Older classifications attempted to separate **concussion**, transient coma for hours followed by apparent complete clinical recovery, from brain **contusion** – that is, bruising – with prolonged coma, focal signs and lasting damage. Pathological support for this division is poor. Mechanisms of TBI are complex and interrelated:
- diffuse axonal injury – shearing and rotational stresses on decelerating brain, sometimes at the site opposite impact (the contre-coup effect)
- neuronal and axonal damage from direct trauma
- brain oedema and raised intracranial pressure
- brain hypoxia
- brain ischaemia.

**Clinical course**

In a mild TBI, a patient is stunned or dazed for a few seconds or minutes. Following this, the patient remains alert without post-traumatic amnesia. Headache can follow; complete recovery is usual. In more serious injuries, duration of unconsciousness, and particularly of post-traumatic amnesia (PTA), helps grade severity. PTA lasting more than 24 hours defines severe TBI. The Glasgow Coma Scale (GCS; see p. 832) is used to record the degree of coma; this has prognostic value. A GCS below 5/15 at 24 hours implies a serious injury; 50% of such patients die or remain in a vegetative or minimal conscious state (see p. 836). However, prolonged coma of up to some weeks is occasionally followed by good recovery.

Recovery after severe TBI takes many weeks or months. During the first few weeks, patients are often intermittently restless or lethargic, and have focal deficits such as hemiparesis or aphasia. Gradually, they become more aware, though they may remain in PTA, being unable to lay down any continuous memory despite being awake. This amnesia may last some weeks or more, and may not be obvious clinically. PTA is one predictor of outcome. PTA of over a week implies that persistent organic cognitive deficit is almost inevitable, although return to unsupported paid work may be possible.

**Late sequelae**

Sequelae of TBI are major causes of morbidity and can have serious social and medicolegal consequences. They include:
- **Incomplete recovery**, e.g. cognitive impairment, hemiparesis.
- **Post-traumatic epilepsy** (see p. 854).
- **The post-traumatic (post-concussional) syndrome**. This describes the vague complaints of headache, dizziness and malaise that follow even minor head injuries. Litigation is frequently an issue. Depression is prominent. Symptoms may be prolonged.
- **Benign paroxysmal positional vertigo** (see p. 906).
- **Chronic subdural haematoma** (see p. 847).
- **Hydrocephalus** (see p. 876).
- **Chronic traumatic encephalopathy**. This follows repeated and often minor injuries. It is known as the ‘punch-drunk syndrome’ and consists of cognitive impairment and extrapyramidal and pyramidal signs, seen typically in professional boxers.

### Management

**Immediate management**

Attention to the airway is vital. If there is coma, depressed fracture or suspicion of intracranial haematoma, CT imaging and discussion with a neurosurgical unit are essential. Indications for CT vary from imaging all minor head injuries in some centres to more stringent criteria elsewhere.

In many severe TBI cases, assisted ventilation will be needed. Intracranial pressure monitoring is valuable. Hypothermia lowers intracranial pressure when used early after a TBI; an effect on outcome has been seen only in specialized neurotrauma centres. Care of the unconscious patient is described on page 833. Prophylactic antiepileptic drugs have been shown to be of no value in prevention of late post-traumatic epilepsy. Trials using progesterone have shown no benefit.
Rehabilitation

TBI cases require skilled, prolonged and energetic support. Survivors with severe physical and cognitive deficits require rehabilitation in specialized units. Rehabilitation includes care from a multidisciplinary team, including prominent physiotherapists, occupation therapists, speech and language therapists, and clinical psychologists. Many survivors are left with cognitive problems (amnesia, neglect, disordered attention and motivation) and behavioural/emotional problems (temper dyscontrol, depression and grief reactions). Long-term support for both patients and families is necessary.

SPINAL CORD DISEASE

The cord extends from C1, the junction with the medulla, to the lower vertebral body of L1, where it becomes the conus medullaris. Blood supply is from the anterior spinal artery and a plexus on the posterior cord. This network is supplied by the vertebral arteries and by several branches from lumbar and intercostal vessels, including the artery of Adamkiewicz.

Spinal cord compression

The principal features of chronic and subacute cord compression are spastic paraparesis or tetraparesis, radicular pain at the level of compression, and sensory loss below the compression (Box 26.62).

For example, in compression at T4 (see Fig. 21.16), a band of pain radiates around the thorax, characteristically worse on coughing or straining. Spastic paraparesis develops over months, days or hours, depending on underlying pathology. Numbness commencing in the feet rises to the level of compression. This is called the sensory level and is usually 2–3 dermatome levels below the level of anatomical compression. Retention of urine and constipation develop.

Aetiology

Disc and vertebral lesions. Central cervical disc and thoracic disc protrusion causes cord compression (see p. 892). Chronic compression due to cervical spondylotic myelopathy is frequently seen in clinical practice and is the most common cause of a spastic paraparesis in an elderly person.

Trauma. Any trauma to the back is potentially serious and the patient should be immobilized until the extent of the injury can be determined.

Spinal cord tumours. Extramedullary tumours, such as meningiomas and neurofibromas, cause cord compression (Fig. 26.56 and Box 26.63) gradually over weeks to months, often with root pain and a sensory level (see p. 892). Vertebral body destruction by bony metastases, such as in prostate or breast cancer, is a common cause of spinal cord compression.

Intramedullary tumours (e.g. ependymomas) are less common and typically progress slowly, sometimes over many years. Sensory disturbances similar to syringomyelia may develop (see p. 879).

Tuberculosis. Spinal tuberculosis is the most common cause of cord compression in countries where the disease is common. There is destruction of vertebral bodies and disc spaces, with local spread of infection. Cord compression and paraparesis follow, culminating in paralysis: Pott's paraplegia.

Spinal epidural abscess. This is described on page 874.

Epidural haemorrhage and haematoma. These are rare sequelae of anticoagulant therapy, bleeding disorders or trauma, and can follow LP when clotting is abnormal. A rapidly progressive cord or cauda equina lesion develops.

Management

Acute spinal cord compression is a medical emergency. Early diagnosis and treatment are vital. MRI is the imaging technique of choice.

Routine tests (e.g. chest X-ray) may indicate a primary neoplasm or infection. Surgical exploration is frequently necessary; if decompression is not performed promptly, irreversible cord damage ensues. Results are excellent if benign tumours and haematomas are removed early. Radiotherapy is used to treat cord malignancies, or compression due to inoperable malignant vertebral body disease causing cord compression.

Other spinal cord disorders

Inflammatory cord lesions (transverse myelitis)

See page 868.

Fig. 26.56 Thoracic meningioma (arrowed) compressing the spinal cord: T2-weighted MRI.

Box 26.62 Causes of spinal cord compression

- Spinal cord tumours
  - Extramedullary, e.g. meningioma or neurofibromatosis
  - Intramedullary, e.g. ependymoma or glioma
- Vertebral body destruction by bone metastases, e.g. prostate primary
- Disc and vertebral lesions:
  - Chronic degenerative and acute central disc prolapse
- Trauma
- Inflammatory:
  - Epidural abscess
  - Tuberculosis
  - Granulomatous
- Epidural haemorrhage/haematoma

Box 26.63 Principal spinal cord neoplasms

### Extramedullary

- Metastases:
  - Bronchus
  - Breast
  - Prostate
  - Lymphoma
  - Thyroid
  - Melanoma

- Meningioma
- Neurofibromatosis
- Ependymoma

### Intramedullary

- Glioma
- Ependymoma
- Haemangioblastoma
- Lipoma
- Teratoma
Anterior spinal artery occlusion
There is acute paraplegia and loss of spinothalamic (pain and temperature) sensation, with infarction of the anterior two-thirds of the spinal cord. This may result from aortic atherosclerosis, dissection, trauma or cross-clamping in surgery. Vasculitis, emboli, haematological disorders causing thrombosis and severe hypotension are other causes. Occlusion of the artery of Adamkiewicz, which supplies the thoracic anterior spinal artery, causes watershed infarction of the cord, typically at the T8 level where perfusion is relatively poor.

Arteriovenous malformations of the cord
Although rare, spinal arteriovenous malformations (AVMs) may be difficult to diagnose but are potentially curable. The two main types seen are dural arteriovenous fistulas (acquired) and true intramedullary AVMs (probably congenital but gradually enlarging). Dural arteriovenous fistulas occur mainly in middle-aged men due to formation of a direct connection between an artery and vein in a dural nerve root sleeve. This causes arterialization of veins with venous hypertension, and thus oedema and congestion of the spinal cord at and below the affected level. Presentation is with a gradually progressive myelopathy over months or a few years, often with thoracic back pain. MRI usually shows cord swelling (Fig. 26.57) and may show the enlarged arterialized veins over the surface of the cord. Spinal angiography demonstrates the fistula and allows endovascular ablation with glue, often with complete resolution of symptoms if permanent neuronal damage has not already occurred.

Genetic disorders – hereditary spastic paraparesis (HSP)
Several genetic disorders may present with a gradually evolving upper motor neuron syndrome resembling a myelopathy. Typically, spasticity and stiffness dominate the clinical picture rather than weakness, especially in hereditary spastic paraparesis (HSP). Muscle relaxants, such as baclofen, improve gait. There are 28 known genes associated with HSP; some causing ‘pure’ spasticity and others with associated neurological features, such as thinning of the corpus callosum.

Other genetic disorders such as adrenoleukodystrophy may cause a slowly progressive spastic paraparesis (including in manifesting female carriers), as can the spinocerebellar ataxias (see p. 887) or presenilin-1 mutations (see p. 883).

Vitamin B12 deficiency
Subacute combined degeneration of the cord resulting from vitamin B12 deficiency (see p. 891) is the most common example of metabolic disease causing spinal cord damage. Abuse of nitrous oxide may precipitate functional B12 deficiency with normal serum B12 levels.

Other causes of a spastic paraparesis
Motor neurone disease may present initially with a spastic paraparesis before lower motor neurone features develop (see p. 885). Para-neoplastic disorders, radiotherapy, copper deficiency, liver failure and rare toxins (e.g. lathyrisium) may cause spinal cord damage. Not all causes of paraparesis relate to spinal cord pathology; beware a parasagittal cerebral meningioma presenting with a paraparesis due to bilateral compression of the leg area of the motor cortex.

Care of the patient with paraplegia
Where patients are left with a severe paraplegia, there are several issues in long-term care, and specialist nursing is vital.

Bladder management. The bladder does not empty and urinary retention results. Patients self-catheterize or develop reflex bladder emptying, helped by abdominal pressure. Early treatment of urine infections is essential. Chronic kidney disease may develop from chronic obstruction or repeated urinary tract infection.

Bowel function. Constipation and impaction must be avoided. Following acute paraplegia, manual evacuation is necessary; reflex emptying develops later.

Skin care. Risks of pressure ulcers and their sequelae are serious. Meticulous attention must be paid to cleanliness and regular turning. The sacrum, iliac crests, greater trochanters, heels and malleoli should be inspected frequently (see p. 683). Pressure-relieving mattresses are useful initially until patients can turn themselves. If pressure ulcers develop, plastic surgery may be required. Pressure palsies, such as those of ulnar nerves, can occur.

Lower limbs. Passive physiotherapy helps to prevent contrac-
tures. Severe spasticity, with flexor or extensor spasms, may be helped by muscle relaxants such as baclofen or by botulinum toxin injections.

Rehabilitation. Many patients with traumatic paraplegia or tetraplegia return to self-sufficiency (especially if the level is at C7 or below). A specialist spinal rehabilitation unit is necessary. Light-weight, specially adapted wheelchairs provide independence. Ten-
don transfer operations may allow functional grip if hands are weak. Autonomic dysreflexia may be a problem. Patients with paraplegia have substantial practical, psychological and sexual needs.

Syringomyelia and syringobulbia
A syrinx is a fluid-filled cavity within the spinal cord. Syringobulbia means a cavity in the brainstem. Syringomyelia is frequently associated with the Arnold–Chiari malformation (see p. 876). The abnormality at the foramen magnum probably allows normal pulsatile CSF pressure waves to be transmitted to fragile tissues of the cervical cord and brainstem, causing secondary cavity formation. The syrinx is in continuity with the central canal of the cord. Syrinx formation may also follow spinal cord trauma and lead to secondary damage years later, and can also be caused by intrinsic cord tumours.

Pathophysiology
The expanding cavity in the cord gradually destroys spinothalamic neurones, anterior horn cells and lateral corticospinal tracts. In the medulla (syringobulbia), lower cranial nerve nuclei are affected.

Clinical features
Cases associated with the Arnold–Chiari malformation usually develop symptoms around the age of 20–30. Upper limb pain
exacerbated by exertion or coughing is typical. Spinothalamic sensory loss – pain and temperature – leads to painless upper limb burns and trophic changes. Paraparesis develops. The following are typical signs of a substantial cervical syrinx (Fig. 26.58):

- a ‘suspended’ area of dissociated sensory loss – i.e. spinothalamic loss in the arms and hands without loss of light touch
- loss of upper limb reflexes
- muscle wasting in the hand and forearm
- spastic paraparesis – initially mild
- brainstem signs – as the syrinx extends into the brainstem (syringobulbia) there may be tongue atrophy and fasciculation, bulbar palsy, a Horner’s syndrome and impairment of facial sensation.

Investigations and management

MRI demonstrates the cavity and herniation of cerebellar tonsils. Syringomyelia is gradually progressive over several decades. Sudden deterioration sometimes follows minor trauma or occurs spontaneously. Surgical decompression of the foramen magnum often causes the syrinx to collapse.

NEURODEGENERATIVE DISEASES

Neurodegenerative disease is an umbrella term for disorders characterized by progressive neuronal cell loss with distinct patterns in different disorders. These disorders are increasing in an ageing population.

Dementia

Dementia is a clinical syndrome with multiple causes, defined by:

- an acquired loss of higher mental function, affecting two or more cognitive domains, including:
  - episodic memory (acquisition of new information) – usually (but not always) involved
  - language function
- being of sufficient severity to cause significant social or occupational impairment
- being chronic and stable (which distinguishes it from delirium, which is acute and fluctuating).

Although dementia is usually progressive, it is not invariably so, and may even be reversible in some cases. Dementia robs patients of their independence, and is a serious burden on carers and a major socioeconomic challenge for society as a whole.

Epidemiology

Dementia is common and becoming even more so as a result of an ageing population and better case ascertainment. Age is the main risk factor, followed by family history. Over the age of 65, there is a 6% prevalence; over the age of 85, the prevalence increases to 20%.

Clinical assessment

There are two main considerations:

- Does the patient have dementia?
- Are the pattern of cognitive deficits, tempo of progression or associated features suggestive of a distinct cause? Cognitive problems need to be interpreted in the context of estimated pre-morbid abilities (e.g. based on educational attainments or occupation).

Taking a history from a spouse or relative is essential. Patients may tend to downplay or deny symptoms (anosognosia) or constantly look to the relative for answers (the ‘head-turning sign’). See Box 26.64 for the key elements in history-taking.

Box 26.64 Taking a dementia history

- Memory:
  - Is the patient repetitive, e.g. with questions?
  - Is there a temporal gradient of amnesia – preservation of more distant memories with amnesia for recent events?
  - Is there difficulty learning to use new devices, e.g. computer, mobile phone?
- Functional ability:
  - Has work performance or ability to cook and do domestic tasks declined?
  - Has responsibility for finances and administration shifted to the spouse?
  - Does the patient get easily muddled?
- Personality and frontal lobe function:
  - Has personality altered?
  - More aggressive/apathetic/lacking initiative
  - Disinhibition
  - Change in food preference or religiosity
- Language:
  - Difficulty with word finding or remembering names
- Visuospatial ability:
  - Does the patient get lost in familiar places?
  - Difficulty dressing, e.g. putting jacket on the wrong way round
- Psychiatric features:
  - Features of depression
  - Tempo of progression
  - Family history of dementia
  - Alcohol and drug use
  - Medication
- Any other neurological problems, e.g. parkinsonism, gait disorder, strokes
- frontotemporal executive function
- visuospatial function
- apraxia

Taking a dementia history

- Does the patient have dementia?
- Are the pattern of cognitive deficits, tempo of progression or associated features suggestive of a distinct cause? Cognitive problems need to be interpreted in the context of estimated pre-morbid abilities (e.g. based on educational attainments or occupation).

Taking a history from a spouse or relative is essential. Patients may tend to downplay or deny symptoms (anosognosia) or constantly look to the relative for answers (the ‘head-turning sign’). See Box 26.64 for the key elements in history-taking.
Examination
Conversation with the patient during history-taking may be as revealing as formal cognitive assessment but many patients hide deficits well behind an intact social façade.

Bedside cognitive assessment
The mini-mental state examination (MMSE; see p. 805) is commonly used to assess cognitive function but has its limitations, such as relative insensitivity to milder cognitive impairment and to frontal lobe dysfunction, especially in those with pre-morbid abilities. The Addenbrooke’s Cognitive Examination (ACE) is a tool developed to address the deficiencies of the MMSE but is short enough to use in clinical practice.

It is useful to ask patients to give an account of recent news events to assess episodic memory.

Individual cognitive domains can be tested separately in detail: for example, clock drawing for visuospatial (parietal lobe) function, naming and reading tasks for language function, verbal fluency, conceptual similarity to test abstract thinking, and stop-go tasks, which are components of the Frontal Assessment Battery (FAB).

Check for primitive reflexes (frontal release signs), such as grasp, palmo-mental and pout reflexes, and perseveration or utilization behaviour with frontal lobe involvement.

Test:
• limb praxis – copying hand gestures and miming tasks, e.g. ‘show me how you brush your teeth’.
• oro-buccal praxis, e.g. ‘show me how you would blow out a candle’.

Complete neurological examination to look for evidence of papilloedema, parkinsonism, myoclonus and gait disorders, for example, is also necessary, in addition to is general examination and assessment of mental state.

Investigations
Investigations (Box 26.65) are aimed at identifying treatable causes and helping support a clinical diagnosis of dementia type. For most patients, this should include the elements listed below.

Blood tests. These should include a full blood count and measurement of vitamin B₁₂, thyroid function, urea and electrolytes, liver function, glucose and ESR.

Brain imaging. CT is adequate to exclude structural lesions (Fig. 26.59), such as tumours or hydrocephalus. The superior anatomical resolution of MRI helps identify patterns of regional brain atrophy and so distinguish between different types of degenerative dementia (e.g. hippocampal atrophy in Alzheimer’s disease (AD) versus temporal lobe and frontal atrophy in frontotemporal dementia). Imaging also allows assessment of brain ‘vascular load’. MRI is always preferable to CT in patients with cognitive disorders.

Detailed neuropsychometric assessment (see p. 831). Appropriate in most patients, this allows quantification of the relative involvement of different cognitive domains and may be helpful if performed serially over time to assess progression.

Younger patients (<65 years). More intensive investigation may be necessary. This may include EEG, genetic tests (e.g. for Huntington’s, familial AD and FTD genes), voltage-gated potassium channel antibodies, anti-neuronal antibodies (for paraneoplastic limbic encephalitis), HIV serology and metabolic tests; on rare occasions, brain biopsy may be appropriate.

CSF examination. Measurement of CSF protein biomarkers has been shown to be useful in distinguishing between different types of dementia; for example, in AD, CSF tau is raised and Aβ42 reduced. In Creutzfeldt–Jakob disease (CJD) and other rapidly progressive dementias, protein 14–3–3 is increased. A new CSF assay for abnormal prion protein, real-time quaking induced conversion (rt-QUIC), has proved to be highly sensitive and specific for CJD.

New imaging modalities. Radionuclide scans using radioactively labelled ligands that bind directly to amyloid allow amyloid deposition in the brain to be directly visualized and have great potential for earlier and more accurate diagnosis of AD. Amyloid imaging is now beginning to enter clinical practice in some specialist centres.

Mild cognitive impairment
Mild cognitive impairment (MCI) is an intermediate state between normal cognition and dementia. Often mild memory impairment, greater than expected for age but not sufficient to classify as dementia, is the only symptom (‘amnestic MCI’). MCI may be a pre-dementia state, with 10–15% of patients per year developing overt AD.

Causes of dementia
There are many causes of dementia (Box 26.66), by far the most common being AD. Cause varies according to age (Fig. 26.60).

Alzheimer’s disease
Although technically a definitive diagnosis can only be made by histopathology, in practice the clinical features are sufficiently characteristic that a diagnosis can usually be made with considerable
accuracy in life, supported by diagnostic investigations. The key clinical features are:

- **Memory impairment.** Episodic (day-to-day) memory is affected. There is progressive loss of ability to learn, retain and process new information. There is a characteristic temporal gradient, with relative preservation of distant memory and amnesia for more recent events. Patients often refer to this as ‘short-term memory loss’, which technically refers to loss of working memory: for example, digit span, which is preserved in AD.
- **Language.** This usually becomes impaired as the disease advances. Difficulty with word finding is characteristic.
- **Apraxia.** Ability to carry out skilled motor activities is impaired (see p. 804).
- **Agnosia.** There is a failure to recognize objects such as clothing, and places or people.
- **Frontal executive function.** Organizing, planning and sequencing are impaired.
- **Parietal presentation.** Presentation with visuospatial difficulties and difficulty with orientation in space and navigation may occur. Parietal lobe involvement is also seen as a later feature in many typical presentations.
- **Posterior cortical atrophy (PCA).** This is the least common presentation of AD with visual disorientation due to initial involvement of the occipital lobes and occipitoparietal regions. Patients have complex visual symptoms that may be difficult to describe; they often say that it is easier to see distant than close-up objects. Memory is initially well preserved.
- **Personality.** In contrast to other dementias such as frontotemporal dementia, basic personality and social behaviour remain intact until late AD.
- **Anosognosia.** Lack of insight by the patient into their difficulties is common; they may be reluctant to seek medical attention but be brought to clinic by a family member.
- **Tempo.** Onset is insidious and often not noticed by family members initially. Progression is gradual but inexorable over a decade or longer, with eventual severe deficits in multiple cognitive domains.
- **Late non-cognitive features.** Myoclonus may develop, sometimes followed by seizures (the cortex is the main site of pathology). Sleep–wake cycle reversal and incontinence may place a great strain on carers. Motor function is usually strikingly preserved so patients are capable of wandering and getting lost. Swallowing may become impaired, leading to aspiration pneumonia – often a terminal event.

**Investigations**

MRI typically shows characteristic atrophy of mesial temporal lobe structures, including hippocampi, progressing eventually to generalized cerebral atrophy. Imaging may be normal in the early stages and selective regional atrophy is seen in AD variants such as ‘posterior presentations’, for example posterior cortical atrophy (PCA) with occipital lobe atrophy. Characteristic MRI and psychometric testing abnormalities are sufficient to make a diagnosis if the clinical picture is suggestive (a progressive amnestic cognitive disorder in an older person). CSF tau and β-amyloid measurement is helpful in cases of diagnostic difficulty but not yet widely available (see above).
Molecular pathology and aetiology

Although the cause of AD is still not known, a great deal is now understood about the molecular pathology. The pathological hallmarks are:

- The deposition of β-amyloid (Aβ) in amyloid plaques in the cortex.
- Structural and conformational changes in tau protein, i.e. hyperphosphorylation and formation of paired helical filaments, which are the binding blocks of neurofibrillary tangles. These protein aggregates damage synapses and ultimately lead to neuronal death. Early pathological changes in the brain, including Aβ deposition, pre-date clinical symptoms and diagnosis by up to 25 years.

Amyloid may also be laid down in cerebral blood vessels, leading to amyloid angiopathy.

The amyloid precursor protein (APP) is processed by secretase enzymes to form pathogenic Aβ1-42 monomers, which polymerize into amyloid plaques (Fig. 26.61).

A basal forebrain cholinergic deficit occurs and may explain the therapeutic response to cholinesterase inhibitor drugs.

Genetics of AD

A first-degree relative with AD confers a doubled lifetime risk of AD. There are rare autosomal dominant monogenic early-onset forms of familial AD with high penetrance, caused by mutations in specific genes; taken together, these account for only 1% of cases of AD.

Other genes. The E4 allele of the apolipoprotein E gene confers an increased risk of AD (2–3 times lifetime risk), especially if two copies of the E4 allele are inherited (6–8 times risk). Several other candidate genes have been identified as risk factors for AD in large genome-wide association studies.

Amyloid precursor protein (APP). Point mutations in the APP gene can cause AD, and the presence of three copies of the APP gene on chromosome 21 in Down’s syndrome patients is responsible for the high incidence of AD in that condition.

Presenilin (PS)-1 and 2. Mutations in these genes affect the γ-secretase enzyme function (see Fig. 26.61). PS1 mutations account for 50% of monogenic forms of AD. The PS1/2 and APP genes may be sequenced for mutations in selected early-onset cases with a family history.

Environmental risk factors

Age is the main risk factor for AD, as incidence increases exponentially with age. Head trauma and vascular risk factors also increase AD risk. Epidemiological studies show that taking anti-inflammatory drugs over a long period may confer some protection.

Dementia with Lewy bodies and Parkinson’s disease dementia

Dementia with Lewy bodies (DLB) is characterized by the early feature of visual hallucinations, fluctuating cognition with variation in attention and alertness, sleep disorders (especially REM sleep behaviour disorder), dysautonomia and parkinsonism. The visual hallucinations often take the form of people or animals, or the sense of a presence (‘extra-campine hallucinations’). Memory loss may be absent in the early stages. Delusions and transient loss of consciousness occur. Lewy bodies, inclusions containing aggregates of the protein α-synuclein first described in Parkinson’s disease, are found in the cortex.

In DLB, the cognitive features dominate; parkinsonism may evolve later and is typically mild. In Parkinson’s disease dementia (PDD), cognitive problems are a late feature, occurring at least 1 year after onset and usually after the age of 75. Both conditions may respond to cholinesterase inhibitors. Patients with DLB may be very sensitive to neuroleptic drugs with dramatic worsening.

Vascular dementia

This common cause of dementia is due to different mechanisms, including multi-infarct dementia, cerebral small-vessel disease and post-stroke dementia. Most vascular dementias are of mixed cause. Vascular dementia is distinguished from AD by its clinical features and imaging. Dementia can be progressive and similar to AD. There is sometimes a history of TIA’s, or the dementia follows a succession of cerebrovascular events, or has a stepwise course. Apractic gait disorder, pyramidal signs and urinary incontinence are common additional features. Widespread small-vessel disease seen on MRI is the typical finding and may produce a variety of cognitive deficits, reflecting the site of ischaemic damage.

Frontotemporal dementia

Frontotemporal dementia (FTD) is the term used to describe a group of neurodegenerative disorders characterized by asymmetric frontal lobe and temporal lobe atrophy on MRI and at postmortem (also called Pick’s disease). Onset is usually below the age of 65 and there is often a family history. FTD is considerably less common than AD, prevalence being approximately 10 per 100 000 before the age of 65. There are three distinct presentations, depending on which anatomical region is affected first.

Frontal presentation. This behavioural variant is characterized by personality change, emotional blunting, apathy, disinhibition, carelessness and behavioural change with striking preservation of episodic memory.

Temporal presentations. Primary progressive aphasia is characterized by progressive impairment of language function.
Involvement of the left temporal lobe produces ‘semantic dementia’, with fluent speech relatively lacking in meaningful content and progressive difficulty with comprehension of the meaning of words (e.g. a patient may respond to the MMSE question ‘What season is it?’ by asking ‘What is a season?’). The second temporal lobe presentation is progressive non-fluent aphasia due to peri-Sylvian atrophy, with loss of verbal fluency and increasingly telegraphic speech.

The frontal and temporal presentations eventually merge as cognitive decline becomes more widespread.

Pathology

About 25% of cases are familial, associated with mutations in the tau and progranulin genes or hexanucleotide repeat expansion in the C9ORF72 gene. The characteristic pathology consists of deposition of abnormally aggregated proteins: phosphorylated tau, transactive response DNA-binding protein 43 (TDP-43) or fused in sarcoma (FUS). Ten per cent of patients have overlap syndromes with motor neuron disease or parkinsonian disorders such as progressive supranuclear palsy. There is no cure or specific treatment at present.

Prion diseases, including Creutzfeldt–Jakob disease

Prion diseases (see p. 535) are transmissible neurodegenerative disorders with a long incubation period, caused by accumulation of misfolded native prion protein (PrP\(^c\)). Misfolding and conformational change in PrP\(^c\) is caused either by exposure to the abnormal misfolded isoform of the protein (PrP\(^\text{Sc}\)) or by mutations in the PrP gene (PRNP), leading to toxic accumulation of PrP\(^\text{Sc}\) as amyloid in beta-pleated sheets. Neuronal cell damage and ‘spongiform’ change in the brain result (see p. 535), the clinical correlate being a rapidly progressive dementia in most cases.

Creutzfeldt–Jakob disease

Creutzfeldt–Jakob disease (CJD) is the most common prion disease in humans, the animal equivalents being bovine spongiform encephalopathy (BSE) in cattle and scrapie in sheep. CJD may be sporadic, iatrogenic or familial.

Sporadic CJD is the most common form, occurring over the age of 50, with an incidence of approximately 1 per million. It is thought to be due to spontaneous somatic mutations in the PRNP gene or stochastic conformational change in PrP\(^c\) to PrP\(^\text{Sc}\) with a subsequent ‘domino effect’ inducing misfolding in other PrP molecules. A rapidly progressive dementia leads to death within 6 months of onset. Rapidly progressive cognitive decline should always lead to suspicion of CJD. The presence of myoclonus is also a clinical clue (present in 90%).

New forms of monoclonal antibody treatment are being studied.

Iatrogenic CJD is transmitted from neurosurgical instruments (prions are resistant to sterilization), transplant material (e.g. corneal grafts) and cadaveric pituitary-derived growth hormone taken from patients with CJD or presymptomatic CJD. Iatrogenic CJD has a long incubation period of several years.

Familial CJD (rare) is associated with PRNP gene mutations. Other clinical phenotypes, such as familial fatal insomnia, also occur.

Variant CJD

Variant CJD (vCJD) was first seen in the UK in 1995. vCJD patients are younger than sporadic cases, with a mean age of 29. Early symptoms are neuropsychiatric, followed by ataxia and depression with myoclonus or chorea. The diagnosis can be confirmed by tonsillar biopsy but a sensitive blood test has been developed. vCJD has a longer course than sporadic CJD – up to several years. vCJD and BSE are caused by the same prion strain, giving rise to speculation that transmission from animal to human food chain took place: that is, infection from BSE-infected cattle to humans (see p. 535). Transmission via blood transfusion may also occur. Most patients with vCJD and sporadic CJD have a specific polymorphism at codon 129 of the PRNP gene that leads to susceptibility.

Other dementias

Other neurodegenerative disorders may include dementia as one of their clinical manifestations. For example, corticobasal degeneration (CBD), progressive supranuclear palsy (PSP) and dementia may be a feature of a number of genetic and metabolic disorders, such as Huntington’s disease (see p. 862) and the leukodystrophies.

Management of dementia

It is rare for a reversible cause for dementia to be found, such as normal pressure hydrocephalus or frontal meningioma. Other disorders, such as limbic encephalitis or severe depression, may present as dementia mimics and every effort should be made to distinguish these treatable conditions from degenerative dementias.

Management is supportive, to preserve dignity and to provide care for as long as possible in the familiar home environment. The burden of illness frequently falls on relatives. Dementia clinical nurse specialists form a central part of the multidisciplinary team.

General measures. Some evidence suggests that participation in cognitively demanding activities in later life may protect against or delay the onset of dementia. High-dose B vitamins may possibly slow conversion from MCI to AD in patients with above-average levels of the amino acid homocysteine. There is some recent evidence supporting use of vitamin E to slow progression.

Cognitive enhancing drugs. These have a modest symptomatic benefit in AD, equivalent to an increase in 1–2 points on the MMSE. They are not disease-modifying, so do not slow or prevent progression. Whilst there has been some dispute about the place for these drugs, they contribute to patients being able to prolong independence and remain at home for longer than might otherwise be the case.

Cholinesterase inhibitors (donepezil, rivastigmine and galantamine) increase brain acetylcholine levels by inhibiting CNS acetylcholinesterase. Patients with AD have a central cholinergic deficit. There is usually a small but significant improvement in memory, cognition and function. Cholinesterase inhibitors are also effective in DLB and Parkinson’s dementia but not in FTD or vascular dementia. Side-effects, particularly cholinergic gastrointestinal symptoms, may be a problem. An ECG should be performed to exclude cardiac conduction deficits before starting therapy.

Memantine is an NMDA receptor antagonist. It is used in moderate or severe AD or where cholinesterase inhibitors are not tolerated. There is some evidence that combination of memantine and cholinesterase inhibitors is better than either used alone. It is generally well tolerated.

Psychiatric and behavioural problems. Depression is common in dementia and may be difficult to distinguish from dementia symptoms, such as apathy and worsening cognitive function. A trial of an antidepressant is appropriate where depression is suspected. Distinguishing depressive pseudodementia from organic dementia can be difficult but is crucial. Behavioural disturbance (e.g. due to agitation or delusions) and hallucinations may occur in late-stage disease. Use of antipsychotic medications is associated with significantly increased stroke risk in patients with dementia and should be used only as a last resort.
**Drugs in development.** The greatest need is for disease-modifying therapies that halt or slow progression in early-stage disease before significant irreversible neuronal damage has accumulated. Potential treatments in development include anti-amyloid therapies, such as monoclonal antibodies directed against Aβ and inhibitors of secretase enzymes that process APP into Aβ fragments.

