to the patient and obtain consent. See list of contraindications and cautions below.

Technique
• Place the patient on the edge of the bed in the left lateral position, with knees and chin as close together as possible
• Mark the third and fourth lumbar spinous processes. The fourth lumbar spine usually lies on a line joining the iliac crests
• Using sterile precautions, inject 2% lidocaine into the dermis by raising a bleb in either the third or fourth lumbar interspace
• Push the LP needle through the skin in the midline, steadily forwards and slightly towards the head, with the head and spine bolstered horizontally with pillows
• When you feel the needle penetrate the dura, withdraw the stylet and allow a few drops of CSF to escape
• You can then measure CSF pressure with a manometer connected to the needle. The patient’s head must be on the same level as the sacrum. Normal CSF pressure is 60–150 mm of CSF. The level rises and falls with respiration and heartbeat, and rises on coughing
• Collect CSF specimens in three sterile bottles and take a sample for CSF glucose, together with a simultaneous blood glucose sample
• Record CSF naked-eye appearance: clear, cloudy, yellow (xanthochromic) or red
• Ask the patient to lie flat after the procedure to avoid subsequent headaches; this manoeuvre is probably of little value, however
• Analgesics may be required for post-LP headaches

Contraindications
• Suspicion of a mass lesion in the brain or cord. Caudal herniation of the cerebellar tonsils (coning) may occur if an intracranial mass is present and the pressure below is reduced by removal of CSF
• Any cause of raised intracranial pressure
• Local infection near the LP site
• Congenital lesions in the lumbosacral region (e.g. meningo(myelo)cele)
• Platelet count <40 x 10⁹/L and other clotting abnormalities, including anticoagulant drugs
• Unconscious patients and those with papilloedema must have a CT scan before LP

Notes
• Contraindications are relative; there are circumstances when LP is carried out despite them, for instance in the treatment of idiopathic intracranial hypertension
• Composition of normal CSF is shown in Box 26.25

Repeated CSF examination is often necessary in chronic infection such as tuberculosis. Post-LP headaches, worse on standing, are a common complaint for several days (or more). Prolonged headaches can be treated with caffeine or by an ‘autologous intrathecal blood patch’: injection of 20 mL of the patient’s venous blood into the lumbar epidural space.
Biopsy
Interpretation of brain, tonsillar, muscle and nerve histology requires specialist neuropathology services.

Brain and meninges
Brain biopsy (e.g. of a non-dominant frontal lobe) is rarely used to diagnose inflammatory and degenerative brain diseases. CT and MR stereotactic biopsies of intracranial lesions are standard procedures.

Muscle
Muscle biopsy (usually quadriceps), with light/electron microscopy and immunohistochemical analysis, is performed routinely for diagnosis of inflammatory, metabolic and dystrophic disorders (see p. 894).

Peripheral nerve
Nerve biopsy, usually of the (sensory) sural nerve or superficial sensory branch of the radial nerve, can be of value in the diagnosis of peripheral neuropathy: for example, if vasculitis, amyloid deposition or malignant infiltration is suspected. There may be significant complications (wound healing and pain), so it should be undertaken only where all other investigations are non-diagnostic and where there is clinical evidence of a severe or progressive neuropathy.

Psychometric assessment
Psychometric testing, performed by neuropsychologists, assesses cognitive function in more detail than bedside testing during clinical examination. Decline in intellectual function, as compared with estimated pre-morbid IQ, is seen following brain injury or in dementia, for example. Individual cognitive domains, such as various types of memory, language, visuospatial function and frontal executive function, are tested separately, as they may be differentially involved in different disorders, the pattern of involvement often being of considerable diagnostic value. Serial testing at intervals of 6–12 months may be needed to show clear evidence of progression in neurodegenerative disorders such as dementias.

Routine tests
Standard blood tests, such as full blood count, erythrocyte sedimentation rate (ESR), biochemistry, glucose/HbA1c, C-reactive protein, creatine kinase and protein electrophoresis, are helpful to identify underlying disorders such as diabetes, metabolic disorders and other systemic disorders that may underlie neurological presentations (e.g. coma or peripheral neuropathy). Relevant tests are covered in disease-specific sub-sections.

Specialized tests in specific diseases
An increasing number of highly specialized tests are employed to diagnose individual (sometimes rare) diseases (Box 26.27).

Genetic tests
Several hundred neurogenetic disorders are now recognized and, for many of these, specific molecular genetic investigations are available for diagnostic and predictive testing (see p. 886). As genetic testing is complex and expensive, it should only be undertaken after senior specialist advice. Testing of panels of disease genes (e.g. for dementias or muscular dystrophies) is now available. Informed patient consent is required, as a positive test may have implications for other family members. Predictive testing in non-affected, at-risk individuals should only be undertaken after detailed genetic counselling by a specialist.

Immunological tests
An increasing number of autoimmune neurological disorders are recognized, many of which are associated with specific antibody tests (see Box 26.27). Many of these are paraneoplastic syndromes but an increasing number of non-cancer-related autoimmune syndromes have been identified, such as forms of encephalitis or myasthenia gravis. In addition, monoclonal paraproteins associated with plasma cell dyscrasias may cause immune-mediated peripheral neuropathy.

UNCONSCIOUSNESS AND COMA

Consciousness is dependent on the functioning of two separate anatomical and physiological systems:

- The ascending reticular activating system (ARAS), projecting from brainstem to thalamus. This determines arousal (the level of consciousness).
- The cerebral cortex, which determines the content of consciousness. Impaired functioning of either anatomical system may cause coma.

Disturbed consciousness: definitions

- **Coma**: a state of unrousalable unresponsiveness. Level of consciousness represents a continuum between being alert and deeply comatose. It may be quantified using the Glasgow Coma Scale (GCS) with a score between 3 and 15 (Box 26.28). Coma may be conveniently defined as a GCS score of 8 or lower. Terms such as stupor and obtundation have been superseded by the GCS score and are no longer used.

- **Delirium**: a confusional state in which reduced attention is a cardinal feature, usually with altered behaviour, cognition, orientation and a fluctuating level of consciousness (from agitation to hypoarousal; see p. 796).

Mechanisms and causes of coma

Altered consciousness is produced by four mechanisms affecting the ARAS in the brainstem or thalamus, and/or widespread impairment of cortical function (Box 26.29 and Fig. 26.21).

- **Brainstem lesion**. A discrete brainstem or thalamic lesion, e.g. stroke, may damage the ARAS.

- **Brainstem compression**. A supratentorial mass lesion within the brain compresses the brainstem, inhibiting the ARAS, e.g. ‘coning’ from a brain tumour or haemorrhage. Mass lesions within the posterior fossa are particularly prone to causing brainstem compression and hydrocephalus.

- **Diffuse brain dysfunction**. Generalized severe metabolic or toxic disorders (e.g. alcohol, sedatives, uraemia, hypercapnia) depress cortical and ARAS function.

- **Massive cortical damage**. Unlike brainstem lesions, extensive damage of the cerebral cortex and cortical connections is required to cause coma, e.g. meningitis or hypoxic–ischaemic damage after cardiac arrest (Fig. 26.22).

A single focal hemisphere (or cerebellar) lesion does not produce coma, unless it compresses the brainstem. Cerebral oedema frequently surrounds masses, increasing their pressure effects.

- Metabolic acidosis
- Hyperthermia, hyperpyrexia
- Seizures – post-ictal state and non-convulsive status
- Metabolic rarities, e.g. porphyria
- Extensive cortical damage
- Hypoxic–ischaemic brain injury, e.g. cardiac arrest
- Encephalitis, meningitis, cerebral malaria
- Subarachnoid haemorrhage

**Direct effect within brainstem**
- Brainstem haemorrhage, infarction or demyelination
- Brainstem neoplasm, e.g. glioma
- Wernicke–Korsakoff’s syndrome

**Pressure effect on brainstem**
- Tumour, massive hemisphere infarction with oedema, haematoma, abscess
- Cerebellar mass

**Fig. 26.21 Anatomy of vegetative state, locked-in syndrome and brainstem death. (Adapted from Bates D. Coma and brainstem death. Medicine 2004; 32.)**

The most common causes of coma are:
- metabolic disorders – 35%
- drugs and toxins – 25%
- mass lesions – 20%
- other – including trauma, stroke and CNS infections.
The unconscious patient

Immediate assessment and management

- Check the airway, breathing, circulation, disability and exposure/examination.
- Use a point of care testing device to measure blood glucose; if the patient is hypoglycaemic, give glucose (25 mL 50%).
- Treat seizures with buccal midazolam; if not terminated, use intravenous phenytoin.
- If there is fever and meningism, give intravenous antibiotics.
- Give intravenous naloxone or flumazenil (for overdose) and thiamine (in Wernicke's encephalopathy) in people who use excess alcohol.

**Obtain as much history as possible.** A limited history is one of the problems in assessing the unconscious patient. What were the circumstances? Ask paramedics, police and witnesses. Contact the patient’s relatives, friends and GP, and obtain past hospital notes. Look for drug details/bottles and identification data.

General and neurological examination

General examination

(See Fig. 26.23.)

- Measure the patient’s temperature (with a low-reading rectal thermometer if hypothermic). Check for meningism.
- Sniff the patient’s breath for ketones, alcohol and hepatic fetor.
- Survey the skin for signs of trauma or spinal injury, rash (meningococcal sepsis), jaundice or stigmata of chronic liver disease, cyanosis and injection marks.
- Assess the respiratory pattern, e.g. Cheyne–Stokes (alternating hyperpnoea and periods of apnoea indicating bilateral cerebral or upper brainstem dysfunction) or Kussmaul respirations (deep, sighing hyperventilation seen in diabetic ketoacidosis and uraemia).

Neurological examination

Neurological examination aims to determine:

- depth of coma (GCS)
- brainstem function
- lateralization of pathology.

Depth of coma

**GCS.** Assessment of the GCS score is repeated regularly to determine whether the patient’s level of consciousness is progressively declining. Use a painful stimulus (e.g. nail-bed pressure) to each limb and central area (sternal rub or pressure over the supraorbital nerve), and record the best response. Shout commands.

**Fundi.** Look for papilloedema and subhyaloid retinal haemorrhage (seen in subarachnoid haemorrhage).

Brainstem function

**Pupils**

Record their size and reaction to light (Fig. 26.24):

- **Dilation of one pupil** that then becomes fixed to light indicates compression of the IIIrd nerve. This may indicate a potential neurosurgical emergency (Fig. 26.25).
- **Bilateral mid-point reactive pupils** (i.e. normal pupils) are characteristic of metabolic comas and secondary coma due to sedative drugs (except opiates).
Bilateral light-fixed, dilated pupils are one cardinal sign of brain death. They can occur in deep coma of any cause, but particularly in barbiturate intoxication and hypothermia.

Bilateral pinpoint, light-fixed pupils occur with pontine lesions (e.g. haemorrhage) and with opiates. Mydriatic drugs and previous pupillary surgery can cause diagnostic difficulty.

Eye movements and position
- Disconjugate eyes (divergent ocular axes) indicate a brainstem lesion, e.g. skew deviation (one eye up, one eye down; Fig. 26.26).
- Conjugate gaze deviation means the eyes deviate towards the lesion in the frontal lobe and the normal limbs (unopposed activity of the intact frontal eye fields drives eyes to the opposite side); and away from the lesion in the brainstem and towards the weak limbs (the PPRF in the pons controls lateral gaze to the ipsilateral side; see p. 812) (Fig. 26.27).
- Vestibulo-ocular reflex means that passive head-turning produces conjugate ocular deviation away from the direction of rotation (doll’s eye reflex). This reflex disappears in deep coma, brainstem lesions and brain death (Fig. 26.28).

Other brainstem reflexes
- Corneal reflex.
- Gag/cough reflex (via endotracheal tube if intubated).
- Respiratory drive (see p. 932).

Lateralizing signs
Coma makes it difficult to recognize lateralizing signs. These are helpful:
- Asymmetry of response to visual threat in a stuporose patient: suggests hemianopia.
- Asymmetry of face: drooping or dribbling on one side; blowing in and out of mouth when the paralysed cheek does not move.
Unconsciousness and coma

- **Asymmetry of tone**: unilateral flaccidity or spasticity – may be the only sign of hemiparesis.
- **Asymmetry of decerebrate and decorticate posturing**.
- **Asymmetrical response** to painful stimuli.
- **Asymmetry of tendon reflexes and plantar responses**: both plantars are often extensor in deep coma.

**Coma ‘look-alikes’**

- Psychogenic coma.
- ‘Locked-in’ syndrome – complete paralysis, except for vertical eye movements/blinking in ventral pontine infarction. Patients have a functioning cerebral cortex and are fully aware but unable to communicate, except through eye movements (Box 26.30).
- Severe paralysis, e.g. myasthenic crisis or severe Guillain–Barré syndrome.

**Diagnosis and investigations in coma**

Often the cause is evident (e.g. head injury, metabolic disorder, overdose). Where lateralizing signs or brainstem pathology are found on examination, a mass lesion or infarction/haemorrhage is likely (note that hypoglycaemia may also cause focal signs). If no cause is obvious after clinical assessment, further investigations are essential.

**Blood and urine**

- **Drug screen** – blood alcohol and salicylates, urine toxicology including screening for benzodiazepines, narcotics, amphetamine.
- **Biochemistry** – urea, electrolytes, glucose, calcium, liver biochemistry.
- **Metabolic and endocrine studies** – thyroid stimulating hormone, cortisol.
- **Arterial blood gases** – for acidosis or high CO₂ levels.
- **Other** – e.g. cerebral malaria (request thick blood film; see p. 563) and porphyria (p. 755).

**Brain imaging**

CT brain imaging is the most readily available and safest modality in the unconscious patient (MRI is useful where CT is normal but presents greater monitoring challenges in the unconscious patient). CT is quick and effective in demonstrating all types of brain haemorrhage and most mass lesions; infarcts may be missed in the early stages and where only the brainstem is affected.

**CSF examination**

LP should be performed in coma only after careful risk assessment. It is contraindicated when an intracranial mass lesion is a possibility; CT is essential to exclude this. CSF examination is likely to alter therapy only if undiagnosed meningoencephalitis or other infection is present, or in subarachnoid haemorrhage where CT may give a false-negative result, particularly after 24 hours.

</tbody>
</table>

EEG = electroencephalography; MCS = minimally conscious state; PET = positron emission tomography; VS = vegetative state.

**Electroencephalography**

EEG is of some value in the diagnosis of metabolic coma, encephalitis and non-convulsive status epilepticus.

**General management**

Comatose patients need careful nursing, meticulous attention to the airway, and frequent monitoring of vital functions.

Longer-term essentials are:

- skin care – turning (to avoid pressure ulcers and pressure palsies)
- oral hygiene – mouthwashes, suction
- eye care – prevention of corneal damage (lid taping, irrigation)
- fluids – nasogastric or intravenous
- feeding – via a fine-bore nasogastric tube or via PEG
- sphincters – catheterization when essential (use a penile urinary sheath if possible in men); rectal evacuation.

**Prognosis in coma and the vegetative state**

Prognosis depends on the cause of coma and the extent of brain damage sustained. Metabolic and toxic causes of coma have the best prognosis when the underlying problem can be corrected. Following hypoxic–ischaemic brain injury, such as after cardiac arrest, only 11% make a good recovery; after stroke, the prognosis is worse still, with only 7% recovering. Of those patients who do not recover consciousness, a substantial proportion will remain in a vegetative or minimally responsive state.

- **Vegetative state (VS)** is usually a consequence of extensive cortical damage. Brainstem function is intact and so breathing is normal without the need for mechanical ventilation, and the patient appears awake with eye-opening and sleep–wake cycles. However, there is no sign of awareness or response to environmental stimuli, except reflex movements. Feeding is via gastrosomy. Patients may remain in this state for years. It is considered permanent (PVS) if there is no recovery after 12 months where trauma is the cause, and after 6 months for all other causes. Prolonged support of patients after this time presents a number of ethical issues; families may apply to the courts for withdrawal of feeding in PVS.

- **Minimally conscious state (MCS)** describes patients with some, often fluctuating, limited awareness, with inconsistent but reproducible responses, e.g. movements in response to voice; crying or laughing in response to emotional stimuli; and vocalization in response to questions. A patient may emerge from VS into MCS. Distinguishing VS from MCS requires careful specialist assessment over a long period. Functional brain imaging has recently been used for this purpose.

- **Brainstem death** is discussed on page 236. Distinction between these states is essential before addressing issues of prognosis and cessation of supportive care.

**Further reading**

**STROKE**

Stroke is the third most common cause of death in high-income countries (11% of all deaths in the UK) and the leading cause of adult disability worldwide. Approximately two-thirds of the global burden of stroke is in middle- and low-income countries. Stroke rates are higher in Asian and black African populations than in Caucasians. Stroke risk increases with age but one-quarter of all strokes occur before the age of 65. The death rate following stroke is 20–25%, and 40% of surviving patients are dependent at 6 months.

**Definitions**

- **Stroke.** To the public, stroke means weakness, usually permanent on one side, often with loss of speech. Stroke is *defined* as a syndrome of rapid onset neurological deficit caused by focal cerebral, spinal or retinal infarction or haemorrhage. Tissue injury is confirmed by neuroimaging. Hemiplegia following middle cerebral artery thromboembolism is the typical example.

- **Transient ischaemic attack (TIA)** means a brief episode of neurological dysfunction due to temporary focal cerebral or retinal ischaemia without infarction, e.g. a weak limb, aphasia or loss of vision, usually lasting seconds or minutes with complete recovery. TIAs may herald a stroke. The arbitrary time of less than 24 hours is no longer used.

**Pathophysiology**

The underlying pathology responsible for stroke is either infarction or haemorrhage. Stroke mechanism and pathophysiology depend on the population studied but are broadly as follows (Fig. 26.30):

- ischaemic stroke/infarction (85%)
  - thrombotic
  - large-artery stenosis
  - small-vessel disease
  - cardio-embolic
  - hypoperfusion

**Fig. 26.30 Pathophysiology of ischaemic stroke.** ICA, internal carotid artery; MCA, middle cerebral artery; PFO, patent foramen ovale.
Ischaemic stroke
Arterial disease and atherosclerosis are the main pathological processes causing stroke. Arterial branch points, such as the origin of the great vessels arising from the aorta, the proximal internal carotid artery and its distal intracranial branches, are particularly affected (Fig. 26.31). Non-Caucasian populations tend to have more intracranial narrowing and white populations more extracranial disease (which is strongly correlated with co-morbid coronary artery and peripheral vascular disease).

Thrombosis. Thrombosis at the site of ruptured mural plaque leads to artery-to-artery embolism or vessel occlusion.

Large-artery stenosis. This usually causes stroke by acting as an embolic source rather than by occluding the vessel (which may not in itself cause stroke if it occurs gradually and collateral circulation is adequate).

Small-vessel disease. Small penetrating arterial branches supply the deep brain parenchyma and are affected by a different pathological process: an occlusive vasculopathy – lipohyalinosis – that is a consequence of hypertension. This leads to small infarcts called ‘lacunes’ and/or gradual accumulation of diffuse ischaemic change in deep white matter.

Cardio-embolic stroke. The heart is a common source of embolic material. Atrial fibrillation (and other arrhythmias) leading to thrombosis in a dilated left atrium is the most common cause. Cardiac valve disease, including congenital valve disorders, infective endocarditis, polycythaemia and rheumatic disorders, may cause embolization. Mural thrombosis may occur in a damaged or akinetic segment of the ventricle. A patent foramen ovale (PFO), which is a common variant, may occasionally allow passage of fragments of thrombus (e.g. from a lower limb deep vein thrombosis) from the right atrium to the left when Valsalva causes shunting of blood across the PFO. Pulmonary arteriovenous fistulas may also act as a conduit for paradoxical embolization. Rarer causes include fat emboli after long bone fracture, atrial myxomas and iatrogenic causes, such as cardiac bypass and air embolism. Simultaneous infarcts in different vascular territories are very suggestive of a proximal source of emboli in the heart or aorta.

Hypoperfusion. Severe hypotension, such as in cardiac arrest, may lead to border-zone infarction in the watershed areas between vascular territories, particularly if there is severe stenosis of proximal carotid vessels. The parieto-occipital area between the middle and posterior cerebral artery territories is particularly vulnerable.

Carotid and vertebral artery dissection
Dissection accounts for around 1 in 5 strokes below the age of 40 and is sometimes a sequel of trivial neck trauma or hyperextension; for example, after whiplash, osteopathic manipulation, hairwashing in a salon or exercise. Subtle collagen disorders, such as partial forms of Marfan’s syndrome, may be a predisposing factor.

Most dissections are in large extracranial neck vessels. Blood penetrates the subintimal vessel wall, forming a false lumen, but it is thrombosis within the true lumen due to tissue thromboplastin release that leads to embolization from the site of dissection and stroke, sometimes days after the initial event.

Pain in the neck or face is often the clue leading to diagnosis. Horner’s syndrome or lower cranial nerve palsies may occur with carotid dissection, as these structures are intimately associated with the carotid artery in the neck.

Venous stroke
Only 1% of strokes are venous. Thrombosis within intracranial venous sinuses, such as the superior sagittal sinus, or in cortical veins, may occur in pregnancy, hypercoagulable states and thrombotic disorders, or with dehydration or malignancy. Cortical infarction, seizures and raised intracranial pressure result.

Haemorrhagic stroke
See page 846.

Transient ischaemic attacks
TIAs are usually the result of microemboli but different mechanisms produce similar clinical events. For example, TIAs may be caused by a fall in cerebral perfusion (e.g. a cardiac dysrhythmia, postural hypotension or decreased flow through atheromatous arteries). Infarction is usually averted by autoregulation. Rarely, tumours and subdural haematomas cause episodes that are indistinguishable from thromboembolic TIAs. Principal sources of emboli to the brain are cardiac thrombus and atheromatous plaques/thrombus within the aortic arch and carotid and vertebral systems. Cardiac thrombus often results from atrial fibrillation (which can be paroxysmal) or myocardial infarction. Cardiac valve disease may be a source of emboli: for example, calcific material or vegetations in infective endocarditis. Polycythaemia is also a cause.

Risk factors for stroke
The principal risk factors are those for atherosclerosis: age, smoking, dyslipidaemia, diabetes, obesity, inactivity and genetic/ethnic factors.

++, major correlation with reduced stroke risk; +, moderate correlation; SAH, subarachnoid haemorrhage.

Hypertension is overall the most modifiable stroke risk factor in the population; stroke is decreasing in the 40–60 age group partly because hypertension is now more effectively identified and treated (Box 26.31). There is a linear relationship between blood pressure and stroke risk (see Fig. 31.3).

On an individual rather than population basis, anticoagulation for atrial fibrillation is the intervention resulting in the greatest stroke risk reduction.

Other risk factors and rarer causes of stroke

- Thrombocythaemia, polycythaemia and hyperviscosity states – thrombophilia (e.g. protein C deficiency, factor V Leiden) is weakly associated with arterial stroke but predisposes to cerebral venous thrombosis.
- Anticardiolipin and lupus anticoagulant antibodies (anti-phospholipid syndrome; see p. 459) predispose to arterial thrombotic strokes in young patients.
- Low-dose, oestrogen-containing oral contraceptives do not increase stroke risk significantly in healthy women but probably do so in combination with other risk factors, e.g. uncontrolled hypertension or smoking.
- Migraine is a rare cause of cerebral infarction.
- Vasculitis (systemic lupus erythematosus (SLE), polyarteritis, giant cell arteritis, granulomatous CNS angitis) is a rare cause of stroke.
- Amyloidosis can present as recurrent cerebral haemorrhage (see p. 1357).
- Hyperhomocysteinaemia predisposes to thrombotic strokes. Folic acid therapy does not reduce the incidence.
- HIV, neurosyphilis, mitochondrial disease, Fabry’s disease (see p. 1367).
- Sympathomimetic drugs such as cocaine, and possibly over-the-counter cold remedies containing vasoconstrictors; neuroleptics in older patients.
- CADASIL (cerebral dominant arteriopathy with subcortical infarcts and leukoencephalopathy) is a rare inherited cause of stroke/vascular dementia.

Vascular anatomy

Knowledge of normal arterial anatomy and likely sites of atheromatous plaques and stenoses helps understanding of the main stroke syndromes.

The circle of Willis is supplied by the two internal carotid arteries (the anterior cerebral circulation) and by the vertebrobasilar posterior cerebral circulation. The distribution of the anterior, middle and posterior cerebral arteries that supply the cerebrum is shown in Figs 26.32 and 26.33 (see also Figs 26.30 and 26.31).

Clinical syndromes

**Transient ischaemic attack (TIA)**

**Clinical features**

TIA s cause sudden loss of function, usually lasting for minutes only, with complete recovery and no evidence of infarction on imaging. The previous classical definition of a duration of less than 24 hours is no longer used. Clinical features of the principal forms of TIA are given in Box 26.32. Hemiparesis and aphasia are the most common.

**Amaurosis fugax**

This is a sudden transient loss of vision in one eye. When it is due to the passage of emboli through the retinal arteries, the embolus is sometimes visible through an ophthalmoscope during an attack (Hollenhorst plaque). A TIA causing an episode of amaurosis fugax
Stroke 839

Diagnosis

Diagnosis of TIA is often based solely on its description. It is unusual to witness an attack, as they are so brief. Consciousness is usually preserved in TIA. There may be clinical evidence of a source of embolus, such as:

- carotid arterial bruit (stenosis)
- atrial fibrillation or other dysrhythmia
- valvular heart disease/endocarditis
- recent myocardial infarction.

An underlying condition may be evident:

- atheroma
- hypertension
- postural hypotension
- bradycardia or low cardiac output
- diabetes mellitus
- rarely, arteritis, polycythaemia, neurosyphilis, HIV
- antiphospholipid syndrome (see p. 459).

Differential diagnosis

TIAs can be distinguished, usually on clinical grounds, from other transient episodes (see p. 857). Occasionally, events identical to TIAs are produced by mass lesions. Focal epilepsy is usually recognized by its positive features (e.g. limb jerking and loss of consciousness) and progression over minutes. In a TIA, involuntary limb movements do occur occasionally – limb-shaking TIA – and are pathognomonic of severe carotid stenosis causing transient focal cerebral hypoperfusion. Cerebral amyloid angiopathy can cause TIA-like events; identification on imaging is necessary, as antiplatelet therapy is contraindicated.

Migraine aura causing visual loss or dysphasia, particularly when it occurs without subsequent headache in elderly people, often causes diagnostic difficulty. Headache, common but not invariable in migraine, is rare in TIA. Positive visual phenomena such as shimmering, which are typical of migraine, are not seen in TIA. The onset and evolution of symptoms is usually slower with migraine aura than TIA (minutes rather than seconds). Limb weakness is rarely due to migraine.

Prognosis

Prospective studies show that 5 years after a single thromboembolic TIA:

- 30% have had a stroke, a third of these in the first year
- 15% have suffered a myocardial infarct.

TIAs in the anterior cerebral circulation carry a more serious prognosis than those in the posterior circulation (see Box 26.32).

The ABCD² score (Box 26.33) was until recently used to stratify stroke risk in the first 2 days. Now all patients with a suspected TIA event should be referred to a TIA clinic and be seen, investigated and managed within 24 hours.

Investigations should include Doppler ultrasound of the internal carotid arteries, cardiac echo, ECG and 24-hour tape, MRI brain
Cerebral infarction

Major thromboembolic cerebral infarction usually causes an obvious stroke. The clinical picture is thus very variable, depending on the infarct site and extent.

Following vessel occlusion, brain ischaemia occurs, with electrical neuronal failure causing symptoms, followed by infarction and cell death. The infarcted region is surrounded by a swollen ischaemic area that does not function but is structurally intact. This is the ischaemic penumbra, which is detected on MRI and can retain function following revascularization.

Within the ischaemic area, hypoxia leads to neuronal damage. There is a fall in ATP with release of glutamate, which opens calcium channels with release of free radicals. These alterations lead to inflammatory damage, necrosis and apoptotic cell death.

Clinical features

An acute onset (over minutes) of ‘negative’ symptoms indicating focal deficits in brain function, such as weakness, sensory loss, dysphasia and visual loss, are the characteristic defining features of ischaemic stroke. The exact clinical picture depends on the vascular territory affected.

Anterior circulation infarcts

This includes infarcts in the territory of the internal carotid, middle cerebral (MCA), anterior cerebral (ACA) and ophthalmic arteries. Complete MCA occlusion results in devastating stroke with contralateral hemiplegia and facial weakness, hemisensory loss and neglect syndromes (parietal lobe – severe if the non-dominant side is affected), eye deviation towards the affected side (frontal eye fields), aphasia (dominant hemisphere lesions) and hemianopia.

Brain swelling of infarcted tissue leads to a high risk of death due to coning – malignant MCA infarction. Decompressive craniectomy (Fig. 26.34) within the first 48 hours has been shown to reduce mortality and slightly improve the long-term severe disability.

A similar picture to MCA stroke is caused by internal carotid occlusion, although collateral circulation may reduce the infarct size (see Fig. 26.31). MCA branch occlusions produce fragments of the picture described above, such as hemiparesis, monoparesis and aphasia. Occlusion of lenticulostriate perforating arteries (or MCA occlusion with collateral circulation protecting the cortex) causes infarction of deep subcortical structures such as the internal capsule, resulting in hemiplegia and hemisensory deficits.

ACA infarcts are significantly less common than MCA infarcts and typically produce hemiparesis affecting the leg more than arm, and frontal lobe deficits such as apathy or apraxia.

Posterior circulation infarcts

- **Brainstem infarction** causes complex signs, depending on the relationship of the infarct to cranial nerve nuclei, long tracts and brainstem connections (Box 26.34).
- **The lateral medullary syndrome** (Wallenberg’s syndrome) is a common brainstem vascular syndrome presenting as acute vertigo with cerebellar and other signs, including Horner’s syndrome (Box 26.35 and Fig. 26.35). It follows thromboembolism in the posterior inferior cerebellar artery (PICA) or its branches, vertebral artery thromboembolism or dissection.
- **Cerebellar infarcts** occur in isolation or as part of a more extensive brainstem syndrome. Swelling of the cerebellum may cause brainstem compression and coma or obstructive hydrocephalus necessitating decompressive surgery.
- **Basilar artery thrombosis** is more common than embolism. The clinical picture depends on the level of the occlusion and the branch vessels affected. High lesions cause midbrain infarction, including coma and locked-in syndrome (see p. 832) or top of the basilar syndrome, when the posterior cerebral artery (PCA) is also affected, causing devastating midbrain, occipital lobe and thalamic infarction.
- **Posterior cerebral artery infarcts** are typically embolic. Homonymous hemianopia results from unilateral lesions, cortical blindness (Anton’s syndrome) from bilateral lesions (see Fig. 26.33 and p. 807). Neglect syndromes and visualagnosias are associated with involvement of more anterior visual association areas. The PCA supplies the thalamus, and posteromedial temporal lobe and infarction of these structures causes confusion or memory impairment.

Lacunar infarction

Lacunes are small (<1.5 cm²) infarcts seen on MRI or at postmortem. Hypertension is the major risk factor. Strokes without cortical features, such as pure motor stroke, pure sensory stroke, sudden

unilateral ataxia and sudden dysarthria with a clumsy hand, are typical lacunar syndromes. Lacunar infarction is often symptomless.

**Multi-infarct dementia (vascular dementia)**

Multiple lacunes or larger infarcts cause generalized intellectual loss seen with advanced cerebrovascular disease. In the late stages, there is dementia (see p. 883), pseudobulbar palsy and a shuffling gait – *marche à petits pas* (small steps), sometimes called ath- erosclerotic parkinsonism. **Binswanger’s disease** is a term for widespread low attenuation in cerebral white matter, usually with dementia, TIA and stroke episodes in hypertensive patients (the changes being seen on imaging/autopsy).

**Watershed (border-zone) infarction**

Severe cerebral hypoperfusion, such as hypotension after cardiac arrest or bypass surgery, causes ischaemia in the border zones between areas supplied by the anterior, middle and posterior cerebral arteries (affecting the occipitoparietal cortex, hippocampi and motor pathways). Complex patterns of visual loss (e.g. **Balint’s syndrome**), memory loss, intellectual impairment and sometimes motor deficits are typical. A vegetative state or minimally conscious state may result from severe hypoxic–ischaemic encephalopathy after prolonged cerebral hypoperfusion (see p. 836).

**Investigations in stroke**

The purpose of investigations in stroke is to:
- confirm the clinical diagnosis, distinguish between haemorrhage and thromboembolic infarction, and exclude stroke mimics, e.g. tumour
- identify an underlying cause for the purposes of secondary prevention and identification of stroke mimics.

Investigations in thromboembolic stroke and TIA are listed in Box 26.36.

**Neuroimaging**

- **CT** will demonstrate haemorrhage immediately but cerebral infarction is often not detected in the acute phase or only subtle changes are seen (Fig. 26.36A). Repeat CT at 24–48 hours may be helpful.
- **MRI** is more sensitive than CT for early changes of infarction (diffusion-weighted sequences, DWI; Fig. 26.36B) and for small infarcts (Fig. 26.37). MRI also clearly demonstrates the extent and anatomy of an infarct and shows evidence of clinically silent simultaneous infarcts that indicate an embolic cause. MRI can also help identify the underlying cause, e.g. arterial dissection using specific sequences to show the false lumen (**crescent sign**) or venous cortical infarcts. Many stroke mimics, such as demyelination, are shown with MRI but not CT. For these reasons, MRI is increasingly used in routine assessment of stroke and is essential in younger patients or in those where the cause is uncertain.
• **Vascular imaging** by carotid Doppler within 24 hours is essential to identify high-grade symptomatic carotid stenosis requiring surgery. CT or MR angiography is now widely used to corroborate the results of Doppler, to identify arterial stenosis in the posterior circulation or intracranial vessels that are not visible on Doppler, and also to identify arterial dissection and venous sinus thrombosis. Catheter angiography is rarely needed following ischemic stroke.

**Cardiac investigations**

Identification of a cardio-embolic source of stroke, principally atrial fibrillation, is achieved with electrocardiography (ECG) or 24-hour ECG. Other causes, such as valve disease, patent foramen ovale or mural thrombus, require transthoracic echocardiography, or transesophageal echo in selected patients. Recent research has shown that prolonged cardiac monitoring (e.g. with an implantable loop recorder) demonstrates paroxysmal atrial fibrillation in a significant minority of people with stroke of unknown cause.

**Other investigations**

In young patients with stroke or in those individuals where there is no evidence of atherosclerosis or an embolic source, more specialist investigations may be required to look for an underlying vasculitic, inflammatory, infective, metabolic or genetic cause (see Box 26.36).

**Acute stroke: immediate care and thrombolysis**

(See Box 26.37.) Stroke is a medical emergency. Paramedics and members of the public are encouraged to make the diagnosis of stroke on a simple history and examination – **FAST**:

- **F**ace – sudden weakness of the face
- **A**rm – sudden weakness of one or both arms
- **S**peech – difficulty speaking, slurred speech
- **T**ime – the sooner treatment can be started, the better.

During initial assessment, immediate, continued and meticulous attention to the airway, blood pressure and swallowing is essential. Management of unconscious or stuporose patients is outlined on page 832.

**Thrombolysis**

Thrombolysis significantly increases the chances of having no or minimal disability after stroke, by reducing infarct size (Figs 26.38 and 26.39; Box 26.38). Earlier treatment within the 4.5-hour time window significantly improves outcome, so every minute counts.
Approximately 10% of patients are potential candidates for thrombolysis; most being excluded due to late presentation outside the time window for treatment. Two recent studies have shown benefit, with a low complication rate, from endovascular therapy (usually performed with retrievable stents) following alteplase therapy. In both studies, patients with proximal vessel occlusion and salvageable brain tissue were selected, with improved function and reduced mortality after treatment.

In a recent meta-analysis of five trials, endovascular thrombectomy has been shown to benefit most patients with an acute stroke caused by occlusion of the proximal anterior circulation. Currently thrombectomy is performed routinely for selected cases in a number of centres.

### Antiplatelet therapy and anticoagulation

High-dose aspirin (300 mg) is started 24 hours after thrombolysis, or as soon as haemorrhage is excluded if thrombolysis is contraindicated, and continued for 2 weeks before switching to clopidogrel. The number needed to treat (NNT) to prevent one stroke is 100.

Anticoagulants are started for atrial fibrillation-associated cardio-embolic stroke usually after 2 weeks to reduce the risk of acute haemorrhagic transformation of infarcts (NNT = 12). For arterial dissection, the risk of recurrent embolic stroke from the site of dissection is considered to be high enough to justify immediate anticoagulation or antiplatelet therapy, although controlled trial evidence is lacking. Venous sinus or cortical vein thrombosis causing stroke is also treated with anticoagulation. In addition to warfarin for oral anticoagulation, direct oral anticoagulants (DOACs; see p. 1061) that inhibit factor Xa or thrombin are now available. They have the advantage over warfarin of a wider therapeutic index with a lower rate of haemorrhage, no need for monitoring and few drug interactions.

### Decompressive craniectomy

This should be performed within 48 hours in MCA strokes causing infarction of more than 50% of the MCA territory to prevent coning and improve long-term outcome (see p. 840).

### Stroke units

Direct admission to a stroke unit has been demonstrated to be one of the most effective interventions in acute stroke, saving lives and reducing long-term disability. Specialized multidisciplinary...
teams and clear protocols for aspects of care, such as swallowing assessment, thromboembolism prevention, treatment of infections, management of hyperglycaemia and other medical complications, improve quality and consistency of care, and thus outcomes. Early mobilization and access to physiotherapy, occupational therapy and speech therapy, as well as initiation of secondary prevention and patient education, are equally necessary. Early supported discharge and assessment of rehabilitation needs are also better coordinated on a stroke unit than a general ward.

Secondary prevention interventions

**Antihypertensive therapy**

Recognition and good control of high blood pressure are the major factors in primary and secondary stroke prevention. Transient hypertension, often seen following stroke, usually does not require treatment, provided diastolic pressure does not rise above 100 mmHg. Sustained severe hypertension needs treatment after 72 hours (see p. 1144); blood pressure should be lowered slowly to avoid any sudden fall in perfusion.

**Lipid-lowering therapy**

Statins, typically atorvastatin 40 mg, should be offered to all patients unless there is a contraindication, aiming for a target total cholesterol below 4 mmol/L (low-density lipoprotein <2 mmol/L).

**Lifestyle modification and education**

Education of patient and family is an essential aspect of secondary prevention. Smoking cessation and advice about diet, exercise, weight reduction and alcohol consumption should be started on the stroke unit and continued after discharge.

**Surgery and stenting for carotid stenosis**

High-grade symptomatic carotid stenosis is associated with a significant risk of recurrent stroke during the weeks after TIA or stroke. Carotid endarterectomy should be performed within 2 weeks in patients with 70–99% stenosis on the affected side, provided the initial stroke was not severely disabling. A second imaging modality, such as CT angiography, should be performed to confirm the results of Doppler studies. For patients with moderate symptomatic stenosis (50–69%), there is a modest benefit with intervention over the 3% stroke risk associated with the procedure itself. Carotid stenting is an alternative to surgery in some patients (major stroke risk is the same for surgery and stenting, but the chance of minor non-disabling stroke is higher for stenting).

The case for intervention in asymptomatic stenosis is debatable. Patients with 70–99% stenosis may have a modest stroke risk reduction at 5 years, but moderate stenosis should be treated conservatively. Screening asymptomatic individuals for carotid stenosis is not helpful. Carotid occlusion is always treated conservatively (there is no risk of distal embolization).

**Thrombolysis in acute ischaemic stroke**

**Eligibility**

- Clinical diagnosis of acute ischaemic stroke
- Assessment by experienced team
- Persisting neurological deficit
- Imaging excludes haemorrhage
- Timing of onset well established
- Thrombolysis should commence as soon as possible and up to 4.5 h after acute stroke

**Exclusion criteria**

### Historical

- Stroke or head trauma within the prior 3 months
- Any prior history of intracranial haemorrhage
- Major surgery within 14 days
- Gastrointestinal or genitourinary bleeding within the previous 21 days
- Arterial puncture at a non-compressible site within 7 days
- Lumbar puncture within 7 days

### Clinical

- Rapidly improving stroke syndrome
- Minor and isolated neurological signs
- Seizure at the onset of stroke if the residual impairments are due to post-ictal phenomena
- Symptoms suggestive of subarachnoid haemorrhage, even if the CT is normal
- Persistent systolic blood pressure (BP) >185, diastolic BP >110 mmHg, or requiring aggressive therapy to control BP
- Pregnancy
- Active bleeding or acute trauma (fracture)

### Laboratory

- Platelets <100,000/mm³
- Serum glucose ≤2.8 mmol/L or >36.2 mmol/L
- International Normalized Ratio (INR) >1.7 if on warfarin
- Elevated partial thromboplastin time if on heparin

**Dose of i.v. alteplase (tissue plasminogen activator)**

- Total dose 0.9 mg/kg (max. 90 mg)
- 10% of total dose by initial i.v. bolus over 1 min
- Remainder infused intravenously over 60 min

See Figure 21.38.
are still inadequately researched. Baclofen and/or botulinum toxin are sometimes helpful in the management of severe spasticity.

Speech and language therapists have a vital understanding of aphasic patients’ problems and frustration. Return of speech is hastened by conversation generally. If swallowing is unsafe because of the risk of aspiration, either nasogastric feeding or percutaneous gastrostomy will be needed. Video-fluoroscopy while attempting to swallow is helpful.

Physiotherapy, occupational and speech therapy have a vital role in assessing and facilitating the future care pathway. Stroke is frequently devastating and, particularly during working life, radically alters the patient’s remaining years. Many become unemployable, lose independence and are financially embarrassed. Loss of self-esteem makes depression common.

At home, aids and alterations may be needed: stair and bath rails, portable lavatories, hoists, sliding boards, wheelchairs, tripods, stair lifts, electric blinds and modified sleeping arrangements, kitchen, steps, flooring and doorways. Liaison between hospital-based and community care teams, and primary care physician, is essential.

Prognosis

About 25% of patients die within 2 years of a stroke, nearly 10% within the first month (see Fig. 26.39). This early mortality is higher following intracranial haemorrhage than ischaemic stroke. Poor outcome is likely when there is coma, a defect in conjugate gaze and hemiplegia. Many complications, such as aspiration or pressure ulcers, are preventable, particularly in the elderly. Coordinated care reduces deaths.

Recurrent strokes are, however, common (10% in the first year) and many patients die subsequently from myocardial infarction. Of initial stroke survivors, some 30–40% remain alive at 3 years.

Gradual improvement usually follows stroke, with a plateau in recovery after 12 months. One-third of survivors return to independent mobility and one-third have disability requiring institutional care.

Intracranial haemorrhage

Aetiology

Intracerebral haemorrhage causes approximately 10% of strokes. It is associated with a higher mortality than ischaemic stroke (up to 50%). A large haematoma may act as a space-occupying lesion, causing raised intracranial pressure with brain displacement and herniation. Aetiology includes:

- Hypertension. Rupture of microaneurysms (Charcot-Bouchard aneurysms, 0.8–1.0 mm in diameter) and degeneration of small, deep, penetrating arteries are the principal pathologies. Such haemorrhage is usually massive, often fatal, and occurs in chronic hypertension and at well-defined sites: basal ganglia, pons, cerebellum and subcortical white matter. Vasopressor drugs, such as cocaine, may cause haemorrhage. Alcohol is also a risk factor (probably as a result of impaired coagulation/platelet function).

- Cerebral amyloid angiopathy (CAA). Deposition of amyloid-β in the walls of small and medium-sized arteries in normotensive patients, particularly over 60 years, causes lobar intracerebral haemorrhage (especially posterior, i.e. occipital/parietal lobes), which is often recurrent. CAA is associated with particular apolipoprotein E genotypes (E2) and is more common in patients with Alzheimer’s disease. Cerebral microbleeds are usually seen on MRI sequences sensitive to haemosiderin deposition. CAA may occasionally cause TIA-like, transient neurological symptoms.

- Secondary. Arteriovenous malformations, cavernomas, aneurysms and dural venous thrombosis cause around 20% of intracerebral haemorrhages. Coagulopathies, anticoagulants and thrombolysis may cause haemorrhage. Haemorrhagic transformation of a large ischaemic infarct may sometimes present as a haemorrhage.