**Financial and legal issues.** Patients may want to set up a Lasting Power of Attorney (if they retain mental capacity to do so in legal terms) to allow a spouse or relative to deal with their financial affairs on their behalf when they lose the capacity to do so. Patients and carers may be entitled to state financial benefits.

**Driving.** After a diagnosis of dementia, patients in the UK have a duty to inform the Driver and Vehicle Licensing Authority (DVLA), who may request a driving safety assessment.

#### Motor neuron disease

Motor neuron disease (MND) is a devastating condition causing progressive weakness and eventually death, usually as a result of respiratory failure or aspiration. It is relatively uncommon, with an annual incidence of 2/100,000. Presentation is usually between the ages of 50 and 75. Below age 70, men are affected more often than women. Amyotrophic lateral sclerosis (ALS) is the term more commonly used for MND in some countries.

**Pathogenesis**

MND predominantly affects upper and lower motor neurones in the spinal cord, cranial nerve motor nuclei and cortex. However, other neuronal systems may also be affected; 5% of patients also develop FTD (see p. 883) and up to 40% have some measurable frontal lobe cognitive impairment. MND is usually sporadic and of unknown cause, with no established environmental risk factors. Ubiquitinated cytoplasmic inclusions containing the RNA processing proteins TDP-43 and FUS are the pathological hallmarks found in axons, indicating that protein aggregation may be involved in pathogenesis, as with other neurodegenerative disorders. Oxidative neuronal damage and glutamate-mediated excitotoxicity have also been implicated in pathogenesis.

Between 5% and 10% of cases of MND are familial, and mutations in the free radical scavenging enzyme superoxide dismutase (SOD-1) and in a number of other genes, including TDP-43 and FUS, have been identified. A hexanucleotide GGGGCC repeat expansion in the C9ORF72 gene on chromosome 9 accounts for a significant proportion of familial cases of MND–FTD overlap.

**Clinical features**

Four main clinical patterns are seen. These different presentations usually merge as MND progresses. The sensory system is not involved and so sensory symptoms such as numbness, tingling and pain do not occur.

- **Amyotrophic lateral sclerosis (ALS).** This is the classic paraneoplastic presentation with simultaneous involvement of upper and lower motor neurones, usually in one limb, spreading gradually to other limbs and trunk muscles. The typical picture is one of progressive focal muscle weakness and wasting (e.g. in one hand), with muscle fasciculations due to spontaneous firing of abnormally large motor units formed by surviving axons branching to innervate muscle fibres that have lost their nerve supply. Cramps are a common but non-specific symptom. Examination often reveals upper motor neurone signs, such as brisk reflexes (a brisk reflex in a wasted muscle is a classic sign), extensor plantar responses and spasticity. Sometimes, an asymmetric spastic paraparesis is the presenting feature, with lower motor neurone features developing months later. Relentless progression of signs and symptoms over months allows confirmation of a diagnosis that may initially be suspected.

- **Progressive muscular atrophy.** This is a pure lower motor neurone presentation with weakness, muscle wasting and fasciculations, usually starting in one limb and gradually spreading to involve other adjacent spinal segments.

- **Progressive bulbar and pseudobulbar palsy** (20%). The lower cranial nerve nuclei and their supranuclear connections are initially involved. Dysarthria, dysphagia, nasal regurgitation of fluids and choking are the presenting symptoms. A fasciculating tongue with slow, stiff tongue movements is the classic finding in a mixed bulbar palsy. Emotional incontinence with pathological laughter and crying may occur in pseudobulbar palsy.

- **Primary lateral sclerosis** (rare, 1–2%). This is the least common form of MND and is confined to upper motor neurones, causing a slowly progressive tetraparesis and pseudobulbar palsy.

### Diagnosis

Diagnosis is largely clinical. There are no diagnostic tests but investigations allow exclusion of other disorders and may confirm subclinical involvement of muscle groups, such as paraspinal muscles. Denervation of muscles due to degeneration of lower motor neurones is confirmed by EMG.

Cervical spondylosis causing radiculopathy with myelopathy (upper and lower motor neurone signs) can cause diagnostic difficulty. Motor neuropathies, such as multifocal motor neuropathy, can also appear like MND (see p. 889).

### Prognosis and management

Survival for more than 3 years is unusual, although there are rare MND cases who survive for a decade or longer.

No treatment has been shown to influence outcome substantially. Riluzole, a sodium-channel blocker that inhibits glutamate release, slows progression slightly, increasing life expectancy by 3–4 months on average. Non-invasive ventilatory support and feeding via a gastrostomy help prolong survival. Patients should be supported by a specialist multidisciplinary team with access to palliative care and a clinical nurse specialist.

CONGENITAL DISORDERS

Cerebral palsy
Cerebral palsy (CP) is an umbrella term encompassing disparate disorders that are apparent at birth or in childhood and are characterized by non-progressive motor deficits. It is the most common form of physical disability in childhood and most affected children survive into adulthood. A variety of intrauterine and neonatal cerebral insults may cause CP, including prematurity and its complications, hypoxia, intrauterine infections and kernicterus. In many cases, no specific cause can be identified.

Clinical features
Failure to achieve normal milestones is usually the earliest feature. Specific motor syndromes become apparent later in childhood or, rarely, in adult life.

- **Spastic diplegia** – lower limb spasticity, with scissoring of gait.
- **Athetoid cerebral palsy** (see p. 862).
- **Infantile hemiparesis** – may be noted at birth or later. One hemisphere is hypotrophic and the contralateral, hemiparetic limbs small (hemiatrophy).
- **Ataxic and dystonic CP**.
- **Co-morbidity** – particularly epilepsy and learning difficulty, which are common and at least as disabling as the motor deficit.

Dysraphism
Failure of normal fusion of the fetal neural tube leads to a group of congenital anomalies. Folate deficiency during pregnancy is contributory and supplements should always be given (see p. 1242). Antiepileptic drugs, such as valproate, are also implicated (see p. 856). If there is access from the skin, such as from a sinus connecting to the subarachnoid space, bacterial meningitis may follow.

- **Meningoencephalocele** involves extrusion of brain and meninges through a midline skull defect; protrusion can be minor or massive.
- **Spina bifida** is failure of lumbosacral neural tube fusion. Several varieties occur.
- **Spina bifida occulta** is isolated failure of vertebral arch fusion (usually lumbar), often seen incidentally on X-rays (3% of the population). A dimple or a tuft of hair may overlie the anomaly; clinical abnormalities are unusual.
- **Meningomyelocele** may occur with spina bifida.
  Meningomyelocele consists of elements of spinal cord and lumbosacral roots within a meningeal sac. This herniates through a vertebral defect. In severe cases, both lower limbs and sphincters are paralysed. Meningocele is a meningeal defect alone. The defect should be closed in the first 24 hours after birth.

Fig. 26.62 Plexiform neurofibroma.

Neurocutaneous syndromes

**Neurofibromatosis type 1 (von Recklinghausen’s disease)**
One of the most common neurogenetic disorders, neurofibromatosis type 1 (NF-1) has a prevalence of 1 in 3000. Inheritance is autosomal dominant but 50% of cases are due to new mutations with no family history. The protein is called neurofibromin 1. NF-1 is characterized by multiple skin neurofibromas and pigmentation (café-au-lait patches – see p. 685, axillary freckling and Lisch nodules of the iris). The neurofibromas arise from the neurilemmal sheath.

Skin neurofibromas present as soft subcutaneous, sometimes pedunculated, lumps (see p. 685). They increase in number throughout life. Plexiform neurofibromas (Fig. 26.62) may develop on major nerves and proximal nerve roots, sometimes involving the spinal cord. Treatment is surgical removal if pressure symptoms develop. Associated features include learning difficulties, malignant transformation of neurofibromas, and bone abnormalities including scoliosis and fibrous dysplasia.

**Neurofibromatosis type 2**
Neurofibromatosis type 2 (NF-2) is much less common than NF-1. It is also autosomal dominant; the gene product, merlin or schwannomin, is a cytoskeletal protein. Many neural tumours occur:
- acoustic neuromas (usually bilateral) in 90%
- meningiomas
- gliomas (including optic nerve glioma)
- cutaneous neurofibromas (30%).

**Tuberous sclerosis (epiloia)**
Features of this rare multisystem, autosomal dominant condition include adenoma sebaceum, renal tumours and glial overgrowth...
in the brain (cortical tubers and subependymal nodules). Epilepsy (70%) and learning difficulties (50%) are common complications.

**Von Hippel–Lindau disease**

This rare condition is dominantly inherited. Cerebellar, spinal and retinal haemangioblastomas develop and can be surgically removed. Tumours – renal cell carcinoma and phaeochromocytomas – may also occur. Polycythaemia sometimes develops.

**Spinocerebellar ataxias**

A wide variety of genetic disorders cause cerebellar ataxia as the sole or predominant clinical feature. Many are due to trinucleotide repeat insertions (see p. 29).

**Early-onset ataxia**

Most early (<20 years of age) childhood-onset inherited ataxias are autosomal recessive. Friedreich's ataxia is by far the most common, caused by a GAA trinucleotide repeat expansion in the frataxin gene (involved in mitochondrial iron metabolism). Onset is in the early teens with progressive difficulty in walking due to cerebellar ataxia and sensory neuropathy. Associated features include scoliosis, cardiomyopathy, optic atrophy, areflexia and diabetes.

ataxia telangiectasia and ataxia with vitamin E deficiency are other rarer forms of autosomal recessive inherited ataxia.

**Late-onset ataxia**

Adult-onset (>20 years of age) inherited ataxias are usually dominantly inherited and there are some 30 different genetic forms, many caused by CAG trinucleotide repeats. There are three main categories of autosomal dominant cerebellar ataxia (ADCA):

- **ADCA-1**: progressive ataxia with variable additional features, including peripheral neuropathy, pyramidal and extrapyramidal signs, and cognitive impairment. ADCA-1 is caused by mutations in loci SCA1-3.
- **ADCA-2**: progressive ataxia with macular dystrophy. ADCA-2 is rare and involves the SCA7 gene.
- **ADCA-3**: late adult-onset 'pure' ataxia. ADCA-3 is associated with the SCA6 gene in 50%. Non-genetic phenocopies must be excluded.

**PARANEOPLASTIC SYNDROMES**

Neurological disease may accompany malignancy in the absence of metastases. These paraneoplastic syndromes are associated with anti-neuronal antibodies, believed to be involved in the generation of signs and symptoms. Numerous anti-neuronal antibodies have been described.

Clinical pictures include:

- sensorimotor neuropathy (see p. 895)
- Lambert–Eaton myasthenic–myopathic syndrome (LEMS; see p. 889) and myasthenia gravis with thymoma
- motor neurone disease variants (see p. 885)
- spastic paraparesis (see p. 879)
- cerebellar syndrome (see p. 820)
- limbic encephalitis (see p. 871)
- paraneoplastic stiff person syndrome (see p. 897).

The neurological syndrome usually precedes evidence of the neoplasm: often a small-cell bronchial carcinoma, or breast or ovarian cancer. Diagnosis is based on the clinical pattern and antibody profile. Neuroimaging is typically normal. Treatment is often unsatisfactory.

**PERIPHERAL NERVE DISEASE**

**Mechanisms of damage to peripheral nerves**

Peripheral nerves consist of two principal cellular structures: the nerve nucleus with its axon, and the myelin sheath, which is produced by Schwann cells between each node of Ranvier (see Fig. 26.1). Blood supply is via vasa nervorum. Several mechanisms, some coexisting, cause nerve damage.

**Demyelination**

Schwann cell damage leads to myelin sheath disruption. This causes a marked slowing of conduction, seen, for example, in Guillain–Barré syndrome and many genetic neuropathies.

**Axonal degeneration**

Axon damage causes the nerve fibre to die back from the periphery. Conduction velocity initially remains normal (compare demyelination) because axonal continuity is maintained in surviving fibres. Axonal degeneration typically occurs in toxic neuropathies. A wide range of toxic and metabolic disorders damage peripheral nerves, as their long axons (requiring cellular transport of proteins from cell body to nerve terminals) make them uniquely vulnerable. This explains the concept of length-dependent neuropathy with the longest, most vulnerable axons (to the toes) being affected first.

**Compression**

Focal demyelination at the point of compression causes disruption of conduction. This typically occurs in entrapment neuropathies, such as carpal tunnel syndrome.

**Infarction**

Microinfarction of vasa nervorum occurs in diabetes and arteritis, such as polyarteritis nodosa and eosinophilic granulomatosis with polyangiitis (see p. 991). Wallerian degeneration occurs distal to the infarct.

**Infiltration**

Infiltration of peripheral nerves occurs by inflammatory cells in leprosy and granulomas, such as sarcoid, and by neoplastic cells.

**Nerve regeneration**

Regeneration occurs either by remyelination – Schwann cells produce new myelin sheaths around an axon – or by axonal growth down the nerve sheath with sprouting from the axonal stump. Axonal growth takes place at up to 1 mm/day.

**Types of peripheral nerve disease**

(See Fig. 26.63.)

- **Neuropathy** simply means a pathological process affecting a peripheral nerve or nerves.
- **Mononeuropathy** means a process affecting a single nerve.
- **Mononeuritis multiplex** means that several individual nerves are affected.
- **Polyneuropathy** describes diffuse, symmetrical disease, usually commencing peripherally. The course may be acute, chronic, static, progressive, relapsing or towards recovery. Polyneuropathies are motor, sensory, sensorimotor and autonomic. They are classified broadly into demyelinating and
Peripheral nerve compression and entrapment

Nerves are vulnerable to mechanical compression at a few key sites (Box 26.67), such as the common peroneal nerve at the head of the fibula, or the ulnar nerve at the elbow. Entrapment develops in relatively tight anatomic passages, such as the carpal tunnel. Focal demyelination predominates at the compression site, and some distal axonal degeneration occurs.

These neuropathies are recognized largely by their clinical features. Diagnosis is confirmed by nerve conduction studies. The most common are mentioned here. All are seen more frequently in people with diabetes.

Mononeuropathies

Mononeuropathies (axonal or demyelinating) can be assessed by electrical nerve studies (see p. 829). The type of neuropathy axonal types, depending on which principal pathological process predominates. It is often impossible to separate these clinically. Many systemic diseases cause neuropathies. Widespread loss of tendon reflexes is typical, with distal weakness and distal sensory loss.

- Radiculopathy means disease affecting nerve roots and plexopathy, the brachial or lumbosacral plexus.

Diagnosis is made by clinical pattern, nerve conduction studies/EMG, nerve biopsy, usually sural or radial, and identification of systemic or genetic disease.

Peripheral nerve compression and entrapment

This common mononeuropathy, median nerve entrapment at the wrist, is usually known as carpal tunnel syndrome (CTS). CTS is typically not associated with any underlying disease. It is, however, seen in:

- hypothyroidism
- pregnancy (third trimester)
- rheumatoid disease
- acromegaly
- amyloidosis, including in dialysis patients.

Symptoms, signs and management are discussed on page 421.

Ulnar nerve compression

The nerve is compressed in the cubital tunnel at the elbow. This follows prolonged or recurrent pressure and elbow fracture (“tardy ulnar palsy”, as onset is very delayed).

There is clawing of the hand, wasting of interossei and hypothenar muscles, and weakness of interossei and medial two lumbricals with sensory loss in the little finger and splitting of the ring finger. Decompression and transposition of the nerve at the elbow is sometimes helpful but often disappointing.

Radial nerve compression

The radial nerve is compressed acutely against the humerus: for example, when the arm is draped over a hard chair for several hours, known as Saturday night palsy. Wrist drop and weakness of brachioradialis and finger extension follow. Recovery is usual, though not invariably, within 1–3 months. Posterior interosseous nerve compression in the forearm also leads to wrist drop, without weakness of brachioradialis.

Lateral cutaneous nerve of the thigh compression

This is also known as meralgia paraesthetica and is described on page 425.

Common peroneal nerve palsy

The common peroneal nerve is compressed against the head of the fibula following prolonged squatting, yoga, pressure from a cast, prolonged bed rest or coma, or for no apparent reason. There is foot drop and weakness of ankle eversion. The ankle jerk (S1) is preserved. A patch of numbness develops on the anterolateral border of the dorsum of the foot and/or lateral calf. Confusion with an L5 motor radiculopathy may occur. Recovery is usual, though not invariably, within several months.

Hereditary neuropathy with pressure palsies

The genetic converse of Charcot–Marie–Tooth disease 1A (see p. 891), this dominantly inherited disorder is due to deletion (as opposed to duplication) of the PMP-22 gene. Patients are susceptible to pressure palsies after minor compression episodes; even the brachial plexus may be involved. There is also a mild background neuropathy that develops gradually. Genetic testing can be performed.

Mononeuritis multiplex

This occurs in:

- diabetes mellitus
- leprosy
- vasculitis, including eosinophilic granulomatosis with polyangiitis
- amyloidosis
- malignancy
- neurofibromatosis
- HIV and hepatitis C infection
- multifocal motor neuropathy with conduction block.

Several nerves, such as the ulnar, median, radial and lateral popliteal, become affected sequentially or simultaneously. When multifocal neuropathy is symmetrical, there is difficulty distinguishing it from polyneuropathy.

**Polyneuropathies (peripheral neuropathy)**

Many diseases cause polyneuropathy. The diagnosis should not stop with identification of the polyneuropathy, but should involve a full diagnostic work-up to identify the underlying cause (Box 26.68). However, despite thorough investigation, the aetiology remains unknown in 50% of cases.

**Clinical features.** Duration, distribution and pattern of the different types of polyneuropathy vary considerably.

**Neurophysiological features.** Nerve conduction studies allow separation into axonal and demyelinating forms.

**Diagnostic investigations** (in addition to neurophysiology). A stepped approach can be taken (Box 26.69).

**Immune-mediated neuropathies**

**Guillain–Barré syndrome (GBS)**

**Clinical features**

Guillain–Barré syndrome (GBS) is also called acute inflammatory demyelinating polyradiculoneuropathy (AIDP). GBS is the most common acute polyneuropathy (3/100,000 per year); it is usually demyelinating or occasionally axonal, and has an immune-mediated, often post-infectious, basis. GBS is monophasic – it does not recur. The clinical spectrum of GBS extends to an acute motor axonal neuropathy (AMAN) and the Miller–Fisher syndrome – a rare proximal form causing ocular muscle palsy and ataxia.

Paralysis follows 1–3 weeks after an infection that is often trivial and seldom identified. *Campylobacter jejuni* and cytomegalovirus infections are well-recognized causes of severe GBS. Infecting organisms induce antibody responses against peripheral nerves. Molecular mimicry – that is, sharing of homologous epitopes between microorganism liposaccharides and nerve gangliosides (e.g. GM1) – is the possible mechanism.

The patient complains of weakness of the distal limb muscles and/or distal numbness. Low back pain is a frequent early feature. The weakness and sensory loss progress proximally, over several days to 6 weeks. Predominant proximal muscle involvement may occur and, rarely, pure sensory forms. Loss of tendon reflexes is almost invariable. In mild cases, there is mild disability before spontaneous recovery begins, but in some 20% respiratory and facial muscles become weak, sometimes progressing to complete paralysis. Autonomic features sometimes develop.

**Diagnosis**

This is established on clinical grounds and confirmed by nerve conduction studies; these show slowing of conduction in the common demyelinating form, prolonged distal motor latency and/or conduction block. CSF protein is often raised to 1–3 g/L; cell count and glucose level remain normal.

In the Miller–Fisher syndrome, antibodies against GQ1b (ganglioside) have a sensitivity of 90%.

The differential diagnosis includes other acute paralytic illnesses, such as botulism, cord compression, muscle disease and myasthenia.

**Course and management**

Paralysis may progress rapidly (hours/days) to require ventilatory support. It is essential for ventilation (vital capacity) to be monitored repeatedly to recognize emerging respiratory muscle weakness. Low-molecular-weight heparin (see p. 1014) and compression stockings should be used to reduce the risk of venous thrombosis.

Immunoglobulin given intravenously within the first 2 weeks reduces duration and severity of paralysis. Patients should be screened for IgA deficiency before immunoglobulin is given, as severe allergic reactions due to IgG antibodies may occur when congenital IgA deficiency is present. Plasma exchange is an alternative. Prolonged ventilation may be necessary. Improvement towards independent mobility is gradual over many months or even years but may be incomplete. Some 5–8% die and 30% are left disabled.

**Chronic inflammatory demyelinating polyradiculoneuropathy**

Chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) develops over months, causing progressive or relapsing proximal and distal limb weakness with sensory loss. Variants, such as the sensory ataxic form and multifocal motor neuropathy, occur. In some cases, cranial nerves may be involved.

There is no single diagnostic test but CSF protein is raised and patchy demyelination is usually seen on nerve conduction studies. Some cases are associated with a serum paraprotein. Nerve biopsy is sometimes required. CIDP responds to long-term immunosuppression with steroids or to intravenous immunoglobulin in the acute stages.

**Multifocal motor neuropathy with conduction block**

A distal immune-mediated focal demyelinating motor neuropathy (often asymmetrical and predominantly in the hands) develops gradually over months with profuse fasciculation; hence there is confusion with motor neuron disease (see p. 885). Conduction block and denervation are seen electrically. Antibodies to the ganglioside GM1
are found in over 50% of cases; this is non-specific, as antibodies are sometimes seen in other neuropathies, such as GBS.

Treatment is usually with regular intravenous immunoglobulin infusions that produce immediate improvement. Steroids may cause the condition to worsen and should be avoided.

**Paraproteinaemic neuropathies**

Up to 70% of patients with a serum paraprotein have a neuropathy and some 10% of patients with no identifiable cause for their neuropathy have a paraprotein. Most are associated with monoclonal gammopathy of unknown significance (MGUS; see p. 410) but they are also seen in myeloma (see p. 407). The antibody may be pathogenic for the neuropathy (e.g. anti-MAG) or coincidental in some cases.

**IgM paraproteins:** usually a demyelinating neuropathy. The paraproteins are often directed against myelin-associated glycoprotein (anti-MAG). The anti-MAG phenotype is a slowly progressive distal neuropathy with ataxia and prominent tremor.

**POEMS syndrome (Polyneuropathy (demyelinating), Organomegaly (hepatomegaly 50%), Endocrinopathy (reduced testosterone usually), an M (paraprotein band, and Skin changes); probably caused by vascular endothelial growth factor (VEGF) release from a plasmacytoma. Treatment is of the plasmacytoma/plasma cell dyscrasia.

**Chronic sensorimotor neuropathy: no cause found**

This situation is common. Progressive symmetrical numbness and tingling occur in hands and feet, spreading proximally in a glove and stocking distribution. Distal weakness also ascends. Tendon reflexes are lost. Symptoms may progress, remain static or occasionally remit. Autonomic features are sometimes seen.

Nerve conduction studies usually show axonal degeneration. Nerve biopsy helps to classify some cases: for example, diagnosing CIDP or unsuspected vasculitis.

**Metabolic, toxic and vitamin deficiency neuropathies**

Causes of the most common neuropathies are shown in Box 26.70.

**Metabolic neuropathies**

**Diabetes mellitus**

This is the most common cause of neuropathy in developed countries; 50% of patients with diabetes have neuropathy after 25 years. Good glycaemic control is protective against this microvascular complication of diabetes. Several varieties of neuropathy occur (see p. 731):

- **distal symmetrical sensory neuropathy:** usually mild and asymptomatic; related to diabetes duration and glycaemic control
- **acute painful sensory neuropathy** (reversible with improved glycaemic control)
- **mononeuropathy and multiple mononeuropathy (mononeuritis multiplex):**
  - cranial nerve lesions
  - individual mononeuropathies (e.g. carpal tunnel syndrome) or mononeuritis multiplex
- **diabetic amyotrophy:** a reversible vasculitic plexopathy or femoral neuropathy
- **autonomic neuropathy.**

**Uraemia**

Progressive sensorimotor neuropathy develops in chronic uraemia. Response to dialysis is variable; the neuropathy usually improves after transplantation.

**Thyroid disease**

A mild chronic sensorimotor neuropathy is sometimes seen in both hyperthyroidism and hypothyroidism. Myopathy also occurs in hyperthyroidism (see p. 614).

**Porphyria**

In acute intermittent porphyria (see p. 755), there are episodes of a severe, mainly proximal neuropathy in the limbs, sometimes with abdominal pain, confusion and coma. Alcohol, barbiturates and intercurrent infection can precipitate attacks.

**Amyloidosis**

Polyneuropathy or multifocal neuropathy develops (see p. 1357).

**Toxic neuropathies**

**Alcohol**

Polyneuropathy, mainly in the lower limbs, occurs with chronic alcohol use. It is a common cause of neuropathy. A myopathy may accompany it. For other neurological consequences of alcohol, see Box 26.71.

**Drugs and industrial toxins**

Many drugs (Box 26.72) and a wide variety of industrial toxins cause polyneuropathy. Toxins include:

- lead – motor neuropathy
- acrylamide (plastics industry), trichlorethylene, hexane, fat-soluble hydrocarbons, e.g. solvent abuse; see p. 792
- arsenic, thallium and heavy metals.

**Vitamin deficiency**

- B1 (thiamine)
- B6 (pyridoxine)
- Nicotinic acid
- B12

**Other**

- Hereditary sensorimotor neuropathies, e.g. Charcot–Marie–Tooth
- Other polyneuropathies:
  - Neuropathy in cancer
  - Neuropathy in systemic diseases
  - Autonomic neuropathy
  - HIV-associated neuropathy
  - Critical illness neuropathy

**Toxic**

- Drugs (see Box 26.72)
- Alcohol
- Industrial toxins, e.g. lead, organophosphates

Vitamin deficiency neuropathies

Vitamin deficiencies cause nervous system damage that is potentially reversible if treated early, and progressive if not. Deficiencies, often of multiple vitamins, develop in malnutrition.

Thiamine (vitamin B₁)

Dietary deficiency causes beriberi (see p. 1240). Its principal features are polyneuropathy and cardiac failure. Thiamine deficiency also leads to Wernicke's encephalopathy and Korsakoff psychosis. Alcohol is the most common cause in Western countries and, rarely, anorexia nervosa or vomiting of pregnancy.

Wernicke–Korsakoff's syndrome. This thiamine-responsive encephalopathy is due to damage in the brainstem and its connections. It consists of:

- eye signs – nystagmus, bilateral lateral rectus palsies, conjugate gaze palsies
- ataxia – broad-based gait, cerebellar signs and vestibular paralysis
- cognitive change – acutely, stupor and coma; later, an amnestic syndrome with confabulation.

Wernicke–Korsakoff’s syndrome is under-diagnosed. Thiamine should be given parenterally if the diagnosis is a possibility. Untreated Wernicke–Korsakoff’s syndrome commonly leads to an irreversible amnestic state. Erythrocyte transketolase activity is reduced but the test is rarely available.

Pyridoxine (vitamin B₆)

Deficiency causes a mainly sensory neuropathy. In practical terms, this is seen as limb numbness developing during anti-tuberculosis therapy in slow isoniazid acetylators (see p. 971). Prophylactic pyridoxine 10 mg daily is given with isoniazid.

Vitamin B₁₂ (cobalamin)

Deficiency causes damage to the spinal cord, peripheral nerves and brain.

Subacute combined degeneration of the cord (SACD). Combined cord and peripheral nerve damage is a sequel of addisonian pernicious anaemia and, rarely, other causes of vitamin B₁₂ deficiency (see p. 334). Initially, there is numbness and tingling of fingers and toes; distal sensory loss, particularly of the posterior column; absent ankle jerks; and, with cord involvement, exaggerated knee jerks and extensor plantars. Optic atrophy and retinal haemorrhage may occur. In later stages, sphincter disturbance, severe generalized weakness and dementia develop. Exceptionally, dementia develops in the early stages.

Activated vitamin B₁₂, methylnsalicylic acid and homocysteine levels should be checked. Macrocytosis with megaloblastic marrow is usual, though not invariable, in SACD. Parenteral B₁₂ reverses nerve damage but has little effect on the cord and brain. Copper deficiency is a very rare cause of a similar picture. Nitrous oxide abuse may cause functional B₁₂ deficiency.

Genetic neuropathies

Inherited neuropathy may occur as ‘pure’ neuropathy disorders (e.g. Charcot–Marie–Tooth disease) or as part of a neurological multisystem disorder (e.g. spinocerebellar ataxias; see p. 887).

Charcot–Marie–Tooth disease

Charcot–Marie–Tooth (CMT) disease is a complex group of heterogeneous hereditary motor and sensory neuropathies (HMSNs) with multiple causative genes. Distal limb wasting and weakness typically progress slowly over many years, mostly in the legs, with variable loss of sensation and reflexes. In advanced disease, severe foot drop results but patients usually remain ambulant. Mild cases have pes cavus and toe clawing that can pass unnoticed.

- **HSMN la (CMT 1A)** – the most common (70% of CMT; 1:2500 births) autosomal dominant demyelinating neuropathy, caused by duplication (or point mutation) of a 1.5 megabase portion p11.2 of chromosome 17 encompassing the peripheral myelin protein 22 gene (PMP-22, 1p11.2).
- **HSMN Ib (CMT 1B)** – the second most common autosomal dominant demyelinating neuropathy due to mutations in the myelin protein zero gene (MPZ) on chromosome 1 (q22).
- **HSMN II (CMT 2)** – rare axonal polyneuropathies also caused by MFN2 or KIF1B on chromosome 1p36 and other mutations; there is prominent sensory involvement with pain and paraesthesia.
- **Distal spinal muscular atrophy** – a rare cause of the CMT phenotype.
- **CMT with optic atrophy**, deafness, retinitis pigmentosa and spastic paraparesis.
- **CMTX** – an X-linked dominant HMSN on chromosome Xq13.1; the gene product is a gap junction B1 protein (GJB1) or connexin 32.

Hereditary motor and sensory neuropathy type III

HMSN III is a rare childhood demyelinating sensory neuropathy (Déjérine–Sottas disease) leading to severe incapacity during adolescence. Nerve roots become hypertrophied. CSF protein is greatly elevated to 10 g/L or more. Point mutations, either of PMP-22 gene or of P0, can generate this phenotype.

Other polyneuropathies

Neuropathy in cancer

Polyneuropathy is seen as a paraneoplastic syndrome (non-metastatic manifestation of malignancy). Polyneuropathy occurs in myeloma and other plasma cell dyscrasias via several mechanisms, including direct effects of paraproteins, amyloidosis and nerve infiltration, POEMS and effects of chemotherapy. Individual nerves may be infiltrated with malignant cells, such as lymphoma.

Neuropathies in systemic diseases

Vasculitic neuropathy occurs in SLE (see p. 457), polyarteritis nodosa (p. 465), granulomatosis with eosinophilia (p. 991) and
Neurology

892

rheumatoid disease (p. 442). Both multifocal neuropathy and symmetrical sensorimotor polyneuropathy occur.

**Autonomic neuropathy**

Autonomic neuropathy causes postural hypotension, urinary retention, erectile dysfunction, nocturnal diarrhoea, diminished sweating, impaired pupillary responses and cardiac arrhythmias. This can develop in diabetes and amyloidosis, and may complicate GBS and Parkinson’s disease. Many varieties of neuropathy cause autonomic problems in a mild form. Occasionally, such as with amyloidosis, a severe autonomic neuropathy may occur.

**Neuromuscular weakness complicating critical illness**

Some 50% of critically ill intensive care unit patients with multiple organ failure and/or sepsis develop an axonal polyneuropathy (see p. 231). Typically, distal weakness and absent reflexes are seen during recovery from critical illness. Resolution is usual.

**Plexus and nerve root lesions**

The common conditions that cause these are summarized in Box 26.73.

**Cervical and lumbar degeneration**

Spondylosis (see p. 892) describes vertebral and ligamentous degenerative changes occurring during ageing or following trauma. Several factors produce neurological signs and symptoms:

- osteophytes – local overgrowth of bony spurs or bars
- thickening of spinal ligaments
- congenital narrowing of the spinal canal
- disc degeneration and protrusion (posterior and lateral protrusion: cord and root compression)
- vertebral collapse (osteoarthritis, infection)
- rheumatoid synovitis (see p. 442)
- ischaemic changes within cord and nerve roots.

Narrowing of disc spaces, osteophytes, narrowing of exit foramina and narrowing of the spinal canal are also seen on X-rays and MRI in the **symptomless** population, commonly in the mid- and lower cervical and lower lumbar region, and so imaging must not be over-interpreted.

**Lateral cervical disc protrusion**

The patient complains of pain in the arm. A C7 protrusion is the most common problem (Fig. 26.64). There is root pain that radiates to the C7 myotome (triceps, deep to scapula and extensor aspect of forearm), with a sensory disturbance, tingling and numbness in the C7 dermatome.

In an established C7 root lesion there is:

- weakness/wasting – triceps, wrist and finger extensors
- loss of the triceps jerk (C7 reflex arc)
- C7 dermatome sensory loss.

Although the initial pain can be very severe, most cases recover with rest and analgesics. It is usual to immobilize the neck. Disc protrusion with root compression is seen on MRI. Root decompression is sometimes helpful.

**Lateral lumbar disc protrusion**

The L5 and S1 roots are commonly compressed by lateral prolapse of L4–L5 and L5–S1 discs; the root number below a disc interspace is compressed. There is low back pain and **sciatica**: pain radiating from the back to buttock and leg. Onset is typically acute. This can follow lifting, bending or minor injury. When pain follows such an event, it is tempting to ascribe the disc protrusion to it. However, commonly, lateral lumbar disc protrusion is apparently spontaneous; lifting or injury is usually only bringing forward an inevitable disc prolapse.