Clinical features and investigations

At the bedside, there is no entirely reliable way of distinguishing between haemorrhage and ischaemic infarcts. Intracerebral haemorrhage is more often associated with severe headache or coma. Patients on oral anticoagulants should be assumed to have had a haemorrhage unless it is proved otherwise.

Brain haemorrhage is seen on CT imaging immediately (compare infarction; see p. 843) as intraparenchymal, intraventricular or subarachnoid blood. Routine MRI may not identify an acute small haemorrhage reliably in the first few hours. MRI and MR angiography are necessary to identify underlying vascular malformations such as AVMs or aneurysms. Catheter angiography may be required in selected patients with no obvious risk factors or no underlying cause identified on imaging.

Management of haemorrhagic stroke

Medical

Treatment should be on a stroke unit or a neurological intensive care unit. Frequent monitoring of GCS and neurological signs is essential, as neurosurgery may be required. Antiplatelet drugs are, of course, contraindicated. Anticoagulation should be rapidly reversed where possible (for patients on warfarin give intravenous vitamin K and clotting factor concentrates). Control of hypertension is vital with intravenous drugs in an intensive care unit setting for systolic blood pressure higher than 180 mmHg. Measures to reduce intracranial pressure may be required, including mechanical ventilation and mannitol. Recombinant activated factor VII administration may prevent haematoma expansion but has not yet been shown to improve outcome.

Surgical

Cerebellar haematomas may cause obstructive hydrocephalus or coma due to brainstem compression; urgent neurosurgical clot
evacuation is lifesaving (and is required where the haematoma is >3 cm or the patient is drowsy or deteriorating). The role of surgical decompression for non-cerebellar bleeds is less clear-cut and liaison with neurosurgeons is vital. Use of minimally invasive surgical techniques to evacuate haematomas is an area of active research. Placement of an external ventricular drain is needed if obstructive hydrocephalus develops; for example, with extension of the haemorrhage into the ventricular system.

### Subarachnoid haemorrhage

Subarachnoid haemorrhage (SAH) means spontaneous arterial bleeding into the subarachnoid space, and is usually clearly recognizable clinically from its dramatic onset. SAH accounts for some 5% of strokes and has an annual incidence of 6 per 100 000.

### Aetiology

The causes of SAH are shown in Box 26.39; it is unusual to find any contributing disease.

#### Saccular (berry) aneurysms

Saccular aneurysms (Fig. 26.40) develop within the circle of Willis and adjacent arteries. Common sites are at arterial junctions:

- between posterior communicating and internal carotid artery – posterior communicating artery aneurysm
- between anterior communicating and anterior cerebral artery – anterior communicating and anterior cerebral artery aneurysm
- at the trifurcation or bifurcation of the middle cerebral artery – middle cerebral artery aneurysm.

Other aneurysm sites are on the basilar, posterior inferior cerebellar, intracavernous internal carotid and ophthalmic arteries. Saccular aneurysms are an incidental finding in 1% of autopsies and can be multiple.

Aneurysms cause symptoms either by spontaneous rupture, when there is usually no preceding history, or by direct pressure on surrounding structures; for example, an enlarging unruptured posterior communicating artery aneurysm is the most common cause of a painful IIIrd nerve palsy (see p. 813).

#### Arteriovenous malformation

Arteriovenous malformation (AVM) is a vascular developmental malformation, often with a fistula between arterial and venous systems, causing high flow through the AVM and high-pressure arterIALIZATION of draining veins. An AVM usually presents following a spontaneous intracerebral haemorrhage or with a seizure, often focal in onset. The risk of a first haemorrhage in unruptured AVMs (20% fatal and 30% resulting in permanent disability) is approximately 2–3% per year. Once an AVM has caused a haemorrhage, the risk of rebleeds is increased to approximately 10% per year. AVMs may be ablated with endovascular treatment (catheter injection of glue into the nidus, usually), microsurgery or stereotactic radiotherapy. A multidisciplinary team approach with neurologist, interventional neuroradiologist and neurosurgeon is required in deciding on treatment options. There is no clear consensus on the best treatment modality or, indeed, whether the considerable risk of intervention is lower than with a conservative approach.

Cavernous haemangiomas (cavernomas) are common (0.1–0.5% prevalence) and consist of a tangle of low-pressure dilated vessels without a major feeding artery; they are frequently symptomless (Fig. 26.41) and seen incidentally on imaging. Multiple cavernomas often have a genetic basis. Cavernomas may cause seizures. Small haemorrhages may occur but are usually low-pressure bleeds and rarely cause severe deficits. Surgical resection is rarely needed, except where the cavernoma is gradually enlarging or causing significant neurological symptoms.
Intracranial haemorrhage

Clinical features of subarachnoid haemorrhage

There is a sudden, very severe headache, often occipital (mean time to peak headache 3 min). Headache is usually followed by vomiting and often by coma and death. Survivors of SAH may remain comatose or drowsy for hours, days or longer. SAH is a possible diagnosis in any sudden headache.

Following major SAH, there is neck stiffness and a positive Kernig’s sign. Papilloedema is sometimes present, with retinal and/or subhyaloid haemorrhage (tracking beneath the retinal hyaloid membrane). Minor bleeds cause few signs but almost invariably do cause headache (approximately 17% of patients have small ‘sentinel bleeds’ in the weeks before presenting with SAH).

Investigations

CT imaging is the immediate investigation (Fig. 26.42). Subarachnoid and/or intraventricular blood is usually seen (sensitivity of CT to detect subarachnoid blood is 95% within 24 hours of onset but much lower over subsequent days). Lumbar puncture is not necessary if SAH is confirmed by CT, but should be performed if doubt remains. CSF becomes yellow (xanthochromic) within 12 hours of SAH and remains detectable for 2 weeks. Visual inspection of supernatant CSF is usually sufficiently reliable for diagnosis. Spectrophotometry to estimate bilirubin in the CSF released from lysed cells is used to define SAH with certainty. CT angiography or catheter angiography to identify the aneurysm or other source of bleeding is performed in patients potentially fit for surgery. In some, no aneurysm or source of bleeding is found, despite a definite SAH.

Differential diagnosis

SAH must be differentiated from migraine. This is sometimes difficult but a short time to maximal headache intensity and the presence of neck stiffness usually indicate SAH. Thunderclap headache is used (confusingly) to describe either SAH or a sudden (benign) headache for which no cause is ever found. The syndrome of reversible cerebral vasoconstriction (Call-Fleming’s syndrome) presents with thunderclap headache. Acute bacterial meningitis occasionally causes a very abrupt headache, when a meningeal microabscess ruptures; SAH also occasionally occurs at the onset of acute bacterial meningitis. Cervical arterial dissection can present with a sudden headache.

Complications

Blood in the subarachnoid space can lead to obstructive hydrocephalus, seen on CT. Hydrocephalus can be asymptomatic but may cause deteriorating consciousness following SAH. Shunting may be necessary. Arterial spasm (visible on angiography and a cause of coma or hemiparesis) is a serious complication of SAH and a poor prognostic feature.

Management

Immediate treatment of SAH involves bed rest and supportive measures. Hypertension should be controlled. Nimodipine, a calcium-channel blocker given for 3 weeks, reduces mortality.

All SAH cases should be discussed urgently with a neurosurgical centre. Nearly half of SAH cases are either dead or moribund before reaching hospital. Of the remainder, a further 10–20% rebleed and die within weeks. Failure to diagnose SAH – for example, mistaking SAH for migraine – contributes to this mortality.

Where angiography demonstrates an aneurysm (the cause of the vast majority of SAHs), endovascular treatment by placing platinum coils via a catheter in the aneurysm sac, to promote thrombosis and ablation of the aneurysm, is now the first-line treatment. Endovascular coiling has a lower complication rate than surgery but direct surgical clipping of the aneurysm neck is still required in some selected cases. For asymptomatic (unruptured) aneurysms over 8 mm in diameter, the risk of treatment is less than the risk of haemorrhage if not treated. Patients who remain comatose or who have persistent severe deficits after SAH have a poor outlook.

Subdural and extradural bleeding

These conditions can cause death following head injuries unless treated promptly.

Subdural haematoma

Subdural haematoma (SDH) means accumulation of blood in the subdural space following rupture of a vein. This usually follows a head injury, sometimes a trivial one. The interval between injury and symptoms can be days, or may extend to weeks or months. Chronic, apparently spontaneous, SDH is common in the elderly, and also occurs with anticoagulants.

Headache, drowsiness and confusion are common; symptoms are indolent and can fluctuate. Focal deficits, such as hemiparesis or sensory loss, develop. Epilepsy occasionally occurs. Stupor, coma and coning may follow.

Extradural haemorrhage

Extradural haemorrhage (EDH) typically follows a linear skull vault fracture tearing a branch of the middle meningeal artery. Extradural blood accumulates rapidly over minutes or hours. A characteristic picture is that of a head injury with a brief duration of unconsciousness, followed by improvement (the lucid interval). The patient then becomes stuporous; there is an ipsilateral dilated pupil and contralateral hemiparesis, with rapid transtentorial coning. Bilateral fixed, dilated pupils, tetraplegia and respiratory arrest follow. An acute progressive SDH presents similarly.

Management

Possible extradural or subdural bleeding needs immediate imaging. CT (Fig. 26.43A) is the most widely used investigation because of
its immediate availability. MRI is more sensitive for the detection of small haematomas. T1-weighted MRI (Fig. 26.43B) shows bright images due to the presence of methaemoglobin.

**EDHs require urgent neurosurgery; if it is performed early, the outlook is excellent.** When the patient is far from a neurosurgeon, such as in wartime or at sea, drainage through skull burr holes has been lifesaving when an EDH has been diagnosed clinically.

**Subdural bleeding** usually needs less immediate attention but close neurosurgical liaison is necessary. Even large collections can resolve spontaneously without drainage. Serial imaging is required to assess progress.

**Cortical venous thrombosis and dural venous sinus thrombosis**

Intracranial venous thromboses are usually (>50%) associated with a prothrombotic risk factor, such as oral contraceptives, pregnancy, genetic or acquired prothrombotic states, and dehydration. Head injury is also a cause. Infection, such as from a para-nasal sinus, may be present. Venous thromboses can also arise spontaneously.

**Cortical venous thrombosis**

The venous infarct leads to headache, focal signs (e.g. hemiparesis) and/or seizures. Cortical haemorrhagic infarction is shown on MRI.

**Dural venous sinus thromboses**

Cavernous sinus thrombosis causes eye pain, fever, ptosis and chemosis. External and internal ophthalmoplegia with papilloedema develops.

Thrombosis of the dural venous sinuses, such as when the sagittal sinus causes raised intracranial pressure with headache, papilloedema and frequently seizures, may progress to coma.

**Management**

MRI and MR venography (MRV) show occluded sinuses and/or veins. Treatment is with heparin initially, followed by warfarin or other oral anticoagulants for 6 months. Anticonvulsants are given if necessary.

**Further reading**

**HEADACHE, MIGRAINE AND FACIAL PAIN**

Headache is an almost universal experience and one of the most common symptoms in medical practice. It varies from an infrequent and trivial nuisance to a pointer to serious disease. Headache symptoms are unpleasant, disabling and common worldwide, and have a substantial economic impact because of time lost from work.

**Mechanisms**

Pain receptors are located at the base of the brain in arteries and veins, and throughout meninges, extracranial vessels, scalp, neck and facial muscles, paranasal sinuses, eyes and teeth. Curiously, brain substance is almost devoid of pain receptors. Head pain is mediated by the Vth and IXth cranial nerves and upper cervical sensory roots.

**Clinical approach to the patient with headache**

In assessing patients with headache, the aim should be to make a confident diagnosis based on the history. Examination is helpful in excluding underlying medical disorders as a cause of headache but will not distinguish between different types of primary headache.

There is an internationally agreed classification for headaches that defines all headache patterns. Headache is divided into primary headache disorders such as migraine, and secondary headaches due to underlying pathology such as raised intracranial pressure or meningitis (Box 26.40). It is also useful to distinguish between episodic (recurrent) headache, single first headache episodes and patients with chronic headache.

In an outpatient clinic setting, most headaches will be benign. Fewer than 1% of outpatients with non-acute headache have a serious underlying cause but in the emergency department there will be a much higher prevalence of serious underlying pathology presenting with headache. New-onset severe headache in those without a previous headache history, especially in older patients (>50), requires exclusion of underlying pathology causing secondary headache.

There are some widely believed ‘headache myths’. Headaches are not caused by hypertension, except rarely with malignant hypertension (see p. 1138). Eye strain from refractive error does not cause headache and sinusitis is rarely the explanation for recurrent or chronic headache.

**Taking a history for ‘headaches’**

Ask about:

- **Headache location** (e.g. hemicranial), severity and character (e.g. throbbing versus non-throbbing).
- Associated symptoms, e.g. nausea, photophobia, phonophobia and motion sensitivity.
- Presence of autonomic symptoms, e.g. tearing or ptosis.
- Relieving or exacerbating features, e.g. effect of posture.
- Headache pattern: is headache episodic and part of a pattern of previous similar headaches? Age at onset and headache frequency.
- Duration of headache episodes (helpful in distinguishing between different primary headache types).
Headache, migraine and facial pain

Some causes of secondary headache

- Raised intracranial pressure, e.g. idiopathic intracranial hypertension
- Infections, e.g. meningitis, sinusitis
- Giant cell arteritis
- Intracranial haemorrhage, esp. subarachnoid haemorrhage or subdural haematoma
- Low cerebrospinal fluid volume (low-pressure) headache
- Post-traumatic headache
- Cervicogenic headache
- Acute glaucoma

Examination

Examination should include fundoscopy to look for papilloedema. In older patients, temporal arteries should be palpated for loss of pulsatility and tenderness that may be features of giant cell arteritis (GCA). Fever and neck stiffness suggest meningitis. Examination is generally normal in patients with primary headache disorders.

Investigations

Investigations, including brain imaging, do not contribute to the diagnosis of primary headache disorders. Neuroimaging is indicated only where history or examination suggests an underlying secondary cause. Older patients with new-onset headache and those with ‘red flag’ symptoms should have brain CT. In patients over 50 with new headache, the ESR should be checked to exclude GCA.

Primary headache disorders

Migraine

Migraine is the most common cause of episodic headache (15–20% of women and 5–10% of men); in 90%, onset is before 40 years of age. Episodes of headache are associated with sensory sensitivity such as to light, sound or movement, and sometimes with nausea and vomiting. There is a spectrum of severity between individuals and from one attack to another. Migraine is usually high-impact, with inability to function normally during episodes. Headache frequency in migraine varies from an occasional inconvenience to frequent headaches severely impacting on quality of life, and may transform into chronic daily headache.

Mechanisms

Genetic factors play a part in causing the neuronal hyperexcitability that is probably the biological basis of migraine. Migraine is polygenic but a rare form of familial migraine is associated with mutations in the α-1 subunit of the P/Q-type voltage-gated calcium channel or neuronal sodium channel (SCN1A), and a dominant loss-of-function mutation in a potassium channel gene (TRESK) has been identified in some patients with migraine with aura.

The pathophysiology of migraine is now thought to have a primarily neurogenic rather than vascular basis. Spreading cortical depression – a wave of neuronal depolarization followed by depressed activity slowly spreading anteriorly across the cerebral cortex from the occipital region – is thought to be the basis of the migraine aura. Activation of trigeminal pain neurones is the basis of the headache. The innervation of the large intracranial vessels and dura by the first division of the trigeminal nerve is known as the trigeminovascular system. Release of calcitonin gene-related peptide (CGRP), substance P and other vasoactive peptides, including 5-HT, by activated trigeminovascular neurones causes painful meningeal inflammation and vasodilation. Peripheral and central sensitization of trigeminal neurones and brainstem pain pathways makes otherwise innocuous sensory stimuli (such as CSF pulsation and head movement) painful, and light and sound are perceived as uncomfortable.

Clinical features

Migraine without aura

Migraine typically starts around puberty with increasing prevalence into the fourth decade. There is a spectrum of severity and associated features, but attacks have recognizable core features (Box 26.41). Most migraine attacks are usually of sufficient severity to prevent sufferers continuing with normal activities; sleep usually helps. A ‘washed-out’ feeling follows the attack. The scalp may be tender to touch during episodes (allodynia) and the preference is to be still in a dark, quiet environment.

Some patients recognize changes in routine as trigger factors:

- Sleep (too little or too much).
- Stress (including letdown after a period of stress).
- Hormonal factors for women – changes in oestrogen levels, e.g. menstrual migraine (usually just before menses) and worsening with the oral contraceptive pill and menopause.
- Eating – skipping meals and alcohol. Contrary to popular belief, individual foods are rarely a trigger.
- Other – sensory stimuli, such as bright lights or loud sounds; physical exertion; and changes in weather patterns, e.g. stormy weather. Minor head injuries may trigger a worsening of migraine frequency and severity.

Migraine with aura

Approximately 25% of migraine sufferers experience focal neurological symptoms immediately preceding the headache phase in some or all attacks; this is termed migraine aura. Most never experience aura, and the presence of aura is therefore not required for a diagnosis of migraine. Aura usually evolves over 5–20 minutes, with symptoms changing as the wave of spreading neuronal depression moves across the surface of the cortex. It rarely lasts longer than 60 minutes and is followed immediately by the headache phase.

Visual aura is the most common type, with positive visual symptoms such as shimmering, teichopsis (zigzag lines, also called fortification spectra) and fragmentation of the image (like looking...
through a pane of broken glass) often accompanied by patches of loss of vision, which may move across the visual field (scotomas) and even evolve into hemianopia or tunnel vision. Positive sensory symptoms (mainly tingling), dysphasia and, rarely, loss of motor function may also occur, and may occur successively within the same episode of aura following the visual symptoms.

**Migraine aura** usually presents no diagnostic difficulty, but problems with diagnosis may sometimes arise in men over the age of 50 who develop migraine aura for the first time without subsequent headache (sometimes referred to as aseptic migraineous aura). This is frequently misdiagnosed as a TIA (see p. 839). Distinguishing the two conditions is often difficult and relies on the characteristic evolution of symptoms over minutes and the presence of positive symptoms in aura, in contrast to TIA where symptom onset is acute and negative symptoms (visual loss as opposed to visual distortion and teichopsia) are the norm. There may also be a history of previous typical migraine aura in early adult life to help distinguish the conditions.

**Migraine-related dizziness**

Vertigo is now recognized as being a migrainous symptom in some individuals, with attacks lasting for hours in the context of migraine attacks. There is an overlap with what is sometimes described as basilar migraine, a poorly defined migraine subtype associated with brainstem aura-type symptoms before or during attacks, including perioral paraesthesiae, diplopia, unsteadiness and, rarely, reduced level of consciousness.

**Hemiplegic migraine**

This rare autosomal dominant disorder causes a hemiparesis and/or coma and headache, with recovery within 24 hours. Some patients have permanent cerebellar signs, as it is allelic with episodic ataxia. It is distinct from more common forms of migraine.

**Management**

General measures include:

- explanation
- avoidance of trigger factors and lifestyle modification where possible.

**Acute treatment of attacks**

Analgesics, such as high-dose dispersible aspirin (900mg), paracetamol 1g or an NSAID (e.g. naproxen 250–500mg), are often effective, with an anxiolytic such as metoclopramide if necessary. Acute treatment should be taken as soon as possible after onset of headache. Patients should be aware that repeated use of analgesics leads to further headaches (see medication overuse headache, p. 851).

Triptans (5-HT<sub>1B/1D</sub> agonists) are specific for migraine and may be effective where simple analgesics are insufficient. Sumatriptan was the first marketed; almotriptan, eletriptan, frovatriptan, naratriptan, rizatriptan and zolmitriptan are now available, with various routes of administration. Subcutaneous sumatriptan injection may be effective where vomiting prevents absorption of oral medication (note that nasal triptan sprays rely on gastrointestinal rather than nasal absorption). Triptans should be avoided when there is vascular disease, and like analgesics, they should not be overused. CGRP antagonists, e.g. telcagepant, are likely to be future effective therapy for migraine.

**Migraine suppression medication**

When migraine episodes are frequent (>1–2 per month, for example) and impacting on quality of life, migraine suppression medication should be offered. The key principles are that a period of 3–6 months’ treatment is usually sufficient to reduce headache frequency and severity by approximately 50%, with the effect of ‘resetting’ migraine frequency beyond the treatment period. However, these medications will not be effective where ongoing analgesic overuse is an issue. Treatment options include:

- **Anticonvulsants.** Valproate (800 mg) or topiramate (100–200 mg daily) are generally the most effective options.
- **Beta-blockers,** e.g. propranolol slow-release 80–160 mg daily.
- **Tricyclics,** e.g. amitriptyline 10 mg, increasing weekly in 10 mg steps to 50–60 mg.
- **Candesartan.** Up to 16 mg daily.
- **Antidepressants,** e.g. venlafaxine up to 150 mg daily.
- **Botulinum toxin.** This was recommended as a treatment for chronic migraine (see p. 851). The technique involves 31 injections over the scalp and neck repeated every 3 months. Its effect is inconsistent.
- **Pizotifen.** This is rarely used. Flunarizine (a calcium antagonist) and methysergide are used in refractory patients.

**Tension-type headache**

The exact pathogenesis of tension-type headache (TTH) remains unclear. There is overlap with migraine, and many headaches traditionally subsumed under this category probably, in fact, represent mild migraine. Since there are no diagnostic tests to separate TTH from mild migraine it is difficult to know if the conditions are biologically distinct. In contrast to migraine, pain is usually of mild to moderate severity, bilateral and relatively featureless, with tight band sensations, pressure behind the eyes, and bursting sensations being described.

Depression is also a frequent co-morbid feature. TTH is often attributed to cervical spondylosis, refractive errors or high blood pressure; evidence for such associations is poor.

Simple analgesics are often effective but overuse should be avoided. Physical treatments, such as massage, ice packs and relaxation, are often recommended. Frequent or chronic TTH may respond to migraine suppression medications as above, with tricyclics often being used first-line.

**Trigeminal autonomic cephalalgias**

The trigeminal autonomic cephalalgias are a group of primary headache disorders characterized by unilateral trigeminal distribution pain (usually in the ophthalmic division of the nerve) and prominent ipsilateral autonomic features.

**Cluster headache**

Cluster headache is distinct from migraine and much rarer (1 per 1000). It affects adults, mostly males aged between 20 and 40. Patients describe recurrent bouts (clusters) of excruciating unilateral retro-orbital pain with parasympathetic autonomic activation in the same eye, causing redness or tearing of the eye, nasal congestion or even a transient Horner’s syndrome. The pain is reputed to be the worst known to humans, and patients often contemplate, and sometimes commit, suicide, such is the severity of the pain. Unlike with migraine attacks, patients prefer to move about or rock rather than remain still.

Attacks are shorter than migraine, usually 30–90 minutes, and may occur several times per day, especially during sleep. Clusters last 1–2 months, with attacks most nights, before stopping completely and typically recurring a year or more later, often at the same time of year. Although the cause is not known, hypothalamic activation is seen on functional imaging studies during an attack.
Management. Analgesics are unhelpful. Subcutaneous sumatriptan is the drug of choice for acute treatment, as no other drug works quickly enough. High-flow oxygen is also used. Most prophylactic migraine drugs are unhelpful. Verapamil, lithium and/or a short course of steroids help terminate a bout of cluster headaches.

Paroxysmal hemicrania and SUNCT

Paroxysmal hemicrania is a rare condition with similarities to cluster headache, differing mainly in that attacks are briefer (10–30 min) and more frequent (>5 per day, at any time of day) and do not occur in clusters. Women are more often affected than men. There is a rapid and complete response to indomethacin.

Short-lasting unilateral neuralgiform headache with conjunctival injection and tearing (SUNCT) is very rare. Attacks are short, 5 seconds to 2 minutes, and very frequently occur in bouts. Distinguishing SUNCT from trigeminal neuralgia can be difficult.

Other primary headache disorders

• Primary stabbing headache (‘ice pick headache’) involves momentary jabs or stabs of localized pain occurring either in the same spot or moving about the head. Symptoms wax and wane, and are more common in patients with other primary headache disorders, particularly migraine. Treatment is usually not needed but this type of headache responds well to indomethacin.

• Primary cough headache is a sudden, sharp head pain on coughing. No underlying cause is found but intracranial pathology should be excluded. The problem often resolves spontaneously. Indomethacin is the treatment of choice; LP with removal of CSF can help.

• Primary sex headache is characterized by explosive headache at or before orgasm. It often resolves spontaneously after several attacks. Investigation to exclude SAH is required after the first episode.

• Other varieties of primary headache include hemicrania continua, primary exertional headache, hypnic headache (headache triggered by sleep) and primary thunderclap headache.

Chronic daily headache

This is defined as headache on 15 or more days per month for at least 3 months. Up to 4% of the population are affected by daily or near-daily headache. Although there are many possible causes, including secondary headache disorders, in practice, primary headache disorders, particularly migraine, are responsible for the majority. Where migraine is the cause, the term chronic migraine is now preferred.

Overuse of analgesic medication or triptans (termed medication overuse headache) is often a major factor leading to and maintaining chronicity, particularly in those with migraineous biology. Use of ten or more doses per month of any analgesic or triptan, particularly codeine or opiate-containing drugs such as co-codamol, or numerous over-the-counter analgesics, may eventually lead to transformation of episodic headache into chronic daily headache.

Explanation that medication overuse is part of the problem is essential to help patients withdraw from or substantially reduce analgesic intake. This is a difficult process for many patients, especially as there may be a period of transient rebound worsening of headache after withdrawal. Concurrent introduction of migraine suppression medication (see above) may help withdrawal but will not be effective if patients cannot withdraw from frequent analgesic use. Occasionally, hospital admission for analgesic withdrawal with parenteral administration of dihydroergotamine is required.

Secondary headache disorders

Raised intracranial pressure headache

Any headache present on waking and made worse by coughing, straining or sneezing may be due to raised intracranial pressure (ICP) caused by a mass lesion. Vomiting often accompanies pressure headaches. Visual obstructions (momentary bilateral visual loss with bending or coughing) are characteristic and seen in the presence of papilloedema. Occasionally, where ICP rises quickly, papilloedema may not be present.

Neuroimaging is mandatory if raised ICP is suspected. Where no mass lesion, venous sinus thrombosis or hydrocephalus is detected on imaging in the presence of papilloedema, idiopathic intracranial hypertension may be the cause and LP is performed to measure CSF opening pressure.

Idiopathic intracranial hypertension

Idiopathic intracranial hypertension (IIH) probably results from reduced CSF resorption. IIH typically develops in younger, overweight female patients, many of whom have polycystic ovaries. Headaches and transient visual obstructions due to the florid papilloedema are the presenting features. A VIth nerve palsy may develop – a false localizing sign (see p. 813). CSF pressure is very elevated, with normal constituents. Brain imaging is normal, although ventricles may be small and appear ‘slit-like’.

Various drugs, such as tetracyclines, and vitamin A supplements have been implicated. Other causes of papilloedema should be excluded. Sagittal sinus thrombosis can cause a similar picture and should always be looked for on MR venography.

IIH is usually self-limiting. However, optic nerve damage can result from longstanding severe papilloedema with progressive loss of peripheral visual fields. Regular monitoring of visual fields with perimetry is essential. Repeated LP, acetazolamide and thiazide diuretics are used to reduce CSF production. Weight reduction is helpful. Ventriculoperitoneal shunt insertion or optic nerve sheath fenestration to protect vision is sometimes necessary.

Low-CSF-volume (low-pressure) headache

Although most often seen following LP, CSF leaks may occur spontaneously, leading to postural headache, worse on standing or sitting and relieved completely by lying flat. The patient may give a history of vigorous Valsalva, straining or coughing just prior to onset. Leptomeningeal enhancement may be seen on MRI but is not reliably present. LP is generally avoided for obvious reasons but may reveal low opening pressure. The site of the leak is usually within the spine; thus treatment consists of injection of autologous blood into the spinal epidural space to seal the leak (a ‘blood patch’), or occasionally surgical repair of the dural tear. Intravenous caffeine infusion and bed rest are sometimes effective.

Post-traumatic headache

Pre-existing migraine may worsen following head injury. De novo headache sometimes follows a minor head injury but post-traumatic headache is an ill-defined entity. Improvement over a few weeks is the norm, but where litigation is ongoing, symptoms can persist for long periods. Subdural haematoma and low-pressure headache need to be considered as a possible cause.
**Facial pain**

The face has many pain-sensitive structures: teeth, gums, sinuses, temporomandibular joints, jaw and eyes. Dental causes are common and should always be considered. Facial pain is also caused by specific neurological conditions.

**Trigeminal neuralgia**

Trigeminal neuralgia typically starts in the sixth and seventh decades; hypertension is the main risk factor. Compression of the trigeminal nerve at or near the pons by an ectatic vascular loop is the usual cause. High-resolution MRI studies may demonstrate the vascular loop in contact with the nerve in a high proportion of cases. In younger patients, multiple sclerosis or a cerebellopontine angle tumour (acoustic schwannomas, meningiomas, epidermoid) is more likely to be the cause.

**Clinical features**

Paroxysms of knife-like or electric shock-like pain, lasting seconds, occur in the distribution of the Vth nerve. Pain tends to commence in the mandibular division (V\(_3\)) but may spread over time to involve the maxillary (V\(_2\)) and, occasionally, the ophthalmic divisions (V\(_1\)). Bilateral trigeminal neuralgia is rare (3%) and usually due to intrinsic brainstem pathology, such as demyelination. Episodes occur many times a day with a refractory period after each. They may be brought on by stimulation of one or more trigger zones in the face. Washing, shaving, a cold wind and chewing are examples of trivial stimuli that provoke pain. The face may be screwed up in agony. Spontaneous remissions last months or years before (almost invariable) recurrence. There are no signs of Vth nerve dysfunction on examination.

**Management**

Carbamazepine (600–1200mg daily) reduces the severity of attacks in the majority. Oxcarbazepine, lamotrigine and gabapentin are also used. If drugs fail or are not tolerated, a number of surgical options are available that, in general, are more effective than medical treatments. Percutaneous radiofrequency selective ablation of the trigeminal ganglion is performed as a day-case procedure; recurrence may occur after an average of 2 years. Microvascular decompression of the nerve in the posterior fossa has a high long-term success rate (approximately 90%).

**Atypical facial pain**

Facial pain differs from trigeminal neuralgia in quality and distribution, and trigger points are absent. The condition is probably heterogeneous in aetiology but is believed by some (on little evidence) to be a somatic manifestation of depression. Tricyclic antidepressants and drugs used in neuropathic pain are sometimes helpful.

**Other causes of facial pain**

Facial pain occurs in the trigeminal autonomic cephalgias (see above), occasionally in migraine and in carotid dissection.

**Giant cell arteritis (temporal arteritis)**

A granulomatous large-vessel arteritis is seen almost exclusively in people over 50 (see p. 464).

**Clinical features**

- **Headache.** This is almost invariable in giant cell arteritis (GCA). Pain develops over inflamed superficial temporal and/or occipital arteries. Touching the skin over an inflamed vessel (e.g. when combing the hair) causes pain. Arterial pulsation is soon lost; the artery becomes hard, tortuous and thickened. The scalp over inflamed vessels may become red. Rarely, gangrenous patches appear.

- **Facial pain.** Pain in the face, jaw and mouth is caused by inflammation of facial, maxillary and lingual branches of the external carotid artery in GCA. Pain is characteristically worse on eating (jaw claudication). Mouth opening and protruding the tongue become difficult. A painful, ischaemic tongue occurs rarely.

- **Visual problems.** Visual loss from arterial inflammation and occlusion occurs in 25% of untreated cases. Posterior ciliary artery occlusion causes anterior ischaemic optic neuropathy in three-quarters of these. Other mechanisms are central retinal artery occlusion, cilio-retinal artery occlusion and posterior ischaemic optic neuropathy. There is sudden monocular visual loss (partial or complete), usually painless. Amaurosis fugax (see p. 838) may precede permanent blindness.

When the posterior ciliary vessels are affected, ischaemic optic neuropathy causes the disc to become swollen and pale; retinal branch vessels usually remain normal. When the central retinal artery is occluded, there is sudden permanent unilateral blindness, disc pallor and visible retinal ischaemia. Bilateral blindness may develop, with the second eye being affected 1–2 weeks after the first.

**Diagnosis and management**

See page 465.

---

**EPILEPSY AND LOSS OF CONSCIOUSNESS**

### Epilepsy

An epileptic seizure can be defined as a sudden synchronous discharge of cerebral neurones causing symptoms or signs that are apparent either to the patient or to an observer. For example, a limited discharge affecting only part of the cortex may cause a subjective aura apparent only to the patient, or a generalized seizure may cause a convulsion witnessed by an observer of which the patient may be unaware. This definition excludes disorders such as migrainous aura that are more gradual in onset and usually more prolonged, and EEG discharges that do not have a clinical correlate. Epilepsy is an ongoing liability to recurrent epileptic seizures.

### Epidemiology

Epilepsy is common. Its population prevalence is 0.7–0.8% (higher in developing countries). Approximately 440 000 people in the UK have epilepsy. The incidence of epilepsy is age-dependent; it is highest at the extremes of life, most cases starting before the age of 20 or after the age of 60. The cumulative incidence (lifetime risk) of epilepsy is over 3% and the lifetime risk of having a single seizure is 5%. The fact that the prevalence is much lower than the cumulative incidence in part reflects the fact that epilepsy often goes into remission.
Epilepsy and loss of consciousness

**Box 26.42 Classification of seizures**

1. Generalized seizures
   A. Tonic–clonic seizures (grand mal)
   B. Absence seizures with 3 Hz spike-and-wave discharge (petit mal)
   C. Myoclonic seizures
   D. Tonic, clonic and atonic seizures

2. Focal seizures (originating within one hemisphere). Characterized according to one or more features:
   A. Aura
   B. Motor (without impaired awareness, e.g. Jacksonian seizures)
   C. Awareness and responsiveness altered or retained (e.g. with impaired awareness, in temporal lobe seizures)
   A focal seizure can evolve into bilateral convulsive seizure – secondary generalization

3. Unknown (insufficient evidence to characterize as focal, generalized or both)

**Classification**

Seizures are divided by clinical pattern into two main groups (Box 26.42 and Fig. 26.44): focal seizures and generalized seizures.

- **A focal seizure** is caused by electrical discharge restricted to a limited part of the cortex of one cerebral hemisphere. Focal seizures are further characterized according to whether or not there is:
  - aura, e.g. smell or auditory hallucination, déjà vu, fear, visual distortion, sensory symptoms such as tingling, abdominal rising sensation
  - motor features, e.g. one limb jerking (a Jacksonian seizure)
  - loss of awareness or responsiveness, e.g. in many temporal lobe seizures.
- **In a generalized seizure**, there is simultaneous involvement of both hemispheres, always associated with loss of consciousness or awareness.

Focal seizures with electrical activity confined to one part of the brain may spread after a few seconds, due to failure of inhibitory mechanisms, to involve the whole of both hemispheres, causing a bilateral tonic–clonic seizure. The patient may remember the initial focal seizure before losing consciousness, in which case this is called an aura; sometimes, however, the spread of electrical activity is so rapid that the patient does not experience any warning before a bilateral tonic–clonic seizure.

**Generalized tonic–clonic seizures (grand mal seizures)**

**Prodrome.** There is often no warning before generalized tonic–clonic seizures (GTCS), or there may be an aura prior to a bilateral tonic–clonic seizure.

**Tonic–clonic phase.** An initial tonic stiffening is followed by the clonic phase with synchronous jerking of the limbs, reducing in frequency over about 2 minutes until the convulsion stops. The patient may utter an initial cry and then falls, sometimes suffering serious injury. The eyes remain open and the tongue is often bitten. There may be incontinence of urine or faeces.

**Post-ictal phase.** A period of flaccid unresponsiveness is followed by gradual return of awareness with confusion and drowsiness lasting 15 minutes to an hour or longer. Headache is common after a GTCS.

**Myoclonic, tonic and atonic seizures**

Myoclonic seizures or ‘jerks’ take the form of momentary brief contractions of a muscle or muscle groups: for example, causing a sudden involuntary twitch of a finger or hand. They are common in primary generalized epilepsies. Tonic seizures consist of stiffening of the body, not followed by jerking. Atonic seizures involve a sudden collapse with loss of muscle tone and consciousness.

**Focal seizure types**

**Focal seizures with aura**

The nature of the aura helps to localize the seizure focus. Temporal lobe auras include déjà vu or jamais vu; fear (may be mistaken for panic attacks); olfactory, gustatory or auditory hallucinations; altered perception, such as macropsia or micropsia; an abdominal rising sensation; nausea; and vertigo. With some frontal seizures, conjugate gaze (see p. 807) deviates away from the epileptic focus and the head turns; this is known as an adverse seizure. Occipital
lone auras include visual phenomena such as zigzag lines and coloured scotomas. Some auras are vague or hard for patients to describe but they are generally stereotyped: that is, the same on each occasion.

**Focal motor seizures**
These originate within the motor cortex. Jerking typically begins on one side of the mouth or in one hand, sometimes spreading to involve the entire side. This local spread of activity is called the **Jacksonian march** of a seizure. Local temporary paralysis of the limbs affected sometimes follows: Todd’s paralysis.

**Focal seizures with altered awareness or responsiveness**
These usually arise from the temporal lobe (60%) or the frontal lobe. There is often a preceding aura followed by a period of complete or partial loss of awareness of surroundings, lasting for 1–2 minutes on average (as opposed to 10 seconds in absence seizures), which the patient generally does not remember subsequently. This stage is accompanied by speech arrest and often by **automatisms**: semi-purposeful stereotyped motions such as lip smacking or dystonic limb posturing, or more complex motor behaviours such as walking in a circle or undressing. The attacks may be followed by a short period of post-ictal confusion or may develop into a **bilateral tonic–clonic seizure**.

**Epilepsy syndromes and aetiology of epilepsy**
The range of causes of epilepsy (Box 26.43) is different at different ages and in different countries.
- **Children and teenagers**: genetic, perinatal and congenital disorders predominate.
- **Younger adults**: trauma, drugs and alcohol are common.
- **Older ages (>60 years)**: vascular disease and mass lesions such as neoplasms are important.

**Primary generalized epilepsies**
Presenting in childhood and early adult life, primary generalized epilepsies (PGEs) account for up to 20% of all patients with epilepsy. The cause is thought to be polygenic with complex inheritance. The brain is structurally normal but abnormalities of ion channels influencing neuronal firing, abnormalities of neurotransmitter release and synaptic connections are probably the underlying molecular pathological substrates. They include:

- **Childhood absence epilepsy**: absence seizures. Spontaneous remission by age 18 is usual.
- **Juvenile myoclonic epilepsy** (JME; Box 26.44): this accounts for 10% of all epilepsy patients. Typically, myoclonic jerks start in the teenage years (and are usually ignored by the patient; ask about jerks when taking an epilepsy history – see Box 26.44), followed by generalized tonic–clonic seizures that bring the patient to medical attention. One-third of patients also have absences. Seizures and jerks often occur in the morning after waking. Lack of sleep, alcohol and strobe or flickering lights are seizure triggers in JME. JME usually responds well to treatment, is usually associated with EEG abnormalities and requires life-long treatment.
- **Monogenic disorders**: research has identified a number of single-gene epilepsy disorders, e.g. autosomal dominant nocturnal fronto temporal lobe epilepsy (caused by mutations in the nicotinic acetylcholine receptor gene). Many are due to mutations of neuronal voltage-gated channels, e.g. potassium and sodium channels, or ligand-gated channels and receptors (channelopathies).

**Focal epilepsy**
Almost any process disrupting the cortical grey matter can cause epilepsy. Seizures arise from the affected area of cortex, with or without **bilateral tonic–clonic seizures** (these may obscure the focal onset). A focal seizure onset often indicates a structural cause and detailed imaging is required to identify this. In general, the response to treatment is less good than with PGE.

**Hippocampal sclerosis**
This is a major cause of epilepsy. Hippocampal sclerosis (damage with scarring and atrophy of the hippocampus and surrounding cortex) is the main pathological substrate causing temporal lobe epilepsy and the leading cause of localization-related epilepsy. Childhood febrile convulsions are the main risk factor. Hippocampal sclerosis is usually visible on MRI. It is one of the more common causes of refractory epilepsy, in which case it may be amenable to surgical resection of the damaged temporal lobe.

**Genetic and developmental disorders**
Over 200 genetic disorders, such as tuberous sclerosis, include epilepsy among their features. These account for less than 2% of epilepsy cases. Neuronal migration defects during brain development, dysplastic areas of cerebral cortex and hamartomas contribute to seizures in both infancy and adult life.

**Trauma, hypoxia and neurosurgery**

**Traumatic brain injury**. This may cause epilepsy, sometimes years after the event. The risk is not increased after mild injury (loss of consciousness or post-traumatic amnesia <30 min). Depressed

---

**Box 26.43 Causes of epilepsy**

- Primary generalized epilepsy, e.g. juvenile myoclonic epilepsy
- Developmental, e.g. neuronal migration abnormalities, cortical dysplasia
- Hippocampal sclerosis
- Brain trauma and surgery
- Intracranial mass lesions, e.g. tumour
- Vascular, e.g. cerebral infarction, arteriovenous malformation, venous sinus thrombosis
- Infectious, e.g. viral encephalitis, meningitis, cerebral tuberculosis, HIV, cerebral toxoplasmosis, neurocysticercosis
- Immune, e.g. NMDA receptor antibody and potassium channel antibody encephalitis
- Genetic, e.g. channelopathies
- Metabolic abnormalities, e.g. hyponatraemia, hypocalcaemia
- Neurodegenerative disorders, e.g. Alzheimer’s
- Drugs, e.g. ciclosporin, lidocaine, quinolones, tricyclic antidepressants, antipsychotics, lithium, stimulant drugs such as cocaine
- Alcohol withdrawal

**Box 26.44 Juvenile myoclonic epilepsy**

- 10% of all epilepsy patients
- Starts in teenage years
- Clinical features:
  - Myoclonic jerks
  - Generalized tonic–clonic seizures
  - Absence in one-third
  - Triggers: sleep deprivation, alcohol, strobe lighting
- Abnormal EEG
- Good response to treatment
- Requires life-long treatment
skull fracture, penetrating injury and intracranial haemorrhage increase risk significantly.

**Perinatal brain injury and cerebral palsy.** Periventricular leukomalacia and brain haemorrhage associated with prematurity and fetal hypoxia, may cause early-onset epilepsy. One-third of children with cerebral palsy have epilepsy.

**Brain surgery.** This is followed by seizures in up to 17% of cases. Prophylactic anticonvulsant use after surgery is not recommended.

### Brain tumours and other mass lesions
Mass lesions involving the cortex cause epilepsy. Seizures are one of the most common presenting features of brain tumours. Brain tumours cause 6% of cases of adult-onset epilepsy.

### Vascular disorders
**Stroke and small-vessel cerebrovascular disease** is the most common cause of epilepsy after the age of 60.

### Cortical venous thrombosis or venous sinus thrombosis
Arteriovenous malformations commonly cause epilepsy.

*Cavernous haemangiomas* (cavernomas) usually present with epilepsy (see Fig. 26.41).

### Neurodegenerative disorders
Neurodegenerative disorders involving the cerebral cortex, such as Alzheimer’s disease, are associated with an increased risk of epilepsy.

### Infection
Seizures are often the presenting feature of encephalitis, cerebral abscess and tuberculomas. They also occur in chronic meningitis (e.g. tuberculosis) and may rarely be the first sign of acute bacterial meningitis. Neurocysticercosis is a major cause of seizures in countries where the pork tapeworm is endemic, such as India and South America. HIV and complications of immunosuppression, such as cerebral toxoplasmiosis, may also lead to seizures.

### Immunological disorders
Autoimmune antibody-mediated encephalitis, such as that due to antibodies against potassium channels or NMDA or glycine receptors, typically present with seizures, as may autoimmune limbic encephalitis.

### Alcohol and drugs
Chronic alcohol use is a common cause of seizures. These occur either during heavy drinking bouts or during periods of withdrawal. Alcohol-induced hypoglycaemia and head injury also lead to seizures.

Several drugs, including antipsychotics, tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs), lithium, class Ib anti-arrhythmics such as lidocaine, ciclosporin and mefloquine, sometimes provoke fits, either in overdose or at therapeutic doses in individuals with a low seizure threshold. Stimulant drugs such as cocaine also cause seizures.

Withdrawal of antiepileptic drugs (especially barbiturates) and benzodiazepines may provoke seizures.