Straight-leg raising is limited. There is reflex loss, such as ankle jerk in an S1 root lesion, and weakness of plantar flexion (S1) or great toe extension (L5). Sensory loss is found in the affected dermatome.

Most sciatica resolves with initial rest and analgesia, followed by early mobilization. MRI is sometimes appropriate. Surgery is indicated when a substantial persistent symptomatic disc lesion is shown.

**Acute low back pain**

Acute low back pain is extremely common. Often, pain is of disc or facet joint origin. Significant nerve root compression is unusual. Maintenance of activity and a trial of gentle manipulation are recommended (see also p. 423).

**Cervical spondylotic myelopathy**

This is a relatively common disorder of older adults. Posterior disc protrusion (Fig. 26.65), common at C4–5, C5–6 and C6–7 levels, causes spinal cord compression. Congenital spinal canal narrowing, osteophytic bars, ligamentous thickening and ischaemia are contributory. Usually, there are no or few neck symptoms. The patient complains of slowly progressive difficulty walking as a spastic paraparesis develops. A reflex level in the upper limbs and evidence of
Muscle diseases

Muscle diseases

**Definitions**
- **Myopathy** means a disease of voluntary muscle.
- **Myositis** indicates inflammation.
- **Muscular dystrophies** are inherited disorders of muscle cells.
- **Myasthenia** means fatiguable (worse on exercise) weakness – seen in neuromuscular junction diseases.
- **Myotonia** is sustained contraction/slow relaxation.
- **Channelopathies** are ion channel disorders of muscle cells.
- **Weakness** is the predominant feature of muscle disease. A selection of these conditions is given in Box 26.74.

**Pathophysiology**

Muscle fibres are affected by:
- acute inflammation and fibre necrosis (e.g. polymyositis, infection)
- genetically determined metabolic failure (e.g. Duchenne muscular dystrophy)
- infiltration by inflammatory tissue (e.g. sarcoidosis)
- fibre hypertrophy and regeneration
- mitochondrial diseases
- immunological damage, e.g. myasthenia gravis and Lambert–Eaton myasthenic syndrome
- ion channel disorders, e.g. chloride channel mutations in hereditary myotonias.
**Box 26.74 Muscle disease: classification**

- Acquired
  - Inflammatory
  - Polymyositis
  - Dermatomyositis
- Inclusion body myositis
  - Viral, bacterial and parasitic infection
  - Sarcoidosis
- Endocrine and toxic
  - Corticosteroids/Cushing's
  - Thyroid disease
  - Calcium disorders
  - Alcohol misuse
  - Drugs, e.g. statins
- Myasthenic
  - Myasthenia gravis
  - Lambert–Eaton myasthenic–myopathic syndrome (LEMS)
- Genetic dystrophies
  - Duchenne
  - Facioscapulohumeral
  - Limb girdle and others
- Myotonic
  - Myotonic dystrophy
  - Myotonia congenita
- Channelopathies
  - Hypokalaemic periodic paralysis
  - Hyperkalaemic periodic paralysis
- Metabolic
  - Myophosphorylase deficiency (McArdle’s syndrome)
  - Other defects of glycogen and fatty acid metabolism
- Mitochondrial disease

**Diagnosis**

Clinical features, including the distribution of weakness, wasting or hypertrophy, and the tempo of progression and presence of family history contribute to a clinical diagnosis. Several investigations help make a definitive diagnosis.

**Serum muscle enzymes**

Serum creatine kinase (CK) is a marker of muscle fibre damage and is greatly elevated in many dystrophies, such as Duchenne, and in inflammatory muscle disorders, such as polymyositis.

**Neurogenetic tests**

These are essential in muscular dystrophies and mitochondrial disease.

**Electromyography**

Characteristic EMG patterns are as follows:

- **Myopathy.** Short-duration spiky polyphasic muscle action potentials are seen. Spontaneous fibrillation is occasionally recorded.
- **Myotonic discharges.** A characteristic high-frequency whine is heard.
- **Decrement and increment.** In myasthenia gravis, a characteristic decrement in evoked muscle action potential follows repetitive motor nerve stimulation. The reverse occurs, i.e. increment, following repetitive stimulation in LEMS (see p. 895).
- In **deneration,** profuse fibrillation potentials are seen.

**Muscle biopsy**

Unlike neural tissue, skeletal muscle can be easily biopsied to provide a definitive diagnosis using powerful molecular immunohistochemical techniques. Histology and muscle histochemistry of fibre types demonstrate denervation, inflammation and dystrophic changes. Electron microscopy is often valuable. In dystrophies, immunohistochemistry in specialist laboratories allows identification of the abnormal muscle protein and a precise molecular diagnosis.

**Imaging**

MRI shows **signal changes** within muscles in some cases of myositis, and fatty replacement of muscle in chronically damaged muscles.

**Inflammatory myopathies**

Inflammatory myopathies, including polymyositis, dermatomyositis and inclusion body myositis, are described on pages 462 and 463. Granulomatous muscle infiltration and inflammation may occur in sarcoidosis and other disorders such as rheumatoid arthritis, causing a mild myopathy. Viral myositis may also occur, and muscles may be involved in other infections such as neorocysticercosis (see p. 872).

**Metabolic and endocrine myopathies**

**Corticosteroids and Cushing’s syndrome**

Proximal weakness occurs with prolonged high-dose steroid therapy and in Cushing’s syndrome (see p. 600). Selective type-2 fibre atrophy is seen on biopsy.

**Thyroid disease**

Several myopathies occur (see also p. 617). Thyrotoxicosis can be accompanied by severe proximal myopathy. There is also an association between thyrotoxicosis and myasthenia gravis, and between thyrotoxicosis and hypokalaemic periodic paralysis (see p. 896). Both associations are seen more frequently in South-east Asia. In ophthalmic Graves’ disease, there is swelling and lymphocytic infiltration of extraocular muscles (see p. 618).

**Hypothyroidism** is sometimes associated with muscle pain and stiffness, resembling myotonia. A proximal myopathy also occurs.

**Disorders of calcium and vitamin D metabolism**

Proximal myopathy develops in hypocalcaemia, rickets and osteomalacia (see p. 483).

**Hypokalaemia**

Acute hypokalaemia (e.g. with diuretics) causes flaccid paralysis reversed by potassium, given slowly (see p. 188). Chronic hypokalaemia leads to mild, mainly proximal, weakness. (See also periodic paralysis; p. 896).

**Alcohol and drugs**

Severe myopathy with muscle pain, necrosis and myoglobinuria occurs in acute excess. A subacute proximal myopathy occurs with chronic alcohol use. A similar syndrome occurs in diamorphine and amphetamine addicts.

**Drugs**

Drug-induced muscle disorders include proximal myopathy (steroids), muscle weakness (lithium), painful muscles (fibrates), rhabdomyolysis (a fibrate combined with a statin, or interaction between statins and other drugs such as certain antibiotics) and malignant hyperpyrexia. Most respond to drug withdrawal.

**Myophosphorylase deficiency (McArdle’s syndrome)**

McArdle’s syndrome is a muscle-only glycogenosis where there is a deficiency of muscle glycogen phosphorylase (PYGM). It presents with muscle cramps, fatigue, anaesthetic problems and myoglobinuria after exercise in adults. Diagnosis is made on a muscle biopsy with analysis of PYGM at 11q13. Patients have a normal life span.Sucrose should be given before exercise.
Malignant hyperpyrexia

Widespread skeletal muscle rigidity with hyperpyrexia as a sequel of general anaesthesia or neuroleptic drugs, such as haloperidol, is due to a genetic defect in the sarcoplasmic reticulum calcium-release channel of the muscle ryanodine receptor, RyR1. Death during or following anaesthesia can occur in this rarity, sometimes inherited as an autosomal dominant trait. Dantrolene is of some help for rigidity.

Neuromuscular junction disorders

Myasthenia gravis

Myasthenia gravis (MG) is an autoimmune disorder of neuromuscular junction (NMJ) transmission, characterized by weakness and fatiguability of proximal limb, bulbar and ocular muscles, the latter sometimes in isolation. The prevalence is about 4 in 100,000. MG is twice as common in women as in men, with a peak age incidence around 30 and a second smaller peak in incidence in older men.

Antibodies to acetylcholine receptor protein (anti-AChR antibodies) are pathogenic. Immune complexes of anti-AChR IgG and complement are deposited at the postsynaptic membranes, causing destruction of AChRs. Antibodies against muscle-specific receptor tyrosine kinase (anti-MuSK antibodies) have been identified in anti-AChR antibody-negative cases.

Thymic hyperplasia is found in 70% of MG patients below the age of 40. In some 10%, a thymic tumour is found (paraneoplastic myasthenia), the incidence increasing with age; antibodies to striated muscle can be demonstrated in some of these patients.

There is an association between MG and other autoimmune disorders: thyroid disease, rheumatoid disease, pernicious anaemia and SLE. Transient MG is sometimes caused by D-penicillamine treatment.

Clinical features

Weakness and fatiguability are typical. Limb muscles (proximal), extraocular muscles, speech, facial expression and mastication muscles are commonly affected. Symptoms are worse towards the end of the day. Fluctuating diplopia and ptosis (often asymmetric) are frequently early symptoms and symptoms may be confined to the eyes: ocular myasthenia. Respiratory difficulties can occur in generalized myasthenia. Early complaints of fatigue are frequently dismissed.

Complex extraocular palsies, ptosis and fatiguable proximal weakness are found on examination (prolonged upgaze should be checked and limb power tested after repetitive contractions). The reflexes are initially preserved but may be fatiguable: that is, they disappear following repetitive activity. Wasting is sometimes seen after many years.

Investigations

- **Serum anti-AChR and anti-MuSK antibodies.** Anti-AChR antibodies are present in some 80–90% of cases of generalized MG. In pure ocular MG, anti-AChR antibodies are detectable in less than 30% of cases. These antibodies are highly specific for MG and confirm the diagnosis. Anti-MuSK antibodies define a subgroup of MG patients characterized by weakness predominantly in bulbar, facial and neck muscles.

- **Repetitive nerve stimulation and single-fibre EMG.** A characteristic decrement occurs in the evoked muscle action potential during repetitive stimulation. Single-fibre EMG of orbicularis oculi is more sensitive than repetitive stimulation and shows block and jitter.

- **Imaging and other tests.** Mediastinal MRI or CT is needed to look for thymoma in all cases. Antibodies to striated muscle suggest a thymoma.

Course and management

MG fluctuates in severity; most cases have a protracted, life-long course. Respiratory impairment, nasal regurgitation and dysphagia occur; emergency ventilation may be required. Simple monitoring tests, such as the duration for which an arm can be held outstretched, and the vital capacity are useful.

Exacerbations are usually unpredictable and unprovoked but may be brought on by infections and by aminoglycosides and other drugs.

Drug treatment

**Oral anticholinesterases**

Pyridostigmine (60 mg tablet) is widely used. The duration of action is 3–4 hours, the dose (usually 3–16 tablets daily) determined by response. Pyridostigmine prolongs acetylcholine action by inhibiting cholinesterase. Overdose of anticholinesterases causes severe weakness (cholinergic crisis). Muscarinic side-effects, such as colic and diarrhoea, are common; oral propantheline (antimuscarinic) helps to reduce this. Anticholinesterases help weakness but do not alter the natural history of myasthenia.

**Immunosuppressant drugs**

These drugs are used in patients who do not respond to pyridostigmine or who have severe weakness. Steroids are usually used. There is improvement in 70%, although this may be preceded by an initial relapse; steroid dose should be increased slowly. Azathioprine, mycophenolate and other immunosuppressants are also used as steroid-sparing agents.

**Thymectomy**

Thymectomy improves myasthenia in patients with thymic hyperplasia and positive AChR antibodies (approximately one-third improve, one-third enter remission and one-third do not benefit). When a thymoma is present, the potential for malignancy makes surgery necessary but the myasthenia may not improve.

**Plasmapheresis and intravenous immunoglobulin**

These produce a rapid dramatic response and are used in exacerbations and severe myasthenic crisis.

**Other rare myasthenic syndromes** exist, such as congenital myasthenia.

Lambert–Eaton myasthenic–myopathic syndrome

Lambert–Eaton myasthenic–myopathic syndrome (LEMS) is a paraneoplastic manifestation of small-cell bronchial carcinoma due to defective acetylcholine release at the neuromuscular junction. A smaller proportion of cases are autoimmune without underlying malignancy. Proximal limb muscle weakness, sometimes with ocular/bulbar muscles, develops, with some absent tendon reflexes: a cardinal sign. Weakness tends to improve after a few minutes of muscular contraction, and absent reflexes return (compare myasthenia). Diagnosis is confirmed by repetitive nerve stimulation (increment;
see above). Antibodies to voltage-gated calcium channels are found in most cases (90%). Treatment with 3,4-diaminopyridine (DAP) is reasonably safe and effective.

### Muscular dystrophies

These progressive, genetically determined disorders of skeletal and sometimes cardiac muscle have a complex clinical and neurogenic classification.

#### Duchenne muscular dystrophy and Becker's muscular dystrophy

These are inherited as X-linked recessive disorders, though one-third of cases are spontaneous mutations. Duchenne muscular dystrophy (DMD) occurs in 1 in 3000 male infants. There is absence of the gene product dystrophin, a rod-shaped cytoskeletal muscle protein in DMD. In Becker's dystrophy, dystrophin is present but levels are low. DMD is usually obvious by the fourth year, and often causes death by the age of 20.

Dystrophin is essential for cell membrane stability. Deficiency leads to reduction in three glycoproteins (α-, β-, and γ-sarcoglycans) in the dystrophin-associated protein complex (DAP complex) that links dystrophin to laminin within cell membranes.

Becker's muscular dystrophy is less severe than Duchenne and weakness only becomes apparent in young adults.

#### Clinical features

A boy with DMD is noticed to have difficulty running and rising to his feet; he uses his hands to climb up his legs (Gowers’ sign). There is initially a proximal limb weakness with calf pseudohypertrophy. The myocardium is affected. Severe disability is typical by the age of 10.

#### Investigations

The diagnosis is often suspected clinically. CK is grossly elevated (100–200 times normal). Biopsy shows variation in muscle fibre size, necrosis, regeneration and replacement by fat, and on immunohistochemistry, absence of dystrophin.

#### Management

There is no curative treatment but new gene-editing therapies are in development. Steroids may delay progression. Physiotherapy helps prevent contractures in the later stages. Non-invasive respiratory support and multidisciplinary care improve life expectancy.

**Carrier detection.** Females with an affected brother have a 50% chance of carrying the DMD gene. In carriers, 70% have a raised CK, and usually EMG abnormalities and/or changes on biopsy. Carrier and prenatal diagnosis is available with genetic counselling.

### Limb-girdle and facioscapulohumeral dystrophies

These less severe but disabling dystrophies are summarized in Box 26.75. There are many other varieties of dystrophy; facioscapulohumeral dystrophy is one of the most common. Genes for numerous forms of limb-girdle muscular dystrophy have been identified. CK is usually moderately elevated.

### Myotonias

Myotonias are characterized by continued, involuntary muscle contraction after cessation of voluntary effort: that is, failure of muscle relaxation. EMG is characteristic (see p. 829). The two most common myotonias are described below. Patients with myotonia tolerate general anaesthetics poorly.

#### Myotonic dystrophy

This autosomal dominant condition is a genetic disorder with two different triple repeat mutations: most commonly, an expanded CTG repeat in a protein-kinase (DMPK) gene (DM1). The less common variety (DM2) is caused by an expanded CCTG repeat in a zinc finger protein gene. There is a correlation between disease severity, age at onset and approximate size of triplet repeat mutations. There is progressive distal muscle weakness, with ptosis, weakness and thinning of the face and sternomastoids. Myotonia is typically present. Muscle disease is part of a syndrome comprising:

- cataracts
- frontal baldness
- cognitive impairment (mild)
- oesophageal dysfunction (and aspiration)
- cardiomyopathy and conduction defects (sudden death can occur in type 1)
- small pituitary fossa and hypogonadism
- glucose intolerance
- low serum IgG.

This gradually progressive condition usually becomes evident between 20 and 50 years.

#### Myotonia congenita

Autosomal dominant myotonia, usually mild, becomes evident in childhood. The gene, CLC1, codes for a muscle chloride channel. The myotonia, which persists, is accentuated by rest and by cold. Diffuse muscle hypertrophy occurs, meaning that although physically weak, the patient will have bulky muscles.

### Channelopathies

#### Hypokalaemic periodic paralysis

This disorder is characterized by generalized weakness, including that of bulbar muscles, which often starts after a heavy carbohydrate meal or following exertion. Attacks last for several hours. The disorder often first comes to light in the teenage years and tends
to remit after the age of 35. Serum potassium is usually below 3.0 mmol/L in an attack. The weakness responds to (slow) intravenous potassium chloride. It is usually inherited as an autosomal dominant trait caused by mutation in a muscle voltage-gated calcium channel gene (CACLN1A3). Other mutations in the sodium channels (SCNA4) and potassium channels (KCNE3) also occur. Acetazolamide sometimes helps prevent attacks. Weakness can be caused by diuretics. A similar condition can also occur with thyrotoxicosis.

**Hyperkalaemic periodic paralysis**

This condition, also autosomal dominant, is characterized by attacks of weakness, sometimes with exercise. Attacks start in childhood and tend to remit after the age of 20; they last about 30–120 minutes. Myotonia may occur. Serum potassium is elevated. An attack can be terminated by intravenous calcium gluconate or chloride. There are point mutations in a muscle voltage-gated sodium-channel gene (SCN4A). Acetazolamide or a thiazide diuretic can be helpful.

A very rare normokalaemic, sodium-responsive periodic paralysis also occurs.

**Stiff person syndrome**

Stiff person syndrome (SPS) is a rare autoimmune disease, more common in females, causing axial muscle stiffness with abnormal posture, spasms and falls. Attacks of stiffness are sometimes provoked by noise or emotion, but sometimes occur spontaneously. Between attacks, which last from hours to days or even weeks, the patient may appear normal.

Widespread muscle stiffness is typical during an attack; there are no other neurological signs. SPS has been mistaken for Parkinson’s, dystonia and non-organic conditions. Anti-glutamic acid decarboxylase antibodies (anti-GAD) are found in very high titre in more than 50% of cases and are believed to be involved in the generation of muscle stiffness. Continuous motor activity in paraspinal muscles is seen on EMG.

Treatment with diazepam, other muscle relaxants and intravenous immunoglobulin can be helpful during attacks.

A form of SPS is also seen occasionally as a paraneoplastic condition associated with antibodies to the synaptic protein amphiphysin (see Box 6.10).

**Mitochondrial diseases**

These comprise a complex group of rare disorders involving muscle, peripheral nerves and CNS, characterized by morphological and biochemical abnormalities in mitochondria. Mitochondrial DNA is inherited maternally (see p. 18). The spectrum is wide, ranging from optic atrophy (see Leber’s; p. 26) to myopathies, neuropathies and encephalopathy.

- **MELAS** (mitochondrial encephalomyopathy, lactic acidosis, stroke-like episodes) is one well-recognized form.
- Chronic progressive ophthalmoplegia (CPEO) is another.
- **MERRF** describes myoclonic epilepsy with abnormal muscle histology, the muscle appearance being described as ragged red fibres.

INTRODUCTION TO ENT

ENT is a broad specialty that, in addition to covering diseases of the ears, nose and throat, is also concerned with diseases of the trachea and the skull base and is responsible for head and neck cancer, facial plastic surgery, sleep-disordered breathing as well as congenital head and neck anomalies.

One-fifth of general practice relates to ENT conditions and whilst only 3% of emergency department visits are related to ENT diagnoses, they are often the most life-threatening (e.g. acute airway obstructions and major upper airway haemorrhage). Common emergency presentations include severe and complicated upper respiratory tract infections, epistaxis, upper airway compromise, ingested or inhaled foreign bodies and penetrating neck injuries. An ENT surgeon typically begins medical treatment in specialist ENT or ophthalmology surgical outpatient services. Medical ophthalmology and clinical audiology services led by physicians are often present in specialist centres that address pathology in these organs caused by systemic diseases.

Key skills in these areas include:
- developing an appropriate diagnostic approach to the four key symptoms of ear disease: pain, discharge, hearing loss and dizziness
- recognizing life-threatening disorders of the throat, including retropharyngeal abscesses and airway compromise
- appropriately identifying sight-threatening eye emergencies and understanding their urgent management.

Learning opportunities include attending ENT and ophthalmology outpatient clinics and practising clinical skills including physical examination, otoscopy and fundoscopy.
endocrinologists for thyroid disease, respiratory physicians for tracheal disease, sleep-disordered breathing and allergies, neurosurgeons for skull base disease, etc.) and allied health professionals (e.g. speech and language therapists for speech and swallowing problems, electrophysiologists for voice assessment, audiologists for hearing and balance issues, teachers of the deaf for cochlear implant patients and psychologists for body dysmorphic disorders).

**CLINICAL APPROACH TO THE PATIENT WITH AN ENT COMPLAINT**

When a patient presents with a location-specific symptom, it is wise to ask about other symptoms that are specific to that site. **Box 27.1** and **Fig. 27.1** list symptoms that frequently present depending on the anatomical location of the lesion. Keep in mind that the nose communicates with the ear through the Eustachian tube and with the throat through the nasopharynx, so symptoms of a disease can cross from one location to another (e.g. patients with chronic rhinosinusitis often complain of pressure in their ears).

The nature, character and chronological features of each symptom should be systematically explored. Concomitant medical problems, medication use, occupation and environmental factors are not only frequently the cause of many ENT complaints but can also be impacted by ENT treatments and so it is essential to get a full history. Whilst a comprehensive history is essential, there are certain high-yield pointers that can sometimes help make common ENT diagnoses.

**Ear symptoms**

**Hearing loss**

Upper respiratory tract infections can precede hearing loss caused by acute otitis media (painful) or otitis media with effusion (painless). Trauma can cause conductive hearing loss secondary to haemotympanum (blood in the middle ear) or disruption to the ossicular chain; additionally it can relate to trauma of the otic capsule (bony covering of inner ear) causing sensorineural hearing loss. Chemotherapy, aspirin, aminoglycoside antibiotics and loop diuretics can all cause sensorineural hearing loss. Fluctuating hearing loss in children normally signifies otitis media with effusion, whereas in adults it signifies cochlear hydrops, autoimmune conditions and Ménière’s (if associated with vertigo and tinnitus). Many types of hearing loss run in families and occupational exposure to loud noise is a common cause of hearing loss.

**Vertigo**

Duration of vertigo is a key feature that helps distinguish the different pathologies. Vertigo, defined as rotatory sensation, when lasting for seconds is typically benign paroxysmal positional vertigo (BPPV), when lasting for hours is typically Ménière’s and when lasting for days is often caused by labyrinthitis/vestibular neuronitis. Vertigo that is triggered by loud noises suggests a breach in the otic capsule.

**Tinnitus**

Unilateral tinnitus may signify retrocochlear pathology (e.g. vestibular schwannoma). The nature of tinnitus can help identify causes: ringing, buzzing, humming and blowing tinnitus tends to be idiopathic and requires very little investigation beyond examination and a hearing test. However, tinnitus that is unilateral, pulsatile, related to body sounds (voice echoing in ears, sound of eyeballs moving), or objective (i.e., third party can also hear sound) needs further investigations. Loud noise exposure is the commonest cause of tinnitus and so occupational history is important.

**Nose symptoms**

**Nasal blockage**

If unilateral, this usually represents a fixed anatomical obstruction such as a nasal septal fracture-deviation or nasal polyps. If in a child, consider a foreign body. Alternating nasal blockage suggests an exaggerated nasal cycle and is a sign of nasal mucosa disease such as allergic or chronic rhinosinusitis. Chronic use of topical decongestants can lead to fixed nasal blockage and so previous medication history is important. A history of asthma and aspirin sensitivity may suggest rhinitis or nasal polyps. Knowledge about pets and seasonal variations can sometimes help with the diagnosis.

**Rhinorrhoea**

Unilateral clear rhinorrhoea that increases with positions of raised intracranial pressure may signify a cerebrospinal fluid (CSF) leak. Rhinorrhoea associated with nasal itch and frequent sneezing is normally allergy driven. Blood-stained rhinorrhoea may signify malignant disease. Offensive rhinorrhoea usually signifies sinus infections. Rhinorrhoea that initiates in response to changes in ambient or food temperature usually represents vasomotor rhinitis.

**Dysosmia**

A sudden history of anosmia following an upper respiratory infection can signify permanent and irreversible damage to the olfactory sensory lining. Gradual anosmia, especially related to other sinus symptoms (e.g. nasal blockage), may represent a failure of odourants penetrating the olfactory niche. Cacosmia (offensive smell in absence of offensive external stimulus) may represent a localized sinus infection or neurological condition. Many medications can lead to anosmia and so a full medication history is essential. Heavy metal exposure and nutritional deficiencies can also lead to anosmia and need to be explored in the history.
Clinical approach to the patient with an ENT complaint

Throat symptoms

Odynophagia/dysphagia
Acute odynophagia with dysphagia is invariably related to throat infections. Chronic odynophagia is frequently related to acid reflux into the throat, but may be a sign of underlying malignancy, especially if the patient has risk factors and has suffered weight loss. Acute dysphagia usually relates to a vascular event (e.g. bulbar stroke) or impacted foreign bodies (e.g. food bolus). Chronic dysphagia to liquids more than solids may signify neurological pathology (e.g. bulbar palsy), whilst dysphagia to solids more than liquids may signify anatomical obstruction (e.g. oesophageal stricture, malignancy, pharyngeal pouch). Chronic dysphagia associated with regurgitation of undigested foods relates to pharyngeal pouch, while chronic dysphagia on the background of longstanding gastro-oesophageal reflux disease is more likely to represent a stricture.

Dyspnoea
Acute dyspnoea associated with sore throat usually signifies an infection of the upper airway and is usually preceded with coryzal symptoms. Dyspnoea resulting from upper airway disease usually presents with noisy breathing (e.g. stridor). The timing of breathing noises helps identify the location of the pathology. Inspiratory stridor signifies partial obstruction anywhere from the epiglottis to the voicebox, expiratory stridor usually signifies partial obstruction of the tracheobronchial tree, while stridor present during inspiration and expiration usually denotes disease of the area around the vocal cords.

Dysphonia
Acute dysphonia, especially with preceding symptoms of an upper respiratory tract infection, usually represents acute laryngitis. Chronic dysphonia that is worse in the morning may be related to gastro-oesophageal reflux, whereas dysphonia that gets worse throughout the day signifies voice abuse. Chronic dysphonia that does not fluctuate may suggest anatomical lesions such as a vocal cord cyst or polyp. A strained high pitch voice may suggest adductor spasmodic dysphonia, a breathy voice suggests vocal cord palsy or abductor spasmodic dysphonia, and a whispering voice suggests laryngitis. Malignancy should be considered in all patients with chronic dysphonia and a history of smoking and heavy drinking. Professional voice users are more prone to several laryngeal conditions from muscle tension dysphonia to vocal cord nodules and so an occupational history is vital.

DISORDERS OF THE EAR

ANATOMY AND PHYSIOLOGY

The ear can be divided into three parts: outer, middle and inner (Fig. 27.2).

The outer ear has a skin-lined tube 2.5 cm long leading down to the tympanic membrane (the ear drum). Its outer third is cartilaginous and contains hair and sebaceous and ceruminous glands, but the walls of the inner two-thirds are bony. The outer ear is self-cleaning, as the skin is migratory so there are no indications to use cotton wool buds. Wax should only be seen in the outer third.

The middle ear is an air-containing cavity derived from the branchial clefts. It communicates with the mastoid air cells superiorly, and the Eustachian tube connects it to the nasopharynx medially. The Eustachian tube ventilates the middle ear and maintains equal air pressure across the tympanic membrane. It is normally closed but opens via the action of the palatal muscles to allow air entry when swallowing or yawning. A defect in this mechanism, such as with a cleft palate, will prevent air entering the middle ear cleft, which may then fill with fluid. Lying within the middle ear cavity are the three ossicles (malleus, incus and stapes), which transmit sound from the tympanic membrane (Fig. 27.3) to the inner ear. On the medial wall of the
The inner ear contains the cochlea for hearing and the vestibule and semicircular canals for balance. There is a semicircular canal arranged in each body plane and these canals are stimulated by rotatory movement. The facial, cochlear and vestibular nerves emerge from the inner ear and run through the internal acoustic meatus to the brainstem (see Fig. 26.8).

Physiology of hearing

The ossicles, in the middle ear, transmit sound waves from the tympanic membrane to the cochlea. They amplify the waves by about eighteen-fold to compensate for the loss of sound waves moving from the air-filled middle ear to the fluid-filled cochlea. Hair cells in the basilar membrane of the cochlea detect the vibrations and transduce these into nerve impulses, which pass to the cochlear nucleus and then eventually to the superior olivary nuclei of both sides; thus lesions central to the cochlear nucleus do not cause unilateral hearing loss.

If the ossicles are diseased, sound can also reach the cochlea by vibration of the temporal bone (bone conduction).
CLINICAL APPROACH TO THE PATIENT WITH A DISORDER OF THE EAR

Examination

The pinna and post-auricular region should first be examined for erythema, scars or swellings. An auroscope is used to examine the external ear canal whilst the pinna is retracted backwards and upwards to straighten the canal. Look for wax, discharge or foreign bodies. The tympanic membrane should always be seen with a light reflex anteroinferiorly. Previous repeated infections may cause a thickened, whitish drum but fluid in the middle ear may show as dullness of the drum. Perforations can be described as marginal if they involve the annulus, subtotal if the pars tensa is absent, and total if both pars tensa and the annulus are absent.

Rinne test

(See Fig. 27.4.)

- Normally, a tuning fork, 512 Hz, will be heard as louder if held next to the ear (i.e. air conduction) than it will if placed on the mastoid bone (Rinne-positive).
- If the tuning fork is perceived louder when placed on the mastoid (i.e. via bone conduction), then a defect in the conducting mechanism of the external or middle ear is present (true Rinne-negative).

Weber test

(See Fig. 27.5.) A tuning fork placed on the forehead or vertex of a patient with normal hearing (or with symmetrical hearing loss) should be perceived centrally by the patient. A patient with unilateral conductive hearing loss will hear the sound loudest in the affected ear, whereas a patient with unilateral sensorineural hearing loss will report the sound to be loudest in the unaffected ear.

Pure-tone audiometry

The patient is asked to respond when they hear sounds presented as pure tones at varying sound intensities and frequencies. Sounds are presented to each ear (representing air conduction) and then to each mastoid in turn (representing bone conduction). An audiogram is produced by the lowest sound intensity that is reliably perceptible at each frequency tested at both ears and mastoids (Fig. 27.6).

COMMON DISORDERS OF THE EAR

There are four main symptoms related to ear pathology: pain (otalgia), discharge (otorrhoea), hearing loss and dizziness (vertigo). The sequence and combination of symptoms can differentiate between most conditions and therefore history is often the most useful diagnostic tool.

The painful ear (otalgia)

A painful ear is a common complaint but, due to the complex innervation, may be referred from distant sites and can thus on occasion have an obscure aetiology.

Otitis externa

When the natural barriers to infection are overcome, the skin of the ear canal can become infected. Discharge and itch are the initial presenting symptoms, followed by pain and then reduction in hearing as the ear canal closes off. Infection can spread to the pinna, causing cellulitis. Although the causative organism is most commonly bacterial (pseudomonal species, followed by staphylococcal species), it can also be fungal. There may be swelling of the pre-auricular or post-auricular lymph nodes that can be mistaken for mastoiditis.

Examination often reveals debris in the canal, which needs to be removed either by gentle mopping or preferably by suction, viewed directly under a microscope. The tympanic membrane is normal, when visible. In severe cases, the canal may be swollen...
and a view of the tympanic membrane impossible. Any foreign body seen should be removed with great care by trained personnel.

**Treatment** is with topical combination antibiotic and steroid drops in the first instance: for example dexamethasone 0.05%, framycetin sulfate 0.5% and gramicidin 0.005% drops, or hydrocortisone acetate 1% and gentamicin 0.3% drops, or a spray such as dexamethasone 0.1% with neomycin sulfate 3250 units. If symptoms do not resolve in 3–4 days, then microsuction in an ENT department is necessary.

Finafloxacin ear drops are used if there is a perforation, to reduce ototoxicity.

**Otitis media**

Otitis media is an infection of the middle ear seeded from the upper respiratory tract through the Eustachian tube. Therefore, the most commonly encountered pathogens are similar to those that cause upper respiratory tract infections: respiratory syncytial virus (RSV), *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Moraxella catarrhalis*. Otitis media most commonly affects children under the age of 10. Infection causes inflammation of the middle ear mucosa and inflammatory exudate in the middle ear space. Due to the middle ear fluid, otitis media presents with otalgia and hearing disturbance. If it does not resolve, it can lead to tympanic membrane perforation and discharge. There are no mucous glands in the external ear canal. If the discharge is serous, then middle ear pathology is unlikely. Otitis media classically presents with otalgia followed by discharge, whereas otitis externa presents with discharge followed by otalgia. Rare complications of otitis media include mastoiditis as the middle ear inflammatory fluid escapes from the middle ear into the mastoid, or meningitis as the infection spreads through the tegmen into the intracranial cavity. Examination shows a healthy ear canal with an erythematous and occasionally bulging tympanic membrane.