### Metabolic abnormalities
Seizures can be caused by:
- hypocalcaemia, hypoglycaemia, hyponatraemia
- acute hypoxia
- uraemia, hepatic encephalopathy
- porphyria.

### Diagnosis of the first fit and investigations

The diagnosis of a seizure is essentially a clinical one, based on taking a history from the patient and any witnesses (Boxes 26.45 and 26.46). Investigations have a limited role in distinguishing between a seizure and other causes of a blackout or attack (see p. 857).

The majority of patients referred to a first fit clinic have not had a seizure. The most common error is to misdiagnose a syncopal blackout for a seizure.

#### Which investigations are needed?
Blood tests, including serum calcium, and an ECG (rhythm, conduction abnormalities, QT interval) are necessary in most patients following an episode of loss of consciousness (Box 26.47).

### Electroencephalography
EEG is most useful to categorize epilepsy and understand its cause, rather than as a means of confirming a doubtful diagnosis of epilepsy. EEG has a high false-negative rate in epilepsy (>20% even
with awake and sleep recordings) and a low false-positive rate (1% of people without epilepsy have epileptiform changes on EEG).

- **EEG abnormalities in epilepsy:** focal cortical spikes (e.g. over a temporal lobe) or generalized spike-and-wave activity (in PGE). Epileptic activity is continuous in status epilepticus.

- **Sleep recordings or 24-hour ambulatory EEG** increase sensitivity when routine EEG is normal.

- **Inpatient EEG video telemetry** is helpful for diagnosis in attacks of uncertain cause.

### Brain imaging

MRI is indicated in most patients after a first seizure, particularly in focal-onset seizures and in older patients where the chance of a focal brain lesion is greatest. In patients below the age of 30 with a definite electroclinical diagnosis of PGE, brain imaging is not essential.

### Recurrence risk after a first fit

Some 70–80% of people will have a second seizure, the risk being highest in the first 6 months after the initial seizure. The vast majority of those who have a second seizure will have further seizures if not started on treatment. The risk of seizure recurrence is significantly increased by features of PGE on EEG, focal seizures and the presence of structural brain lesions.

### Management

#### Emergency measures

Most seizures last only minutes and end spontaneously. A prolonged seizure (>5 min) or repeated seizures may be terminated with rectal diazepam, intravenous lorazepam or buccal midazolam. Oxygen should be given and the airway monitored in the post-ictal phase.

### Status epilepticus

This medical emergency (Box 26.48) means continuous seizures for 30 minutes or longer (or two or more seizures without recovery of consciousness between them over a similar period). Status epilepticus has a mortality of 10–15%. The longer the duration of status, the greater the risk of permanent cerebral damage. Rhabdomyolysis may lead to acute kidney injury in convulsive status, the greater the risk of permanent cerebral damage. Rhabdomyolysis may lead to acute kidney injury in convulsive status. The greater the risk of permanent cerebral damage. Rhabdomyolysis may lead to acute kidney injury in convulsive status.

Over 50% of cases occur without a previous history of epilepsy. Some 25% with apparent refractory status have pseudostatus (non-epileptic attack disorder).

Not all status is convulsive. In absence status, for example, status is non-convulsive; the patient is in a continuous, distant, stuporous state. Focal status also occurs. Epilepsia partialis continua is continuous seizure activity in one part of the body, such as a finger or a limb, without loss of consciousness. This is often due to a cortical neoplasm or, in the elderly, a cortical infarct.

### Antiepileptic drugs and common seizure types

#### Generalized tonic–clonic seizures (grand mal)

- Sodium valproate
- Levetiracetam
- Lamotrigine
- Carbamazepine
- Oxcarbazepine
- Topiramate

#### Focal seizures with or without secondary generalization

- Carbamazepine
- Lamotrigine
- Levetiracetam
- Sodium valproate
- Oxcarbazepine
- Topiramate

#### Myoclonic seizures

- Sodium valproate
- Levetiracetam
- Topiramate

#### Second-line and/or add-ons

- Phenobarbital
- Clobazam
- Clonazepam
- Phenytoin
- Clobazam
- Gabapentin
- Pregabalin
- Zonisamide
- Lacosamide
- Tiagabine
- Clonazepam
- Clobazam
- Lamotrigine
- Piracetam

- Carbamazepine
- Oxcarbazepine

### Antiepileptic drugs

Antiepileptic drugs (AEDs; Box 26.49) are indicated when there is a firm clinical diagnosis of epilepsy and a substantial risk of recurrent seizures. Some general principles apply:

- **Introduce AEDs at low dose and slowly titrate upwards until the seizures are controlled or side-effects become unacceptable.**

- **Aim for monotherapy:** 70% of patients will have good seizure control with a single AED.

- **If seizures are not controlled with the first AED, gradually introduce a second agent and then slowly withdraw the first AED. If the patient is still not seizure-free, then combination therapy is required.**
Epilepsy is one of the few disorders where non-generic (‘brand name’) prescribing is justified to ensure consistent drug levels.

Routine monitoring of AED levels is not needed and should be reserved for assessing compliance and toxicity. Measuring sodium valproate levels is rarely useful, as levels fluctuate widely.

There are interactions between AEDs (and with other medications), e.g. between sodium valproate and lamotrigine. New-generation AEDs have fewer interactions.

Phenytoin is no longer considered a first-line AED; it is now principally used in emergency control of seizures (see status epilepticus above). Levetiracetam is increasingly used in most types of epilepsy.

Unwanted effects of drugs

Intoxication with most AEDs causes unsteadiness, nystagmus and drowsiness. Side-effects are more common with multiple AED usage. Skin rashes are seen particularly with lamotrigine, carbamazepine and phenytoin. A wide variety of idiosyncratic drug reactions may occur, such as blood dyscrasias with carbamazepine.

Epilepsy in women

See page 1458.

Epilepsy and driving

Patients should be asked to stop driving after a seizure and to inform the regulatory authorities if they hold a driving licence. After a seizure, a temporary driving ban until seizure-free is usual but regulations vary from country to country. Many driving regulatory bodies also suggest refraining from driving while withdrawing from AEDs.

Lifestyle and safety

People with epilepsy (the term ‘epileptic’ is no longer used) should be encouraged to lead lives as unrestricted as reasonably possible, though observing simple safety measures such as avoiding swimming and dangerous sports like rock-climbing. Advice at home includes leaving bathroom and lavatory doors unlocked and taking showers rather than baths. Epilepsy triggers, such as sleep deprivation, excess alcohol and drugs, should be avoided, as should strobe lighting where there is EEG evidence of a photo-paroxysmal response.

Drug withdrawal

Withdrawal of AEDs should be considered after a seizure-free period of at least 2–3 years. There is a 50% seizure recurrence rate after withdrawal so detailed discussion and explanation are essential.

Refractory epilepsy

- Seizures may persist despite treatment, especially with temporal lobe epilepsy.
- Re-evaluate the diagnosis.
- Consider concordance (compliance).
- Combine AEDs and use the maximum tolerated dose.
- Refer to a specialist unit for consideration of epilepsy surgery.
- Other non-pharmaceutical treatments, such as vagal nerve stimulation and the ketogenic low-carbohydrate diet, may sometimes be useful.

Epilepsy surgery

Temporal lobectomy will result in seizure freedom in 50–70% of selected patients with uncontrolled seizures caused by hippocampal sclerosis (defined by imaging and confirmed by EEG).

Other causes of blackouts

The simple faint that over half the population experiences at some time (particularly in childhood, youth or pregnancy) is due to sudden reflex bradycardia with vasodilation of both peripheral and splanchnic vasculature (neurocardiogenic or vasovagal syncope).

- Precipitants: a common response to prolonged standing, fear, venesection or pain. Syncope almost never occurs in the recumbent posture.
- Prodrome: usually brief. There is dizziness and a light-headed feeling, often with nausea, sweating, a feeling of heat and visual grey-out.
- Blackout: patients usually lie still but jerking and twitching movements can occur and are sometimes mistaken for a convolution. Their appearance is pale. Incontinence of urine or faeces can occur and is not a good discriminator between seizure and syncope.
- Recovery: rapid, usually taking place over seconds, but may be followed by a feeling of general fatigue (as opposed to post-ictal drowsiness and confusion following a seizure).

Other types of syncope

Cardiac syncope (Stokes–Adams attacks) is potentially serious and often treatable. Typically, there is little or no warning. Cardiac arrhythmias, such as those due to heart block, or left ventricular outflow tract obstruction may be the cause. Syncope during exercise is often cardiac in origin.

- Micturition syncope occurs during micturition in men, particularly at night.
- Cough syncope occurs when venous return to the heart is obstructed by bouts of severe coughing; it is also seen with laughter occasionally.
- Postural hypotension (see p. 1029) can cause syncope and occurs in the elderly, in autonomic neuropathy, and with some drugs, such as antihypertensives.
- Carotid sinus syncope (see p. 1029) is due to a vagal response caused by pressure over the carotid sinus baroreceptors in the neck: for example, due to a tight collar.
- Convulsive syncope is when collapsing in a propped-up position following a syncope results in delayed restoration of cerebral blood flow and may lead to a secondary anoxic seizure following syncope.

</table>
Investigations
A 12-lead ECG should always be performed after a syncope to identify heart block, pre-excitation or long QT syndrome. Cardiac ECG holter monitoring and echocardiography are required where cardiac syncope is suspected. An implantable loop recorder is occasionally needed for infrequent events with a possible cardiac origin. Tilt-table testing (see p. 1038) is sometimes diagnostic but has low sensitivity.

Other conditions
Non-epileptic attack disorder (pseudoseizures) regularly causes difficulty in diagnosis. Attacks may look like generalized fits. Usually, there are bizarre thrashing, non-synchronous limb movements, but there can be extreme difficulty in separating these attacks from seizures. EEG videotelemetry is valuable. Apparent status epilepticus can occur. The serum prolactin level is of some value; this rises during a grand mal seizure but not during a pseudoseizure (or a partial seizure).

Panic attacks (see p. 786) trigger sudden sympathetic activation and often hyperventilation, leading to respiratory alkalosis. They cause some or all of the following symptoms: dizziness, chest pains or tightness, a feeling of choking or shortness of breath, tingling in face and extremities, palpitations, trembling and a feeling of dissociation or of impending doom. Consciousness is usually preserved and attacks are easily recognized. Blood gases should be measured.

Hypoglycaemia (see p. 716) causes confusion followed by loss of consciousness, sometimes with a convulsion, dysphasia or hemiparesis. There is often a warning, with hunger, malaise, shaking and sweating. Prompt recovery occurs with intravenous (or oral) glucose. Prolonged hypoglycaemia causes widespread cerebral damage. Hypoglycaemic attacks unrelated to diabetes are rare (see p. 647). Feeling faint after fasting does not indicate anything serious.

Vertigo, when acute, can be sufficiently severe as to cause prostration; a few seconds’ unresponsiveness sometimes follows.

Migraine, in the form of severe basilar migraine and familial hemiplegic migraine, may occasionally lead to loss of consciousness.

Drop attacks are instant, unexpected episodes of lower limb weakness with falling, largely in women over 60 years. Awareness is preserved. They are due to sudden change in lower limb tone, presumably of brainstem origin. Sudden attacks of leg weakness also occur in hydrocephalus.

TIAs are almost never a cause of loss of consciousness.

Sleep disorders
Sleep architecture and insomnia are discussed on page 775. Myoclonic jerks when falling asleep are a normal phenomenon (see p. 862). Seizures may occur predominantly or solely during sleep.

Narcolepsy and cataplexy
Narcolepsy is caused by abnormalities of the brain neurotransmitter hypocretin (orexin), which is a regulator of sleep. CSF levels are usually low, thought in most cases to be due to autoimmune damage to the hypothalamic cells secreting the neurotransmitter. Narcolepsy is strongly associated with human leucocyte antigen (HLA)-DR2 and HLA-DQB1*0602 antigens. The prevalence is estimated at 30–50/100 000. There are four main clinical features but not all patients have the full tetrad:

• Excessive daytime sleepiness (EDS). This is the usual presenting symptom and the main cause of disability. Patients have frequent irresistible sleep attacks during the day, often in inappropriate circumstances, e.g. during meals or conversations or while driving. EDS may be quantified with the Epworth Sleepiness Scale. Night-time sleep may be disrupted and, paradoxically, insomnia may occur.

• Cataplexy. This is sudden loss of muscle tone leading to head droop or even falling with intact awareness. Attacks are often set off by sudden surprise or emotion, e.g. laughter.

• Hypnagogic/hypnopompic hallucinations. These terms refer to dream-like hallucinations occurring while falling asleep or waking from sleep; these are often frightening.

• Sleep paralysis. A brief paralysis on waking or while falling asleep is due to intrusion of rapid eye movement (REM) atonia into wakefulness. This occasionally occurs in people without narcolepsy.

Diagnosis and management
Multiple sleep latency testing demonstrating a rapid transition from wakefulness to sleep and a short time to onset of REM sleep confirms the diagnosis. HLA testing may also be useful.

Good sleep hygiene advice is necessary. Modafinil dexamethamine and methylphenidate are used to treat EDS, often with only partial response. Tricyclic antidepressants, particularly clomipramine, or SSRIs can improve cataplexy. Sodium oxybate is also used.

Parasomnias
Disruptive motor or verbal behaviours occurring during sleep are divided into REM and non-REM parasomnias, depending on which stage of sleep they arise in. They include sleepwalking, night terrors, confusional arousals and REM sleep behaviour disorder (which may be an early feature of Parkinson’s disease).

Obstructive sleep apnoea
See page 960.

Restless leg syndrome (Willis–Ekbom disease)
Also known as Wittmaack–Ekbom’s syndrome, this affects about 10% of adults, both women and men, and is also seen in children. Most people do not seek medical advice but it can be quite severe in 2–3%. The syndrome is characterized by an unpleasant sensation of ‘wanting to move’ the legs with throbbing or pulling, and usually occurs when the person is resting, sitting or lying; it can be totally or partially relieved by stretching or walking. It often occurs in the evenings or night-time and appears to be more frequent in the elderly. The condition is usually idiopathic and there is a familial tendency. It has been associated with pregnancy, Parkinson’s disease, uraemia or a haematinic deficiency. Some drugs have been implicated.

There is no specific treatment. Dopamine agonist drugs and benzodiazepines may help. Some suggest a decreased use of alcohol or caffeine.

MOVEMENT DISORDERS

Disorders of movement divide broadly into two categories:
- **hypokinesias** – characterized by slowed movements with increased tone (parkinsonism)
- **hyperkinesias** – excessive involuntary movements.

Both types may coexist; for example, in Parkinson’s disease, where there are both slowed movements and tremor. Many of these disorders (not all) relate to dysfunction of the basal ganglia.

**Parkinsonian disorders**

**Idiopathic Parkinson’s disease**

In 1817, James Parkinson, a physician in Hoxton, London, published *The Shaking Palsy*, describing this common worldwide condition that has a prevalence of 150/100 000. Parkinson’s disease (PD) is clinically and pathologically distinct from other parkinsonian syndromes.

**Aetiology**

The causes of idiopathic PD are still not fully understood. The relatively uniform worldwide prevalence suggests that a single environmental agent is not responsible. There may be multiple interacting risk factors, including genetic susceptibility.

**Age and gender**

Prevalence increases sharply with age, particularly over 70 years, with prevalence of 1 in 200 over age 80. Ageing changes are likely to be a factor in causation. Prevalence is higher in men (1.5 : 1 male to female).

**Environmental factors**

Epidemiological studies consistently show a small increased risk with rural living and drinking well water. Pesticide exposure has been implicated and pesticide-induced rodent models of PD exist, which increases biological plausibility of a link. The chemical compound methyl-phenyl tetrahydropyridine (MPTP), a potent mitochondrial toxin, causes severe parkinsonism, leading to suggestions that oxidative stress may be a factor leading to neuronal cell death in idiopathic PD. Studies consistently show that non-smokers have a higher risk of PD than smokers (even after controlling for shorter life expectancy in smokers), an observation that is difficult to explain.

**Genetic factors**

Idiopathic PD is not usually familial but twin studies show there is a significant genetic component in early-onset PD (onset before 40). Several genetic loci for Mendelian inherited monogenic forms of PD have now been identified (Box 26.51), designated PARK 1–11. Most of these are rare but together they account for a large proportion of early-onset and familial PD, and a small proportion (perhaps 1–2%), of sporadic late-onset cases. The main significance of the PARK genes is that they provide insights into the pathophysiological mechanisms underlying PD that may be relevant to sporadic cases. Polymorphisms in these and other genes may, in combination, constitute a susceptibility to PD that can be triggered by environmental factors or the ageing process.

**Pathology**

The pathological hallmarks of PD are the presence of neuronal inclusions called Lewy bodies (see p. 883) and loss of the dopaminergic neurons from the pars compacta of the substantia nigra in the midbrain that project to the striatum of the basal ganglia (see Fig. 26.11). Lewy bodies contain tangles of α-synuclein and ubiquitin, and become gradually more widespread as the condition progresses, spreading from the lower brainstem to the midbrain and then into the cortex. Degeneration also occurs in other basal ganglia nuclei. The extent of nigrostriatal dopaminergic cell loss correlates with the degree of akinesia.

**Clinical features**

PD almost always presents with the typical motor symptoms of tremor and slowness of movement but it is likely that the pathological process starts many years before these symptoms develop. By the time of first presentation, on average 70% of dopaminergic nigrostriatal cells have already been lost.

**Prodromal pre-motor symptoms**

Patients develop a variety of non-specific non-motor symptoms during the approximately 7 years, sometimes longer, before the motor symptoms become manifest. These include:
- anosmia (present in 90%) – the olfactory bulb is one of the first structures to be affected
- depression/anxiety (50%)
- aches and pains
- REM sleep behaviour disorder
- autonomic features – urinary urgency, hypotension
- constipation
- restless legs syndrome.

**Motor symptoms**

These develop slowly and insidiously, and are often initially attributed to ‘old age’ by patients. The core motor features of PD are:
- akinesia
- tremor
- rigidity
- postural and gait disturbance.

Slowness causes difficulty rising from a chair or getting into or out of bed. Writing becomes small (micrographia) and spidery, tending to tail off. Relatives often notice other features: slowness and an impassive face. Idiopathic PD is almost always more prominent initially on one side. The diagnosis is usually evident from the overall appearance.

AD, autosomal dominant; AR, autosomal recessive.
Akinesia
Poverty/slowing of movement (also called bradykinesia) is the cardinal clinical feature of parkinsonism and the main cause of disability. What distinguishes it from slowness of movement from other causes is a progressive fatiguing and decrement in amplitude and speed of repetitive movements, such as opening and closing the hand or finger tapping.

There is difficulty initiating movement. The upper limb is usually affected first and is almost always unilateral for the first years. Rapid dexterous movements are impaired, causing difficulty writing (micrographia) and doing up buttons and zips, for example. Facial immobility gives a mask-like semblance of depression. Frequency of spontaneous blinking diminishes, producing a serpentine stare.

Tremor
Tremor is the presenting symptom in 70% of patients. It typically starts in the fingers or hand (3–6 Hz) and is unilateral initially, spreading later to the leg on the same side and, after some years, to the opposite side. The tremor is present at rest, and reduces or stops completely when the hand is in motion. It is often described as pill-rolling because the patient appears to be rolling something between thumb and forefinger. As with most tremors, it is made worse by emotion or stress.

Rigidity
This is a sign rather than a symptom. Stiffness on passive limb movement is described as ‘lead pipe’, as it is present throughout the range of movement and, unlike spasticity, is not dependent on speed of movement. When stiffness occurs with tremor (not always visible), a ratchet-like jerkiness is felt, described as ‘cogwheel’ rigidity.

Postural and gait changes
A stooped posture is characteristic. Gait gradually becomes shuffling with small stride length, slow turns, freezing and reduced arm swing. Postural stability eventually deteriorates, leading to falls, but this is a late-stage feature that should arouse suspicion of an alternative diagnosis if present during the first 5 years.

Speech and swallowing
Speech becomes quiet, indistinct and flat. Drooling may be an embarrassing problem and swallowing difficulty is a late feature that may eventually lead to aspiration pneumonia as a terminal event.

Cognitive and psychiatric changes
Cognitive impairment is now recognized to be common in late-stage PD (80%) and may develop into dementia. Visual hallucinations on treatment, and psychosis are not uncommon, and may herald evolving cognitive decline. Cholinesterase inhibitors (see p. 884) may be helpful. Depression is common, probably due to involvement of serotonergic and adrenergic systems, and is a cause of reduced quality of life in PD. Anxiety is also co-morbid with PD.

Clinical evolution of PD
Most patients respond well to treatment and there is generally a period of several years in which symptoms are well controlled with relatively little disability. Response to dopaminergic drugs is never lost but treatment-related fluctuations may develop (see below), which can be limiting, especially for patients with early age at onset. Eventually, usually by the mid-seventies, late-stage, treatment-unresponsive features, such as cognitive impairment, swallowing difficulty, loss of postural stability and falls, start to emerge.

The rate of progression is very variable, with a benign form running over several decades. Usually, the course is over 10–20 years, death resulting from bronchopneumonia and immobility.

Diagnosis
There is no laboratory test; diagnosis is made by recognizing physical signs and distinguishing idiopathic PD from other parkinsonian syndromes. Patients with suspected PD should be referred to a specialist without initiation of treatment.

MRI is normal and not necessary in typical cases. Dopamine transporter (DAT) imaging using SPECT or PET makes use of a radiolabelled ligand binding to dopaminergic terminals to assess the extent of nigrostriatal cell loss. It may occasionally be needed to distinguish PD from other causes of tremor or from drug-induced parkinsonism, but it cannot discriminate between PD and other akinetic–rigid syndromes.

Management
Education about the condition is necessary and physical activity is beneficial and should be encouraged. Dopamine replacement with levodopa or a dopamine agonist improves motor symptoms and is the basis of pharmacological therapy. Treatment of non-motor symptoms, such as depression, constipation, pain and sleep disorders, is also necessary and significantly improves quality of life.

Dopamine replacement may not always be needed in early-stage PD and is only started when symptoms begin to cause disability. The mechanism of action of drugs in PD is shown in Fig. 26.45.