**Treatment** of the acute case is initially with non-steroidal anti-inflammatory drugs. Otitis media is often viral in origin – for example, following a cold – and will settle within 72 hours without antibacterial treatment. In people with systemic features or after 72 hours, a systemic antibiotic, such as amoxicillin, should be given, particularly in children under 2 years old. Topical therapy is of no value. If there is tenderness and swelling over the mastoid, then an urgent ENT opinion should be obtained.

**Referred otalgia**

Pain may be referred from:

- the teeth and temporomandibular joint from the auriculotemporal nerve (a branch of the mandibular (Vth cranial) nerve)
- cervical spinal problems from C1 to C3
- tonsil and tongue base problems from the glossopharyngeal (Jacobson’s) nerve
- the larynx and pharynx from the vagus (Arnold’s) nerve
- Ramsay Hunt syndrome, causing vesicles along the distribution of the VIIth cranial nerve.

The innervation of the pinna is from the auriculotemporal branch of the trigeminal and the first two cervical nerves (Fig. 27.7). Therefore, dental pain, temporomandibular joint dysfunction and upper.

![Fig. 27.7 Sensory innervation of the ear.](image_url)

Due to the sophisticated embryology of ear structures, the sensory innervation is complicated. Therefore otalgia can be referred from many sites, and knowledge of aural sensory innervation is a good guide for a comprehensive examination in idiopathic ear pain. The **auriculotemporal nerve** (a branch of the mandibular division of the trigeminal nerve) supplies innervation to the superolateral pinna and roof of the external auditory canal (EAC). Pathology related to the upper teeth, temporomandibular joint and parotid gland can cause referred otalgia through this nerve. The **lesser occipital nerve** (a branch from the second cervical nerve) supplies most of the medial surface of the pinna and the posterior wall of the EAC. Cervical osteoarthritis can cause referred otalgia through this nerve. The **greater auricular nerve** (a branch from the third cervical nerve) supplies the inferior portion of the pinna, including the lobule. Cervical osteoarthritis can cause referred otalgia through this nerve. The **Vagus (Arnold’s) nerve** (a branch of the vagus cranial nerve) supplies the EAC floor and lateral surface of the tympanic membrane. Tumours of the larynx and pharynx can cause referred otalgia through this nerve. The **Jacobson’s nerve** (a branch of the glossopharyngeal nerve) supplies innervation to the mucosa of the middle ear, including the medial surface of the tympanic membrane. Tonsillitis and pharyngitis can cause referred otalgia through this nerve. CN, cranial nerve.
cervical osteoarthritis can all present as otalgia. The ear canal is innervated by the above-mentioned nerves, and also by the facial and vagus nerves (see Fig. 27.7). Hence Ramsay Hunt syndrome (varicella reactivation along the sensory division of the facial nerve) causes otalgia with ear canal vesicles, whereas cancer of the larynx and pharynx can occasionally present as otalgia due to referred pain along the vagus nerve. The middle ear is innervated by the glossopharyngeal nerve and therefore infections of the pharynx are associated with otalgia.

**The discharging ear (otorrhoea)**

Discharge from the ear is usually due to infection of the outer or middle ear. The most common cause is otitis externa, followed by otitis media with a perforated tympanic membrane (see earlier).

**Cholesteatoma**

Although cholesteatoma is a rarer cause of the otorrhoea, it has severe implications if missed and should be considered in any non-resolving or recurrent case of otorrhoea. Cholesteatoma is defined as keratinizing squamous epithelium within the middle ear cleft and can present with foul-smelling otorrhoea. Examination shows a defect in the tympanic membrane full of white, cheesy material. Mastoid surgery is required to remove this sac of squamous debris, as it can erode local structures such as the ossicles or facial nerve, or even extend intracranially to cause meningitis or an intracranial abscess.

**Hearing loss**

Deafness can be conductive or sensorineural and these can be differentiated at the bedside by the Rinne and the Weber tests (Box 27.2) or with pure-tone audiometry. **Conductive hearing loss** has many causes (Box 27.3) but wax is the most common.

**Perforated tympanic membrane**

This arises from trauma or chronic middle ear disease when recurrent infection results in a permanent defect. Surgical repair is indicated only if the patient is symptomatic with recurrent discharge. The larger the perforation, the greater the impact on hearing.

**Otitis media and otitis externa**

As discussed above, both of these infections lead to hearing loss but the sequence of events will help differentiate the conditions: hearing loss is common and early in otitis media, but rare and late in otitis externa.

**Secretory otitis media with effusion ('serous otitis media' or 'glue ear')**

This is common in children because Eustachian tube dysfunction may lead to poorly ventilated middle ears. The vacuum created by poor ventilation leads to a non-inflammatory effusion. The effusion resolves naturally in the majority of cases but can persist or recur, causing a hearing loss that impacts on speech and language skills and on educational progress. The presenting complaint is hearing loss or speech delay but little association with otalgia.

**Examination** shows a dull tympanic membrane with loss of light reflex (Fig. 27.8) and occasionally fluid with air bubbles visible in the middle ear. Children with glue ear frequently have adenoidal hypertrophy and nasal blockage.

**Management** involves insertion of a grommet (tymanostomy tube) into the tympanic membrane, which ventilates the middle ear cavity, if the symptoms are persistent and troublesome. Antibiotic–glucocorticoid ear drops are more effective than oral antibiotics. Adenoidectomy can be added to the procedure if there is a strong history of complete nasal blockage or recurrent upper respiratory tract infections. Grommets are extruded from the tympanic membrane as it heals (over 6 months to 2 years). Developmental outcomes are not improved by grommet insertions. In most children,
Vertigo is usually rotatory when it arises from the ear. The presence of otalgia, otorrhoea, tinnitus or hearing loss suggests an otologic aetiology. Vestibular causes can be classified according to the duration of the vertigo. Common causes are summarized as follows:

- seconds (<1 min) – benign paroxysmal positional vertigo
- minutes to hours – Ménière’s disease
- hours to days – labyrinthine or central pathology.

**Benign paroxysmal positional vertigo**

Benign paroxysmal positional vertigo (BPPV) is thought to occur when otoconia (tiny crystals of calcium carbonate) are dislodged from the utricle into the semicircular canals, commonly the posterior canal. Positional vertigo is precipitated by head movements, usually to a particular position, and often occurs when turning in bed or on sitting up. The onset is typically sudden and distressing. The vertigo lasts seconds (<1 min) and the phenomenon becomes less severe on repeated movements (fatigue). There is no serious underlying cause but it sometimes follows vestibular neuronitis (see p. 817), head injury or ear infection. It occurs in 50% of older people and is the most common cause of head injury in those under 50 years of age.

**Diagnosis**

Diagnosis is made on the basis of the history and by the Hallpike manoeuvre (Fig. 27.9). A positive Hallpike test confirms BPPV, which can be cured in over 90% of cases by the Epley manoeuvre. This involves gentle but specific manipulation and rotation of the patient’s head to shift the loose otoconia from the semicircular canals.

The differential diagnosis includes a cerebellar mass, but in that case positional nystagmus (and vertigo) is immediately apparent (no latent interval) and does not fatigue.

**Ménière’s disease**

This is a rare condition characterized by recurring, episodic, rotatory vertigo lasting 30 minutes to a few hours; attacks are recurrent over months or years. Classically, it is associated with a low-frequency sensorineural hearing loss, a feeling of fullness in the affected ear, loss of balance, tinnitus and vomiting. There is a build-up of endolymphatic fluid in the inner ear, although its precise aetiology is still unclear.

**Management**

Vestibular sedatives, such as cinnarizine, are used in the acute phase. Preventative measures, such as a low-salt diet, betahistine and avoidance of caffeine, are useful. If the disease cannot be controlled, then a chemical labyrinthectomy, perfusing the round window orifice with ototoxic drugs such as gentamicin, is used. Gentamicin destroys the vestibular epithelium; therefore, the patient has severe vertigo for around 2 weeks until the body compensates
for the lack of vestibular input on that side. The patient will happily trade occasional mild vertigo when the balance system is challenged against the unpredictable, severe and disabling attacks of vertigo involved in Ménière’s disease. There is a risk of sensorineural hearing loss and complete vestibular failure if Ménière’s starts in the previously unaffected side. The final option is surgical decompression of the endolympathic compartment of the inner ear to relieve the endolympathic hydrops.

**Labyrinthine or central causes of vertigo**  
(See Box 26.15.) These are managed with vestibular sedatives in the acute phase. Most patients will settle over a few days but continuous true vertigo with nystagmus suggests a central lesion. A patient with a deficit of vestibular function due to viral labyrinthitis or neuronitis should be able to cease vestibular sedatives within 2 weeks; long-term use can give parkinsonian side-effects, delay central compensation and thus prolong the vertigo. Vestibular rehabilitation by a physiotherapist or audiological scientist can speed up the compensation process, although most patients will be able to do this themselves with time.

**Tinnitus**

This is a sensation of a sound when there is no auditory stimulus. It can occur without hearing loss and results from heightened awareness of neural activity in the auditory pathways. Patients describe a hissing or ringing in their ears and this can cause much distress. It usually does not have a serious cause but vascular malformation, such as aneurysms, or vascular tumours can be associated. In these cases, the tinnitus is pulsatile and most commonly unilateral.

**Management**

This is difficult. A tinnitus masker (a mechanically produced, continuous soft sound) can help. Cognitive behavioural therapy through audiological services are of use and rehabilitate patients well.

---

**DISORDERS OF THE NOSE**

**ANATOMY AND PHYSIOLOGY**

(See Fig. 27.10.) The function of the nose is to facilitate smell and respiration:

- Smell is a sensation conveyed by the olfactory epithelium in the roof of the nose. The olfactory epithelium is supplied by the 1st cranial nerve (see p. 809).
- The nose also filters, moistens and warms inspired air and, in doing so, assists the normal process of respiration.

The external portion of the nose consists of two nasal bones attached to the rest of the facial skeleton and to the upper and lower lateral cartilages. The internal nose is divided by a midline septum that comprises both cartilage and bone. This divides the internal nose in two, from the external nostril to the posterior choanae. The posterior choanae are in continuity with the nasopharynx posteriorly.

---

**Epistaxis**

Nose bleeds vary in severity from minor to life-threatening. Little’s area (see Fig. 27.11A) is a frequent site of nasal haemorrhage. First aid measures should be administered immediately, including external digital compression of the anterior lower portion of the external nose, ice packs and leaning forward. The patient should be asked to avoid swallowing any blood running posteriorly, as this causes nausea.

Not infrequently, small, recurrent epistaxes occur and these may require a visit to the emergency department for an examination and simple local anaesthetic cautery with a silver nitrate stick. If the bleeding continues profusely, then resuscitation in the form of intravenous access, fluid replacement or blood, and oxygen can be administered. If further intervention is necessary, consider should be given to intranasal cautery of the bleeding vessel, or...
intranosal packing using a variety of commercially available nasal packs (see Fig. 27.11B). In addition to direct treatment of the epistaxis, a cause should be sought and treated appropriately (Box 27.4). If the above treatments fail, surgical ligation of the sphenopalatine artery can be undertaken endoscopically or an interventional arterial embolization can be performed for the problematic vessel.

**Rhinitis**

See page 945.

**Nasal obstruction**

Nasal obstruction is a symptom and not a diagnosis. It can significantly affect a patient’s quality of life. Causes include:

- **Rhinitis** (see p. 945). The most common aetiology is allergy-based. Rhinitis results in erythema of the nasal mucosa and hypertrophy of inferior turbinates. If an allergen is identified, then allergen avoidance is the mainstay of treatment. Topical steroids and/or antihistamines can be tried. If rhinitis is severe, then referral to an allergy clinic for immunotherapy is warranted. Short-term benefit can be gained in severe nasal blockage by surgically reducing the inferior turbinate.

- **Septal deviation.** Correction can be undertaken surgically.

- **Nasal polyps.** This condition occurs with inflammation and oedema of the sinus nasal mucosa. This oedematous mucosa prolapses into the nasal cavity and can cause significant nasal obstruction. In allergic rhinitis (see p. 945), the mucosa lining the nasal septum and inferior turbinates are swollen and a dark-red or plum colour. Nasal polyps can be identified as glistening swellings, which are insensitive. Treatment with intranasal steroids helps, but if polyps are large or unresponsive to medical treatment, then surgery is necessary.

- **Foreign bodies.** These are usually seen in children who present with unilateral nasal discharge. Clinical examination of the nose with a light source often reveals the foreign body, which requires removal, either in clinic or in theatre, with a general anaesthetic.

- **Sinonasal malignancy.** This is extremely rare. The diagnosis must be considered if unusual unilateral symptoms are seen, including nasal obstruction, epistaxis, pain, epiphora (watery eye), cheek swelling, paraesthesia of the cheek, unilateral serous otitis media and proptosis of the orbit.

**Sinusitis**

Sinusitis is an infection of the paranasal sinuses that is bacterial (mainly *Streptococcus pneumoniae* and *Haemophilus influenzae*) or occasionally fungal. It is most commonly associated with an upper respiratory tract infection and can occur with asthma. Symptoms include frontal headache, purulent rhinorrhoea, facial pain with tenderness, and fever. Sinusitis can be confused with a variety of other conditions, such as migraine, trigeminal neuralgia and cranial arteritis.

**Management**

Treatment for a bacterial sinusitis includes nasal decongestants, such as xylometazoline; broad-spectrum antibiotics, such as co-amoxiclav because *H. influenzae* can be resistant to amoxicillin; anti-inflammatory therapy with topical corticosteroids, such as fluticasone propionate (nasal spray) to reduce mucosal swelling; and steam inhalations.

If the symptoms of sinusitis are recurrent (Box 27.5) or complications such as orbital cellulitis arise, then an ENT opinion is appropriate and a computed tomography (CT) scan of the paranasal sinuses is undertaken. Plain sinus X-rays are now rarely used to image the sinuses.

CT scan of the sinuses (Fig. 27.12) or an MRI scan can demonstrate bony landmarks and soft tissue planes.

**Functional endoscopic sinus surgery (FESS)** is used for ventilation and drainage of the sinuses.
**Anosmia**

Olfaction is mainly under the control of cranial nerve I, although irritating nasal sensations are carried by cranial nerves V, IX and X. Anosmia is a complete loss of the sense of smell and *hyposmia* is a decreased sense of smell:

- **A conductive deficit** of smell occurs if odorant molecules do not reach the olfactory epithelium high in the nose.
- **A sensorineural loss** of smell is incurred if the neural transmission of smell is affected.
- Some conditions predispose to a mixed (conductive and sensorineural) loss of smell.

The main cause of a loss of smell is nasal obstruction due to upper respiratory infection or nasal polyps. Other causes include sinonasal disease, old age, drug therapy and head injury/trauma. It is difficult to predict the speed and extent of recovery in the latter causes. In many, anosmia is idiopathic, but before this diagnosis is accepted, an assessment of the patient for the possibility of an intranasal tumour or intracranial mass should be undertaken.

**Fractured nose**

People with a fractured nose present with epistaxis, bruising of the eyes and nasal bridge swelling. Initially, it is often difficult to assess whether the bones are deviated, particularly if there is significant swelling. Reduction of the fracture should be undertaken in the first 2 weeks after injury and can be achieved by manipulation. However, if the fracture sets, a more formal rhinoplasty may have to be undertaken at a later stage. The patient should be examined for a head injury and the nose should also be checked for a septic haematoma (Fig. 27.13). This is painful, can cause nasal obstruction, is fluctuant to touch on the nasal septum, and requires immediate drainage to prevent destruction of the septal cartilage.
prevents full closure will result in air escaping between the vocal cords during phonation and a ‘breathy’ voice.

**Clinical Approach to the Patient with a Disorder of the Throat**

**Examination**

Good illumination is essential. Look at the teeth, gums, tongue, floor of mouth and oral cavity. The tonsils, soft palate and uvula are easily seen, and a gag reflex (see p. 817) is present. The remainder of the pharynx and larynx can be inspected with a laryngeal mirror or flexible nasendoscope.

Examination of the neck for lymph nodes and other masses is also performed.

**Common Disorders of the Throat**

**Hoarseness (dysphonia)**

There are three essential components for voice production: an air source (the lungs); a vibratory source (the vocal cords); and a resonating chamber (the pharynx and nasal and oral cavities). Although chest and nasal disorders can affect the voice, the majority of hoarseness is due to laryngeal pathology.

Inflammation that increases the ‘mass’ of the vocal cords will cause the vocal cord frequency to fall, giving a much deeper voice. Thus listening to a patient’s voice can often give a diagnosis before the vocal cords are examined.

**Nodules**

Nodules (always bilateral and more common in females) and polyps (Fig. 27.15A) are found on the free edge of the vocal cord, preventing full closure and giving a ‘breathy, harsh’ voice. They are commonly found in professionals who rely on their voice for their livelihood, such as teachers, singers and lawyers. They are usually related to poor technique of voice production and can usually be cured with speech therapy. If surgery is needed, great care must be taken to remain in the superficial layers of the vocal cord in order to prevent deep scarring, which leaves the voice permanently hoarse.

**Reinke’s oedema**

This is due to a collection of tissue fluid in the subepithelial layer of the vocal cord (see Fig. 27.15B). The vocal cord has poor lymphatic drainage, predisposing it to oedema. Reinke’s oedema is associated with irritation of the vocal cords by smoking, voice abuse, acid reflux and, very rarely, hypothyroidism. Treatment is to remove the irritation in most cases, but surgery to incise the cords and reduce the oedema will also allow the voice to return to its normal pitch.

**Acute-onset hoarseness**

Hoarseness, in a smoker, is a danger sign. Any patient with a hoarse voice for over 6 weeks should be seen by an ENT surgeon. Other red flag symptoms will require urgent laryngoscopy (Box 27.6). The voice may be deep, harsh and breathy, indicating a mass on the vocal cord (Fig. 27.16), or it can be weak, suggesting a paralysed left vocal cord secondary to mediastinal disease, such as bronchial carcinoma.

**Early squamous cell carcinoma of the larynx** has a good prognosis. Treatment is with carbon dioxide laser resection or radiotherapy. Spread and growth of the tumour can lead to referred otalgia, and, if the tumour is significant in its size, requires a laryngectomy (removal of the voicebox), with a neck dissection to remove the affected glands in the neck. A patient with a paralysed left vocal cord must have a CT of the neck and chest. Medialization of the paralysed cord to allow contact with the opposite cord can return the voice and give a competent larynx. This can be done under local or general anaesthesia, producing an immediate result whatever the long-term prognosis of the chest pathology.

**Stridor**

Stridor, or noisy breathing, can be divided into the following types:

- **Inspiratory**: obstruction is at the level of the vocal cords or above.
- **Mixed** (both inspiratory and expiratory): obstruction is in the subglottis or extrathoracic trachea.
- **Expiratory**: obstruction is in the intrathoracic trachea or distal airways.

All people with stridor, both paediatric and adult, are potentially at risk of asphyxiation and should be investigated fully. Severe stridor may be an indication for either intubation or a tracheostomy (Box 27.7).

**Management**

**Tracheostomy**

Tracheostomy tubes (Fig. 27.17) are:

- **Cuffed or uncuffed**. A high-volume, low-pressure cuff is used to prevent aspiration and to allow positive-pressure ventilation.
Common disorders of the throat

Fenestrated or unfenestrated. A fenestrated cuff has a small hole on the greater curvature of the tube (both outer and inner), allowing air to escape upwards to the vocal cords; the patient can therefore speak. This tube often has a valve that allows air to enter from the stoma but closes on expiration, directing the air through the fenestration.

Most long-term tracheostomy tubes have an inner and an outer tube. The inner tube fits inside the outer tube and projects beyond its lower end. A major problem with a tracheostomy tube is crusting of its distal end with dried secretions, and this arrangement allows the inner tube to be removed, cleaned and replaced as frequently as required, without disrupting the outer tube.

When to decannulate a patient is often a difficult issue if laryngeal competence is unclear. Movement of the vocal cords requires an ENT examination and a speech therapist’s involvement. The tracheostomy tube itself can also produce problems due to compression of the oesophagus with a cuffed tube and prevention of the larynx from rising during normal swallowing.

Tonsillitis and pharyngitis

Viral infections of the throat are common and, although many practitioners may be under pressure from the patient to give antibiotics, they should not be used. The vast majority of infections are self-limiting, settling with rest, analgesia and encouragement of fluid intake. Fungal infections, usually candidiasis, are uncommon and may indicate an immunocompromised patient or undiagnosed diabetes.

Tonsillitis

Tonsillitis, with a good history of pyrexia, dysphagia, lymphadenopathy and severe malaise, is usually bacterial; β-haemolytic streptococcus is the most common organism, which responds to penicillin V.

Glandular fever

Glandular fever (see p. 524) can also present with tonsillitis. Although, clinically, the tonsils have a confluent white exudate, there is often a petechial rash on the soft palate and an accompanying lymphadenopathy.

Box 27.7 Indications for tracheostomy

- Upper airway obstruction (real or anticipated)
- Long-term ventilation
- Bronchial lavage
- Incompetent larynx with aspiration

Box 27.8 Indications for tonsillectomy

- Suspected malignancy
- Obstructive sleep apnoea due to tonsillar hypertrophy
- Recurrent tonsillitis: five attacks a year for at least 2 years
- Quinsy in a patient with a history of recurrent tonsillitis

Quinsy (peritonsillar abscess)

Quinsy is a collection of pus outside the capsule of the tonsil, usually located adjacent to its superior pole. The patient often has trismus, making examination difficult, but the pus pushes the uvula across the midline to the opposite side. The area is usually hyperaemic and smooth but unilateral tonsil ulceration is more likely to be a malignancy. In either case, urgent referral to an ENT specialist is essential.

Indications for a tonsillectomy are shown in Box 27.8. This is carried out under a general anaesthetic and current surgical techniques include diathermy dissection, laser excision and coblation (using an ultrasonic dissecting probe). There are strong advocates for each technique and much will depend on the individual surgeon’s preference. Some departments carry out tonsillectomy as a day-case procedure, as most reactionary bleeding will occur within the first 8 hours postoperatively.

Snoring

Snoring is caused by high-pressure airflow, resulting in vibration of soft tissue above the level of the larynx. It is a common symptom (50% of 50-year-old males will snore to some extent) and can be considered to be related to obstruction of three potential areas: the nose, the palate or and the hypopharynx (see Fig. 28.27). There is a strong association between snoring and sleep-disordered breathing, such as in obstructive sleep apnoea (see p. 960).

The Epworth questionnaire (see Box 28.29) can assist in identification of sleep apnoea. People with a history of habitual, non-positional, heroic snoring (can be heard through a wall) require a full ENT examination and can be investigated by sleep nasendoscopy, in which a sedated, snoring patient has a flexible nasendoscope inserted to identify the source of vibration.

Nasal pathology, such as polyps, can be removed surgically with good results and most patients will benefit from lifestyle changes, such as weight loss. Stiffening or shortening the soft palate via surgery, often using a laser, can help for palatal snorers but hypopharyngeal snorers require either a dental prosthesis at night to hold the mandible forwards or continuous positive airway pressure (CPAP) via a mask (see p. 962).
Dysphagia

Dysphagia occurs because of any lesion between the throat and stomach. The two conditions described here are the ones usually dealt with by ENT departments. Gastroenterology departments see causes further down the gullet.

Pharyngeal pouch

A pharyngeal pouch is a herniation of mucosa through the fibres of the inferior pharyngeal constrictor muscle (cricopharyngeus) (Fig. 27.18A). An area of weakness known as Killian’s dehiscence allows a pulsion diverticulum to form. Patients present with a neck swelling following a failed swallow attempt. They can occasionally compress the swelling to allow food particles to be pushed back into the oesophagus. They may also complain that a gurgling sound is heard in the neck following a swallow as liquid and food collect in the pouch. Occasionally, patients present with recurrent pneumonia following aspiration of food into the trachea. Diagnosis is made with a barium swallow (Fig. 27.19) and treatment is surgical, either via an external approach through the neck where the pouch is excised or, more commonly, via endoscopy with stapling of the party wall (see Fig. 27.18B).

Foreign bodies

Foreign bodies in the pharynx can be divided into three general categories: soft food bolus, coins (smooth) and bones (sharp). Soft food bolus can be initially treated conservatively with muscle relaxants for 24 hours. Impacted coins should be removed at the earliest opportunity but sharp objects require emergency removal to avoid perforation of the muscle wall.

If the patient perceives the foreign body to be to one side, then it should be above the cricopharyngeus and an ENT examination will locate it; common areas are the tonsillar fossae, base of tongue, posterior pharyngeal wall and valleculae. Radiology will identify coins, and a clinical decision can be made to see whether a coin will pass down to the stomach; in this case no further treatment is required as it will exit naturally. Some departments advocate the use of a metal detector to monitor the position of the coin in the patient, who is usually a child or has a mental disorder. Fish can be divided into those with a bony skeleton (teleosts) and those with a cartilaginous skeleton (elasmobranchs), and therefore radiology is useful only in some cases. Radiology can also identify air in the cervical oesophagus, indicating a radiolucent foreign body lying distally. A soft tissue lateral neck radiograph is the investigation of choice to delineate some of the features above.

Globus pharyngeus

This is a functional disorder and is not a true dysphagia. It is a condition with classic symptoms of an intermittent sensation of a lump in the throat. This is perceived to be in the midline at the level of the cricoid cartilage and is worse when swallowing saliva; indeed, it often disappears when ingesting food or liquids. ENT examination is clear and normal laryngeal mobility can be felt when gently rocking the larynx across the postcricoid tissues. A contrast swallow will not only show the structures below the pharynx but also assess the swallowing dynamically. Treatment is with explanation and reassurance. Antidepressants may be tried. Any suspicious area will require an endoscopy with biopsy.

http://www.britishsnoring.co.uk Interactive version of the Epworth Sleepiness Scale.
It is the cornea and the sclera that give the mechanical strength and shape to the exposed surface of the eye.

The cornea occupies the central aspect of the globe and is one of the most richly innervated tissues in the body. This clear, transparent, avascular structure, measuring 12 mm horizontally and 11 mm vertically, provides 78% of the focusing power of the eye. The eyelids prevent the cornea from drying and becoming an irregular surface by distributing the tear film over the surface of the globe with each blink.

Anatomically, the cornea is made up of five layers:
- epithelium
- Bowman’s layer (membrane)
- stroma
- Descemet’s membrane
- endothelium.

The endothelial cells lining the inner surface of the cornea are responsible for maintaining the clarity of the cornea by continuously pumping fluid out of the tissue. Any factor that alters the function of these cells will result in corneal oedema and cause blurred vision.

The sclera is an opaque white structure covering four-fifths of the globe and is continuous with the cornea at the limbus. The six extraocular muscles responsible for eye movements are attached to the sclera, and the optic nerve perforates it posteriorly.

The conjunctiva covers the anterior surface of the sclera. This richly vascularized and innervated mucous membrane stretches from the limbus over the anterior sclera (where it is called the bulbar conjunctiva) and is then reflected on to the undersurface of the upper and lower lids (the tarsal conjunctiva). The area of conjunctival reflection under the lids makes up the upper and lower fornix.

The anterior chamber is the space between the cornea and the iris, and is filled with aqueous humour (Fig. 27.20). This fluid is produced by the ciliary body (2 μL/min) and provides nutrients and oxygen to the avascular cornea. The outflow of aqueous humour is through the trabecular meshwork and canal of Schlemm adjacent to the limbus. Any factor that impedes its outflow will increase the intraocular pressure. The upper range of normal for intraocular pressure is 21 mmHg.

The uveal tract is made up of the iris anteriorly, the ciliary body and the choroid. The iris is the coloured part of the eye under the transparent cornea. The muscles of the iris diaphragm regulate the size of the pupil, thereby controlling the amount of light entering the eye. The muscles of the ciliary body control the accommodation of the lens, and the secretory epithelium produces the aqueous humour (see above). The highly vascular choroid lines the inner aspect of the sclera and upon this lies the retina.

The lens lies immediately posterior to the pupil and anterior to the vitreous humour. It is a transparent biconvex structure and is responsible for 22% of the refractive power of the eye. By changing its shape, it can alter its refractive power and help to focus objects at different distances from the eye. By the fourth decade of life, this ability to change shape starts to decline and, with time, the lens starts to become less transparent and cataracts begin to develop.

The vitreous humour fills the cavity between the retina and the lens.

The retina is a multilayered structure. The metabolically active region of the retina is represented in Fig. 27.21. There are two types of photoreceptors in the retina: rods and cones. There are approximately 6 million cones, mainly confined to the macula, and these are responsible for detailed central vision and colour vision. The peripheral retina has around 125 million rods that are responsible for peripheral vision. The axons of the ganglion cells form the optic nerve (or disc) of the eye (Fig. 27.22).

The blood supply to the eye is via the ophthalmic artery; in particular, the central retinal artery is responsible for supplying the inner retinal layers. Venous return is through the central retinal and ophthalmic veins. Local lymphatic drainage is to the pre-auricular and submental nodes.

The sensory innervation of the eye is through the trigeminal (Vth) nerve. The six extraocular muscles are supplied by different nerves (see p. 812):
- oculomotor (IIIrd) nerve: medial, superior, inferior rectus and inferior oblique
- trochlear (IVth) nerve: superior oblique
- abducens (VIth) nerve: lateral rectus.

The oculomotor (IIIrd) nerve also supplies the upper lid and, indirectly, the pupil (parasympathetic fibres are attached to it). The facial (VIIth) nerve supplies the orbicularis and other muscles of facial expression.

---

**Fig. 27.20** Cross-section of the eyeball.

**Fig. 27.21** Schematic diagram of the retina.
History and examination

A detailed history gives most of the facts needed to make a working diagnosis. The eye has limited mechanisms by which it can convey a diseased state. Common symptoms include alteration in visual acuity, redness, pain, discharge and photophobia.

It is essential to adopt a systematic approach to the examination of the eye. Different approaches and instruments (including direct ophthalmoscope, slit lamp with or without Goldman or Volk lens) are necessary for examination of the lids and anterior and posterior segments, as well as extraocular movements.

Visual acuity

It is vital for an accurate assessment of visual acuity to be recorded in all people with an eye problem. The visual acuity of each eye is recorded in two ways: distance visual acuity and near visual acuity. Distance vision is measured in Snellen letters or, ever more commonly, in LogMAR letters or figures of different sizes (see below). The recording is given as an expression of the line of letters that can be discerned at a particular distance, usually 6 metres (20 feet); for example 6/60, where 6 equals the distance of the chart from the eye in metres and 60 equals the distance at which the letter subtends 5′ at the nodal point.

The Snellen visual acuity chart (Fig. 27.23) is most commonly employed, but use of the LogMAR chart (logarithm of the Minimum Angle of Resolution; Fig. 27.24) is increasing, largely due to its necessity in studies or research, since it allows better statistical analysis of results. Unlike the Snellen and other visual acuity charts, the LogMAR chart has equal graduation between the letters on a line, as well as the space between lines. There is also a fixed number of letters – five – on each line. Research conducted using a logarithmic progression in size of letters on a test chart provides the most accurate visual acuity measurement. Snellen equivalents can be calculated from the LogMAR charts if necessary (Fig. 27.25).

COMMON DISORDERS OF THE EYE

Refractive errors

The eye projects a sharp and focused image on to the retina. Refractive errors refer to any abnormality in the focusing mechanism of the eye and not to any opacity in the system, such as a corneal or retinal scar.

The refraction of light in emmetropic (normal), myopic (short-sighted; negative lenses will correct) and hypermetropic (long-sighted; positive lenses will correct) eyes is shown in Fig. 27.26.

Astigmatism is a refractive error of the eye in which there is a different degree of refraction in the different meridians of curvature. It may be myopic in one plane and hypermetropic or emmetropic in the other plane. In this situation, the front surface of the eye is shaped more like a rugby ball than a football.

Presbyopia is the term used to describe the normal ageing of the lens, which leads to a change in the refractive state of the eye. As the lens ages, it becomes less able to alter its curvature and this causes difficulty with near vision, especially reading.
Common disorders of the eye

Management

Errors of refraction can be corrected by using spectacles or contact lenses. The latter often result in better-quality vision but carry the risk of infection. They may be the only option in some refractive states such as keratoconus, a degenerative disorder of the eye in which structural changes within the cornea cause it to thin and to take on a more conical shape than its normal gradual curve. A number of surgical techniques can correct these errors of refraction, with varying degrees of accuracy. Phakic intraocular lenses may be used to treat high degrees of myopia but the most popular method remains the excimer laser to re-profile the corneal curvature (using PRK, LASIK and LASEK techniques). The laser either removes corneal tissue centrally to flatten the cornea in myopia or it removes tissue from the peripheral cornea to steepen it in hypermetropia.

Disorders of the lids

The lids afford protection to the eyes and help to distribute the tear film over the front surface of the globe. Excess tears are drained via the puncta and lacrimal system to the nose (Fig. 27.27). Malposition of the lids, factors that affect blinking and lacrimal drainage can all cause problems.

Entropion

The lid margin rolls inwards so that the lashes are against the globe (Fig. 27.28A). The lashes act as a foreign body and cause irritation, leading to a red eye that can mimic conjunctivitis. Occasionally, the constant rubbing of lashes against the cornea causes an abrasion. The most common cause is ageing and surgery is usually required.