Levodopa
Levodopa remains the most effective form of treatment and all patients with PD will eventually need it. It is combined with a dopa

![Fig. 26.45 Drugs in Parkinson's disease.](image-url)
Deep brain stimulation
Stereotactically inserting electrodes into the brain has proven to be a major therapeutic advance in selected patients (usually under age 70) with disabling dyskinesias and motor fluctuations not adequately controlled with medical therapy. Targets include:

- the subthalamic nucleus – response similar to levodopa with reduction in dyskinesia
- the globus pallidus – improves dyskinesia but levodopa is still required for motor symptoms
- the thalamus – for tremor only.

Dopaminergic drugs can be reduced (but not withdrawn) after deep brain stimulation (DBS). Approximately 10% of patients will be candidates at some point, usually patients with younger onset, as they have a higher rate of motor complications such as dyskinesias. There is a trend towards earlier use of DBS before motor complications become severe.

Levodopa intestinal gel infusion
Continuous infusion of this gel into the small intestine using a patient-operated pump is effective for selected patients with severe motor complications. At present, it is used only where apomorphine and DBS are contraindicated, partly because of high costs.

Tissue transplantation
Transplantation of embryonic mesencephalic dopaminergic cells directly into the putamen has produced mixed results but is potentially promising; research is ongoing to refine the technique. Stem cells and gene therapy approaches are in development.

Physiotherapy, occupational therapy and physical aids
Physiotherapy, occupational therapy and speech therapy all have a role to play in managing PD and reducing disability, speech and swallowing problems, and falls. Walking aids are often a hindrance early on, but later a frame or a tripod may help. A variety of external cueing techniques may help with freezing.

Other akinetic–rigid syndromes

Drug-induced parkinsonism
Dopamine-blocking or depleting drugs, particularly neuroleptics (with the exception of clozapine), induce parkinsonism or worsen symptoms in affected patients, and may precipitate symptoms in elderly patients in the presymptomatic phase. Antimuscarinic drugs reduce these symptoms, although tardive dyskinesia may be made worse.

Atypical parkinsonism
A number of neurodegenerative disorders affect the basal ganglia, causing prominent parkinsonism as part of the clinical picture; they may be mistaken for idiopathic PD in the early stages. These include:

- Progressive supranuclear palsy (Steele–Richardson–Olszewski’s syndrome). This causes parkinsonism, postural instability with early falls, vertical supranuclear gaze palsy, pseudobulbar palsy and dementia. Tau deposition is seen pathologically in the substantia nigra, subthalamic nucleus and midbrain.
- Multiple system atrophy (MSA). Autonomic and cerebellar symptoms occur in addition to parkinsonism. Either parkinsonism or cerebellar symptoms predominate. Pathologically, α-synuclein-positive glial cytoplasmic inclusions are found in...
the basal ganglion, cerebellum and motor cortex. Patients do not respond to levodopa therapy. Management is symptomatic and they have a poorer prognosis than patients with Parkinson’s disease.

- **Corticobasal degeneration.** Alien limb phenomena, myoclonus and dementia occur.

  These disorders are relentlessly progressive; although they sometimes respond to levodopa, they usually cause death within a decade. ‘Red flag’ symptoms suggesting one of these disorders include:

  - symmetrical presentation and absence of tremor
  - levodopa unresponsiveness (or poor response)
  - early falls (within first year)
  - additional neurological features.

- **Wilson’s disease**

  This rare and treatable disorder of copper metabolism is inherited as an autosomal recessive trait. Copper deposition occurs in the basal ganglia, cornea and liver (see p. 1301), where it can cause cirrhosis. All young patients (below age 50) with any hyperkinetic movement disorder or with liver cirrhosis should be screened for Wilson’s disease (serum copper and caeruloplasmin should be checked). Intellectual impairment develops. Neurological damage is reversible with early treatment. Diagnosis and treatment with the chelating agent penicillamine are discussed on page 1302.

### Hyperkinetic movement disorders

There are five hyperkinetic movement disorders, which can sometimes be difficult to separate from one another and may occur in combination.

- **tremor** – rhythmic sinusoidal oscillation of a body part
- **chorea** – excessive, irregular movements flitting from one body part to another (‘dance-like’)
- **myoclonus** – brief, electric shock-like jerks
- **tics** – stereotyped movements or vocalizations (may be temporarily suppressed)
- **dystonia** – sustained muscle spasms causing twisting movements and abnormal postures.

- **Essential tremor**

  This common condition, often inherited as an autosomal dominant trait, causes a bilateral, fast, low-amplitude tremor, mainly in the upper limbs. The head and voice are occasionally involved. Tremor is postural, such as when holding a glass or cutlery. Essential tremor occurs at any age but usually starts in early life. Tremor is slowly progressive but rarely produces severe disability. There may be a cerebellar-type action tremor component. Anxiety exacerbates the tremor.

  Treatment is often unnecessary or unsatisfactory. Many patients are reassured to find they do not have PD, with which essential tremor is often confused. Small amounts of alcohol, beta-blockers (propranolol), primidone or gabapentin may help. Symptomimetics (e.g. salbutamol) make all tremors worse. Stereotactic thalamotomy and thalamic DBS are used in severe cases.

- **Chorea**

  There are a wide variety of possible causes of chorea. These include:

  - systemic disease – thyrotoxicosis, SLE, antiphospholipid syndrome, polycythaemia vera
  - genetic disorders – Huntington’s disease and genetic phenocopies, neuroacanthocytosis, benign hereditary chorea
  - structural and vascular disorders affecting the basal ganglia
  - drugs (e.g. levodopa and the oral contraceptive pill)
  - post-infectious (Sydenham’s chorea) – following months after streptococcal infection or as part of acute rheumatic fever
  - pregnancy.

  Treatment is of the underlying cause but dopamine-blocking drugs, such as phenothiazines (e.g. sulpiride) and dopamine-depleting drugs (tetrabenazine), reduce chorea (as the prototypical excessive movement condition the treatment is the opposite of PD).

- **Huntington’s disease**

  Huntington’s disease is a cause of chorea, usually presenting in middle life, initially with subtle ‘fidgetiness’ followed by development of progressive psychiatric and cognitive symptoms.

  Prevalence worldwide is about 5/100,000. HD is due to a CAG trinucleotide repeat expansion, which forms the basis of the diagnostic test (see p. 30). This results in translation of an expanded polyglutamine repeat sequence in huntingtin, the protein gene product, the function of which is unclear. The expansion is thought to be a toxic ‘gain-of-function’ mutation. Most adult-onset patients have 36–55 repeats and there is an inverse relationship between repeat length and age at onset, with juvenile-onset patients having over 60 repeats. Expansion of the unstable CAG repeat during meiosis, particularly spermatogenesis, is the molecular basis for the phenomenon of anticipation (a tendency for successive generations to have earlier onset and more severe disease), particularly when inherited from the father.

  HD is inherited in an autosomal dominant manner with complete penetrance (all gene carriers will develop the disease eventually). Previous family history is often not known. There is no disease-modifying treatment at present, although chorea can improve with treatment, such as risperidone or sulpiride, but progressive neurodegeneration leads to dementia and ultimately death after 10–20 years. Patients with small or intermediate-range expansions may present in old age with isolated chorea.

  Absence of treatment results in a low take-up rate for presymptomatic testing in at-risk individuals. Test centres have protocols for counselling families and addressing ethical issues.

- **Hemiballismus**

  Hemiballismus (see Fig. 26.11) describes violent swinging movements of one side, usually caused by infarction or haemorrhage in the contralateral subthalamic nucleus.

  Acute chorea–hemiballismus also occurs after diabetic hyperosmolar hyperglycaemia, with signal change seen in the basal ganglia on CT or MRI; it is thought to be due to osmotic shifts causing myelinolysis.

- **Myoclonus**

  Cortical myoclonus is usually distal (hands and fingers especially) and stimulus-sensitive (spontaneous but also triggered by touch or loud noises). It is caused by a wide variety of pathologies affecting the cerebral cortex; spinal and brainstem myoclonus are caused by localized lesions affecting these structures.

- **Primary myoclonus**

  **Physiological myoclonus.** Nocturnal myoclonus consisting of sudden jerks (often with a feeling of falling) on dropping off to sleep or waking; it is common and not pathological. The startle response is also a form of brainstem myoclonus.

  **Myoclonic dystonia (DYT11).** Myoclonic ‘lightning jerks’, often with dystonia, are inherited as a rare autosomal dominant disorder.
due to mutations in the ε-sarcoglycan gene. The condition is thought to be allelic with benign essential myoclonus (caused by disruption of the same gene).

**Myoclonus in epilepsy**
Myoclonic jerks occur in several forms of epilepsy (see p. 853). An antiepileptic drug, such as valproate, may be helpful.

**Progressive myoclonic epilepsy–ataxia syndromes**
These rare conditions include genetic and metabolic disorders in which myoclonus occurs with progressive epilepsy, cognitive decline and/or ataxia. *Lafora body disease, neuronal ceroid lipofuscinosis* and *Unverricht–Lundborg* disease are examples.

**Secondary myoclonus**
Myoclonus may be seen in a wide variety of metabolic disorders, including hepatic and renal failure (asterixis), as part of several dementias and neurodegenerative disorders (e.g. Alzheimer’s disease) and encephalitis.

Post-anoxic myoclonus sometimes follows severe cerebral anoxia.

**Tics**
Tics are common (15% lifetime prevalence), brief, stereotyped movements usually affecting the face or neck but which may involve any body part; they include vocal tics. Unlike other movement disorders, they may be transiently suppressed, leading to a build-up of anxiety and overflow after release.

Simple transient tics (e.g. blinking, sniffing or facial grimacing) are common in childhood but may persist. Adult-onset tics are rare and usually have a secondary cause. The borderline between normal and pathological is vague.

**Tourette’s syndrome**
The most common cause of tics, characterized by multiple motor tics and at least one vocal tic, starts in childhood and persists longer than a year. Boys are affected more often than girls in a 3:1 ratio. Behavioural problems, including attention deficit hyperactivity disorder (ADHD) and obsessive–compulsive disorder (OCD), are common and may sometimes be the major cause of disability. There is sometimes explosive barking and grunting of obscenities (coprolalia) and gestures (copropraxia) or echolalia (copying what other people say). Many affected individuals never come to medical attention. The cause is not known but it may be a complex problem with histaminergic neurotransmission.

**Dystonias**
Dystonia (Box 26.52) is most usefully classified by aetiology into:
- **primary dystonias** – where dystonia is the only, or main, clinical manifestation (usually genetic)
- **secondary dystonia** – due to brain injury, cerebral palsy or drugs, for example
- **hereditary degenerative dystonia** – part of a wider neurodegenerative disorder
- **paroxysmal dystonias** – rare, mostly genetic, attacks of sudden involuntary movements with elements of dystonia and chorea.

**Primary dystonias**

**Young onset.** Mutations in the *DYT1* gene locus, seen particularly in the Ashkenazi Jewish population, cause limb-onset dystonia (usually foot), before the age of 28. Most patients have a three base-pair GAG deletion in the *torsinA* endoplasmic reticulum ATPase protein encoded by the *DYT1* gene. Penetration is low (autosomal dominant) and phenotype very variable, but the disorder often spreads over years to become generalized dystonia, and can result in severe disability. Cognitive function remains normal. The condition is rare and the definitive form of treatment for severe cases is DBS (electrodes inserted into the globus pallidus).

**Adult onset.** This is much the most common type of primary dystonia. Onset is usually around 55 and dystonia is usually focal (restricted to one body part), particularly affecting the head and neck, unlike *DYT1* dystonia. Various patterns are recognized.

**Torticollis**
Dystonic spasms gradually develop in neck muscles, causing the head to turn (torticollis) or to be drawn backwards (retrocollis). There may also be a jerky head tremor. A gentle touch with a fingertip at a specific site may relieve the spasm temporarily (sensory trick or ‘geste’).

**Writer’s cramp and task-specific dystonias**
There is a specific inability to perform a previously highly developed, repetitive, skilled movement, such as writing. The movement provokes dystonic posturing. Other functions of the hand remain normal. Overuse may lead to task-specific dystonias in certain occupations, such as musicians, typists and even golfers.

**Blepharospasm and oromandibular dystonia**
These consist of spasms of forced blinking or involuntary movement of the mouth and tongue (e.g. lip-smacking and protrusion of the tongue and jaw). Speech may be affected.

**Dopa-responsive dystonia**
In this rare disorder, dystonia is completely abolished by small doses of levodopa. Typically, dystonic walking begins in childhood and may resemble a spastic paraparesis or even present as cerebral palsy. Dominantly inherited mutations in the GTP cyclohydrolase gene on chromosome 14q26.3 (necessary for synthesis of the co-factor – tetrahydrobiopterin – needed for dopamine synthesis) lead to brain dopamine deficiency. Patients with dystonic gait are sometimes given test doses of levodopa.

**Neuroleptics and movement disorders**
Neuroleptics (antipsychotic drugs used to treat schizophrenia) and related drugs used as antiemetics (e.g. metoclopramide) can cause a variety of movement disorders:
- **Akathisia.** This is a restless, repetitive and irresistible need to move.
- **Parkinsonism.** This is due to D1 and D2 dopamine receptor blockade (see earlier).
- **Acute dystonic reactions.** Spasmodic torticollis, trismus and oculogyric crises (episodes of sustained upward gaze) develop, dramatically and unpredictably, after single doses.
• **Tardive dyskinesia.** These mouthing and lip-smacking grimaces occur after several years of neuroleptic use. They often become temporarily worse when the drug is stopped or the dose reduced. Even if treatment ceases, resolution seldom follows. Atypical neuroleptics are less prone to cause this complication.

### Management

Targeted injection of botulinum toxin into affected muscles is now the principal form of treatment for all focal dystonias. Antimuscarinics (e.g. trihexyphenidyl) are sometimes helpful.

## NEUROINFLAMMATORY DISORDERS

Multiple sclerosis is by far the most common neuroinflammatory disorder in Western populations. Other CNS inflammatory conditions include post-infectious disorders such as acute disseminated encephalomyelitis (ADEM) and transverse myelitis, distinct autoimmune disorders such as neuromyelitis optica (NMO) and multisystem inflammatory disorders such as sarcoidosis and Behçet’s disease.

### Multiple sclerosis

Multiple sclerosis (MS) is a chronic autoimmune, T-cell-mediated, inflammatory disorder of the CNS. Multiple plaques of demyelination are found throughout the brain and spinal cord, occurring sporadically over years (dissemination in space and time is crucial for diagnosis).

MS is a major cause of disability in young adults but several disease-modifying therapies are now available.

### Epidemiology

- **Prevalence.** MS is a common neurological disorder with over 2500000 cases worldwide. In the UK, the prevalence is 1.2/1000. Approximately 80000 people in the UK have MS.
- **Gender.** Women outnumber men by 2 : 1. There is evidence that this ratio is widening, with an increasing proportion of women being affected.
- **Age.** Presentation is typically between 20 and 40 years of age. Presentation after age 60 is rare, although diagnosis may sometimes be much delayed, occurring years after the initial symptoms.

Prevalence varies widely in different geographical regions and ethnic groups. This probably reflects both genetic (see below) and environmental influences in pathogenesis. MS is much more common in white populations and with increasing distance from the equator. Even within the UK, there is a north–south divide, prevalence being higher in Scotland than southern England. Migration studies show that children moving from a low-risk to a high-risk area (e.g. the UK) develop a higher risk of MS, similar to the population of the country to which they migrate, indicating that environmental factors are a factor in pathogenesis.

Other autoimmune disorders occur with increased frequency in patients with MS and their relatives, indicating a genetic predisposition to autoimmunity.

### Aetiology and pathogenesis

MS is a T-cell-mediated autoimmune disease that causes an inflammatory process mainly within the white matter of the brain and spinal cord. The aetiology of MS is complex and not yet fully understood.

### Genetic susceptibility

Multiple genes interact to confer an increased risk of MS, giving a complex polygenic inheritance pattern. Genetic differences between different populations probably account for part of the observed variation in MS incidence around the world.

Family studies show that there is a much-increased risk of MS in first-degree relatives of affected patients (approximately 5% lifetime risk of developing MS). Twin studies confirm a major genetic component to susceptibility, with 30% of monozygotic twins being concordant for MS versus 5% of dizygotic twins.

**Genes.** Variations in some 60 different genes have been identified as conferring an increased risk of MS; 80% of these are genes relating to immune system function and regulation, including HLA and major histocompatibility complex (MHC) polymorphisms. HLA-associated genes include haplotypes HLA-DRB1*1501, DQA1*102 and DQB1*0602. HLA-DR15 appears to be associated with an earlier disease onset.

### Environmental factors

Migration studies (see above) and twin studies indicate that environmental factors play a role in the development of MS but these factors are still largely unknown. Viral infections can precipitate MS relapses, and exposure to infectious agents at critical times in development may trigger MS in genetically susceptible individuals. There is evidence that exposure to Epstein–Barr virus (EBV) may be linked to MS; EBV seropositivity is higher in patients with MS than in the general population. Human herpesvirus 6 (HHV-6) has also been implicated. Exposure to infectious agents in childhood may reduce the risk of developing MS and other autoimmune disorders (the ‘hygiene hypothesis’). There is also some evidence that low levels of vitamin D and lack of sunlight exposure may be a risk factor for MS.

### Pathology

Plaques of demyelination, 2–10 mm in size, are the cardinal features (Fig. 26.46). Plaques occur anywhere in CNS white matter but have a predilection for distinct CNS sites: optic nerves, the periventricular...
region, the corpus callosum, the brainstem and its cerebellar connections, and the cervical cord (corticospinal tracts and posterior columns). MRI studies show that most inflammatory plaques are asymptomatic. Recent advances in pathology and MRI techniques show that the gray matter of the cortex and the sub-pial meninges is also affected from an early stage in MS. Peripheral myelinated nerves are not directly affected in MS.

Acute relapses are caused by focal inflammation causing myelin damage and conduction block. Recovery follows as inflammation subsides and remyelination occurs. When damage is severe, secondary permanent axonal destruction occurs. Progressive axonal damage is the pathological basis of the progressive disability seen in progressive forms of MS. The extent of grey matter damage correlates with the severity of disability and cognitive involvement. The exact relationship between the inflammatory lesions seen in early relapsing–remitting forms of MS and the progressive axonal loss of chronic forms of MS is disputed.

**Clinical features**

No single group of signs or symptoms is diagnostic. A wide variety of possible symptoms may occur, depending on the anatomical site of the lesions; MS has been described as the modern ‘great imitator’. The clinical time course of attacks and tempo of evolution of symptoms are as helpful as the symptoms themselves in making the diagnosis of MS.

**Types of MS**

There are four main clinical patterns (Fig. 26.47):

- **Relapsing–remitting MS (RRMS)** (85–90%). This is the most common pattern of MS. Symptoms occur in attacks (relapses) with a characteristic time course: onset over days and typically recovery, either partial or complete, over weeks. On average, patients have one relapse per year but occasionally many years may separate relapses (benign MS – 10% of patients). Patients may accumulate disability over time if they do not recover fully after relapses.

- **Secondary progressive MS.** This late stage of MS consists of gradually worsening disability progressing slowly over years. Some 75% of patients with relapsing–remitting MS will eventually evolve into a secondary progressive phase by 35 years after onset. Relapses may sometimes occur in this progressive phase (relapsing–progressive MS).

- **Primary progressive MS (PPMS)** (10–15%). This pattern is characterized by gradually worsening disability without relapses or remissions. It typically presents later and is associated with fewer inflammatory changes on MRI.

- **Relapsing–progressive MS** (<5%). This is the least common form of MS. It is similar to PPMS but with occasional supra-added relapses on a background of progressive disability from the outset.

**Clinical presentations**

Three characteristic common presentations of MS are optic neuritis (neuritis), brainstem demyelination and spinal cord lesions.

**Optic neuritis**

See page 810.

**Brainstem demyelination**

A relapse affecting the brainstem causes combinations of diplopia, vertigo, facial numbness/weakness, dysarthria or dysphagia. Pyramidal signs in the limbs occur when the corticospinal tracts are involved. A typical picture is sudden diplopia, and vertigo with nystagmus, but without tinnitus or deafness. Bilateral internuclear ophthalmoplegia (see p. 812) is pathognomonic of MS.

**Spinal cord lesions**

Paraparesis developing over days or weeks (see Box 26.62) is a typical result of a plaque in the cervical or thoracic cord, causing difficulty in walking and limb numbness with tingling, often asymmetric. Lhermitte’s sign may be present (see p. 823). Sometimes the arms are also involved in high cervical cord lesions. A tight band sensation around the abdomen or chest is common with thoracic cord lesions.

**Common symptoms in MS**

Disability and neurological impairments accumulate gradually over the years. Several symptoms are common and many can be improved with symptomatic treatments.

- Visual changes (see p. 810).
- Sensory symptoms – often unusual, e.g. a sensation of water trickling down the skin. Sensory symptoms are the presenting feature in 40% of patients. Reduced vibration sensation and proprioception in the feet are among the most common abnormalities on examination, but examination may be normal despite significant sensory symptoms.
- Clumsy/useless hand or limb – due to loss of proprioception (often a dorsal column spinal plaque).
- Unsteadiness or ataxia.
- Urinary symptoms – bladder hyper-reflexia causing urinary urgency and frequency. Treatment is with antimuscarinics or intravesical botulinum toxin injections.
- Pain – neuropathic pain is common.
- Fatigue – a common and often debilitating symptom, which can occur in patients with otherwise mild disease. This sometimes responds to amantadine or a fatigue management programme.
- Spasticity – may require baclofen or other muscle relaxants. Occasionally, botulinum toxin injections are used for focal spasticity.
- Depression.
- Sexual dysfunction.
- Temperature sensitivity – temporary worsening of pre-existing symptoms with increases in body temperature, e.g. after exercise or a hot bath, is known as Uhthoff’s phenomenon.
**Unusual presentations**

Epilepsy and trigeminal neuralgia (see p. 852) occur more commonly in MS patients than in the general population. Tonic spasms (frequent brief spasms of one limb) are rare but pathognomonic of MS.

**Late-stage MS**

Late MS causes severe disability with spastic tetraparesis, ataxia, optic atrophy, nystagmus, brainstem signs (e.g. bilateral internuclear ophthalmoplegia), pseudobulbar palsy and urinary incontinence. Cognitive impairment, often with frontal lobe features, may occur in late-stage disease. In a proportion of patients, disability eventually becomes severe, with median time to requiring walking aids of 15 years and time to wheelchair use 25 years from onset.

**Diagnosis**

Few other neurological diseases have a similar relapsing and remitting course. The diagnosis of MS requires two or more attacks affecting different parts of the CNS: that is, dissemination in time and space, and exclusion of other possible causes. History and support from investigations, particularly MRI, make the diagnosis. The McDonald criteria formalize the diagnostic features but are designed mainly for research purposes and rarely used in clinical practice.

When taking a history at the time of initial presentation, it is essential to ask about previous episodes of neurological symptoms, often years previously, that may represent episodes of unrecognized demyelination: for example, a severe episode of vertigo lasting weeks or loss of vision in one eye that gradually recovered.

**Investigations**

The purpose of investigations is to provide supportive evidence of dissemination in time and space (i.e. to show scattered demyelinating lesions that evolve over time), to exclude other diseases and to provide evidence of immunological disturbance.

- MRI of brain and cord is the definitive investigation, as it demonstrates areas of demyelination with high sensitivity. Multiple scattered plaques are usually seen (Fig. 26.48A), demonstrating dissemination in space. Typical lesions are oval in shape, up to 2 cm in diameter, and often orientated perpendicular to the lateral ventricles. Occasionally, large ‘tumefactive’ (swelling) lesions are seen (Fig. 26.48B). Acute lesions show gadolinium enhancement for 6–8 weeks. Although a sensitive technique to demonstrate plaques (normal MRI in MS is possible but distinctly rare), it is limited by lower specificity. Over the age of 50, small ischaemic lesions may be difficult to distinguish from demyelination, and in younger patients other neuroinflammatory disorders such as sarcoidosis, Behçet syndrome and vasculitis may produce similar imaging appearances. The presence of spinal cord lesions is quite specific for inflammatory disorders such as MS rather than ischaemic lesions, so cord imaging is often useful where there is diagnostic difficulty.

- Plaques are rarely visible on CT.

- CSF examination is often unnecessary with suggestive MRI and a compatible clinical picture. CSF analysis shows oligoclonal IgG bands in over 90% of cases but these are not specific for MS. The CSF cell count may be raised (5–60 mononuclear cells/mm³).

- Evoked responses, e.g. visual-evoked responses in optic nerve lesions, may demonstrate clinically silent lesions. However, since the advent of MRI, they are less used in diagnosis.

- Blood tests are used to exclude other inflammatory disorders such as sarcoidosis or SLE, or other causes of paraparesis, e.g. adrenoleukodystrophy, HIV, human T-cell lymphotropic virus 1 (HTLV-1) and vitamin B₁₂ deficiency.

**The clinically isolated syndrome**

In patients presenting with a first ever episode of neurological symptoms suggestive of neuroinflammation, termed a ‘clinically isolated syndrome’ (CIS), a diagnosis of MS cannot be made by definition. In up to 70% of such patients, MRI shows multiple clinically silent lesions. An abnormal brain MRI at presentation, with multiple inflammatory-type lesions, confers an 85% chance of developing MS over subsequent years (50% if presenting with optic neuritis). Patients need to be made aware of this possibility.

A second clinical event indicative of a new lesion in a different anatomical location allows the diagnosis of MS to be confirmed. Alternatively, a repeat MRI brain scan at least 1 month later showing either a new lesion or a gadolinium-enhancing lesion is sufficient to demonstrate dissemination in time and space and confirm the diagnosis, even in the absence of new symptoms.

**Management**

There is no cure for MS but, in recent years, several immunomodulatory treatments have been introduced that have dramatically altered the ability to modify the course of the inflammatory relapsing–remitting phase of MS. It is hoped that these will translate into reduced long-term disability but this has yet to be proved.

**General measures**

Education, provision of appropriate written materials and support from a multidisciplinary team, including an MS nurse specialist, are essentials. Treatments are available for various symptoms, e.g. pain, spasticity and urinary features (Box 26.53). Physiotherapy and occupational therapy are helpful where there is persisting impairment between relapses. Infections should be treated early, as they may precipitate relapses or lead to worsening of existing symptoms. Immunizations are safe (but not live vaccines if on disease-modifying drugs).

**Acute relapses**

Short courses of steroids, such as i.v. methylprednisolone 1 g/day for 3 days or high-dose oral steroids, are used for severe relapses. They speed recovery but do not influence long-term outcome.
Disease-modifying drugs

Immunomodulatory disease-modifying drugs (DMDs; Box 26.54), such as β-interferon (both IFN-β1b and 1a, and pegylated β1a) and glatiramer acetate, reduce relapse rate by one-third and serious relapses by up to half in RRMS. They also significantly reduce development of new MRI lesions and may reduce accumulation of disability over the short term. They are self-administered by subcutaneous or intramuscular injection and are generally well tolerated, apart from influenza-like side-effects and injection site irritation. From a health economics point of view, cost is an issue, as these drugs are very expensive. IFN-β and glatiramer acetate are considered first-line DMDs. Current recommendations in the UK are that DMDs are offered to ambulant patients with RRMS where there have been two or more significant relapses over a 2-year period or after one major disabling relapse. When used after CIS, the conversion rate to definite MS is reduced from 50% to 30% over 3 years, but in the UK treatment with DMDs after CIS is rarely recommended. DMDs are not effective in primary progressive or secondary progressive MS.

Oral DMDs

Three oral agents, fingolimod, teriflunomide and dimethyl fumarate, have been licensed for treatment of RRMS. They all reduce relapse rate significantly and, in the case of fingolimod and dimethyl fumarate, are superior to interferons. In general, they seem well tolerated but have more serious adverse events than interferons. Their exact place in MS treatment is not yet established (cost is an issue); in some countries, they are used as first-line DMDs but in the UK are likely to be used where first-line drugs are not tolerated or not sufficiently effective.

Treatment of aggressive RRMS

Immunomodulatory drugs and biological agents (monoclonal antibodies), such as natalizumab and alemtuzumab, have shown high efficacy in preventing relapses and may reduce accumulation of disability significantly (see Box 26.54). They have the potential to cause serious adverse effects and are generally used only in very aggressive disease or where relapses are not reduced by β-IFN or glatiramer acetate.

Haemopoietic stem cell transplantation (AHSCT) may be used to treat aggressive MS, working in part by ‘resetting’ the immune system.

Other drugs and symptomatic therapies

- **Vitamin D.** There is some evidence that vitamin D supplementation may be beneficial in MS but this is still controversial. Some specialists advocate treatment with up to 2000 IU daily.

- **Fampridine** (4-aminopyridine, an oral potassium-channel blocker). This has been shown to improve walking significantly in selected patients with significant MS-related disability.

- **Other symptomatic treatments.** Symptomatic treatments are available for most complications of MS and significantly improve quality of life (see Box 26.53). Urinary urgency and frequency, pain, spasticity and depression are all common and treatable.

### Box 26.53 Symptomatic treatments in multiple sclerosis

**Urinary symptoms**
- Antimuscarinics, e.g. oxybutynin, tolterodine, solifenacin, trospium
- Desmopressin spray ± antimuscarinic
- Intermittent self-catheterization (ISC)
- Botulinum toxin type A intravesical injections (usually also require ISC)
- Bladder training exercises
- Indwelling catheter

**Spasticity**
- Self-management, including stretching, physiotherapy, splinting
- Skeletal muscle relaxants: baclofen, tizanidine, clonazepam
- Gabapentin
- Botulinum toxin type A (electromyelography-guided injections) for focal spasticity
- Cannabinoids: oromucosal spray
- Intrathecal baclofen pump
- Intrathecal phenol – destructive procedure in advanced disease with paraplegia

**Pain**
- As for treatment of neuropathic pain (see p. 825)
- Trigeminal neuralgia – carbamazepine, lamotrigine
- Lhermitte’s – carbamazepine

**Depression**
- Cognitive behavioural therapy
- Antidepressants (see p. 771)

**Impaired mobility**
- Physiotherapy ± walking aids
- Treat spasticity
- Fampridine – selected patients

**Erectile dysfunction**
- Sildenafil, tadalafil or vardenafil

**Tremor**
- Beta-adrenoceptor-blocking drugs
- Botulinum toxin type A injections (head or arms)
- Deep brain stimulation for severe Holmes tremor

**Fatigue**
- Fatigue management programme, treat depression
- Amantadine (often ineffective)

ITP, immune thrombocytopenic purpura; MCA, monoclonal antibody; PML, progressive multifocal leukoencephalopathy.
Prognosis

The clinical course of MS is unpredictable; a high MR lesion load at initial presentation, high relapse rate, male gender and late presentation are poor prognostic features but not invariably so. There is wide variation in severity. Many patients continue to live independent, productive lives; a minority become severely disabled. Life expectancy is reduced by 7 years on average.

Transverse myelitis

Transverse myelitis is an acute inflammatory disorder affecting the spinal cord with cord swelling and loss of function. Typically, one or two spinal segments are affected with part or all of the cord area at that level involved (transverse indicates involvement of the whole cross-section of the cord at the affected level). Clinically, a myelopathy evolves over days, and recovery (often partial) follows over weeks or months. MRI is sensitive and shows cord swelling and oedema with gadolinium enhancement at the affected level(s). Usually, images are also taken of the brain to look for evidence of demyelination. CSF may be inflammatory with an excess of lymphocytes. Causes include:

- **Para-infectious autoimmune inflammatory response.** This is the most common cause and may follow viral infection or immunization, for example.
- **Systemic inflammatory disorders,** e.g. SLE, Sjögren’s, sarcoidosis.
- **Infection.** This may be caused by viruses – e.g. herpesviruses, such as varicella zoster or EBV, HIV, HTLV-1 and 2 (tropical spastic paraparesis); mycobacteria, e.g. tuberculosis; bacteria – e.g. syphilis and Lyme disease; or flatworms – e.g. schistosomiasis.
- **Multiple sclerosis.** Transverse myelitis may occur as part of a relapse or be a presenting feature of MS. If the brain MRI is normal, the risk of later development of MS is around 20%; in those that do develop MS with a normal brain MRI, prognosis is better than average.

- **Neuromyelitis optica** – see below.

  **Treatment** is usually with high-dose steroids or other immunosuppression, or antimicrobial therapy in the case of specific infections.

Neuromyelitis optica

This is a distinct inflammatory relapsing demyelinating disorder, previously thought to be a variant of MS. It is characterized by longitudinally extensive transverse myelitis (>3 segments) and bilateral or recurrent optic neuritis. Limited forms occur, such as recurrent myelitis only. Serum antibodies to aquaporin-4 water channels on astrocytes are diagnostic. It is rarer than MS but there is a higher incidence in Asian and African Caribbean people.

  **Treatment** with steroids and immunosuppressive drugs is essential from the time of diagnosis, as the relapse rate is high and relapses are much more disabling than in MS. A similar syndrome that follows a monophasic course occurs with myelin oligodendrocyte (MOG) antibodies.

Acute disseminated encephalomyelitis

Acute disseminated encephalomyelitis (ADEM) is usually post-infectious, following infections such as measles, mycoplasma, mumps and rubella, and occasionally following 1–2 weeks after immunization. There is a monophasic illness with multifocal brain, brainstem and often spinal cord inflammatory lesions in white matter, with demyelination. ADEM is caused by an immune-mediated host response to infection and occurs principally in children and young adults. Mild cases recover completely. Survivors often have permanent brain damage. Treatment is supportive, with steroids and anticonvulsants.

Other neuroinflammatory conditions

Neurosarcoidosis

Neurosarcoid, with or without systemic sarcoid, causes chronic meningoencephalitis, cord lesions, cranial nerve palsies – particularly bilateral VIIth nerve lesions, polyneuropathy and myopathy (see p. 985). Diagnosis can be difficult if disease is confined to the CNS.

Behçet’s disease

Behçet’s principal features (see p. 466) are recurrent oral and/or genital ulceration, inflammatory ocular disease (uveitis; see p. 921) and neurological syndromes. Brainstem and cord lesions, aseptic meningitis, encephalitis and cerebral venous thrombosis occur. There is a predilection for ethnic groups along the ancient ‘Silk Road’ – Turkey, the Middle East and Asia. Behçet’s is associated with the HLA-B51 allele.

NERVOUS SYSTEM INFECTION

Meningitis

Meningitis usually implies serious infection of the meninges (Box 26.55). Bacterial meningitis is fatal unless treated. Microorganisms reach the meninges either by direct extension from the ears, nasopharynx, cranial injury or congenital meningeal defect, or by bloodstream spread. Immunocompromised patients are at risk of infection with unusual organisms. Non-infective causes of meningeval inflammation include malignant meningitis, intrathecal drugs and blood following subarachnoid haemorrhage.

Pathology

In acute bacterial meningitis, the pia-arachnoid is congested with polymorphs. A layer of pus forms. This may organize to form adhesions, causing cranial nerve palsies and hydrocephalus.

In chronic infection (e.g. tuberculosis), the brain is covered in a viscous grey–green exudate with numerous meningeal tubercles. Adhesions are invariable. Cerebral oedema occurs in any bacterial meningitis.

In viral meningitis there is a predominantly lymphocytic inflammatory CSF reaction without pus formation, polymorphs or adhesions; there is little or no cerebral oedema unless encephalitis develops.

Clinical features

Meningitic syndrome

This is a simple triad: headache, neck stiffness and fever. Photophobia and vomiting are often present. In acute bacterial infection, there is usually intense malaise, fever, rigors, severe headache, photophobia and vomiting, developing within hours or minutes.
Acute septicaemic shock may develop in any bacterial meningitis. Despite early recognition, death from acute septicaemic shock is associated with a petechial rash, sometimes sparse, and a positive Kernig’s sign usually appear within hours. The patient is irritable and often prefers to lie still. Neck stiffness and a positive Kernig’s sign usually appear within hours.

In less severe cases (e.g. many viral meningitides), there are less prominent meningitic signs. However, bacterial infection may also be indolent, with a deceptively mild onset. It may be difficult to distinguish between the sudden headache of subarachnoid haemorrhage, migraine and acute meningitis. Meningitis should be considered seriously in anyone with headache and fever, and in any sudden headache. Neck stiffness should be looked for; it may not be obvious.

Specific varieties of meningitis
Clinical clues point to the diagnosis (Box 26.56). If there is access to the subarachnoid space via skull fracture (recent or old) or occult spina bifida, bacterial meningitis can be recurrent, and the infecting organism is usually pneumococcus.

Acute bacterial meningitis
Onset is typically sudden, with rigors and high fever. Meningococcal septicaemia is associated with a petechial rash, sometimes sparse (Box 26.57 and Fig. 26.49). The meningitis may be part of a generalized meningococcal septicaemia with septic shock and peripheral vascular infarcts (see p. 545). Acute septicaemic shock may develop in any bacterial meningitis.

These organisms account for 70% of acute bacterial meningitis outside the neonatal period. A wide variety of infective agents are responsible for the remaining 30% of cases. Haemophilus influenzae b (Hib) has been eradicated as a cause in many countries by immunization. Malaria often presents with cerebral symptoms and a fever.

The patient is irritable and often prefers to lie still. Neck stiffness and a positive Kernig’s sign usually appear within hours.

In less severe cases (e.g. many viral meningitides), there are less prominent meningitic signs. However, bacterial infection may also be indolent, with a deceptively mild onset.

In uncomplicated meningitis, consciousness remains intact, although anyone with a high fever may be delirious. Progressive drowsiness, lateralizing signs and cranial nerve lesions indicate complications such as venous sinus thrombosis (see p. 837), severe cerebral oedema or hydrocephalus, or an alternative diagnosis such as cerebral abscess (see p. 873) or encephalitis (see p. 871).

**Specific varieties of meningitis**

Clinical clues point to the diagnosis (Box 26.56). If there is access to the subarachnoid space via skull fracture (recent or old) or occult spina bifida, bacterial meningitis can be recurrent, and the infecting organism is usually pneumococcus.

**Acute bacterial meningitis**

Onset is typically sudden, with rigors and high fever. Meningococcal septicaemia is associated with a petechial rash, sometimes sparse (Box 26.57 and Fig. 26.49). The meningitis may be part of a generalized meningococcal septicaemia with septic shock and peripheral vascular infarcts (see p. 545). Acute septicaemic shock may develop in any bacterial meningitis.

**Fig. 26.49 Rash of meningococcal septicaemia with meningitis.** Purpuric lesions are indicated with arrows.

**Viral meningitis**

This is almost always a benign, self-limiting condition lasting 4–10 days. Headache may follow for some months. There are no serious sequelae, unless an encephalitis is present (see p. 871).

**Chronic meningitis (see below)**

For further discussion on chronic meningitis, see later.

**Differential diagnosis**

It may be difficult to distinguish between the sudden headache of subarachnoid haemorrhage, migraine and acute meningitis. Meningitis should be considered seriously in anyone with headache and fever, and in any sudden headache. Neck stiffness should be looked for; it may not be obvious.

**Chronic meningitis** sometimes resembles an intracranial mass lesion, with headache, epilepsy and focal signs. Cerebral malaria can mimic bacterial meningitis.
Management

Recognition and immediate treatment of acute bacterial meningitis (see Box 26.57) are vital. Minutes save lives. Bacterial meningitis has a high mortality and morbidity. Even with optimal care, mortality is around 15%. The following applies to adult patients; management is similar in children.

When meningococcal meningitis is diagnosed clinically by the petechial rash, immediate intravenous antibiotics should be given and blood cultures taken; lumbar puncture is unnecessary. In other causes of meningitis, an LP is performed if there is no clinical suspicion of a mass lesion (see p. 830). If the latter is suspected, an immediate CT scan must be performed because coning of the cerebellar tonsils may follow LP, but normal brain imaging does not exclude raised intracranial pressure and clinical features of raised pressure contraindicate LP. Typical CSF changes are shown in Box 26.58. CSF pressure is characteristically elevated.

Immediate antibiotic treatment in acute bacterial meningitis is shown in Box 26.59. Treatment with antibiotics should be continued for at least 5 days.

Adjunctive immediate high-dose steroid (dexamethasone 0.6 mg/kg i.v. for 4 days), given with or before the first dose of antibiotics, has been shown to reduce neurological complications in bacterial meningitis (e.g. deafness), and some studies also show reduced mortality in Western populations.

Blood should be taken for cultures, glucose and routine tests. Chest and skull films should be obtained if appropriate.

CSF stains demonstrate organisms (e.g. Gram-positive intracellular diplococci – pneumococcus; Gram-negative cocci – meningococcus). Ziehl–Neelsen stain demonstrates acid-fast bacilli (tuberculosis), though TB organisms are rarely numerous. Indian ink stains fungi.

Meticulous attention should focus on microbiological studies in suspected CNS infection with close liaison between clinician and microbiologist. Specific techniques, such as polymerase chain reaction for meningocci and viruses, or CSF bacterial antigen testing, are invaluable. Syphilis serology should always be carried out.

Local infection (e.g. paranasal sinus) should be treated surgically if necessary. Repair of a depressed skull fracture or meningeal tear may be required.

Prophylaxis

Meningococcal infection should be notified to the public health authorities, and advice sought about immunization and prophylaxis of contacts. Chemoprophylaxis with rifampicin or ciprofloxacin should be offered to all close contacts. MenC vaccine is given in the UK and MenB, a meningococcal B vaccine, is now available for population immunization of infants and for use in outbreaks. A combined A and C meningococcal vaccine is sometimes used prior to travel from the UK to endemic regions, such as Africa or Asia, and there is a quadrivalent ACWY vaccine for specific events, such as the Hajj and Umrah in Mecca.

Pneumococcal conjugated vaccine is now given to infants in many countries and pneumococcal polysaccharide vaccine is offered to older adults and those with, for example, immunodeficiency or splenectomy. Pneumococcal immunization has reduced the incidence of pneumococcal meningitis.

Hib (Haemophilus influenzae) vaccine is given routinely in childhood in the UK and many other countries, virtually eliminating a common cause of fatal meningitis.

Chronic meningitis

Tuberculous meningitis (TBM) and cryptococcal meningitis typically commence with vague headache, lassitude, anorexia and vomiting. Acute meningitis can occur but is unusual. Meningitic signs often take some weeks to develop. Drowsiness, focal signs (e.g. diplopia, papilloedema, hemiparesis) and seizures are common. Syphilis, sarcoidosis and Behçet’s also cause chronic meningitis. In some cases of chronic meningitis, an organism is never identified.

Investigation and management of tuberculous meningitis

TBM is a common and serious disease worldwide. Brain imaging, usually with MRI, may show meningeal enhancement, hydrocephalus and tuberculomas (see p. 876), although it may remain

normal (see Box 26.58 for CSF changes). In many cases, the sparse tuberculous organisms cannot be seen on staining and PCR testing should be performed, although results may be negative. Repeated CSF examination is often necessary and will be some weeks before cultures are confirmatory. Treatment with anti-tuberculosis drugs (see p. 971) – rifampicin, isoniazid and pyrazinamide – must commence on a presumptive basis and continue for at least 9 months. Ethambutol should be avoided because of its eye complications. Adjunct corticosteroids, such as prednisolone 60 mg for 3 weeks, are now recommended (often tapered off). Relapses and complications (e.g., seizures, hydrocephalus) are common in TBM. The mortality remains over 60%, even with early treatment.

Malignant meningitis

Malignant cells can cause a subacute or chronic, non-infective, meningitic process. A meningitic syndrome, cranial nerve lesions, paraparesis and root lesions are seen, often in confusing and fluctuating patterns. CSF cytology may demonstrate malignant cells but yield is low so multiple LPs may be required to confirm the diagnosis. Treatment with intrathecal cytotoxic agents is sometimes helpful.

Cells in a sterile CSF (pleocytosis)

A raised CSF cell count is present without an evident infecting organism. CSF pleocytosis, i.e. a mixture of lymphocytes and polymorphs, is the usual situation (Box 26.60).

Encephalitis

Encephalitis means acute inflammation of brain parenchyma, usually viral. In viral encephalitis, fever (90%) and meningoism are usual; in contrast to meningitis, however, the clinical picture is dominated by brain parenchyma inflammation. Personality and behavioural change is a common early manifestation, which progresses to a reduced level of consciousness and even coma. Seizures (focal and generalized) are very common and focal neurological deficits, such as speech disturbance, often occur (especially in herpes simplex encephalitis).