Ectropion

The lid margin rolls outwards and is not apposed to the globe. As a result, the lacrimal punctum is not in the correct anatomical position to drain tears and patients usually complain of a watery eye. Underlying factors include age, VIth nerve palsy and cicatricial skin conditions. Surgery is usually required.
Dacryocystitis

Patients who have inflammation of the lacrimal sac usually present with a painful lump at the side of the nose adjacent to the lower lid (see Fig. 27.28B). This should be treated with oral broad-spectrum antibiotics such as a cephalosporin, and patients should be watched carefully for signs of cellulitis. All patients should be referred to the ophthalmologist, as some have an underlying mucocele or dilated sac, and will require surgery.

Blepharitis

This is an extremely common condition in which inflammation of the lid margins may involve the lashes and lash follicles (Fig. 27.29A), resulting in styes, or inflammation and blockage of meibomian glands (see Fig. 27.29B) leading to chalazion (see Fig. 27.29C). Common underlying causes of blepharitis include meibomian gland dysfunction, seborrhoea and Staphylococcus aureus infection. Patients can be asymptomatic or complain of itchy, burning eyes because of tear film instability resulting from meibomian gland dysfunction. Staph. aureus is frequently responsible for chronic blepharoconjunctivitis and some patients may develop keratitis in the cornea (Fig. 27.30).

Management

Lid hygiene is the mainstay of treatment for blepharitis, as it helps to reduce the bacterial load and unblock meibomian glands. A short course of topical chloramphenicol or fusidic acid is useful in chronic cases, but in severe cases or cases where acne rosacea is suspected, oral doxycycline is used. Some patients are left with a lump once the acute inflammatory phase has subsided. Most of these patients find the lump, or chalazion, cosmetically unacceptable and require incision and curettage. People with keratitis should be referred to the ophthalmologist for topical steroids.

Conjunctivitis

The most common cause of a red eye, inflammation of the conjunctiva can arise from a number of causes, viral, bacterial and allergic being the most frequently encountered. Common features in all types include soreness, redness and discharge; in general, the visual acuity is good. History should include the speed of onset of the inflammation, the colour and consistency of the discharge, whether the eye is itchy, and if there has been a recent history of a cold or sore throat. In the neonate, it is vital to exclude gonococcal or chlamydial conjunctivitis associated with maternal sexually transmitted infection. The differential diagnosis of conjunctivitis is shown in Box 27.9.

Bacterial conjunctivitis

Bacterial conjunctivitis is uncommon, making up 5% of all cases of conjunctivitis. In the vast majority of patients, it causes a sore

Clinical features

**Gonococcal conjunctivitis** should be suspected when the onset of symptoms is rapid, the discharge is copious, and ocular inflammation includes chemosis (conjunctival oedema) and lid oedema. Gonococci are a cause of conjunctivitis, giving rise to a palpable pre-auricular node. Less acute or subacute purulent conjunctivitis with moderate discharge can be attributed to organisms such as *Haemophilus influenzae* and *Streptococcus pneumoniae*. Chronic conjunctivitis is usually associated with mild conjunctival injection and scant purulent discharge. Common organisms include *Staphylococcus aureus* and *Moraxella lacunata*.

Management

Prompt treatment with oral and topical penicillin is given in gonococcal conjunctivitis to ensure a reduced rate of corneal perforation. A Gram-stain of the conjunctival swab can quickly confirm the presence of diplococci. Gonococcal conjunctivitis is a notifiable disease in the UK. Empirical treatment for both subacute and chronic conjunctivitis involves a topical broad-spectrum antibiotic, such as chloramphenicol. Swabs should be taken if these cases do not respond to this initial treatment. Antibiotic resistance is increasing.

**Chlamydial conjunctivitis**

*Chlamydia trachomatis* (see p. 1416) in developed countries causes a sexually transmitted infection that is most prevalent in sexually active adolescents and young adults. Direct or indirect contact with genital secretions is the usual route of infections but shared eye cosmetics can also be involved. Neonatal chlamydial conjunctivitis is a notifiable disease in the UK and should be suspected in newborns with a red eye. Mothers should be asked about sexually transmitted infections.

Clinical features

The onset of symptoms is slow, and patients may complain of mild discomfort for weeks. In these cases, the red eye is associated with a scanty mucopurulent discharge and a palpable pre-auricular lymph node. In chronic cases, it is not unusual to see superior corneal vascularization. In neonates, the onset of the red eye is typically around 2 weeks after birth, whereas gonococcal conjunctivitis occurs within days of birth. Conjunctival swabs should be taken and a nucleic acid amplification test (NAAT; see p. 1416) performed prior to commencement of treatment.

Management

Topical erythromycin twice daily is commenced and patients referred to the sexual health clinic. Neonates should be started on topical erythromycin and referred to the paediatrician, as there may be associated otitis media or pneumonia.

### Box 27.10 Trachoma

- A very common cause of blindness worldwide (see p. 553)
- Found mainly in the tropics and the Middle East
- Caused by *Chlamydia trachomatis* but not usually sexually transmitted
- Chronic conjunctival inflammation causes progressive scarring, trichiasis, entropion and subsequent corneal scarring
- The result may be severe visual impairment or blindness from corneal opacification or ulceration

Trachoma

See Box 27.10.

Viral conjunctivitis

**Adenoviral conjunctivitis**

This is highly contagious and can cause epidemics in communities. Transmission is through direct or indirect contact with infected individuals. The onset of symptoms may be preceded by a cold or influenza-like symptoms. Inflammation is commonly associated with chemosis, lid oedema and a palpable pre-auricular lymph node. Some patients develop a membrane on the tarsal conjunctiva (Fig. 27.31) and haemorrhage on the bulbar conjunctiva. Viral conjunctivitis can cause deterioration in visual acuity owing to corneal involvement (focal areas of inflammation). In 50% of these patients, the conjunctivitis is unilateral.

The condition is largely self-limiting in the majority of cases. Lubricants, together with a cold compress, can be a soothing element of management for patients. Adhering to strict hygiene and keeping towels separate from those of the rest of the household go a long way towards reducing the spread of the infection. In people with corneal involvement or intense conjunctival inflammation, topical steroids are indicated.

Herpes simplex conjunctivitis

Primary ocular herpes simplex conjunctivitis is typically unilateral. It usually causes a palpable pre-auricular lymph node, and cutaneous vesicles develop on the eyelids and the skin around the eyes in the majority. Over 50% of these patients develop a dendritic corneal ulcer (Fig. 27.32). The organism responsible for this condition is the herpes simplex virus (HSV), usually HSV-1, although HSV-2 can give rise to ocular infection.

Primary ocular HSV infection is self-limiting but most clinicians choose treatment with topical aciclovir in order to limit the risk of corneal epithelial involvement.

**Molluscum contagiosum conjunctivitis**

This is typically unilateral; it produces a red eye that generally goes unrecognized and comes to the forefront because patients fail to improve and the cornea starts to become involved. On close inspection, pearly, umbilicated nodules, filled with the DNA poxvirus, can be seen on the lid margin.
Seasonal/perennial conjunctivitis

Seasonal allergic conjunctivitis and perennial conjunctivitis, affecting 20% of the general population in the UK, are allergic reactions to grass and tree pollen and fungal spores. Seasonal allergic conjunctivitis occurs mainly in spring and summer. Perennial allergic conjunctivitis occurs all year round but peaks in the autumn; causes include allergens, such as house-dust mites.

The main symptoms include itching, redness, soreness, watering and a stringy discharge. Occasionally, the conjunctiva may become so hyperaemic that chemosis results. This is usually associated with swollen lids.

Lowering the allergen load (reducing dust; see p. 946) is helpful. Medical treatment includes the use of antihistamine drops such as azelastine and emedastine, together with topical mast-cell-stabilizing agents such as sodium cromoglicate and nedocromil. Olopatadine (twice daily) has dual action and is very effective. Corticosteroid drops should be avoided. Oral antihistamines help the itching.

Corneal disorders

Trauma

Corneal abrasions

Trauma resulting in the removal of a focal area of epithelium on the cornea is very common. Abrasions usually occur when the eye is accidentally poked with a finger, a foreign body flies into the eye or something brushes against the eye.

Symptoms include severe pain, due to exposure of the corneal nerve endings, lacrimation and inability to open the eye (blepharospasm). Blinking and eye movement can aggravate the pain and foreign body sensation. The visual acuity is usually reduced. Most cases will need topical anaesthetic drops such as oxybuprocaine or tetracaine to be administered before it is possible to examine the eye. The cornea should be inspected with a blue light after instillation of fluorescein drops. The orange dye will stain the area of the abrasion. Under blue light, the abrasion lights up as green. Occasionally, foreign bodies can lodge on the undersurface of the upper lid and give rise to linear vertical abrasions. Eversion of the upper lid is necessary in all cases of abrasions (Fig. 27.34).

Treatment consists of a broad-spectrum topical antibiotic, such as chloramphenicol drops or ointment four times a day for 5 days. The role of padding is controversial but common practice is to pad the affected eye for 24 hours once chloramphenicol ointment has been applied to the eye.

Corneal foreign body

Occasionally, when something flies into the eye, it sticks on the cornea (Fig. 27.35A). It may be associated with lacrimation and pho(topophobia. Examination is best attempted following instillation of a topical anaesthetic and should include eversion of the upper lid (see Fig. 27.35B). Corneal foreign bodies can usually be seen directly with a white light.

The corneal foreign body should be removed. Treatment involves a topical antibiotic, such as chloramphenicol four times a day for 5 days, or fusidic acid twice a day for 5 days.

High-velocity trauma

In cases of high-velocity trauma, corneal perforation or an intraocular foreign body should be suspected. Examination may show...
Common disorders of the eye

a corneal laceration and a foreign body may also be embedded in the cornea. The foreign body may be present on the iris or in the lens or vitreous. Other clues pointing towards a penetrating injury include a large subconjunctival haemorrhage, a flat anterior chamber with low intraocular pressure, and the presence of blood in the anterior chamber (hyphaema). Urgent referral to the ophthalmologist is mandatory, ensuring that no drops are instilled into the eye and that a plastic shield is placed over the eye to minimize further risk of trauma.

Blunt trauma usually results in periorbital bruising and gross lid oedema, which can make examination to exclude perforating injury difficult. These patients should be referred to the ophthalmologist for a detailed ocular examination to exclude a perforation, retinal detachment or a traumatic hyphaema (Fig. 27.36).

Keratitis

This is a general term used to describe corneal inflammation. Common causes include herpes simplex virus, contact lens-associated infection and blepharitis. Symptoms include the sensation of a foreign body or pain (depending on the size and depth of the ulcer), photophobia and lacrimation. Vision is reduced if the ulcer affects the visual axis.

Herpes simplex keratitis

Corneal epithelial cells infected with the virus eventually undergo lysis and form an ulcer, which is typically dendritic in shape (see Fig. 27.32). The ulcer stains with fluorescein and can be observed easily with a blue light. Topical immunosuppression, such as with steroid drops, or systemic immunosuppression, such as in AIDS, can lead to the centrifugal spread of the virus, such that the ulcer increases in area and is referred to as a geographic ulcer. Recurrent attacks of HSV keratitis can be triggered by ultraviolet light, stress and menstruation. All these factors are responsible for activating the virus, which normally lies dormant in the ganglion of the Vth nerve.

Treatment consists of aciclovir ointment five times a day for 2 weeks; this is usually very effective.

Contact lens-related keratitis

A small number of contact lens wearers develop infective corneal ulcers, which are potentially sight-threatening (Fig. 27.37). The organisms usually responsible include Gram-positive and Gram-negative bacteria. Patients should be referred to an ophthalmologist for scraping of the ulcer and commencement of antibiotic treatment.

Keratoconus

Keratoconus is an eye condition in which the normally round, dome-shaped cornea progressively thins and causes a cone-shaped bulge to develop. Aetiology is uncertain but genetic factors play a role, and the condition is more common in people with allergic diseases such as asthma, in Down’s syndrome and in some disorders of collagen such as Marfan’s disease. Keratoconus affects up to 1 in 1000 people and is more common in individuals of Asian heritage. It is usually diagnosed in teenagers and young people.

Management

In the early stages, spectacles or soft contact lenses may be used to correct vision. As the cornea becomes thinner and steeper, rigid gas-permeable contact lenses may be necessary.

Corneal cross-linking is a new treatment that can stop keratoconus becoming worse. It is effective in more than 9 out of 10 patients, with a single 30-minute day-case procedure, but is only suitable when the corneal shape is continuing to deteriorate. In very advanced cases, where contact lenses fail to improve vision, a corneal transplant may be needed.

Corneal dystrophy

Corneal dystrophies may be classified anatomically as comprising:
- epithelial and subepithelial dystrophies
- epithelial–stromal TGFBI corneal dystrophies
- stromal dystrophies
- endothelial dystrophies.

The most common endothelial dystrophy, Fuchs’ corneal dystrophy, is a genetically associated degenerative disorder leading to corneal oedema and vision loss. The gene involved is TCF4. The condition affects both eyes; it is more common in females and is of gradual onset, leading to blindness in the 40–60 age group. There is
an accumulation of deposits (guttae) in the cornea with thickening of Descemet’s membrane. Treatment is by corneal transplantation.

**Cataracts**

Cataract (Fig. 27.38) is by far the most common cause of preventable blindness in the world, having an effective surgical treatment. In the UK, approximately 250,000 cataract operations are performed each year, making it the most common surgical procedure.

**Aetiology**

Age-related opacification of the lens (cataract) is the commonest cause of visual impairment, with 30% of people over 65 years having visual acuities below that required for driving (Snellen acuity less than 6/12). The common causes of cataracts are summarized in Box 27.11.

In young patients, familial or congenital causes should be excluded. Any history of ocular inflammation is noted. Cataracts diagnosed in infants demand urgent referral to the ophthalmologist in order to minimize the subsequent development of amblyopia.

**Clinical features**

Gradual painless deterioration of vision is the most common symptom. Other symptoms are dependent on the type of cataract: for example, a posterior capsular type would lead to glare and problems with night driving. Early changes in the lens are correctable by spectacles but eventually the opacification needs surgical intervention.

**Investigations**

Blood glucose, serum calcium and liver biochemistry should be measured to diagnose metabolic disorders.

**Management**

Small-incision extracapsular or phacoemulsification cataract extraction with the insertion of an intraocular lens is the treatment of choice (see Fig. 27.37C). Recent advances have enabled surgeons to perform multiple steps in the surgical process with the excimer laser to enhance visual outcomes. Lens technology has also improved and toric lenses are available to treat astigmatism, and multifocal or accommodative lenses to overcome intraocular lens-induced presbyopia.

**Glaucoma**

Glaucoma is due to increased pressure inside the eye, which is sufficiently elevated to cause optic nerve damage and result in visual field defects, with loss of sight (Fig. 27.39). Normal intraocular pressure (IOP) is 10–21 mmHg. Some types of glaucoma can result in an IOP exceeding 70 mmHg. Glaucoma is the second most common cause of blindness worldwide and the third most common cause of blind registration in the UK.

**Primary open-angle glaucoma**

Primary open-angle glaucoma (POAG) is the most common form of glaucoma. High intraocular pressures result from reduced outflow of aqueous humour through the trabecular meshwork (Fig. 27.40A). Common risk factors include age (0.02% of 40-year-olds versus 10% of 80-year-olds), race (black Africans are at five times greater risk than whites), positive family history and myopia.

**Fig. 27.40 Glaucoma.** (A) Primary open-angle glaucoma. (B) Angle-closure glaucoma.
Clinical features
POAG causes a gradual, insidious, painless loss of peripheral visual field, causing loss of vision. It is initially asymptomatic and the central vision remains good until the end-stage of the disease. Usually, glaucoma is identified during a routine ophthalmic examination. Diagnosis is only made if the IOP is measured. The optic disc is inspected and shows an enlarged cup with a thin neuroretinal rim. Visual fields are assessed and show a normal blind spot with scotomas.

Management
Treatment aims to reduce the IOP, either by reducing aqueous production or by increasing aqueous drainage:
- **Beta-blockers**, such as timolol, carteolol and levobunolol, reduce aqueous production and are the most commonly prescribed topical agents. These drugs are contraindicated in people with chronic obstructive pulmonary disease, asthma or heart block.
- **Prostaglandin analogues**, such as latanoprost, bimatoprost and travoprost, increase aqueous outflow and are available (alone or in combination with beta-blockers) for POAG, as they can reduce IOP by 30%.
- **Carbonic anhydrase inhibitors**, such as dorzolamide and acetazolamide, reduce aqueous production and are available in topical preparations. Acetazolamide is also available orally and, in this form, is the most potent drug for reducing IOP. It should not be used in patients who have a sulphonamide allergy.
- **Selective laser trabeculoplasty (SLT)** is a form of laser surgery that can lower the IOP by about 30% when used as initial therapy. It is useful when eye-drop medications are not lowing the eye pressure enough or are causing significant side-effects. It may sometimes be used as initial treatment in glaucoma, although effects commonly last 1–5 years only.

Acute angle-closure glaucoma
Acute angle-closure glaucoma (AACG) is an ophthalmic emergency. There is a sudden rise in intraocular pressure to levels over 50 mmHg. This occurs due to reduced aqueous drainage when the ageing lens pushes the iris forwards against the trabecular meshwork (see Fig. 27.40B). People most at risk of developing AACG are those with shallow anterior chambers, such as hypermetropes and women. The attack is more likely to occur under reduced light conditions when the pupil is dilated.

Clinical features
AACG causes sudden onset of a red, painful eye and blurred vision. Patients become unwell, with nausea and vomiting, and complain of headache and severe ocular pain. The eye is injected and tender, and feels hard. The cornea is hazy and the pupil is semi-dilated (Fig. 27.41). Box 27.12 shows the differential diagnosis of the acute red eye. Box 27.13 shows features that require urgent referral to an ophthalmologist.

Management
Prompt treatment is required to preserve sight and includes:
- i.v. acetazolamide 500mg (provided there are no contraindications) to reduce IOP, and
- instillation of pilocarpine 4% drops to constrict the pupil to improve aqueous outflow and prevent iris adhesion to the trabecular meshwork.

Other topical drops, such as beta-blockers and prostaglandin analogues, can also be instilled if available, provided there are no contraindications. Analgesia and antiemetics are given as required.

Patients must be referred to an ophthalmologist immediately so that reduction in IOP can be monitored and other agents, such as oral glycerol or i.v. mannitol, can be administered to non-responding patients. Definitive treatment involves making a hole in the periphery of the iris of both eyes either by laser or by surgical means.

Uveitis
Uveitis is inflammation of the uveal tract, which includes the iris, ciliary body and choroid. It is classified according to the part of the uveal tract that the inflammation affects:
- **Anterior uveitis** is inflammation that affects the anterior part of the uveal tract. This can include the iris (iritis), or both the iris and the ciliary body (iritis-cyclitis). It is the most common type of uveitis.
- **Intermediate uveitis** is inflammation that affects the middle part of the uveal tract or eye, mainly the vitreous. It can also affect the underlying retina.
- **Posterior uveitis** is inflammation that affects the posterior part of the eye. It can affect the choroid, optic nerve head and the retina (or any combination of these structures). It includes choroiditis, retinitis and neuroretinitis.
- **Panuveitis** is inflammation affecting the whole of the uveal tract.

The most common symptoms of uveitis are blurred vision, pain, redness, photophobia and floaters. Each symptom is determined by the location of the inflammation, such that photophobia and pain are common features of iritis while floaters are commonly seen with posterior uveitis.

**Anterior uveitis (iritis)**
The classic presentation entails a triad of eye symptoms: redness, pain and photophobia. Vision can be normal or blurred, depending on the degree of inflammation. The eye can be generally red or the injection can be localized to the limbus. The anterior chamber shows features consistent with inflammation, including cells, keratic precipitates on the corneal endothelium, fibrin or hypopyon (pus), and the pupil may have adhered to the lens (posterior synechiae) (Fig. 27.42). The IOP may be normal or raised, either due to cells clogging up the trabecular meshwork, or due to posterior synechiae causing aqueous humour to build up behind the iris and force the iris against the trabecular meshwork and so reduce aqueous drainage.

**Management**
This consists of reducing inflammation with the use of topical steroids such as dexamethasone 0.1% and dilating the pupil with cyclopentolate 1% to prevent formation of posterior synechiae. Dilation also allows fundoscopy to exclude posterior segment involvement. If the IOP is raised, this is treated with topical beta-blockers, prostaglandin analogues, or oral or i.v. acetazolamide. Referral should be made to the ophthalmologist.

**Intermediate uveitis**
This usually causes painless blurred vision, most commonly associated with floaters. It is unusual to experience photophobia and redness. Both eyes are commonly affected in intermediate uveitis.

**Posterior uveitis**
This commonly causes painless, blurred vision and can progress to severe visual loss. It is commonly associated with floaters and scotomata, or blind spots in the visual field.

Autoimmune diseases associated with uveitis include rheumatoid arthritis and Behçet’s disease, ankylosing spondylitis and positive HLA-B27 (see p. 448), reactive arthritis, sarcoidosis, psoriasis and inflammatory bowel disease (Crohn’s disease and ulcerative colitis; see p. 1202). Infections, a rare cause of uveitis, include herpes simplex, herpes zoster, toxoplasmosis, cytomegalovirus, syphilis, tuberculosis, HIV infection and Lyme disease. In a number of patients, no cause is found (idiopathic uveitis).

**Management**
Steroids are commonly given orally, or more locally by injection into or around the eye. If steroid treatment is needed to treat uveitis in the longer term, second-line immunosuppressive drugs, such as mycophenolate mofetil, ciclosporin or azathioprine, are used.

---

**Box 27.13 Red flags for a red eye**
The following symptoms require urgent referral:
- Severe pain
- Photophobia
- Reduced vision, particularly if sudden
- Coloured halos around point of light in a patient’s vision
- Proptosis
- Smaller pupil in affected eye
- Plus on medical assessment:
  - High intraocular pressure
  - Corneal epithelial disruption
  - Shallow anterior chamber depth
  - Ciliary flush

![Fig. 27.42 Anterior uveitis.](image)
Biological agents, such as rituximab or adalimumab, are showing increasing promise in more severe cases.

**Disorders of the retina**

**Central retinal vein occlusion**
Central retinal vein occlusion (CRVO) usually leads to profound, sudden, painless loss of vision with thrombosis of the central retinal vein at or posterior to the lamina cribrosa, where the optic nerve exits the globe. The thrombus causes obstruction to the outflow of blood, leading to a rise in intravascular pressure. This results in dilated veins, retinal haemorrhage, cotton wool spots and abnormal leakage of fluid from vessels, causing retinal oedema (Fig. 27.43). In severe cases, an afferent papillary defect (p. 811) is present and this suggests the ischaemic variant.

Predisposing factors include increasing age, hypertension and cardiovascular disease, diabetes, glaucoma and, in the younger age group, blood dyscrasias and vasculitis.

**Management**
Treatment of any underlying medical condition is mandatory. Referral to an ophthalmologist is essential to monitor the eye, as some patients can develop retinal ischaemia with resulting neovascularization of the retina and iris. Panretinal photocoagulation should be commenced if there is neovascularization, and intravitreal steroid or anti-vascular endothelial growth factor (anti-VEGF) therapy is also used if there is macular oedema. Patients who develop iris neovascularization – rubeosis – where these new blood vessels block the drainage angle are at risk of developing rubeotic glaucoma.

**Central retinal artery occlusion**
Central retinal artery occlusion (CRAO) results in sudden, painless severe loss of vision. Retinal arterial occlusion results in infarction of the inner two-thirds of the retina. The arteries become narrow and the retina becomes opaque and oedematous. A cherry-red spot is seen at the fovea because the choroidal vasculature shows up through the thinnest part of the retina (Fig. 27.44). An afferent papillary defect is usually present.

Arteriosclerosis-related thrombosis is the most common cause of CRAO. Emboli from atheromas and diseased heart valves are other causes. Giant cell arteritis (see p. 464) must be excluded.

**Management**
CRAO is an ophthalmic emergency since studies have shown that irreversible retinal damage occurs within 90 minutes of onset. Ocular massage and 500 mg i.v. acetazolamide help to reduce ocular pressure and may assist in dislodging the emboli. Breathing into a paper bag allows a build-up of carbon dioxide, which acts as a vasodilator and so helps dislodge the emboli. Other options include making a corneal paracentesis to drain off some aqueous humour, thereby reducing the IOP.

People with CRAO should have a thorough medical evaluation to determine the aetiology of the emboli or thrombus. Some patients may present with transient loss of vision or amaurosis fugax (see p. 838). All people with CRAO and amaurosis fugax should be started on oral aspirin if it is not medically contraindicated.

**Retinal detachment**
This causes a painless, progressive visual field loss. The shadow corresponds to the area of detached retina. If the detachment affects the macula, central vision will be lost. Following a tear in the retina, fluid collects in the potential space between the sensory retina and the pigment epithelium (Fig. 27.45). Patients usually report a sudden onset of floaters, often associated with flashes of light (photopsia) prior to the detachment. These individuals should be referred to an ophthalmologist for a detailed fundal examination.

**Retinitis pigmentosa**
This is a common chronic, inherited, degenerative disease of the retina, which can be primary or part of a syndrome, and leads to blindness. There is constriction of the peripheral vision, leading to tunnel vision and progressive loss of night vision.

Ophthalmoscopy shows bone spicule deposits and attenuated retinal vessels. Several genes are implicated.

There is no treatment but high-dose vitamin A supplementation may slow progression. Gene therapy is being investigated.

**Age-related macular degeneration**
Age-related macular degeneration (AMD) is the most common cause of visual impairment in patients over 50 years in the Western world, and the most common cause of blind registration in this age group. It affects 10% of people over 65 years and 30% over
80 years. Mutations in various genes have been reported: fibulin 5, complement factor H, and the Arg 80 Gly variant of complement C3.

The cause is unknown but suggested risk factors include increasing age, smoking, hypertension, hypercholesterolaemia and ultraviolet exposure.

There are two types:

- **Non-exudative (dry) macular degeneration** describes a painless and progressive loss of central vision. With age, lipofuscin deposits (drusen) are found between the retinal pigment epithelium (RPE) and Bruch’s membrane (Fig. 27.46A; see Fig. 27.21). Drusen may be hard or soft, and there may be focal RPE detachment. Not all people with these changes will be affected visually but some develop distortion and blurring of their central vision. Extensive atrophy of RPE can occur (geographic atrophy).

- **Exudative (wet) AMD** (10% of cases) occurs with the development of abnormal subfoveal choroidal neovascularization in the region of the macula and causes severe central visual loss (see Fig. 27.46B).

**Management**

The Age-Related Eye Disease Study (AREDS) has shown that vitamins C and E, ß-carotene, zinc and copper slow progression of the disease. The subsequent study, AREDS 2, suggests that adding lutein, zeaxanthin and omega 3 does not improve the original AREDS formula overall, unless subjects had little of the supplements in their diets.

People with central distortion or with frank macular pathology should be referred **urgently** to the ophthalmologist for assessment of treatment. Anti-VEGF, such as ranibizumab, aflibercept and bev-acizumab, are given by intravitreal injections with great success; the last of these is unlicensed yet less expensive. The treatment course should be commenced as a **matter of urgency**, as vision is maintained in up to 95% of patients and improves in approximately one-third. Initial monthly monitoring with optical coherence tomography (OCT) is recommended (Fig. 27.47). Laser treatment and photodynamic therapy with verteporfin constituted the treatment of choice in the past for wet AMD but now have limited roles.

Severe visual loss is possible and low-vision aids, such as magnifying glasses, may help to improve a patient’s independence.

**Visual loss**

Every patient with unexplained sudden visual loss requires ophthalmic referral (see Box 27.14 for initial history and examination).

The common causes of blindness are similar across the world (Box 27.15). In developing countries, trachoma due to *Chlamydia trachomatis* (see p. 553) is also a major cause, accounting for 10% of global blindness; onchocerciasis (river blindness, due to *Onchocerca volvulus*; see p. 575) accounts for blindness in about 1 million people, although this figure is decreasing with community treatment programmes. In leprosy, 70% of patients have ocular involvement, and blindness occurs in 5–10% of these. Ocular involvement is common in cerebral malaria (see p. 565), although loss of vision is rare.

HIV infection can produce uveitis but the major problem is severe opportunistic infection of the eye when the CD4 count falls (see p. 1432) and anti-retroviral therapy is not available.

Vitamin A deficiency and xerophthalmia affect millions each year; the World Health Organization (WHO) classification of xerophthalmia by ocular signs is shown in Box 33.15.

The WHO lists the most common causes of blindness across the world as cataract, glaucoma, acute macular degeneration, corneal opacity, diabetic retinopathy and infections from bacteria or parasites.
### Box 27.14 Initial history and examination in sudden loss of vision

**Painless loss of vision**
- Cataract
- Open-angle glaucoma
- Retinal detachment
- Central retinal vein occlusion
- Central retinal artery occlusion
- Diabetic retinopathy
- Vitreous haemorrhage
- Posterior uveitis
- Age-related macular degeneration
- Optic nerve compression
- Cerebral vascular disease

**Painful loss of vision**
- Acute angle-closure glaucoma
- Giant cell arteritis
- Optic neuritis
- Uveitis
- Scleritis
- Keratitis
- Shingles
- Orbital cellulitis
- Trauma

Clinical skills for respiratory medicine

- History

The following features of the medical history are especially relevant in respiratory disease:

- **Respiratory symptoms:** cough, sputum production, breathlessness, chest pain, haemoptysis, wheeze. Specify acuity of onset, change over time, change in symptoms with location.

- **Systemic symptoms:** weight loss, malaise, night sweats.

- **Occupational exposure:** all previous occupations, with a specific focus on exposure to asbestos, to organic materials such as hay, mushrooms or cotton, or to animals. Establish any relationship of symptoms to work.

- **Smoking:** smoking history (duration of smoking and number of cigarettes smoked per day), and also attempts made to give up, including use of nicotine replacement substances such as e-cigarettes.

- **Recreational drug use:** especially smoked cannabis.

- **Family history:** respiratory conditions such as emphysema, bronchiectasis or cystic fibrosis.

- **Childhood history:** prematurity, childhood infections such as whooping cough or measles.

- **Travel history:** may be relevant in assessing risk factors for tuberculosis.

- **Pleural disease**

  - Pleural effusion
  - Pneumothorax

- **Tumours of the Respiratory Tract**

  - Bronchiectasis
  - Cystic fibrosis

- **Interstitial Lung Diseases**

  - Idiopathic pulmonary fibrosis
  - Hypersensitivity pneumonitis
  - Rare interstitial lung diseases

- **Lung and Heart–Lung Transplantation**

  - Occupational Lung Disease

- **Miscellaneous Respiratory Disorders**

  - Disorders of the Diaphragm

  - Mediastinal Lesions
Respiratory disease

Examination

**End of the bed:**
- Posture – lying flat or raised
- Colour – cyanosed?
- Respiratory rate
- Pain on breathing (pleuritic)?
- Fever
- Cachexia

- Anaemia
- Horner’s syndrome
- Pursed lips
- Nose – beaky

**Central cyanosis**

- Jugular venous pressure
  - Raised
  - Pulsatile

- Use of accessory muscles
  - Intercostal in drawing

**CO₂ retention flap**

- Bounding pulse

- Clubbing
- Tar staining
- Peripheral cyanosis

**Deep vein thrombosis**

- Oedema (leg or sacral if lying down)
  - Right heart failure
  - Secondary to pulmonary hypertension

**Sputum**

- Volume (↑ bronchiectasis)
- Mucopurulent (infection)
- Purulent (green = infection)
- Blood-stained (cancer, pulmonary embolism, tuberculosis, bronchiectasis)

**Examining the chest**

**Inspection**
- Colour
- Breathlessness
- Deformity
- Scars
- Symmetry of movement
- Abdominal paradox (diaphragm weakening)
- Hyperinflation
- Prominent veins (SVC obstruction)
- Intercostal in drawing
- Scoliosis

**Palpation**
- Tracheal position
- Cricosternal distance
- Supraclavicular fossa nodes
- Apex beat
- Tenderness
  - Costochondritis
- Rib fracture
- Liver
  - Position (low lying)
  - Enlargement

**Percussion**
- Dull
  - Consolidation
  - Collapse
- ‘Stony dull’
  - Fluid (effusion)
- Hyperresonant
  - Pneumothorax

**Auscultation**
- Normal or ‘vesicular’
- Bronchial breathing
- Wheeze
  - Monophonic (single large airway obstruction)
  - Polyphonic (narrowing of small airways)
- Crackles
  - Coarse (consolidation, bronchiectasis)
- Fine, late inspiratory (pulmonary oedema, lung fibrosis)
- Pleural rub
- Vocal resonance
### 1. Preliminaries
- **Patient details:**
  - Which patient, how old, when was this image taken?
- **X-ray details:**
  - Is it a posteroanterior or anteroposterior projection?
  - Is the patient rotated?
  - Is there adequate penetration?
  - Has the patient taken an adequate breath?
- Compare where available to previous X-ray images

### 2. Trachea
- The trachea should be widely patent and should be central in the chest
- The trachea may be pulled towards areas of fibrosis or collapse
- It may be pushed away by masses, a goitre, lymphadenopathy, large pleural effusion or a tension pneumothorax

### 3. Mediastinum
- The aortic notch should be just visible
- The left hilum should be slightly higher than the right
- The hila should be symmetrical in size
- The mediastinum is widened by lymphadenopathy, masses such as thymoma, and aortic aneurysm
- The hila may be pulled up or down by collapsed lobes, or enlarged by the presence of a tumour

### 4. Heart size
- Heart size should be less than 50% of the thoracic width on a PA chest film
- Assess heart borders
- Cardiomegaly may be caused by hypertension, valvular disease, heart failure or cardiomyopathy
- Loss of right heart border may suggest right middle lobe pathology
- Loss of left heart border suggests lingular pathology

### 5. Diaphragm
- The right hemidiaphragm is usually higher than the left
- Look for air/gas under the diaphragm and for elevation of the diaphragm on either side
- Air or gas under the diaphragm indicates a perforated abdominal viscus
- A hemidiaphragm may be pulled up from above by lobar collapse, or pushed up from below by a large mass

### 6. Pleura
- The costophrenic angles should be clearly visible
- Look for lung markings extending to the chest wall
- Look for evidence of a lung edge
- Loss of the costophrenic angle is usually due to the presence of pleural effusions
- Larger pleural effusions may cause a ‘white out’ on one side
- Loss of lung markings or a visible lung edge suggests a pneumothorax

### 7. Lungs
- Is there consolidation of the upper lobe (stops at horizontal fissure), middle lobe/lingula (heart edge unclear) or lower lobe (diaphragm unclear)?
- Inspect each part of the lung looking for round shadows
- Inspect the lung parenchyma for interstitial changes
- Areas of consolidation may often be restricted to a lobe and are usually caused by pneumonia. An air bronchogram (airways outlined) or evidence of cavitation may be seen
- Rounded shadows may be caused by cancer, inflammatory lesions, such as tuberculosis or fungal disease
- Interstitial changes may be caused by pulmonary oedema or fibrosis

### 8. Bones
- Inspect all ribs for evidence of fractures
- Faint bones imply osteopenia
- Are there lytic lesions?
- Think of systemic diseases:
  - Osteoporosis may cause osteopenia or fractures
  - Solid organ cancers or myeloma can cause lytic lesions

### 9. Soft tissue
- Observe the soft tissue around the rib cage
- Air within the skin suggests surgical emphysema

### 10. Miscellaneous
- Look for any externally applied devices
- Nasogastric tubes should bisect the carina and cross the diaphragm
- Chest drains should terminate in the pleural space
- Central venous catheters should end just above the right atrium
- Pacemaker wires, and sternotomy wires imply cardiac disease

---

**Fig. 28.1** A systematic ten-step approach to chest X-ray interpretation.

### FUNCTION OF THE RESPIRATORY SYSTEM

The respiratory system has several key functions, the principal ones being to extract oxygen from the external environment and to dispose of carbon dioxide. This requires the lungs to function as efficient bellows, bringing in fresh air and delivering it to the alveoli, and expelling used air at an appropriate rate. Gas exchange is achieved by exposing thin-walled capillaries to the alveolar gas and matching ventilation to blood flow through the pulmonary capillary bed. The excretion of carbon dioxide by the lungs is involved in acid–base homeostasis.

The lungs expose a large surface area of body tissue to the external environment in order to achieve gas exchange, and hence they can be damaged by dusts, gases and infective agents. Host defence is therefore a key priority for the lung and is achieved by a combination of structural and immunological defences.

The pulmonary circulation also acts as a blood pool reservoir that can allow the body to respond readily to increased oxygen demands in exercise. The lungs act as a filtration system for small pulmonary emboli. The pulmonary circulation also plays a role in innate immunity; for example, in de-priming neutrophils.

Finally, the lungs have a role in speech, as the passage of air through the vocal cords is necessary for phonation.

### Anatomy

#### Nose, pharynx and larynx

See pages 907 and 909.

#### Trachea, bronchi and bronchioles

The trachea is 10–12 cm in length. It lies slightly to the right of the midline and divides at the carina into right and left main bronchi. The carina lies under the junction of the manubrium sterni and the second right costal cartilage. The right main bronchus is more vertical than the left and inhaled material is therefore more likely to end up in the right lung.

---

**Fig. 28.2** Branches of a terminal bronchiole ending in the alveolar sacs.

The right main bronchus divides into the upper lobe bronchus and the intermediate bronchus, which further subdivides into the middle and lower lobe bronchi. On the left the main bronchus divides into upper and lower lobe bronchi only. Each lobar bronchus further divides into segmental and subsegmental bronchi. There are about 25 divisions in all between the trachea and the alveoli.

The first seven divisions are bronchi that have:
- • walls consisting of cartilage and smooth muscle
- • an epithelial lining with cilia and goblet cells
- • submucosal mucus-secreting glands
- • endocrine cells.

The next 16–18 divisions are bronchioles that have:
- • no cartilage and a muscular layer that progressively becomes thinner
- • a single layer of ciliated cells but very few goblet cells
- • granulated Clara cells that produce a surfactant-like substance.

The ciliated epithelium is a key defence mechanism. Each cell bears approximately 200 cilia beating at 1000 beats per minute (b.p.m.) in organized waves of contraction. Mucus, which contains macrophages, cell debris, inhaled particles and bacteria, is moved by the cilia towards the larynx at about 1.5 cm/min (the ‘mucociliary escalator’; see later).

The bronchioles finally divide within the acinus into smaller respiratory bronchioles that have alveoli arising from the surface (Fig. 28.2). Each respiratory bronchiole supplies approximately 200 alveoli via alveolar ducts. The term ‘small airways’ refers to bronchioles of less than 2 mm; the average lung contains about 30,000 of these.

### Alveoli

There are approximately 300 million alveoli in each lung. Their total surface area is 40–80 m². The epithelial lining consists mainly of **type I pneumocytes** (Fig. 28.3). These cells have an extremely thin layer of cytoplasm, which only offers a thin barrier to gas exchange. Type I cells are connected to each other by tight junctions that limit the movements of fluid in and out of the alveoli. Alveoli are not completely airtight; many have holes in the alveolar wall, allowing communication between alveoli of adjoining lobules (pores of Kohn).

**Type II pneumocytes** are slightly more numerous than type I cells but cover less of the epithelial lining. They are found generally in the borders of the alveolus and contain distinctive lamellar vacuoles, which are the source of surfactant. Type I pneumocytes are...
derived from type II cells. Large alveolar macrophages are present within the alveoli and assist in defending the lung.

**Lungs**

The lungs are separated into lobes by invaginations of the pleura, which are often incomplete. The right lung has three lobes, whereas the left lung has two. The positions of the oblique fissures and the right horizontal fissure are shown in Fig. 28.4. The upper lobe lies mainly in front of the lower lobe and therefore physical signs on the right side in the front of the chest are due to lesions of the upper lobe or the middle lobe.

**Pleura**

The pleura is a layer of connective tissue covered by a simple squamous epithelium. The visceral pleura covers the surface of the lung, lines the interlobar fissures, and is continuous at the hilum with the parietal pleura, which lines the inside of the hemithorax. At the hilum, the visceral pleura continues alongside the branching bronchial tree for some distance before reflecting back to join the parietal pleura. In health, the pleurae are in apposition, apart from a small quantity of lubricating fluid.

**Diaphragm**

The diaphragm is covered by parietal pleura above and peritoneum below. The diaphragmatic muscle fibres arise from the lower ribs and insert into the central tendon. Motor and sensory nerve fibres go separately to each half of the diaphragm via the phrenic nerves. Fifty per cent of the muscle fibres are of the slow-twitch type with a low glycolytic capacity; they are relatively resistant to fatigue.

**Pulmonary vasculature and lymphatics**

The lung has a dual blood supply, receiving deoxygenated blood from the right ventricle via the pulmonary artery and oxygenated blood via the bronchial circulation.

The pulmonary artery divides to accompany the bronchi. The arterioles accompanying the respiratory bronchioles are thin-walled and contain little smooth muscle. The pulmonary venules drain laterally to the periphery of the lobules, pass centrally in the interlobular and intersegmental septa, and eventually join to form the four main pulmonary veins.

The bronchial circulation arises from the descending aorta. These bronchial arteries supply tissues down to the level of the respiratory bronchiole. The bronchial veins drain into the pulmonary veins, forming part of the normal physiological shunt.

Lymphatic channels lie in the interstitial space between the alveolar cells and the capillary endothelium of the pulmonary arterioles.

The tracheobronchial lymph nodes are arranged in five main groups: pulmonary, bronchopulmonary, subcarinal, superior tracheobronchial and paratracheal. For practical purposes, these form a continuous network of nodes from the lung substance up to the trachea.

**Nerve supply to the lung**

The innervation of the lung remains incompletely understood. Parasympathetic and sympathetic fibres (from the vagus and sympathetic chain, respectively) accompany the pulmonary arteries and the airways. Airway smooth muscle is innervated by vagal afferents, postganglionic muscarinic vagal efferents and vagally derived non-adrenergic non-cholinergic (NANC) fibres, which use a range of neurotransmitters. Three muscarinic receptor subtypes have been...
identified: M₁ receptors on parasympathetic ganglia, a smaller number of M₂ receptors on muscarinic nerve terminals, and M₃ receptors on airway smooth muscle. The parietal pleura is innervated from intercostal and phrenic nerves but the visceral pleura has no innervation.

Further reading

Physiology

Nose
The major functions of nasal breathing are:
• to heat and moisten the air
• to remove particulate matter.

Nasal secretions contain immunoglobulin A (IgA) antibodies, lysozyme and interferons. In addition, the cilia of the nasal epithelium move the mucous gel layer rapidly back to the oropharynx, where it is swallowed. Bacteria have little chance of settling in the nose. Mucociliary protection is less effective against viral infections because viruses bind to receptors on epithelial cells. The majority of rhinoviruses bind to an adhesion molecule, intercellular adhesion molecule 1 (ICAM-1), which is shared by neutrophils and eosinophils. Many noxious gases, such as sulphur dioxide, are almost completely removed by nasal breathing.

Breathing
Lung ventilation can be considered in two parts:
• the mechanical process of inspiration and expiration
• the control of respiration to a level appropriate for metabolic needs.

Mechanical process
The lungs have an inherent elastic property that causes them to tend to collapse away from the thoracic wall, generating a negative pressure within the pleural space. The strength of this retractive force relates to the volume of the lung: at higher lung volumes the lung is stretched more, and a greater negative intrapleural pressure is generated. Lung compliance is a measure of the relationship between this retractive force and lung volume. At the end of a quiet expiration the retractive force exerted by the lungs is balanced by the tendency of the thoracic wall to spring outwards. At this point, respiratory muscles are resting. The volume of air remaining in the lung after a quiet expiration is called the functional residual capacity (FRC; see Fig. 28.15).

Inspiration from FRC is an active process: a negative intrapleural pressure is created by descent of the diaphragm and movement of the ribs upwards and outwards through contraction of the intercostal muscles. During tidal breathing in healthy individuals, inspiration is almost entirely due to contraction of the diaphragm. More vigorous inspiration requires the use of accessory muscles of ventilation (sternomastoid and scalene muscles). Respiratory muscles are similar to other skeletal muscles but are less prone to fatigue. However, inspiratory muscle fatigue contributes to respiratory failure in patients with severe chronic airflow limitation and in those with primary neurological and muscle disorders.

At rest or during low-level exercise, expiration is passive and results from the natural tendency of the lung to collapse. Forced expiration involves activation of accessory muscles, chiefly those of the abdominal wall, which help to push up the diaphragm.

Control of respiration
Coordinated respiratory movements result from rhythmic discharges arising in an anatomically ill-defined group of interconnected neurones in the reticular substance of the brainstem, known as the respiratory centre. Motor discharges from the respiratory centre travel via the phrenic and intercostal nerves to the respiratory musculature.

Ventilation is controlled by a combination of neurogenic and chemical factors (Fig. 28.5). In healthy individuals the main driver for respiration is the arterial pH, which is closely related to the partial pressure of carbon dioxide in arterial blood. Oxygen levels in arterial blood are usually above the level that triggers respiratory drive. Typical normal values are shown in Box 28.2.

Breathlessness on physical exertion is normal and not considered a symptom unless the level of exertion is very high, such as when walking slowly. Surveys of healthy Western populations reveal that over 20% of the general population report themselves as breathless on relatively minor exertion. Although breathlessness is a very common symptom, the sensory and neural mechanisms underlying it remain obscure. The sensation of breathlessness is derived from at least three sources:
• changes in lung volume, sensed by receptors in thoracic wall muscles signalling changes in their length
• tension developed by contracting muscles, sensed by Golgi tendon organs
• central perception of the sense of effort.

Airways of the lungs
From the trachea to the periphery, the airways decrease in size but increase in number. Overall, the cross-sectional area available for airflow increases as the total number of airways increases. The airflow rate is greatest in the trachea and slows progressively towards the periphery (since the velocity of airflow depends on the cross-sectional area). In the terminal airways, gas flow occurs solely by diffusion. The resistance to airflow is very low (0.1–0.2 kPa/L in a normal tracheobronchial tree), steadily increasing from the small to the large airways.

Airways expand as the lung volume increases. At full inspiration (total lung capacity, TLC) they are 30–40% larger in calibre than at full expiration (residual volume, RV). In chronic obstructive pulmonary disease (COPD) the small airways are narrowed but this can be partially compensated by breathing closer to TLC.

Control of airway tone
Bronchomotor tone is maintained by vagal efferent nerves and can be reduced by atropine or β-adrenoceptor agonists. Adrenoceptors on the surface of bronchial muscles respond to circulating catecholamines; there is no direct sympathetic innervation. Airway tone shows a circadian rhythm, which is greatest at 04.00 and lowest in the mid-afternoon. Tone can be increased transiently by inhaled stimuli acting on epithelial nerve endings, which trigger reflex bronchoconstriction via the vagus. These stimuli include cigarette smoke, solvents, inert dust and cold air. Airway responsiveness to these stimuli increases following respiratory tract infections, even in healthy subjects. In asthma the airways are very irritable, and as the circadian rhythm remains the same, asthmatic symptoms are usually worse in the early morning.

Airflow
Movement of air through the airways results from a difference between atmospheric pressure and the pressure in the alveoli; alveolar pressure is negative in inspiration and positive in expiration.
**Function of the respiratory system**

During quiet breathing the pleural pressure is negative throughout the breathing cycle. With vigorous expiratory efforts (e.g. cough) the pleural pressure becomes positive (up to 10 kPa). This compresses the central airways, but the smaller airways do not close off because the driving pressure for expiratory flow (alveolar pressure) is also increased.

**Flow–volume loops**

The relationship between maximal flow rates and lung volume is demonstrated by the maximal flow–volume (MFV) loop (Fig. 28.6A).

In subjects with healthy lungs, maximal flow rates are rarely achieved even during vigorous exercise. However, in patients with severe COPD, limitation of expiratory flow occurs even during tidal breathing at rest (Fig. 28.6B). To increase ventilation, these patients have to breathe at higher lung volumes and allow more time for expiration, both of which reduce the tendency for airway collapse. To compensate, they increase flow rates during inspiration, where there is relatively less flow limitation.

The volume that can be forced in from the residual volume in 1 second ($FIV_1$) will always be greater than that which can be forced out from TLC in 1 second ($FEV_1$). Thus, the ratio of $FEV_1$ to $FIV_1$ is greater than 1. This phenomenon, and the characteristic flow–volume loop, are diagnostic of extrathoracic airways obstruction (Fig. 28.6C).

**Ventilation and perfusion relationships**

For optimum gas exchange there must be a match between ventilation of the alveoli ($V$) and their perfusion ($Q$). However, in reality there is variation in the ($V/Q$) ratio in both normal and diseased lungs (Fig. 28.7). In the normal lung, both ventilation and perfusion are greater at the bases than at the apices but the gradient for perfusion is steeper, so the net effect is that ventilation exceeds perfusion towards the apices while perfusion exceeds ventilation at the bases. Other
Pulmonary disease often results from a failure of the normal host defence mechanisms of the healthy lung. These can be divided into physical, physiological, humoral and cellular mechanisms.

Alveolar stability
Pulmonary alveoli are polygonal spaces within a sponge-like matrix. Surface tension acting at the curved internal surface tends to cause the alveoli to decrease in size. The surface tension within the alveoli would make the lungs extremely difficult to distend, were it not for the presence of surfactant, which reduces surface tension so that alveoli remain stable.

Defence mechanisms of the respiratory tract
Pulmonary disease often results from a failure of the normal host defence mechanisms of the healthy lung (Fig. 28.8). These can be divided into physical, physiological, humoral and cellular mechanisms.

Physical and physiological mechanisms

Humidification
This prevents dehydration of the epithelium.
Particle removal
Over 90% of particles of more than 10 μm in diameter are removed in the nostril or nasopharynx. This includes most pollen grains, which are typically greater than 20 μm in diameter. Particles between 5 and 10 μm become impacted at the carina. Particles of less than 1 μm tend to remain airborne: thus the particles capable of reaching the deep lung are those in the 1–5 μm range.

Particle expulsion
This is facilitated by coughing, sneezing or gagging.

Respiratory tract secretions
The mucus of the respiratory tract is a gelatinous substance consisting of water and highly glycosylated proteins (mucins). The mucus forms a thick gel that is relatively impermeable to water and floats on a liquid or sol layer found around the cilia of the epithelial cells (see Fig. 28.8). The gel layer is secreted from goblet cells and mucus glands as distinct gobules that coalesce increasingly in the central airways to form a more or less continuous mucus blanket. In addition to the mucins, the gel contains various antimicrobial molecules (lysozyme, defensins), specific antibodies (IgA) and cytokines, which are secreted by cells in airways and are incorporated into the mucus gel. Bacteria, viruses and other particles become trapped in the mucus and are either inactivated or simply expelled before they can do any damage. Under normal conditions the tips of the cilia engage with the undersurface of the gel phase and by coordinated movement they push the mucus blanket upwards and outwards to the pharynx, where it is either swallowed or coughed up. One of the major long-term effects of cigarette smoking is a reduction in mucociliary transport. This contributes to recurrent infection and prolongs contact with carcinogenic material. Air pollutants, local and general anaesthetics, and products of bacterial and viral infection also reduce mucociliary clearance.

Humoral and cellular mechanisms
Non-specific soluble factors
- **Alpha-antitrypsin** (α1-antiprotease, see p. 1302) in lung secretions is derived from plasma. It inhibits chymotrypsin and trypsin, and neutralizes proteases, including neutrophil elastase.

- **Antioxidant defences** include enzymes such as superoxide dismutase and low-molecular-weight antioxidant molecules (ascorbate, urate) in the epithelial lining fluid.

- **Lysozyme** is an enzyme found in granulocytes that has bactericidal properties.

**Congenital defects in mucociliary transport** (cystic fibrosis and immotile cilia syndrome) lead to recurrent infections and eventually to bronchiectasis.

**Function of the respiratory system**

**Fig. 28.7** Relationships between ventilation and perfusion: the alveolar–capillary interface. The centre (b) shows normal ventilation and perfusion. On the left (a) there is a block in perfusion (physiological deadspace), while on the right (c) there is reduced ventilation (physiological shunting). COPD, chronic obstructive pulmonary disease.

**Fig. 28.8** Defence mechanisms present at the epithelial surface.
936  Respiratory disease

- **Lactoferrin** is synthesized from epithelial cells and neutrophil granulocytes, and has bactericidal properties.

- **Interferons** are produced by most cells in response to viral infection and are potent modulators of lymphocyte function.

- **Complement** in secretions is also derived from plasma. In association with antibodies, it plays a major role in cytotoxicity.

- **Surfactant protein A** (SPA) is one of four species of surfactant protein that opsonize bacteria or particles, enhancing phagocytosis by macrophages.

- **Defensins** are bactericidal peptides present in the azurophil granules of neutrophils.

- **Dimeric secretory IgA** targets specific antigens (see p. 1155).

### Innate and adaptive immunity

These mechanisms act as a defence against microbes, inorganic substances such as asbestos, particulate matter such as dust, and other antigens. They aid opsonization so that macrophages can better ingest foreign material.

With infection, neutrophils migrate out of pulmonary capillaries into the air spaces and phagocytose and kill microbes with, for example, antimicrobial proteins (lactoferrin), degradative enzymes (elastase) and oxidant radicals. In addition, neutrophil extracellular traps ensnare and kill extracellular bacteria. Neutrophils also generate a variety of mediators, such as tumour necrosis factor alpha (TNF-α), interleukin 1 (IL-1), and chemokines that attract further inflammatory cells that assist with adaptive immunity.

Microbes are detected by host cells by pattern recognition receptors, such as toll-like receptors. These act via nuclear factor kappa B (NF-κB) transcription factors in the epithelial cells to produce adhesion molecules, chemokines and colony stimulating factors to initiate inflammation. Inflammation is necessary for innate immunity and host defence but can lead to lung damage; there is a fine line between defence and injury.

### Further reading

### Sputum

Approximately 100 mL of mucus is produced daily in a healthy, non-smoking individual. This flows gradually up the airways, through the larynx, and is then swallowed. Excess mucus is expectorated as sputum. Cigarette smoking is the most common cause of excess mucus production.

Mucoid sputum is clear and white but can contain black specks resulting from the inhalation of carbon. Yellow or green sputum is due to the presence of cellular material, including bronchial epithelial cells, or neutrophil or eosinophil granulocytes. Yellow sputum is not necessarily due to infection, since granulocytes in the sputum, as seen in asthma, can give the same appearance. The production of large quantities of yellow or green sputum is characteristic of bronchiectasis.

### Haemoptysis

Haemoptysis (blood-stained sputum) varies from small streaks of blood to massive bleeding. The most common cause of mild haemoptysis is acute infection (Box 28.3), particularly in exacerbations of COPD, but this should not be assumed without investigation. Other common causes are pulmonary infarction (e.g. secondary to pulmonary embolism), bronchial carcinoma and tuberculosis. Pink, frothy sputum is seen in pulmonary oedema, while in bronchiectasis the blood is often mixed with purulent sputum. Massive haemoptysis (>200 mL of blood in 24 h) is usually due to bronchiectasis or tuberculosis, but can also be caused in later stages of lung cancer.

Although a diagnosis can often be made from a chest X-ray (e.g. bronchiectasis, tuberculosis), a normal chest X-ray does not exclude serious disease. However, if the chest X-ray is normal, CT scanning and bronchoscopy are diagnostic in only about 5% of patients with haemoptysis.

### Box 28.3 Causes of haemoptysis

- Malignancy and benign lung tumours, including lung metastasis
- Pulmonary infection, including bacterial pneumonia, tuberculosis, lung abscesses and fungal infection
- Bronchiectasis, including cystic fibrosis
- Pulmonary emboli
- Congestive heart failure
- Pulmonary fibrosis
- Pulmonary vasculitis, e.g. Goodpasture’s syndrome, microscopic polyangiitis
- Severe pulmonary hypertension
- Arteriovenous malformation
- Chest trauma and foreign bodies
- Endometriosis
- Anticoagulation, coagulopathy
- Drugs, e.g. cocaine, thrombolytics

---

**Clinical features of respiratory disease**

### Runny, blocked nose and sneezing

Nasal symptoms are extremely common; ‘runny nose’ (rhinorhoea), nasal blockage and attacks of sneezing can be caused by allergic rhinitis (see p. 945) and by common colds (p. 945). Nasal secretions are usually thin and runny in allergic rhinitis but thicker and discoloured with viral infections. Nose bleeds and blood-stained nasal discharge are common and rarely indicate serious pathology. However, a blood-stained nasal discharge associated with nasal obstruction and pain may be the presenting feature of a nasal tumour (see p. 908). Nasal polyps typically present with nasal blockage and loss of smell.

### Cough

Cough (see also p. 908) is the most common symptom of lower respiratory tract disease. It is caused by mechanical or chemical stimulation of cough receptors in the epithelium of the pharynx, larynx, trachea, bronchi and diaphragm. Afferent receptors go to the cough centre in the medulla, where efferent signals are generated to the expiratory musculature. Smokers often have a morning cough with a little sputum. A productive cough is the cardinal feature of chronic bronchitis, while dry coughing, particularly at night, can be a symptom of asthma or acid reflux. Cough also occurs in asthmatics after mild exertion or forced expiration. Cough can have no definable pathology; psychological causes may be blamed but there is only limited evidence.

A worsening cough is the most common presenting symptom of lung cancer. The normal explosive character of the cough is lost when a vocal cord is paralysed, usually as a result of lung cancer infiltrating the left recurrent laryngeal nerve. Cough can be accompanied by stridor in whooping cough or in laryngeal or tracheal obstruction.

**CLINICAL APPROACH TO THE PATIENT WITH RESPIRATORY DISEASE**

---

### Clinical features of respiratory disease
Breathlessness

Dyspnoea (breathlessness) is a sense of awareness of increased respiratory effort that is unpleasant and recognized by the patient as inappropriate. Patients often complain of tightness in the chest; this must be differentiated from angina (Box 28.4). The degree of breathlessness should be assessed in relation to the patient’s lifestyle. For example, a moderate degree of breathlessness will be totally disabling if the patient has to climb many flights of stairs to reach home. Breathlessness can be graded using the Medical Research Council grading of dyspnoea (Box 28.5).

Orthopnoea (see p. 1028) is breathlessness on lying down. While it is classically linked to heart failure, it is partly due to the weight of the abdominal contents pushing the diaphragm up into the thorax. Such patients may also become breathless on bending over.

Tachypnoea and hyperpnoea are, respectively, an increased rate of breathing and an increased level of ventilation. These may be appropriate responses (e.g. during exercise).

Hyperventilation is inappropriate overbreathing. This may occur at rest or on exertion, and results in a lowering of the alveolar and arterial CO₂ (see Box 25.33).

Paroxysmal nocturnal dyspnoea (see p. 1028) describes acute episodes of breathlessness at night, typically due to heart failure.

Wheeze

Wheeze is a common complaint and results from airflow limitation due to any cause. The symptom of wheezing is not diagnostic of asthma; other causes include vocal cord dysfunction, bronchiolitis and COPD. Conversely, wheeze may be absent in the early stages of asthma.

Cystic Fibrosis

The most common type of chest pain reported in respiratory disease is a localized sharp pain, often termed pleuritic. It is made worse by deep breathing or coughing and the patient can usually localize it. Localized anterior chest pain with tenderness of a costochondral junction is caused by costochondritis. Shoulder tip pain suggests irritation of the diaphragmatic pleura, while central chest pain radiating to the neck and arms is likely to be cardiac. Retrosternal soreness is associated with tracheitis, and malignant invasion of the chest wall causes a constant, severe, dull pain.

Examination of the respiratory system

Nose

See page 907.

Chest

Inspection

Observe the patient as they enter the room or move around the bed. Are they simply breathless at rest? Do they have a cough or are they wheezy? Assessment should be made of mental alertness, cyanosis, breathlessness at rest, use of accessory muscles, shape of the chest wall, any deformity or scars on the chest and movement on both sides. Kyphosis and scoliosis of the spine can cause asymmetry of the chest. CO₂ intoxication causes coarse tremor or flap of the outstretched hands. Prominent veins on the chest may imply obstruction of the superior vena cava. The patient’s face may reveal signs of anaemia, or there may be a Horner’s syndrome due to a Pancoast tumour.

Respiratory rate and rhythm may be altered; the normal respiratory rate is 14–16 breaths per minute. Tachypnoea is an increased respiratory rate. Apnoea is the absence of breathing; some patients have episodes of apnoea during sleep.

Hands should be inspected for evidence of tobacco staining on the fingers, clubbing or a fine tremor (Box 28.6).

Cyanosis (see p. 1030) is a dusky discolouration of the skin and mucous membranes, due to the presence of more than 50 g/L of desaturated haemoglobin. When it has a central cause, cyanosis is visible on the tongue (especially the underside) and lips. Patients with central cyanosis will also be cyanosed peripherally. Peripheral cyanosis without central cyanosis is caused by a reduced peripheral circulation and is noted on the fingernails and skin of the extremities, with associated coolness of the skin.

Finger clubbing is present when the normal angle between the base of the nail and the nail fold is lost (Fig. 28.9). The base of the nail is fluctuant owing to increased vascularity, and there is an increased curvature of the nail in all directions, with expansion of the end of the digit. Some causes of clubbing are given in Box 28.7. Clubbing is not a feature of uncomplicated COPD.

Palpation and percussion

The position of the trachea and apex beat should be checked. The supraclavicular fossa, cervical chains and axilla are examined for enlarged lymph nodes. The distance between the sternal notch and...
In rib fractures, compression of the chest laterally and anteroposteriorly produces localized pain. On percussion, liver dullness is usually detected anteriorly at the level of the sixth rib. Liver and cardiac dullness disappear when the lungs are over-inflated (Box 28.8).

**Auscultation**

The patient is asked to take deep breaths through the mouth. Inspiration should be more prolonged than expiration. Normal breath sounds are caused by turbulent flow in the larynx and sound harsher anteriorly over the upper lobes (particularly on the right). Healthy lungs filter out most of the high-frequency component, and the resulting sounds are called vesicular.

If the lung is consolidated or collapsed, the high-frequency hissing components of breath are not attenuated and can be heard as ‘bronchial breathing’. Similar sounds may be heard over areas of localized fibrosis or bronchiectasis. Bronchial breathing is accompanied by whispering pectoriloquy (whispered, high-pitched sounds can be heard distinctly through a stethoscope).

**Added sounds**

**Wheeze.** Wheeze results from vibrations in the collapsible part of the airways when the large and medium-sized bronchi become constricted. It is usually heard during expiration and is common, but not invariably, present in asthma and COPD. In acute severe asthma, wheeze may not be heard, as airflow may be insufficient to generate the sound. Wheezes may be monophonic (single large airway obstruction) or polyphonic (narrowing of many small airways). An end-inspiratory wheeze or ‘squeak’ may be heard in obliterative bronchiolitis.

**Crackles.** These brief crackling sounds are probably produced by opening of previously closed bronchioles; early inspiratory crackles are associated with diffuse airflow limitation, while late inspiratory crackles are characteristically heard in pulmonary oedema, lung fibrosis and bronchiectasis.

**Pleural rub.** This creaking or groaning sound is usually well localized (said to sound like a foot crunching through fresh-fallen snow). It indicates inflammation and roughening of the pleural surfaces, which normally glide silently over one another, and is heard in association with lung infections and consolidation.

**Box 28.7 Some causes of finger clubbing**

**Respiratory**
- Bronchial carcinoma, including hypertrophic pulmonary osteoarthropathy
- Chronic suppurative lung disease:
  - Bronchiectasis
  - Lung abscess
  - Empyema
- Idiopathic lung fibrosis
- Pleural and mediastinal tumours (e.g. mesothelioma)
- Cryptogenic organizing pneumonia

**Cardiovascular**
- Cyanotic heart disease
- Subacute infective endocarditis
- Atrial myxoma

**Miscellaneous**
- Congenital – no disease
- Cirrhosis
- Inflammatory bowel disease
- Thyroid acropachy

Clinical Approach to the Patient with Respiratory Disease

Box 28.9 The chest X-ray

Check

- **Centring of the image.** The distance between each clavicular head and the spinal processes should be equal.
- **Penetration.** Make sure the image is not too dark and adjust the contrast.
- **View:**
  - **Postero-anterior (PA) views** are used for routine images; the X-ray source is behind the patient.
  - **Anteroposterior (AP) views** are used only in patients who are unable to stand or cannot be taken to the radiology department; the cardiac outline appears bigger and the scapulae cannot be moved out of the way.
  - **Lateral views** were used to localize pathology but have been replaced by CT scans.

Look at

- Shape and bony structure of the chest wall
- Centrality of the trachea
- Elevation/flatness of the diaphragm
- Shape, size and position of the heart
- Shape and size of the hilar shadows
- Shape and size of any lung abnormalities
- Vascular shadowing

**Vocal resonance.** Healthy lung attenuates high-frequency notes, as compared to the lower-pitched components of speech. Consolidated lung has the reverse effect, transmitting high frequencies well; the spoken word then takes on a bleating quality. Whispered (and therefore high-pitched) speech can be clearly heard over consolidated areas, as compared to healthy lung. Low-frequency sounds such as “ninety-nine” are well transmitted across healthy lung to produce vibration that can be felt over the chest wall. Consolidated lung transmits these low-frequency noises less well, and pleural fluid severely dampens or obliterates the vibrations altogether. Tactile vocal fremitus is the palpation of this vibration, usually by placing the edge of the hand on the chest wall. For all practical purposes, this duplicates the assessment of vocal resonance and is not routinely performed as part of the chest examination.

Cardiovascular system examination

This gives additional information about the lungs (see p. 1029).

Additional bedside tests

Review the patient’s observation chart, particularly oxygen saturations and the concentration of additional oxygen that the patient may be receiving. Inspect any sputum pots. Since so many patients with respiratory disease have airflow limitation, airflow should be routinely measured using a peak flow meter or spirometer. This is a much more useful assessment of airflow limitation than any physical sign.

Investigation of respiratory disease

Imaging

Imaging is essential in the investigation of most chest symptoms. Some diseases, such as tuberculosis or lung cancer, may be undetectable on clinical examination but may be obvious on the chest X-ray. Conversely, asthma or chronic bronchitis may be associated with a normal chest X-ray. Always try to obtain previous images for comparison.

Chest X-ray

See Box 28.9 and Fig. 28.1.