Viral encephalitis

(See p. 527.) The viruses isolated from adult UK cases are usually herpes simplex (HSV), varicella zoster (VZV) and other herpes group viruses, HHV-6, 7, enteroviruses and adenovirus. HSV encephalitis typically affects the temporal lobes initially, and is often asymmetric. Frequently, the virus is never identified. Outside the UK, in endemic regions, different pathogens cause encephalitis, including flaviviruses (Japanese encephalitis, West Nile virus, tick-borne encephalitis) and rabies.

Local epidemics can occur. For example, in New York in the 1990s, West Nile virus caused an epidemic and Venezuelan equine virus was isolated from encephalitis cases in South America.

Investigations

- MRI shows areas of inflammation and swelling, generally in the temporal lobes in HSV encephalitis. Raised intracranial pressure and midline shift may occur, leading to coning.
- EEG shows periodic sharp and slow-wave complexes.
- CSF shows an elevated lymphocyte count (95%).
- Viral detection by CSF PCR is highly sensitive for several viruses, such as HSV and VZV. However, a false-negative result may occur within the first 48 hours of symptom onset. Serology (blood and CSF) is also helpful.
- Brain biopsy is rarely required since the advent of MRI and PCR.

Management

Suspected HSV and VZV encephalitis is treated immediately with intravenous aciclovir (10 mg/kg 3 times a day for 14–21 days), even before investigation results are available. Early treatment significantly reduces both mortality and long-term neurological damage in survivors. Seizures are treated with anticonvulsants. Occasionally, decompressive craniectomy is required to prevent coning but coma confers a poor prognosis.

Long-term complications are common and include memory impairment, personality change and epilepsy.

Autoimmune encephalitis

This group of disorders is increasingly being recognized. Autoantibodies directed against neuronal epitopes cause a subacute encephalitis illness: limbic encephalitis or panencephalitis. Limbic encephalitis presents over weeks or months with memory impairment, confusion, psychiatric disturbance, and seizures – usually temporal lobe seizures, reflecting involvement of the hippocampus and mesial temporal lobes.

Paraneoplastic limbic encephalitis (PLE). PLE is seen particularly with small-cell lung cancer and testicular tumours, and is associated with a variety of antibodies, including anti-Hu and anti-Ma2. Antibodies can be detected in 60% of cases. MRI usually shows a hippocampal high signal. PLE precedes the diagnosis of cancer in most cases and should prompt investigation to identify the tumour.

Voltage-gated potassium channel (VGKC) limbic encephalitis. VGKC antibodies (which can be tested for) produce a variety of disorders, including limbic encephalitis with characteristic faciobrachial dystonic seizures, in combination with confusion, agitation and hypoxaemia. This usually occurs in patients over 50 years of age but is rarely associated with cancer (thymoma). Treatment is with high-dose steroids. Neuromyotonia and peripheral nerve hyperexcitability syndromes may also be seen with antibodies to VGKC.

Anti-NMDA receptor antibody encephalitis. This presents as limbic encephalitis followed by coma and often status epilepticus. Orofacial dyskinesias are characteristic. Patients are usually younger, and most have teratomas, such as ovarian.

Patients may respond to immunotherapy: intravenous immunoglobulin or plasma exchange initially, followed by steroids, rituximab or cyclophosphamide. PLE responds less well to treatment.

HIV and neurology

HIV-infected individuals frequently present with or develop neurological conditions. The human immunodeficiency virus itself is directly neuroinvasive and neurovirulent. Immunosuppression leads to indolent, atypical clinical patterns (see p. 1430). HIV patients also have a high incidence of stroke. The pattern of disease is changing with anti-retroviral (ART) therapy.

CNS and peripheral nerve disease in HIV

**HIV seroconversion** can cause meningitis, encephalitis, Guillain–Barré syndrome and Bell’s palsy (the most common cause of Bell’s palsy in South Africa).

**Chronic meningitis** occurs with fungi (e.g. Cryptococcus neoformans or Aspergillus), tuberculosis, Listeria, coliforms or other organisms. Raised CSF pressure is common in cryptococcal meningitis.

**AIDS–dementia complex (ADC).** A progressive, HIV-related dementia, sometimes with cerebellar signs, is still seen where ART is unavailable.

**Encephalitis and brain abscess.** Toxoplasma, cytomegalovirus, herpes simplex and other organisms cause severe encephalitis. Multiple brain abscesses develop in HIV infection, usually due to toxoplasmosis.

**CNS lymphoma.** This is typically fatal (see p. 406).

**Progressive multifocal leukoencephalopathy (PML)** is due to JC virus and occurs with very low CD4 counts (see p. 529).

**Spinal vacuolar myelopathy.** This occurs in advanced disease.

**Peripheral nerve disease.** HIV-related peripheral neuropathy is common (70%) and can be difficult to distinguish from the effects of certain ART toxic to peripheral nerves.

**Other infections and post-infectious inflammatory conditions**

Many other infections involve the CNS and are discussed in Chapter 20: for example, rabies, tetanus, botulism, Lyme disease and leprosy.

**Herpes zoster (shingles)**

This is caused by reactivation of varicella zoster virus (VZV), usually within dorsal root ganglia. Primary infection with VZV causes chickenpox, following which the virus remains latent in sensory ganglia. Development of shingles may indicate a decline in cell-mediated immunity, such as that due to age or malignancy.

**Clinical patterns and complications**

**Dermatomal shingles.** See pages 515 and 671.

**Postherpetic neuralgia.** This is defined as pain lasting for more than 4 months after developing shingles; it occurs in 10% of patients (often elderly). Burning, intractable pain responds poorly to analgesics. Response to treatment is unsatisfactory but there is a trend towards gradual recovery over 2 years. Amitriptyline or gabapentin is commonly used, and topical lidocaine patches may help.

**Cranial nerve involvement.** Only cranial nerves with sensory fibres are affected, particularly the trigeminal and facial nerves. Ophthalmic herpes is due to involvement of V1. This can lead to corneal scarring and secondary panophthalmitis. Involvement of the geniculate ganglion of the facial nerve is also called Ramsay Hunt syndrome (see p. 815).

**Myelitis.** This may occur in the context of shingles, when the inflammatory process spreads from the dorsal root ganglion to the adjacent spinal cord.

**Immunization.** Older adults (p. 516) can be vaccinated against herpes zoster (even those who have had shingles previously), as it boosts immunity against VZV and reduces the incidence of shingles by about 50%.

**Neurosyphilis**

Many neurological symptoms occur, sometimes mixed (see also syphilis; p. 1422).

**Asymptomatic neurosyphilis**

This means positive CSF serology without signs.

**Meningovascular syphilis**

This causes:

- subacute meningitis with cranial nerve palsies and papilloedema
- a gumma – a chronic expanding intracranial mass
- paraparesis – a spinal meningovasculitis.

**Tabes dorsalis**

Demyelination in dorsal roots causes a complex deafferentation syndrome. The elements of tabes are:

- lightning pains
- ataxia, stamping gait, reflex/sensory loss, wasting
- neuropathic (Charcot) joints
- Argyll Robertson pupils (see p. 811)
- ptosis and optic atrophy.

**General paralysis of the insane**

The grandiose title describes dementia and weakness. The dementia of general paralysis of the insane (GPI) is typically similar to that of Alzheimer’s (see p. 882). Progressive cognitive decline, seizures, brisk reflexes, extensor plantar reflexes and tremor develop. Death follows within 3 years. Argyll Robertson pupils are a usual finding. GPI and tabes are rarities in the UK.

**Other forms of neurosyphilis**

In congenital neurosyphilis (acquired in utero), features of combined tabes and GPI develop in childhood: taboparesis.

**Secondary** syphilis can be symptomless or may cause a self-limiting subacute meningitis.

**Management**

Benzylpenicillin 1 g daily i.m. for 10 days in primary infection eliminates any risk of neurosyphilis. Allergic (Jarisch–Herxheimer) reactions can occur; steroid cover is usually given with penicillin.

**Neurocysticercosis**

The pork tapeworm, *Taenia solium*, is endemic in Latin America, Africa, India and much of South-east Asia (see p. 581). Epilepsy is the most common clinical manifestation of neurocysticercosis and one of the most common causes of epilepsy in endemic countries. Most infected people remain asymptomatic.

Brain CT and MRI show ring-enhancing lesions with surrounding oedema when the cyst dies, and later calcification. Multiple cysts are often seen in both brain and skeletal muscle. Serological tests indicate infection but not activity. Biopsy of a lesion is rarely necessary. Management is primarily the control of seizures, and the anthelmintic agent, albendazole, is often given too (usually with steroid cover).

**Subacute sclerosing panencephalitis**

Persistence of measles antigen in the CNS is associated with this rare late sequel of measles. Progressive mental deterioration, fits, myoclonus and pyramidal signs develop, typically in a child. Diagnosis is made by high measles antibody titre in blood and CSF. Measles immunization protects against subacute sclerosing panencephalitis (SSPE), which has now been almost eliminated in the UK.

**Progressive rubella encephalitis**

Some 10 years after primary rubella infection, this causes progressive cognitive impairment, fits, optic atrophy, cerebellar and pyramidal signs. Antibody to rubella viral antigen is produced locally within the CNS. It is even rarer than SSPE.
Mollaret’s meningitis
Recurrent, self-limiting episodes of aseptic meningitis (i.e. no bacterial cause is found) occur over many years. Herpes simplex has been shown to be the cause in most cases.

Whipple’s disease
CNS Whipple’s disease, due to Tropheryma whipplei infection, is characterized by neurological symptoms, e.g. myoclonus, dementia and supranuclear ophthalmoplegia (see p. 1194). Diagnosis of CNS involvement is made by CSF PCR (only 50% sensitivity) or brain biopsy.

Brain and spinal abscesses

Brain abscess
Focal bacterial infection behaves as any expanding mass. The typical bacteria found are *Streptococcus anginosus* and *Bacteroides* species (from the paranasal sinuses and teeth), and staphylococci (associated with penetrating trauma). Mixed infections are common. Multiple abscesses may develop, particularly in HIV infection. Fungi also cause brain abscesses. A parameningeal infective focus (e.g. ear, nose, paranasal sinus, skull fracture) or a distant source of infection (e.g. lung, heart, abdomen) may be present. Frequently, no underlying cause is found. An abscess is more than ten times rarer than a brain tumour in the UK.

Clinical features and management
Headache, focal signs (e.g. hemiparesis, aphasia, hemianopia), epilepsy and raised intracranial pressure develop. Fever, leucocytosis and raised ESR are usual, although not invariable.

Urgent imaging is essential. MRI shows a ring-enhancing mass, usually with considerable surrounding oedema (Fig. 26.50). The search for a focus of infection should include a detailed examination of the skull, ears, paranasal sinuses and teeth, and distant sites of infection.

Fig. 26.50 Pyogenic cerebral abscess. (A) Axial post-contrast CT demonstrating a ring-enhancing lesion in the left temporoparietal region. (B) Subsequent T2-weighted fluid suppressed (FLAIR) images show the extent of surrounding oedema. MRI is also useful to characterize the lesion further, (C) Here, diffusion-weighted and (D) ADC map confirm restricted diffusion within the lesion, which is characteristic of intracranial pyogenic abscess.
such as heart and abdomen. LP is dangerous and should not be performed. Neurosurgical aspiration with stereotactic guidance allows the infective organism to be identified. Treatment is with high-dose antibiotics and, sometimes, surgical resection/decompression. Despite treatment, mortality remains high at approximately 25%. Epilepsy is common in survivors.

**Brain tuberculoma**
Tuberculosis causes chronic caseating intracranial granulomatous masses: tuberculomas. These are the most common intracranial masses in countries where tuberculosis is common, such as India. Brain tuberculomas either present as mass lesions de novo or develop during tuberculous meningitis; they are also found as symptomless intracranial calcification on imaging. Spinal cord tuberculomas also occur. Treatment is described on page 969.

**Subdural empyema and intracranial epidural abscess**

*Intracranial subdural empyema* is a collection of subdural pus, usually secondary to local skull or middle ear infection. Features are similar to those of a cerebral abscess. Imaging is diagnostic.

In *intracranial epidural abscess*, a layer of pus, 1–3 mm thick, tracks along the epidural space, causing sequential cranial nerve palsies. There is usually local infection: in the middle ear, for example. MRI shows the collection; CT is typically normal. Drainage is required, as are antibiotics.

**Spinal epidural abscess**
*Staphylococcus aureus* is the usual organism, reaching the spine via the bloodstream: for example, from a boil. Fever and back pain are followed by paraparesis and/or root lesions. Emergency imaging and antibiotics are essential and surgical decompression is often necessary.

**Further reading**

### BRAIN TUMOURS

**Primary intracranial tumours** account for 3% of all cancers. The most common tumours are outlined in **Box 26.61**, with cerebral metastases being more common than primary intracranial tumours (Fig. 26.51). Symptomless meningiomas (benign) are found quite commonly on imaging or at autopsy.

**Gliomas**
These malignant tumours of neuroepithelial origin are usually seen within the hemispheres, but occasionally in the cerebellum, brainstem or cord (Fig. 26.52). Their cause is unknown. Gliomas are occasionally associated with neurofibromatosis. They tend to spread by direct extension, virtually never metastasizing outside the CNS.

- **Astrocytomas** are gliomas that arise from astrocytes. They are classified histologically into grades I–IV. Grade I astrocytomas grow slowly over many years, while grade IV tumours (glioblastoma multiforme) cause death within several months. Cystic astrocytomas of childhood are relatively benign and usually cerebellar.
- **Oligodendrogliomas** arise from oligodendrocytes. They grow slowly, usually over several decades. Calcification is common.

**Fig. 26.51** Bilateral cerebellar metastases (arrowed): T1-weighted MRI.

**Fig. 26.52** Cerebral glioblastoma multiforme: T1-weighted MRI.
Meningiomas
These benign tumours (Fig. 26.53) arise from the arachnoid and may grow to a large size, usually over years. Those close to the skull erode bone or cause local hyperostosis. They often occur along the intracranial venous sinuses, which they may invade. They are unusual below the tentorium. Common sites are the parasagittal region, sphenoidal ridge, subfrontal region, pituitary fossa and skull base.

Neurofibromas (schwannomas)
These solid benign tumours arise from Schwann cells and occur principally in the cerebellopontine angle, where they arise from the VIIIth nerve sheath (acoustic neuroma; see p. 814). They may be bilateral in neurofibromatosis type 2 (see p. 886).

Other neoplasms
Other less common neoplasms include cerebellar haemangioblastomas, ependymomas of the IVth ventricle, colloid cysts of the IIIrd ventricle, pinealomas, chordomas of the skull base, gliomas of the jugular bulb, medulloblastomas (a cerebellar childhood tumour), craniopharyngiomas (see p. 595) and primary CNS lymphomas (p. 406). For pituitary tumours, see page 592.

Clinical features
Mass lesions within the brain produce symptoms and signs by three mechanisms:
- direct effect – the brain is infiltrated and local function is impaired, producing focal neurological signs
- secondary effects of raised intracranial pressure and shift of intracranial contents (e.g. papilloedema, vomiting, headache)
- provocation of generalized and/or focal seizures.

Although neoplasms, either secondary or primary, are the most common mass lesions in the UK, cerebral abscess, tuberculoma, neurocysticercosis, and subdural and intracranial haematomas can also produce features that are clinically similar.

Direct effects of mass lesions
The hallmark of a direct effect of a mass is local progressive deterioration of function. Tumours can occur anywhere within the brain. Three examples are given:
- A left frontal meningioma caused a frontal lobe syndrome over several years with vague disturbance of personality, apathy and impaired intellect. Expressive aphasia developed, followed by progressive right hemiparesis as the corticospinal pathways became involved. As the mass enlarged further, pressure headaches and papilloedema occurred.
- A right parietal lobe glioma caused a left homonymous field defect (optic radiation). Cortical sensory loss in the left limbs and left hemiparesis followed over 3 months. Partial seizures (episodes of tingling of the left limbs) developed.
- A left VIIIth nerve sheath neurofibroma (acoustic neuroma, schwannoma) in the cerebellopontine angle caused, over 3 years, progressive deafness (VIII), left facial numbness (V) and weakness (VII), followed by cerebellar ataxia on the same side. With a hemisphere tumour, epilepsy and the direct effects commonly draw attention to the problem. The rate of progression varies greatly, from a few days or weeks in a highly malignant glioma, to several years with a slowly enlarging mass such as a meningioma. Cerebral oedema surrounds mass lesions; its effect is difficult to distinguish from that of the tumour itself.

Raised intracranial pressure
Raised intracranial pressure causing headache, vomiting and papilloedema is a relatively unusual presentation of a mass lesion in the brain. These symptoms often imply hydrocephalus: obstruction to CSF pathways. Typically, this is produced early by posterior fossa masses that obstruct the aqueduct and IVth ventricle, but only later by lesions above the tentorium. Shift of the intracranial contents produces features that coexist with the direct effects of any expanding mass:
- Distortion of the upper brainstem as midline structures are displaced either caudally or laterally by a hemisphere mass (see Fig. 26.52). This causes impairment of consciousness, progressing to coning and death as the medulla and cerebellar tonsils are forced into the foramen magnum.
- False localizing signs, termed false only because they do not point directly to the site of the mass. Three examples of false localizing signs are:
  - A Vth nerve lesion, first on the side of a mass and later bilaterally as the Vth nerve is compressed or stretched during its long intracranial course.
  - A IIIrd nerve lesion developing as the temporal lobe uncus herniates caudally, compressing the IIIrd nerve against the petroclinoid ligament. The first sign is ipsilateral pupil dilatation as parasympathetic fibres are compressed.
- **Hemiparesis** on the same side as a hemisphere tumour – that is, the side that might not be expected – from compression of the contralateral cerebral peduncle on the edge of the tentorium.

**Seizures**
Seizures are a common presenting feature of malignant brain tumours. Focal seizures, with or without altered awareness, that may evolve into bilateral tonic–clonic seizures, are characteristic of many hemisphere masses, whether malignant or benign. The pattern of focal seizure is of localizing value (see p. 853).

**Investigations**
**Imaging**
Both CT and MRI are useful in detecting brain tumours; MRI is superior for posterior fossa lesions. Benign and malignant tumours, brain abscess, tuberculosis, neurocysticercosis and infarction have characteristic, but not entirely reliable, appearances, and refined imaging techniques and biopsy are often necessary. MR angiography is used occasionally to define blood supply and MR spectroscopy to identify patterns typical of certain gliomas. PET is sometimes helpful to locate an occult primary tumour with brain metastases.

**Routine tests**
Since metastases are more common than primary tumours, routine tests, such as chest X-ray, should be performed.

**Lumbar puncture**
This is contraindicated when there is any possibility of a mass lesion, as withdrawing CSF may provoke immediate coning. CSF examination is rarely helpful and has been superseded by imaging.

**Biopsy and tumour removal**
Stereotactic biopsy via a skull burr hole is carried out to ascertain the histology of most suspected malignancies. With a benign tumour, such as a symptomatic, accessible meningioma, craniotomy and removal are usual.

**Management**
This is discussed on page 132.

**Further reading**

**HYDROCEPHALUS**

Hydrocephalus is an excessive accumulation of CSF within the head, caused by a disturbance of formation, flow or absorption. High pressure and ventricular dilation result (Fig. 26.54).

**Infantile hydrocephalus**
Head enlargement in infancy occurs in 1 in 2000 live births. There are several causes:
- **Arnold–Chiari malformations.** The cerebellar tonsils descend into the cervical canal (Fig. 26.55). Associated spina bifida is common. Syringomyelia may develop (see p. 879).
- **Stenosis of the aqueduct of Sylvius.** Aqueduct stenosis is either congenital (genetic), or acquired following neonatal meningitis/haemorrhage.
- **Dandy–Walker syndrome.** There is cerebellar hypoplasia and obstruction to IVth ventricle outflow foramina.

**Hydrocephalus in adults**
Hydrocephalus is sometimes an unsuspected finding on imaging. Stable childhood hydrocephalus can become apparent in adult life (‘arrested hydrocephalus’) but can suddenly decompensate. Combinations of headache, cognitive impairment, features of raised intracranial pressure and ataxia develop, depending on how high the CSF pressure rises and how rapid the onset is. Elderly patients with more compliant brains may present with gradual-onset gait apraxia and subtle cognitive slowing.

Hydrocephalus may be caused by:
- **posterior fossa and brainstem tumours** obstructing the aqueduct or IVth ventricular outflow.

**Further reading**

• **subarachnoid haemorrhage**, head injury or meningitis (particularly tuberculous), causing obstruction of CSF flow and reabsorption
• **a lIrd ventricle colloid cyst** causing intermittent hydrocephalus – recurrent prostrating headaches with episodes of lower limb weakness
• **choroid plexus papilloma** (rare) secreting CSF. Frequently, the underlying cause of hydrocephalus remains obscure.

### Management

Ventriculoperitoneal shunting is necessary when progressive hydrocephalus causes symptoms. Removal of tumours is carried out when appropriate. Endoscopic IIIrd ventriculostomy may be performed.

### Normal pressure hydrocephalus

This describes a syndrome of enlarged lateral ventricles in elderly patients with the clinical triad of:
- a gait disorder – gait apraxia
- dementia
- urinary incontinence.

The term is a misnomer, as it is a low-grade hydrocephalus with intermittently raised ICP. Ventriculoperitoneal shunting may be required. A trial of prolonged drainage of lumbar CSF over several days predicts response to shunt insertion.

**TRAUMATIC BRAIN INJURY**

In most Western countries, head injury accounts for about 250 hospital admissions per 100 000 population annually. Traumatic brain injury (TBI) describes injuries with potentially permanent consequences. For each 100 000 people, 10 die annually following TBI; 10–15 are transferred to a neurosurgical unit, the majority of these requiring rehabilitation for a prolonged period of 1–9 months. The prevalence of survivors with a major persisting handicap is around 100/100 000. Road traffic accidents and excessive alcohol use are the principal aetiological factors in this major cause of morbidity and mortality, in many countries.

### Skull fractures

**Linear** skull fracture of the vault or base is one indication of the severity of a blow, but in itself is not necessarily associated with any brain injury. Healing of linear fractures takes place spontaneously. **Depressed** skull fracture is followed by a high incidence of post-traumatic epilepsy. Surgical elevation and debridement are usually necessary. Principal local complications of skull fracture are:
- **meningeal artery rupture** causing extradural haematoma (see p. 847)
- **dural vein tears** causing subdural haematoma (see p. 847)
- **CSF rhinorrhoea/otorrhea** and consequent meningitis.

### Mechanisms of brain damage