Box 28.10 Causes of lung collapse

- Enlarged tracheobronchial lymph nodes due to malignant disease or tuberculosis
- Inhaled foreign bodies (e.g. peanuts) in children, usually in the right main bronchus
- Bronchial casts or plugs (e.g. allergic bronchopulmonary aspergillosis)
- Retained secretions postoperatively and in debilitated patients

Collapse and consolidation

Simple pneumonia is easy to recognize (see Fig. 28.28) but a careful search should be made for any evidence of collapse (Fig. 28.10 and Box 28.10). Loss of volume or crowding of the ribs is the best indicator of lobar collapse. The lung lobes collapse in characteristic directions:

- The lower lobes collapse downwards and towards the mediastinum.
- The left upper lobe collapses forwards against the anterior chest wall.
- The right upper lobe collapses upwards and inwards, giving the appearance of an arch over the remaining lung.
- The right middle lobe collapses anteriorly and inwards, obscuring the right heart border.
- If a whole lung collapses, the mediastinum will shift towards the side of the collapse.

Uncomplicated consolidation does not cause mediastinal shift or loss of lung volume, and so any of these features should raise the suspicion of an endobronchial obstruction.

Pleural effusion

Pleural effusions (see Fig. 28.31) need to be larger than 500mL to cause much more than blunting of the costophrenic angle. On an erect film, they produce a characteristic shadow with a curved upper edge rising into the axilla. If they are very large, the whole of one hemithorax may be opaque, with mediastinal shift away from the effusion.
Fibrosis
Localized fibrosis produces streaky shadowing, and the accompanying loss of lung volume causes mediastinal structures to move to the same side. More generalized fibrosis can lead to a honeycomb appearance (see p. 988), seen as diffuse shadows containing multiple circular translucencies a few millimetres in diameter.

Round shadows
Lung cancer is the most common cause of large round shadows but many other aetiologies are recognized (Box 28.11).

Miliary mottling
This term, derived from the Latin for millet, describes numerous minute opacities, 1–3 mm in size. The most common causes are tuberculosis, pneumoconiosis, sarcoidosis, idiopathic pulmonary fibrosis and pulmonary oedema (see Fig. 30.15), although pulmonary oedema is usually perihilar and accompanied by larger, fluffy shadows. Pulmonary microlithiasis is a rare but striking cause of miliary mottling.

Computed tomography
Computed tomography (CT) provides excellent images of the lungs and mediastinal structures (Fig. 28.11). It is essential in staging bronchial carcinoma by demonstrating tumour size, nodal involvement, metastases and invasion of mediastinum, pleura or chest wall. CT-guided needle biopsy allows samples to be obtained from peripheral masses. Staging scans should assess liver and adrenals, which are common sites for metastatic disease. Mediastinal structures are shown more clearly after injecting intravenous contrast medium.

High-resolution CT (HRCT) samples lung parenchyma with 1–2 mm thickness scans at 10–20 mm intervals and is used to assess diffuse inflammatory and infective parenchymal processes. HRCT scanning does not require any intravenous contrast. It is valuable in:
- evaluation of diffuse disease of the lung parenchyma, including sarcoidosis, hypersensitivity pneumonitis, occupational lung disease and any other form of interstitial pulmonary fibrosis
- diagnosis of bronchiectasis, having a sensitivity and specificity of >90%
- distinction of emphysema from diffuse parenchymal lung disease or pulmonary vascular disease as a cause of a low gas transfer factor with otherwise normal lung function
- suspected opportunistic lung infection in immunocompromised patients
- diagnosis of lymphangitis carcinomatosa.

Multi-slice CT scanners can produce detailed images in two or three dimensions in any plane. This detail is particularly useful for the detection of pulmonary emboli. Pulmonary nodules and airway disease are more easily defined, reducing the need for HRCT.

CT pulmonary angiography (CTPA) is used to investigate for pulmonary embolism and enables visualization of the pulmonary
arteries. Contrast is injected and images are taken in timed fashion, so that the contrast agent is in the pulmonary circulation.

**Magnetic resonance imaging**

Magnetic resonance imaging (MRI) with electrocardiography (ECG) gating allows accurate imaging of the heart and aortic aneurysms. MRI has been used in staging lung cancer and assessing tumour invasion in the mediastinum and chest wall and at the lung apex because it produces good images in the sagittal and coronal planes. Vascular structures can be clearly differentiated, as flowing blood produces a signal void on MRI. Traditionally, MRI has been less useful than CT in parenchymal lung disease; however, it may have a place in interstitial lung disease assessment in the future.

**PET-CT** combines a CT scan and positron emission tomography. Positron-emitting isotopes such as $^{18}$fluorodeoxyglucose ($^{18}$FDG) are used as contrast and are taken up rapidly by metabolically active tissue such as lung cancers. PET imaging is used for lung cancer staging prior to curative treatment such as surgery or radiotherapy. FDG-PET can also be useful in determining an appropriate site for a biopsy and can often assist with differentiating benign from malignant tumours; however, inflammatory lesions may also be FDG-avid.

**Scintigraphic imaging**

Isotopic lung scans were widely used for the detection of pulmonary emboli but are now performed less often, owing to the widespread use of CTPA. They are discussed in more detail on page 1005.

**Ultrasound**

Two-dimensional transthoracic ultrasound is a technique used for assessing a pleural effusion. Ultrasound confirms the presence of pleural fluid and provides details about the nature of the effusion, such as whether it is a simple pleural effusion (single collection), heavily loculated with adhesions or organized (more gelatinous). Ultrasound assists in determining the best site for aspiration and it is recommended that any invasive pleural procedure, such as pleural aspiration and intercostal chest drain placement, is performed with ultrasound screening. Ultrasound-guided biopsy is used for lung masses that abut the pleura or pleural masses, if appropriate. It is also used in bronchoscopy (endobronchial ultrasound, EBUS) to stage and sample mediastinal lymph nodes (see p. 944).

**Respiratory function tests**

In clinical practice, airflow limitation can be assessed by relatively simple tests that have good intra-subject repeatability (Box 28.12). Results must be compared with predicted values for healthy subjects, as normal ranges vary with sex, age, height and ethnic group. Moreover, there is considerable variation between healthy individuals of the same size and age; the standard deviation for the PEFR is approximately 50L/min, and for the FEV$_1$ approximately 0.4L. Repeated measurements of lung function are useful for assessing the progression of disease in individual patients.

**Tests of ventilatory function**

These tests are used mainly to assess the degree of airflow limitation during expiration.

**Spirometry**

The patient takes a maximum inspiration followed by a forced expiration (for as long as possible) into the spirometer. The spirometer measures the 1-second forced expiratory volume (FEV$_1$) and the total volume of exhaled gas (forced vital capacity, FVC). Both FEV$_1$ and FVC are related to height, age, sex and ethnicity, and help to differentiate between an obstructive and a restrictive pattern of respiratory compromise (Fig. 28.12; Box 28.13).

In chronic airflow limitation (particularly COPD and asthma), the total lung capacity (TLC) is usually increased, yet there is nearly always some reduction in the FVC. This is because collapse of small

CT, computed tomography; FEV, forced expiratory volume; FEV$_1$, forced expiratory volume in 1 sec; FVC, forced vital capacity; PEFR, peak expiratory flow rate.
airways causes obstruction to airflow before the normal residual volume (RV) is reached. This trapping of air within the lung is a characteristic feature of these diseases.

**Peak expiratory flow rate**

Peak expiratory flow rate (PEFR) is an extremely simple and cheap test. Subjects take a full inspiration to total lung capacity and then blow out forcefully into the peak flow meter (Fig. 28.13). The best of three attempts is recorded.

Although reproducible, PEFR is mainly dependent on the flow rate in larger airways and it may be falsely reassuring in patients with moderate airflow limitation. PEFR is mainly used to diagnose asthma, and to monitor exacerbations of asthma and response to treatment. Regular measurements of peak flow rates on waking, during the afternoon and before going to bed demonstrate the wide diurnal variations in airflow limitation that characterize asthma and allow objective assessment of response to treatment (Fig. 28.14).

**Other ventilatory function tests**

Measurement of airways resistance in a body box (plethysmograph) is more sensitive but the equipment is expensive and the necessary manoeuvres are too exhausting for many patients with chronic airflow limitation.

**Flow–volume loops**

Plotting flow rates against expired volume (flow–volume loops, see Fig. 28.6) shows the site of airflow limitation within the lung. At the start of expiration from TLC, maximum resistance is from the large airways, and this affects the flow rate for the first 25% of the curve. As air is exhaled, lung volume reduces and the flow rate becomes dependent on the resistance of smaller airways. In COPD, which mainly affects the smaller airways, expiratory flow rates at 50% or 25% of the vital capacity are disproportionately reduced when compared with flow rates at larger lung volumes. Flow–volume loops also show obstruction of large airways: for example, tracheal narrowing due to tumour or retrosternal goitre.

**Box 28.13 FEV₁/FVC ratio**

- **Normal**: approximately 75%
- **Airflow obstruction**: reduced
- **Restriction**: normal or increased

FEV₁, forced expiratory volume in 1 sec; FVC, forced vital capacity.
Lung volumes
The subdivisions of lung volume are shown in Fig. 28.15. Tidal volume and vital capacity can be measured using a simple spirometer but alternative techniques are needed to measure TLC and RV. TLC is measured by inhaling air containing a known concentration of helium and measuring its dilution in the exhaled air. RV can be calculated by subtracting the vital capacity from the TLC.

TLC measurements using this technique are inaccurate if there are large cystic spaces in the lung because helium cannot diffuse into them. Under these circumstances the thoracic gas volume can be measured more accurately using a body plethysmograph (see earlier). The difference between measurements made by these two methods shows the extent of non-communicating air space within the lungs.

Transfer factor
In normal lungs the transfer factor accurately reflects how efficiently oxygen diffuses from alveolar air into blood, and depends on the thickness of the alveolar–capillary membrane. In lung disease the diffusing capacity \((D_{CO})\) is also affected by the ventilation–perfusion relationship. Carbon monoxide is used as a surrogate marker to measure this, as it has a similar diffusion rate to oxygen. A low concentration of carbon monoxide is inhaled and the rate of absorption calculated. To control for differences in lung volume, the uptake of carbon monoxide is expressed relative to lung volume as a transfer coefficient \((K_{CO})\). Gas transfer is reduced in patients with severe degrees of emphysema and fibrosis, but also in heart failure and anaemia. Although relatively non-specific, gas transfer is particularly useful in the detection and monitoring of diseases affecting the lung parenchyma (e.g. idiopathic pulmonary fibrosis, sarcoidosis and asbestosis). The \(K_{CO}\) is raised in pulmonary haemorrhage.

Peripheral oxygen saturation \((S_{a}O_{2})\) can be continuously measured using an oximeter with either ear or finger probes. Pulse oximetry has become an essential part of the routine monitoring of patients in hospital and clinics. It is also useful in exercise testing and reduces the need to measure arterial blood gases.

Measurement of blood gases
This technique is described on page 225, where a guide to interpreting blood gas analyses is provided.

Measurement of the partial pressures of oxygen and carbon dioxide in arterial blood is essential in managing respiratory failure, when repeated measurements are often the best guide to therapy.

Exhaled nitric oxide
Nitric oxide (NO) is produced by the bronchial epithelium and increases in asthma and other forms of airway inflammation. Measuring exhaled NO can guide therapy in asthma that is difficult to control (see p. 951).

Six-minute walk test
In this validated test the distance walked in metres is recorded over a period of 6 minutes. The oxygen saturations, pulse rate and distance are measured.

Cardiopulmonary exercise testing
This provides a functional assessment of cardiopulmonary reserve and provides information about cardiorespiratory and metabolic muscle function. It is usually performed on a treadmill or a cycle ergometer. Oxygen consumption, carbon dioxide production and ventilation can be calculated.

Indications include the investigation of unexplained breathlessness, establishing prognosis in respiratory illnesses and predicting risk in perioperative assessment.

Nocturnal polygraphy
This multichannel sleep study records pulse, oxygen saturation, nasal flow, body position, and thoracic and abdominal wall movements. It is useful in the investigation of sleep-disordered breathing.

Haematological and biochemical tests
It is useful to measure:

- **haemoglobin**: to detect anaemia or polycythaemia
- **packed cell volume**: as secondary polycythaemia occurs with chronic hypoxia
- **routine biochemistry**: often disturbed in lung cancer and infection
- **D-dimer**: to detect intravascular coagulation; a negative test makes pulmonary embolism very unlikely.

Other blood investigations sometimes required include \(\alpha_{1}\)-antitrypsin levels, *Aspergillus* antibodies, viral and mycoplasma serology, autoantibody profiles and specific IgE measurements.

Sputum
Sputum should be inspected for colour:

- Yellowish green indicates inflammation (infection or allergy).
- Blood suggests bronchiectasis, lung cancer (see p. 976) or pulmonary infarction.
Microbiological studies (e.g. Gram stain and culture) are rarely helpful in upper respiratory tract infections or in acute or chronic bronchitis. Conversely, they are of value in:

- pneumonia
- tuberculosis (a specific request to test for acid-fast bacilli (AFB) is required)
- bronchiectasis.

**Sputum cytology**

This may be an adjunct in the management of asthma but is more often used in research studies. Its advantages are its speed, cheapness and non-invasive nature. A reliable cytologist is needed. Sputum can be induced by inhalation of nebulized hypertonic saline (5%). Better samples can be obtained by bronchoscopy and bronchial washings (see later).

**Pleural aspiration**

Diagnostic aspiration may be necessary to determine the aetiology of a pleural effusion, especially if unilateral. This is usually done under ultrasound guidance, using full aseptic precautions. A needle is inserted under local anaesthesia through an intercostal space towards the top of the area identified on ultrasound. Fluid is withdrawn and the presence of any blood is noted. Samples are sent for cytology and biochemical analysis (protein estimation, lactate dehydrogenase (LDH) and bacteriological examination, including culture and Ziehl–Neelsen/auramine staining for tuberculosis). A therapeutic aspiration can be performed in the context of a large pleural effusion to help relieve extreme breathlessness.

**Pleural biopsy**

A pleural biopsy may be a necessary part of the investigation of a unilateral exudative pleural effusion or suspicious pleural thickening. Pleural biopsies may be obtained with CT or ultrasound guidance. An alternative means by which to obtain a pleural biopsy is video-assisted thoracoscopy (VATS). A scope is introduced into the pleural space, allowing direct visualization and biopsy of the parietal pleura. A pleural effusion can be drained during this procedure.

**Intercostal drain placement**

An intercostal chest drain is an indwelling drain that is placed in the pleural space using ultrasound guidance (Box 28.14). It is connected to an underwater seal bottle. Circumstances in which a chest drain is placed include:

- pneumothorax
- large pleural effusion
- empyema.

Occasionally, a long-term pleural drain may be needed for recurrent effusions.

**Fibreoptic bronchoscopy**

This endoscopic procedure allows direct visualization of the endobronchial tree down to the subsegmental level (Fig. 28.16). The procedure is performed under local anaesthesia and sedation.

Indications for bronchoscopy (Box 28.15) are:

- **Visualization and biopsy of an endobronchial lesion** (suspected malignancy). An endobronchial biopsy may be taken.
- **Collapsed lung or lobe**. Bronchoscopy is performed to determine the nature of the obstruction. Possible causes include an aspirated foreign body, a mucus plug (these may be removed during the bronchoscopy by suction, or by using forceps or a dormier basket) or endobronchial tumour (which may be biop-sied). Airway patency may be restored by cryotherapy or laser therapy, and may be maintained if it is possible to place a stent.
- **Microbiological sampling** in the context of unresolved infection or suspected tuberculosis. More distal lesions may be sampled by washing or blind brushing.
- **Diagnosis of diffuse inflammatory and infective lung processes** by bronchoalveolar lavage and transbronchial biopsy. The yield is best in sarcoidosis, lymphangitis carcinomatosa and hypersensitivity pneumonitis. Other fibrotic lung diseases rarely yield diagnostic samples and so it may be preferable to perform open or thoracoscopic lung biopsy.
- **Performance of EBUS** under local anaesthetic and sedation. A dedicated scope is used with an ultrasound probe at the distal end, which allows detailed visualization of the mediastinal nodes. The lymph nodes can be aspirated and samples sent for cytological and microbiological examination. EBUS is performed when CT imaging shows enlarged mediastinal lymph nodes, for which the differential diagnosis includes

---

**Box 28.14 Intercostal drainage**

Explain the nature of the procedure to the patient and obtain written consent.

**Technique**

1. Identify the site for aspiration (using ultrasound in most cases).
2. Carefully sterilize the skin over the aspiration site.
3. Anaesthetize the skin, muscle and pleura with 2% lidocaine.
4. Make a small incision and insert an 8–12 French gauge drain, using the Seldinger technique. A needle is used to enter the pleural space and then withdrawn over a guidewire, over which the catheter is inserted. (A larger-calibre catheter is needed for drainage of empyema, or a 28 French gauge Argyle catheter.)
5. Attach to a three-way tap and 50 mL syringe, and aspirate up to 1000 mL. Stop aspiration if the patient becomes uncomfortable; shock may ensue if too much fluid is withdrawn too quickly.
6. If the drain is to stay in, secure it to skin with suture and sterile dressing.
7. Attach the drain to an underwater seal drainage bottle and allow fluid to drain. Clamp the drain and release periodically, especially if patient becomes uncomfortable (usually up to 1000 mL at a time before clamping for a few hours).
8. Perform a chest X-ray to check the position of the drain.

**Pleuradesis**

1. Instil lidocaine 3 mg/kg and then talc 4–5 g in 50 mL sodium chloride 0.9% solution into the pleural cavity to achieve pleurodesis in recurrent/malignant effusion.

---

**Fig. 28.16 Normal endobronchial appearances as seen at fibre-optic bronchoscopy.**
Diseases of the Upper Respiratory Tract

Box 28.15 Fibreoptic bronchoscopy

Informed written consent is obtained after the nature of the procedure is explained.

**Indications**
- Lesions requiring biopsy seen on chest X-ray
- Haemoptysis
- Stridor
- Positive sputum cytology for malignant cells with no chest X-ray abnormality
- Collection of bronchial secretions for bacteriology, especially tuberculosis
- Recurrent laryngeal nerve paralysis of unknown aetiology
- Infiltrative lung disease (to obtain a transbronchial biopsy)
- Investigation of collapsed lobes or segments and aspiration of mucus plugs

**Disadvantages**
- All patients require sedation to tolerate the procedure
- Minor and transient cardiac dyshrhythmias occur in up to 40% of patients on passage of the bronchoscope through the larynx. Monitoring is required
- Oxygen supplementation is required in patients with $P_{O_2} < 8kPa$
- Fibreoptic bronchoscopy should be performed with care in the very sick, and transbronchial biopsies avoided in ventilated patients owing to the increased risk of pneumothorax
- Massive bleeding may occur after biopsy of vascular lesions or carcinoid tumours. Rigid bronchoscopy may be required to allow adequate access to the bleeding point for haemostasis

Rhinitis

Rhinitis is defined clinically as sneezing attacks, nasal discharge or blockage occurring for more than an hour on most days.

The common cold (acute coryza)

This highly infectious illness (see p. 519) is caused by a variety of respiratory viruses: for example, the rhinoviruses (most common), coronaviruses and adenoviruses. Infectivity from close personal contact (nasal mucus on hands) or droplets is high in the early stages of the infection. There are at least 100 different antigenic strains of rhinovirus, making it difficult for the immune system to confer protection. The incubation period varies from 12 hours to 5 days.

The clinical features are tiredness, slight pyrexia, malaise, and a sore nose and pharynx. Sneezing and profuse, watery nasal discharge are followed by thick mucopurulent secretions that may persist for up to a week. Secondary bacterial infection occurs in only a minority of cases.

Other forms of rhinitis

Rhinitis can be subdivided by the frequency with which symptoms occur:
- for a limited period of the year (seasonal or intermittent rhinitis)
- throughout the whole year (perennial or persistent rhinitis).

Seasonal rhinitis (intermittent)

This is the most common allergic disorder. It is often called ‘hay-fever’, but as this implies that only grass pollen is responsible it is better described as seasonal (or intermittent) allergic rhinitis. Worldwide prevalence varies from 2% to 20%. Prevalence is maximal in the second decade, and up to 30% of UK teenagers and young adults are affected each June and July.

Nasal irritation, sneezing and watery rhinorrhoea occur, but many also suffer from itching of the eyes and soft palate, and occasionally even itching of the ears because of the common innervation of the pharyngeal mucosa and the ear. In addition, approximately 20% suffer from seasonal wheezing. Common seasonal allergens include tree and grass pollens and mould spores.

Since the pollination patterns of plants that give rise to high pollen counts vary from country to country, seasonal rhinoconjunctivitis and accompanying wheeze may occur at different times of year in different regions.

Perennial rhinitis (persistent)

In about 50% of patients with perennial rhinitis, symptoms of sneezing and watery rhinorrhoea predominate, while the other
50% complain mostly of nasal blockage. The patient may lose the senses of smell and taste but rarely has eye or throat symptoms. Sinusitis occurs in about 50% of cases, due to mucosal swelling that obstructs drainage from the sinuses. Perennial rhinitis is most frequent in the second and third decades, decreasing with age, and can be divided into four main types.

**Perennial allergic rhinitis**

The most common cause is allergy to the faecal particles of the house-dust mite, *Dermatophagoides pteronyssinus* or *D. farinae*, which may be found in dust throughout the house (Fig. 28.17). Mites live off desquamated human skin scales and the highest concentrations (4000 mites/g of surface dust) are found in human bedding. The next most common allergens come from domestic pets (especially cats) and are proteins derived from urine or saliva spread over the surface of the animal, as well as skin protein. Allergy to urinary protein from small mammals is a major cause of morbidity among laboratory workers. Industrial dust, vapours and fumes cause occupationally related perennial rhinitis more often than asthma.

The presence of perennial rhinitis makes the nose more reactive to non-specific stimuli, such as cigarette smoke, washing powders, household detergents, strong perfumes and traffic fumes. Although patients often think they are allergic to these stimuli, these are irritant responses and do not involve antibodies.

**Perennial non-allergic rhinitis with eosinophilia**

No extrinsic allergic cause can be identified, either on taking a history or testing the skin, but eosinophilic granulocytes are present in nasal secretions. Most of these patients are intolerant of aspirin/non-steroidal anti-inflammatory drugs (NSAIDs).

**Vasomotor rhinitis**

Patients with this type of perennial rhinitis have no demonstrable allergy or nasal eosinophilia. Watery secretions and nasal congestion are triggered by, for example, cold air, smoke, perfume or newsprint, possibly because of an imbalance of the autonomic nerves controlling the erectile tissue (sinusoids) in the nasal mucosa.

**Nasal polyps**

These are round, smooth, soft, semitranslucent, pale or yellow, glistening structures attached to the sinus mucosa by a relatively narrow stalk or pedicle, occurring in patients with allergic or vasomotor rhinitis. The mechanism(s) of their formation is not known. They contain mast cells, eosinophils and mononuclear cells in large numbers and cause nasal obstruction, loss of smell and taste, and mouth breathing, but rarely sneezing, since the mucosa of the polyp is largely denervated.

**Investigations and diagnosis**

The allergic factors causing rhinitis can usually be identified from the history. Skin-prick testing is used to support the history. A positive test does not necessarily mean that an allergen causes the respiratory disease. However, if there is a compatible clinical history, it is more likely to be relevant. Allergen-specific IgE antibodies can be measured in blood but such tests are much more expensive than skin tests and should be used only in patients who cannot be skin-tested for some reason (e.g. dermatographism, active eczema or inability to stop antihistamines for 3 days before skin tests).

**Management**

**Allergen avoidance**

Removal of a household pet or total enclosure of industrial processes releasing sensitizing agents can lead to cure of rhinitis and, indeed, asthma. However, pollen avoidance is impossible. Contact may be diminished by wearing sunglasses, driving with the car windows shut, avoiding walks in the countryside (particularly in the late afternoon, when the number of pollen grains is highest at ground level) and keeping bedroom windows shut at night. These measures are rarely sufficient in themselves to control symptoms. Exposure to pollen is generally lower in coastal regions, where sea breezes carry pollen grains inland.

Exposure to mite allergen can be reduced by enclosing bedding in fabric specifically designed to prevent its passage, while allowing water vapour through. This is comfortable and also reduces symptoms. Acaricides (substances toxic to mites) are less effective and cannot be recommended. Increased room ventilation and reduced soft furnishings, including carpets, curtains and soft toys, can all help to reduce the mite load.

**H1 antihistamines**

Antihistamines remain the most common therapy for rhinitis; in the UK most can be purchased directly over the counter. They are particularly effective against sneezing and itching of the eyes and palate, but are less effective against rhinorrhoea and have little influence on nasal blockage. First-generation antihistamines (chlorphenamine, hydroxyzine) cause sedation and loss of concentration in all patients (including those who are not aware of the problem) and should no longer be used. Second-generation drugs, such as loratadine (10 mg once daily), desloratadine (5 mg daily), cetirizine (10 mg daily) and fexofenadine (120 mg daily), are at least as potent and do not cause sedation.

**Decongestants**

Drugs with sympathomimetic activity (α-adrenergic agents) are widely used to treat nasal obstruction. They may be taken orally.
or, more commonly, as nasal drops or sprays (e.g. ephedrine nasal drops). Xylometazoline and oxymetazoline are widely used because they have a prolonged action and tachyphylaxis does not develop. Secondary nasal hyperaemia can occur some hours later as a rebound effect and rhinitis medicamentosa can develop if patients take increasing quantities of decongestant to overcome this phenomenon. Although local decongestants are an effective treatment for vasomotor rhinitis, patients must be warned about rebound nasal obstruction and should use the drugs carefully. Ideally, such preparations should be prescribed for only a limited period to open the nasal airways and allow better access for other local therapy, such as topical corticosteroids.

**Anti-inflammatory drugs**

Sodium cromoglicate and nedocromil sodium act by blocking an intracellular chloride channel and influence mast cell and eosinophil activation and nerve function. Topical sodium cromoglicate and nedocromil sodium can be very effective in allergic conjunctivitis but are of limited value in allergic rhinitis.

**Corticosteroids**

The most effective treatment for rhinitis is a topical corticosteroid preparation (e.g. beclometasone, fluticasone propionate, fluticasone furoate or mometasone furoate spray). Topical steroids should be started before the beginning of seasonal symptoms. The combination of a topical corticosteroid with a non-sedating antihistamine taken regularly is particularly effective. Patients should be carefully instructed in how to use the nasal steroid device to achieve optimal drug deposition. In selected cases an α-adrenergic agonist may help to decongest the nose prior to taking the topical corticosteroid. Patients often worry about possible side-effects; nasal steroids can cause epistaxis but the amount used is insufficient to cause systemic effects.

If other therapy has failed, seasonal rhinitis and perennial rhinitis respond readily to a short course (maximum 2 weeks) of treatment with oral prednisolone 5–10 mg daily. Nasal polyps may respond to oral corticosteroids and their recurrence may be prevented by continuous use of topical corticosteroids.

**Leukotriene antagonists**

If there is no response to antihistamines or topical steroids, a leukotriene antagonist (e.g. montelukast 10 mg daily in the evening) may be helpful, especially in patients with a history of NSAID sensitivity or concomitant asthma.

**Immunotherapy**

This is used for patients with seasonal allergic rhinitis who have not responded to standard drugs. Both oral and injectable vaccines are available (see p. 63). Other forms of desensitizing vaccines are under development.

**Sinusitis**

See page 908.

**Pharyngitis**

The most common viruses causing pharyngitis are adenoviruses, of which there are about 32 serotypes. Endemic adenovirus infection causes the common sore throat, in which the oropharynx and soft palate are reddened and the tonsils are inflamed and swollen. Within 1–2 days the tonsillar lymph nodes enlarge. The disease is self-limiting and requires only symptomatic treatment without antibiotics.

Over several decades the proportion of sore throats due to bacterial infections, such as haemolytic streptococcus, has fallen. Many different pathogens have been implicated in pharyngitis but most do not require specific treatment. Persistent and severe tonsillitis should be treated with phenoxymethylpenicillin 500 mg four times daily or cefaclor 250 mg three times daily. Amoxicillin and ampicillin should be avoided if there is a possibility of infectious mononucleosis (see p. 524), as they are likely to cause drug rashes in this context.

**Acute laryngotraceobronchitis**

**Acute laryngitis** is an occasional but striking complication of upper respiratory tract infections, particularly those caused by parainfluenza viruses and measles. The condition is most severe in children under the age of 3 years. Inflammatory oedema extends to the vocal cords and the epiglottis, causing narrowing of the airway; there may be associated tracheitis or tracheobronchitis. The voice becomes hoarse, and there is a barking cough (croup) and audible stridor. Progressive airways obstruction may occur, with recession of the soft tissue of the neck and abdomen during inspiration and, in severe cases, central cyanosis. Steam inhalations are not helpful. Nebulized adrenaline (epinephrine) gives short-term relief. Oral or intramuscular corticosteroids (e.g. dexamethasone) should be given with oxygen and adequate fluids. If steroids are used, endotracheal intubation is rarely necessary. A tracheostomy is infrequently required.

**Acute epiglottitis**

*Haemophilus influenzae* type b (Hib) can cause life-threatening infection of the epiglottis, usually in children under 5 years of age. The child becomes extremely ill with a high fever, and severe airflow obstruction may rapidly occur. This is a life-threatening emergency and requires urgent endotracheal intubation and intravenous antibiotics (e.g. ceftriaxone 25–150 mg/kg). Chloramphenicol (50–100 mg/kg) is also used in some countries. The epiglottis, which is red and swollen, should not be inspected until facilities to maintain the airways are available.

Other manifestations of Hib infection are meningitis, septic arthritis and osteomyelitis. A highly effective vaccine is now available, which is given to infants at 2, 3 and 4 months with their primary immunizations against diphtheria, tetanus and pertussis (DTP). In many countries, this programme has reduced death rates from Hib infections virtually to zero.

**Influenza**

The influenza virus belongs to the orthomyxovirus group and exists in two main forms, A and B. Influenza B is associated with localized outbreaks of mild disease, whereas influenza A causes worldwide pandemics (see p. 520).

**Clinical features**

The incubation period of influenza is usually 1–3 days. The illness starts abruptly with a fever, shivering and generalized aching in the limbs. This is associated with severe headache, soreness of the throat and a dry cough that can persist for several weeks. Diarrhoea occurs in 70% of cases of H5N1 (‘bird flu’). Influenza infection can be followed by a prolonged period of debility and depression that may take weeks or months to clear.

**Complications**

Secondary bacterial infection is common following influenza virus infection, particularly with *Streptococcus pneumoniae* and *H.*
Inhalation of foreign bodies
Children inhale foreign bodies, such as peanuts, more commonly than adults do. In adults, inhalation may occur after excess alcohol or under general anaesthesia (loose teeth or dentures).

When the foreign body is large, it may impact in the trachea. The person chokes and then becomes silent; death ensues unless the material is quickly removed. Guidelines for the management of choking should rapidly be followed (Box 28.16).

More often, impaction occurs in the right main bronchus and produces choking and persistent monophonic wheeze; it may lead to a suppurative pneumonia and/or lung abscess.

Acute and chronic cough
Cough is one of the most common respiratory symptoms reported by patients. Acute cough is often defined as one that lasts less than 3 weeks and chronic cough one that persists more than 8 weeks. The ‘grey’ area in between is often termed subacute cough.

Management of acute cough
Acute cough is often associated with upper respiratory tract infection, particularly in the winter months, and tends to settle after a few weeks (Box 28.17). However, any patient who has worrying symptoms or signs, such as haemoptysis, breathlessness, fever, weight loss, night sweats, chest pain or foreign body inhalation, should undergo urgent chest X-ray to look for lung cancer, pneumonia or tuberculosis, in particular. However, most acute cough is self-limiting and antibiotics are not indicated.

Influenza. Secondary pneumonia caused by Staphylococcus aureus is rarer but more serious, and carries a mortality of up to 20%. Post-infectious encephalomyelitis is rare after influenza infection.

Diagnosis and management
Laboratory diagnosis is not usually necessary in the community, but a definitive diagnosis can be established by demonstrating a four-fold increase in complement-fixing antibody or haemagglutinin antibody measured at onset and after 1–2 weeks, or by taking nasopharyngeal swabs. Viral swabs should be taken for hospital inpatients to facilitate infection control measures.

Management is by bed rest and paracetamol, with antibiotics to prevent secondary infection in those with chronic bronchitis or cardiac or renal disease. Neuraminidase inhibitors help to shorten the duration of symptoms in patients with influenza, if given within 48 hours of the first symptom. Inpatients should be cared for in a side room, with respiratory isolation measures in place to avoid cross-infection.

Prophylaxis
Protection by influenza vaccines is effective in only about 70% of people and lasts for about a year only. New vaccines have to be prepared to cover each change in viral antigenicity and are therefore in limited supply at the start of an epidemic. Nevertheless, routine vaccination is recommended for all individuals over 65 years of age and also for younger people with chronic heart disease, chronic lung disease (including asthma), chronic kidney disease or diabetes mellitus and for those who are immunosuppressed. Hospital and health service personnel should also be vaccinated. Influenza vaccine should be given to individuals who are allergic to egg protein with caution, as some types are manufactured in chick embryos; egg-free vaccines are now available.

Management of chronic cough
All patients with a chronic cough should have a chest X-ray and those with X-ray abnormalities should be investigated appropriately. If the chest X-ray is normal, then the five most likely diagnoses are undiagnosed asthma, postnasal drip, gastro-oesophageal reflux disease (see p. 1162), recent upper respiratory tract infection or smoking.

Spirometry should then be organized. If it reveals reversible airways obstruction, treatment is given as per asthma guidelines.
Otherwise, based on the history, patients should have a trial of treatment for the most likely cause:

- **nocturnal cough or wheeze:** a 2-week trial of oral or inhaled steroids
- **acid reflux:** an 8-week trial of a proton pump inhibitor
- **postnasal drip:** a trial of topical steroids
- **smoking:** smokers should be referred to the local smoking cessation service.

Ensure that the patient is not taking an angiotensin converting enzyme (ACE) inhibitor.

If a chronic cough does not settle after empirical treatment and the aetiology remains unclear, further investigations might include CT chest, bronchoscopy, bronchial provocation testing, oesophageal manometry and imaging of the sinuses. Referral to a specialist cough clinic may also be considered.

**Further reading**

---

**OBSTRUCTIVE RESPIRATORY DISEASE**

**Asthma**

Asthma is a common chronic condition whose cause is incompletely understood. Symptoms include wheeze, chest tightness, cough and shortness of breath, often worse at night. Asthma commonly starts in childhood between the ages of 3 and 5 years and may either worsen or improve during adolescence. Classically, asthma has three characteristics:

- **airflow limitation**, which is usually reversible spontaneously or with treatment
- **airway hyper-responsiveness** to a wide range of stimuli (see later)
- **bronchial inflammation** with T lymphocytes, mast cells, eosinophils with associated plasma exudation, oedema, smooth muscle hypertrophy, matrix deposition, mucus plugging and epithelial damage.

In chronic asthma, inflammation may be accompanied by irreversible airflow limitation as a result of airway wall remodelling, which may involve large and small airways and mucus impaction.

**Prevalence**

In many countries the prevalence of asthma has increased since the mid-1980s. This increase is particularly marked in children and young adults, with up to 15% of the population being affected. Asthma is more common in developed countries, with some of the highest rates in the UK, New Zealand and Australia, and much lower rates in East Asia, Africa and Central and Eastern Europe. Long-term follow-up in developing countries suggests that asthma may become more frequent as individuals adopt a more ‘Westernized’ lifestyle but the environmental factors accounting for this remain unknown. Studies of occupational asthma suggest that a large proportion of the workforce (15–20%) may become asthmatic if exposed to potent sensitizers. Worldwide, asthma kills about 1000 people per day; approximately 300 million people have asthma and this figure is expected to rise to 400 million by 2025.

**Classification**

Asthma is a complex disorder. The current thinking is that symptoms can be caused by several different processes. Asthma can be classified according to its trigger factors, age of onset, inflammatory subtypes or response to therapy. There is considerable overlap between populations separated along these different dimensions and it is now increasingly common to describe clinical subtypes (or endotypes).

Many childhood-onset asthmatics have a wheezing illness with inhaled allergic triggers. Some 90% of children and 70% of adults with persistent asthma have positive skin-prick tests to common inhalant allergens such as dust mite, animal danders, pollens and fungi. Childhood-onset asthma is often accompanied by eczema (atopic dermatitis, see p. 660).

In some people with asthma, inhaled allergens are not relevant. This illness often starts in middle age and attacks are triggered by respiratory infections. Nevertheless, many patients with adult-onset asthma show positive allergen skin tests and, on close questioning, some of these will give a history of childhood respiratory symptoms suggesting that they have allergic asthma.

Non-atopic individuals may develop asthma in middle age from extrinsic causes, such as sensitization to occupational agents like toluene diisocyanate, intolerance to NSAIDs such as aspirin, or prescription of β-adrenoceptor-blocking agents that block the protective effect of endogenous catecholamines. Extrinsic causes must be considered in all cases of asthma and, where possible, avoided.

**Other clinical phenotypes**

Based on the clinical picture, other subtypes or endotypes of asthma are recognized, including ‘brittle asthma’ and steroid-resistant asthma. While eosinophilic airway inflammation is often present in asthma, there are also patients with eosinophilic bronchitis, who have sputum eosinophilia without wheeze. It remains unclear whether this is a pre-asthmatic state or whether anti-eosinophil treatment is helpful.

**Aetiology**

The major factors involved in the development of asthma and stimuli that can precipitate attacks are shown in Fig. 28.18.

**Atopy and allergy**

The term ‘atopy’ was coined in the early 1900s to describe a group of disorders, including asthma and hayfever, that appeared to run in families, have positive skin-prick tests to common inhalant allergens and have circulating allergen-specific antibodies. Allergen-specific IgE is present in 30–40% of the UK population, and elevated serum IgE levels are linked to airway hyper-responsiveness and the prevalence of asthma. Serum total IgE levels are affected by several genetic and environmental factors.

**Genetic factors**

There is no single gene for asthma but several, in combination with environmental factors, appear to influence its development. These include genes that affect the production of cytokines and IgE.

**Environmental factors**

Early childhood exposure to allergens and maternal smoking has a major influence on IgE production. Much interest focuses on the role of intestinal bacteria and childhood infections in shaping the immune system in early life. It has been suggested that growing up
Precipitating factors

Occupational sensitizers
Over 250 materials encountered in the workplace can cause occupational asthma, which accounts for up to 15% of all asthma cases (Box 28.18). These are recognized occupational diseases in the UK and patients in insurable employment are eligible for statutory compensation, provided they apply within 10 years of leaving the occupation in which the asthma developed.

Asthma can be due to:
- low-molecular-weight compounds, e.g. reactive chemicals such as isocyanates and acid anhydrides that bond chemically to epithelial cells to activate them, as well as providing haptons recognized by T cells
- high-molecular-weight compounds, e.g. flour, organic dusts and other large protein molecules involving specific IgE antibodies.

Smoking increases the risk of developing some forms of occupational asthma. The proportion of employees developing occupational asthma depends primarily on the level of exposure. Proper enclosure of industrial processes or appropriate ventilation greatly reduces the risk. Atopic individuals develop occupational asthma more rapidly when exposed to agents causing the development of specific IgE antibody. Non-atopic individuals can also develop asthma when exposed to such agents, but after a longer period of exposure.

Non-specific factors
Due to their AHR, patients with asthma will respond to a wide variety of non-specific direct and indirect stimuli, as well as reacting to specific allergens.

Cold air and exercise
Most asthmatics wheeze after prolonged exercise or inhalation of cold, dry air. Typically, the attack does not occur while exercising but afterwards. Exercise-induced wheeze is driven by release of histamine, prostaglandins (PGs) and leukotrienes (LTs) from mast cells, as well as stimulation of neural reflexes.

Atmospheric pollution and irritant dusts, vapours and fumes
Many patients with asthma experience worsening of symptoms on exposure to tobacco smoke, car exhaust fumes, solvents, strong perfumes or high concentrations of airborne dust. Major epidemics have been recorded when large amounts of allergens are released into the air, and asthma exacerbations increase during summer and winter air pollution episodes associated with climatic temperature inversions: in the presence of high concentrations of ozone, particulates and NO₂ in the summer and particulates, NO₂ and SO₂ in the winter.

Diet
Increased intake of fresh fruit and vegetables has been shown to be protective, possibly owing to the greater consumption of antioxidants or other protective molecules such as flavonoids. Genetic variation in antioxidant enzymes is associated with more severe asthma.
Emotional factors influence asthma both acutely and chronically, but there is no evidence that patients with the disease are any more psychologically disturbed than their non-asthmatic peers. Patients at high risk of life-threatening attacks are understandably anxious.

Drugs

**NSAIDs.** NSAIDs, particularly aspirin and propionic acid derivatives, such as indometacin and ibuprofen, are implicated in triggering asthma in approximately 5% of patients. NSAID intolerance is especially prevalent in those with both nasal polyps and asthma, and is often associated with rhinitis and flushing on drug exposure.

**Beta-blockers.** The airways have a direct parasympathetic innervation that tends to produce bronchoconstriction. There is no direct sympathetic innervation of bronchial smooth muscle, so antagonism of parasympathetically induced bronchoconstriction is critically dependent on circulating adrenaline (epinephrine) acting through β2-receptors on the surface of smooth muscle cells. Inhibition of this effect by non-selective β1-adrenoceptor-blocking drugs, such as propranolol, leads to bronchoconstriction and airflow limitation, but only in asthmatic subjects. Selective β2-adrenergic-blocking drugs, such as atenolol, may also induce attacks of asthma.

Clinical features

The principal symptoms of asthma are wheezing attacks and episodic shortness of breath. Symptoms are usually worst during the night, especially in uncontrolled disease. Cough is a frequent symptom that sometimes predominates, especially in children, in whom nocturnal cough can be a presenting feature. Attacks vary greatly in frequency and duration and may be precipitated by a wide range of triggers (see Fig. 28.18). Asthma is a major cause of impaired quality of life and has an impact on work and recreation, affecting both physical activities and emotions.

Investigations

There is no single satisfactory diagnostic test for all patients with asthma.

Lung function tests

**PEFR** measurements on waking, prior to taking a bronchodilator, before bed and after a bronchodilator are particularly useful in demonstrating the variable airflow limitation that characterizes the disease (see Figs 28.13 and 28.14). The diurnal variation in PEFR is a good measure of asthma activity and is of help in the longer-term assessment of the patient’s disease and its response to treatment.

**Spirometry** is useful, especially in assessing reversibility. Asthma can be diagnosed by demonstrating a greater than 15% improvement in FEV1 or PEFR following inhalation of a bronchodilator. The carbon monoxide (CO) transfer test is normal in asthma.

Histamine or methacholine bronchial provocation test

This was outlined on page 945.

Trial of corticosteroids

All patients who present with severe airflow limitation should undergo a formal trial of corticosteroids. Prednisolone 30 mg orally should be given daily for 2 weeks, with lung function measured before and immediately after the course. A substantial improvement in FEV1 (>15%) confirms the presence of a reversible element and indicates that the administration of inhaled steroids will prove beneficial to the patient. If the trial is for 2 weeks or less, the oral corticosteroid can be withdrawn without tailing off the dose, and should be replaced by inhaled corticosteroids in those who have responded.

Exhaled nitric oxide

This test is a measure of airway inflammation and an index of corticosteroid response; it is used to assess the efficacy of corticosteroids.

Blood and sputum tests

Patients with asthma sometimes have increased numbers of eosinophils in peripheral blood (>0.4 x 10^9/L) but sputum eosinophilia is a more specific diagnostic finding.

Chest X-ray

There are no diagnostic features of asthma on the chest X-ray, although overinflation is characteristic during an acute episode or in chronic severe disease. A chest X-ray may be helpful in excluding a pneumothorax, which can occur as a complication, or in detecting the pulmonary infiltrates associated with allergic bronchopulmonary aspergillosis.

Skin tests

Skin-prick tests should be performed in all cases of asthma to help identify allergic trigger factors. Allergen-specific IgE can be measured in serum if skin-prick test facilities are not available, the patient is taking antihistamines or no suitable allergen extracts are available.

Allergen provocation tests

Allergen inhalation challenge is a useful research tool; it is required when investigating patients with suspected occupational asthma but not in ordinary asthma.

Management

The aims of treatment are to:

- abolish symptoms
- restore normal or best possible lung function
- reduce the risk of severe attacks
- enable normal growth to occur in children
- minimize absence from school or employment.

This involves:

- patient and family education about asthma
- patient and family participation in treatment
- avoidance of identified causes where possible
- use of the lowest effective doses of convenient medications to minimize short-term and long-term side-effects.

Many asthmatics join self-help groups in order to improve their understanding of the disease and to foster self-confidence and fitness.

Control of extrinsic factors

Where specific allergen triggers are identified, these should be avoided if possible. Sublingual allergen immunotherapy (SLIT) with house-dust mites has shown a reduction in the number of asthma attacks in children but is not recommended in adults. Active and passive smoking should be avoided, as should beta-blockers in either tablet or eye-drop form. Individuals intolerant to aspirin should avoid NSAIDs, although...
they may tolerate cyclo-oxygenase-2 (COX-2) inhibitors. About one-third of individuals sensitized to occupational agents may be cured if they are kept permanently away from exposure.

**Drug treatment**

The mainstay of asthma therapy is use of inhaled therapeutic agents, delivered as aerosols or powders directly into the lungs (Box 28.19). The advantages of this method of administration are that drugs are delivered direct to the airways and first-pass metabolism in the liver is avoided; thus lower doses are necessary and systemic unwanted effects are minimized. To help those who cannot coordinate activation of the aerosol and inhalation, several breath-activated or dry powder devices have been developed. Patients vary in their ability to use such devices, and care should be taken to select an appropriate device and train the individual to use it properly.

Several national and international guidelines have been published on the treatment of asthma (Fig. 28.19), based on three principles:

- Asthma should be self-managed, with regular monitoring using a PEFR meter and an individual treatment plan that is discussed with each patient and written down.
- Patients should be taught how to use inhalers and their technique should be checked regularly.
- Use of a metered-dose inhaler
  1. The canister is shaken.
  2. The patient exhales to functional residual capacity (not residual volume), i.e. normal expiration.
  3. The aerosol nozzle is placed to the open mouth.
  4. The patient simultaneously inhales rapidly and activates the aerosol.
  5. Inhalation is completed.
  6. The breath is held for 10 sec if possible. Even with good technique, only 15% of the contents is inhaled and 85% is deposited on the wall of the pharynx and ultimately swallowed.

**Spacers**

These are plastic cones or spheres inserted between the patient’s mouth and the inhaler. Some inhalers have a built-in spacer extension. These are designed to reduce particle velocity so that less drug is deposited in the mouth. Spacers also diminish the need for coordination between aerosol activation and inhalation. They are useful in children and the elderly, and reduce the risk of candidiasis.

| **Diagnosis and assessment** | **Evaluation:**
| • assess symptoms, measure lung function, check inhaler technique and adherence |
| • adjust dose |
| • update self-management plan |
| • move up and down as appropriate |

**Infrequent, short-lived wheeze**

- Consider monitored initiation of treatment with low-dose ICS

**Low-dose ICS**

**Regular preventer**

- Add inhaled LABA to low-dose ICS (fixed dose or MART)

**Initial add-on therapy**

**Additional controller therapies**

- Consider:
  - Increasing ICS to medium dose
  - Adding LTRA

- If no response to LABA, consider stopping LABA

**Specialist therapies**

- Refer patient for specialist care

**Fig. 28.19** Summary of asthma management in adults. ICS, inhaled corticosteroid; LABA, long-acting β agonist; LTRA, leukotriene receptor antagonist; MART, maintenance and reliever therapy. (Scottish Intercollegiate Guidelines Network/British Thoracic Society. SIGN158: British Guideline on the Management of Asthma: A National Clinical Guideline. SIGN/BTS 2019; Fig. 2, p. 80.)
• Asthma is an inflammatory disease, so anti-inflammatory (controller) therapy should be started, even in mild cases.
• Short-acting inhaled bronchodilators (e.g. salbutamol and terbutaline) should be used only to relieve breakthrough symptoms. Increased use of bronchodilator treatment to relieve increasing symptoms is an indication of deteriorating disease.

A list of drugs used in asthma is shown in Box 28.20. These are given in a stepwise fashion, as indicated in Fig. 28.19.

**Beta₂-adrenoceptor agonists**
Beta₂-adrenoceptor agonists are selective for the respiratory tract and do not stimulate the β₁ adrenoceptors of the myocardium. These drugs relax the bronchial smooth muscle and are very effective in relieving symptoms, but do not affect underlying airways inflammation.

• **Short-acting β agonists (SABAs),** such as salbutamol 100 μg (called albuterol in the USA) or terbutaline 250 μg, can be taken as and when required, and should be prescribed as ‘two puffs as required’.

• **Long-acting β₂-adrenoceptor agonists (LABAs),** such as salmeterol or formoterol, are effective by inhalation for up to 12 hours and are given once or twice daily. They should be used in combination with an inhaled corticosteroid as fixed-dose combinations (e.g. salmeterol/fluticasone and formoterol/budesonide) in the same inhaler.

The mildest asthmatics with intermittent attacks are the only people who should rely on SABA treatment alone. Any patients using β₂-adrenoceptor agonists more than three times a week should be started on inhaled corticosteroids.

**Inhaled corticosteroids**
All patients who have regular persistent symptoms (even mild ones) need regular treatment with inhaled corticosteroids. Beclometasone dipropionate (BDP) is the most widely used inhaled steroid and is available in doses of 50, 100, 200 and 250 μg per puff. Other inhaled steroids include budesonide, fluticasone propionate, fluticasone furoate, mometasone furoate and triamcinolone.

Side-effects of inhaled steroids include oral thrush and hoarseness, and patients should be instructed to rinse their mouths out after using the inhaler. Subcapsular cataract formation is rare but can occur in the elderly. Osteoporosis is less likely than with oral steroids but can occur with high-dose inhaled corticosteroids (beclometasone or budesonide >800 μg daily). In children, inhaled corticosteroids at doses above 400 μg daily have been shown to retard short-term growth but final heights are not affected. Inhaled corticosteroid use should be stepped down once asthma comes under control.

**Oral corticosteroids and steroid-sparing agents**
Oral corticosteroids are needed both for acute exacerbations and for longer-term use when other drug regimes have not controlled symptoms. The dose should be kept as low as possible to minimize side-effects. The effect of short-term treatment with prednisolone 30 mg daily is shown in Fig. 28.14. Some patients require continuing treatment with oral corticosteroids. Occasionally, low doses of methotrexate or ciclosporin are used as steroid-sparing agents in some steroid-dependent asthmatics but biologic monoclonal antibodies are now preferentially used in these patients.

**Leukotriene receptor antagonists**
This class of anti-asthma therapy targets the cysteinyl LT1 receptor. Montelukast, pranlukast (only available in South-east Asia) and zafirlukast are given orally and are effective in a subpopulation of asthma patients. However, it is not possible to predict which individuals will benefit; a 4-week trial of leukotriene receptor antagonist (LTRA) therapy is recommended before a decision is made to continue or stop.LTRAs should be tried in any patient who is not controlled on low to medium doses of inhaled steroids; their action is additive to that of LABAs. LTRAs are particularly useful in patients with aspirin-intolerant asthma. Because these drugs are orally active they are helpful in patients with asthma combined with rhinitis and in young children with asthma and/or virus-associated wheezing.

**Antimuscarinic bronchodilators**
Muscarinic receptors are found in the respiratory tract; large airways contain mainly M₁ receptors, whereas the peripheral lung tissue contains M₃ and M₄ receptors (see p. 931). A nebulized short-acting antimuscarinic agent, ipratropium, is used in acute severe exacerbations of asthma (Box 28.21). Short-acting inhaled antimuscarinic agents have not been shown to be of any benefit in patients who have asthma that is not controlled on standard therapy. Longer-acting antimuscarinics (tiotropium, aclidinium) can be tried in more severe cases.

**Anti-inflammatory drugs**
Sodium cromoglicate and nedocromil sodium prevent activation of many inflammatory cells, particularly mast cells, eosinophils and epithelial cells but not lymphocytes, by blocking a specific chloride channel, which in turn prevents calcium influx. These drugs are effective in patients with milder asthma but are not routinely used.

**Monoclonal antibodies**
Omalizumab, a recombinant humanized monoclonal antibody directed against IgE, chelates free IgE and downregulates the number and activity of mast cells and basophils. It is given subcutaneously every 2–4 weeks, depending on total serum IgE level and body weight. Although expensive, it is cost-effective in patients with frequent exacerbations requiring oral corticosteroids. Mepolizumab, reslizumab and benralizumab are newer monoclonal antibodies against interleukin-5 (IL-5) or its receptor. They have been shown to be effective in eosinophilic asthma and, similar to omalizumab, are cost-effective in patients who have recurrent exacerbations despite high-dose inhaled corticosteroids.
Currently in development is a wide range of other monoclonal antibody therapies against Th2 cytokine targets such as thymic stromal lymphopoietin (TSLP), thought to be important in asthma pathology.

**Antibiotics**

There is little evidence that antibiotics are helpful in managing patients with acute asthma. During acute exacerbations, yellow or green sputum containing eosinophils and bronchial epithelial cells may be coughed up. This is usually due to viral rather than bacterial infection and antibiotics are not required.

There is mixed evidence in severe asthma for long-term treatment with the macrolide antibiotic azithromycin, which has both anti-inflammatory and antibacterial actions.

**Bronchial thermoplasty**

Bronchial thermoplasty is a novel approach for moderate to severe persistent asthma. This bronchoscopic procedure uses radiofrequency radiation to heat the bronchial wall and reduce the mass of airway smooth muscle, decreasing bronchoconstriction. It is currently being evaluated.

**Asthma attacks**

Although these may occur spontaneously, asthma exacerbations are most commonly caused by lack of treatment adherence, respiratory virus infections associated with the common cold, and exposure to an allergen or triggering drug, e.g. an NSAID. Whenever possible, patients should have a written personalized plan that they can implement in anticipation or at the start of an exacerbation that includes the early use of a short course of oral corticosteroids. If the PEFR is >150 L/min, patients may improve dramatically on nebulized therapy and may not require hospital admission. Their regular treatment should be increased, to include treatment for 2 weeks with 30–60 mg of prednisolone, followed by substitution with an inhaled corticosteroid preparation. Short courses of oral prednisolone can be stopped abruptly without tailing down the dose.

**Acute severe asthma**

The term acute severe asthma is used to mean an exacerbation of asthma that has not been controlled by the use of standard medication.

- Patients with acute severe asthma typically have:
  - an inability to complete a sentence in one breath
  - a respiratory rate of ≥25 breaths/min
  - a tachycardia of ≥110 b.p.m. (pulsus paradoxus is not useful, as it is present in only 45% of cases)
  - a PEFR of 33–50% of predicted normal or best.

**Features of life-threatening attacks** are:

- a silent chest, cyanosis or feeble respiratory effort
- exhaustion or altered level of consciousness
- bradycardia, hypotension or arrhythmia
- a PEFR of <33% of predicted normal or best (approximately 150 L/min in adults) or $S_{pO_2}$ of <92%.

**Arterial blood gases** should always be measured in asthmatic patients requiring admission to hospital, with particular attention paid to the $P_{aCO_2}$. **Pulse oximetry** is useful in monitoring oxygen saturation during the admission and can reduce the need for repeated arterial puncture.

Features suggesting **very severe life-threatening attacks** are:

- a high $P_{aCO_2}$ of >6 kPa
- severe hypoxaemia: $P_{aO_2}$ <8 kPa despite treatment with oxygen
- a low and/or falling arterial pH.

**Management** (see **Box 28.21**) consists of nebulized short-acting bronchodilators; nebulized antimuscarinics (e.g. ipratropium bromide) are also helpful. Intravenous hydrocortisone should be given together with prednisolone (40–60 mg daily) orally. If symptoms are not controlled, consider a single dose of intravenous magnesium sulphate (1.2 g–2 g infusion over 20 min).

Intravenous β₂-adrenoceptor agonists or aminophylline may be considered. Ventilation is required for patients who deteriorate despite this initial regimen. A chest X-ray is helpful to exclude pneumothorax and other causes of dyspnoea.

**Further reading**

**Acute bronchitis**

Acute bronchitis in previously healthy subjects is often viral. Bacterial infection with *Strep. pneumoniae* or *H. influenzae* is a common sequel to viral infections, and is more likely to occur in cigarette smokers or people with COPD.

The illness begins with an irritating, non-productive cough, together with discomfort behind the sternum. There may be associated chest tightness, wheezing and shortness of breath. Later the cough becomes productive, with yellow or green sputum. There is a mild fever and a neutrophil leucocytosis; wheeze with occasional crackles can be heard on auscultation. In otherwise healthy adults the disease improves spontaneously in 4–8 days without serious illness.

Antibiotics are often given (e.g. amoxicillin 250 mg three times daily), but it is not known whether they hasten recovery in otherwise healthy individuals and in most cases they should not be given.

**Box 28.21 Treatment of acute severe asthma**

**At home**

1. The patient is assessed. Tachycardia, a high respiratory rate and inability to speak in sentences indicate a severe attack.
2. If the peak expiratory flow rate (PEFR) is <150 L/min (in adults), an ambulance should be called.
3. Nebulized salbutamol 5 mg or terbutaline 10 mg is administered.
4. Hydrocortisone 200 mg i.v. is given.
5. Oxygen 40–60% is given if available.
6. Prednisolone 60 mg is given orally.

**In hospital**

1. The patient is reassessed. Oxygen 40–60% is given.
2. The PEFR and $O_2$ saturation are measured.
3. Nebulized salbutamol 5 mg or terbutaline 10 mg is repeated and administered 4-hourly.
4. Nebulized ipratropium bromide 0.5 mg is added to nebulized salbutamol/terbutaline.
5. Hydrocortisone 200 mg i.v. is given.
6. Prednisolone 60 mg is continued at 40–60 mg orally daily for at least 5 days.
7. Ventilation is continued at 40–60% orally for at least 5 days.
8. Arterial blood gases are measured; if the $P_{aCO_2}$ is >8, ventilation may be required.
9. A chest X-ray is performed to exclude pneumothorax.
10. If there is no improvement, i.v. magnesium sulphate is given at 1.2–2 g over 20 min.
11. If there is still no improvement, urgent transfer to the intensive treatment unit is arranged.
**Chronic bronchitis**
Chronic bronchitis, one of the clinical syndromes of COPD (see next section), is classically defined as a daily productive cough for 3 months per year for 2 consecutive years.

**Chronic obstructive pulmonary disease**

**Definition**
Chronic obstructive pulmonary disease (COPD) has been described as ‘a disease state characterized by airflow limitation that is not fully reversible. The airflow limitation is usually both progressive and associated with an abnormal inflammatory response of the lungs to noxious particles or gases.’ COPD is an overarching diagnosis that brings together a variety of clinical syndromes (emphysema, small airways disease and chronic bronchitis) associated with airflow limitation and destruction of the lung parenchyma. There is resultant hyperinflation of the lungs, ventilation/perfusion mismatch, increased work of breathing and breathlessness.

The condition is associated with a number of co-morbidities, such as ischaemic heart disease, hypertension, diabetes, heart failure and cancer, suggesting that it may be part of a generalized systemic inflammatory process.

**Epidemiology and aetiology**
COPD is caused by long-term exposure to toxic particles and gases. In developed countries, cigarette smoking accounts for over 90% of cases. In developing countries, other factors are also implicated, such as inhalation of smoke from biomass heating fuels and cooking in poorly ventilated areas. Only 10–20% of smokers develop COPD, which suggests that there is an underlying individual susceptibility.

Urbanization, air pollution, socioeconomic class and occupation may also play a part in the aetiology but these effects are difficult to separate from that of smoking. Some animal studies suggest that diet could be a risk factor for COPD but this has not been proven in humans.

The economic burden of COPD is considerable. In the UK COPD causes approximately 18 million lost working days annually for men and 2.1 million lost working days for women, accounting for about 7% of all days of absence from work due to sickness. Nevertheless, the number of COPD admissions to UK hospitals has been falling steadily since the mid-1980s.

**Pathophysiology**
Pathologically, there is evidence of airways inflammation and structural changes within the airways and the lung parenchyma.

**Structural changes**
Structurally, there may be evidence of emphysema and small airways disease, with increased mucus-producing goblet cells in the bronchial mucosa, which may lead to chronic bronchitis (Figs 28.20 and 28.21). The physiological consequence of these changes is the development of airflow limitation.

Pathologically, there is evidence of both acute and chronic inflammation; endobronchial biopsies demonstrate a predominance of neutrophils, CD8-predominant lymphocytes and macrophages. This chronic inflammation results in scarring and fibrosis of the small airways. In addition, there is destruction of the alveolar walls, which results in emphysema. The phenotype of COPD will differ, depending on the predominance of small airways disease, emphysema or chronic bronchitis.

**Emphysema**
Emphysema is defined as abnormal and permanent enlargement of air spaces distal to the terminal bronchiole, accompanied by destruction of their walls. It is classified according to the distribution:
- **Centri-acinar emphysema.** Distension and damage of lung tissue are concentrated around the respiratory bronchioles, while the more distal alveolar ducts and alveoli tend to be well preserved. This form of emphysema is extremely common.
- **Pan-acinar emphysema.** This is less common but is the type associated with α1-antitrypsin deficiency (see later). Distension and destruction affect the whole acinus, and in severe cases the lung is just a collection of bullae. Severe airflow limitation and mismatch occur.
Respiratory disease

My chest is full of I don’t sleep soundly I am very limited
I am very limited I have no energy

Irregular emphysema. There is scarring and damage that affect the lung parenchyma patchily, independent of acinar structure. Emphysema leads to expiratory airflow limitation and air trapping. The loss of lung elastic recoil results in an increase in TLC. Premature closure of airways limits expiratory flow while the loss of alveoli decreases capacity for gas transfer.

The classic Fletcher and Peto studies (Fig. 28.22) showed a loss of 50 mL per year in FEV₁ in patients with COPD compared with 20 mL per year in healthy people. A more recent study has shown a 40 mL loss per year but in only 38% of the patients studied. Reliable biomarkers to predict the rate of decline have not been identified.

Pathogenesis

Cigarette smoking
Bronchoalveolar lavage and biopsies of the airways of smokers show increased numbers of neutrophil granulocytes. These granulocytes can release elastases and proteases; an imbalance between protease and antiprotease activity is a causative factor in the development of emphysema.

Mucous gland hypertrophy in the larger airways is thought to be a direct response to persistent irritation resulting from the inhalation of cigarette smoke. The smoke has an adverse effect on surfactant, favouring over-distension of the lungs.

Infections
Respiratory infections are often the precipitating cause of acute exacerbations of the disease. It is less clear whether infection is responsible for the progressive airflow limitation that characterizes disabling COPD. Prompt use of antibiotics and routine vaccinations against influenza and pneumococci are appropriate.

Alpha₁-antitrypsin deficiency
Alpha₁-antitrypsin is a proteinase inhibitor produced in the liver; it is secreted into the blood and diffuses into the lung. Here it inhibits proteolytic enzymes such as neutrophil elastase, which are capable of destroying alveolar wall connective tissue. In α₁-antitrypsin deficiency, the protein accumulates in the liver, leading to low levels in the lung.

More than 75 alleles of the α₁-antitrypsin gene have been described. The three main phenotypes are MM (normal), MZ (heterozygous deficiency) and ZZ (homozygous deficiency). Hereditary deficiency of α₁-antitrypsin accounts for about 2% of UK emphysema cases. Deficiency can also cause liver disease (see p. 1302).

Clinical features

Symptoms
The characteristic symptoms of COPD are productive cough with white or clear sputum, wheeze and breathlessness. Individuals will be more prone to lower respiratory tract infections. Systemic effects include hypertension, osteoporosis, depression, weight loss and reduced muscle mass with general weakness and right heart failure.

Signs
In mild COPD there may be no signs or just quiet wheeze throughout the chest. In severe disease the patient is tachypnoeic, with prolonged expiration. The accessory muscles of respiration are used and there may be intercostal indrawing on inspiration and pursing of the lips on expiration (see p. 932). The cricosternal distance is reduced. Chest expansion is poor, the lungs are hyperinflated and there is loss of the normal cardiac and liver dullness.

Patients who remain responsive to CO₂ are usually breathless and rarely cyanosed. Heart failure and oedema are rare features, except as terminal events. In contrast, patients who become insensitive to CO₂ are often oedematous and cyanosed but not particularly breathless. Those with hypercapnia may have peripheral vasodilation, a bounding pulse, and a coarse flapping tremor of the outstretched hands. Severe hypercapnia causes confusion and progressive drowsiness. Papilloedema may be present but this is neither specific nor sensitive as a diagnostic feature.

Patients in the later stages may develop respiratory failure, pulmonary hypertension and cor pulmonale.
Diagnosis
This is usually clinical and based on a history of breathlessness and sputum production in a chronic smoker. In the absence of a history of cigarette smoking, asthma is a more likely explanation, unless there is a family history suggesting \( \alpha_1 \)-antitrypsin deficiency.

No individual clinical feature is diagnostic. The patient may have signs of hyperinflation and typical pursed lip respiration. There may be signs of over-inflation of the lungs (e.g. loss of liver dullness on percussion) but this also occurs in other diseases such as asthma. Conversely, centri-acinar emphysema may be present without signs of over-inflation. The chest may become ‘barrel-shaped’ but this can also result from osteoporosis of the spine in older men without emphysema.

The degree of breathlessness may be recorded using the Medical Research Council (MRC) dyspnoea score, while the COPD Assessment Test (CAT) is a patient scored symptom tool that measures the impact of the disease on the individual’s health and wellbeing (Box 28.22).

Investigations
- **Lung function tests** show evidence of airflow limitation (see Fig. 28.23). The FEV\(_1\)/FVC ratio is reduced and the PEFR is low. In many patients the airflow limitation is partly reversible (usually a change in FEV\(_1\) of <15%). Lung volumes may be normal or increased; carbon monoxide gas transfer factor is low when significant emphysema is present.
- **Chest X-ray** is often normal, even when disease is advanced. The classic features are over-inflation of the lungs with low, flattened diaphragms, and sometimes the presence of large bullae. Blood vessels may be ‘pruned’, with large proximal vessels and relatively little blood visible in the peripheral lung fields.
- **HRCT scans** are useful, particularly when the plain chest X-ray is normal.
- **Haemoglobin level and packed cell volume** can be elevated as a result of persistent hypoxaemia (secondary polycythaemia; see p. 356).
- **Blood gases** may be helpful to determine if there is any evidence of respiratory failure.
- **Sputum examination** may reveal *Strep. pneumoniae*, *H. influenzae* and *Moraxella catarrhalis*, which can cause infective exacerbations. Many acute episodes are viral in origin.
- **ECG** is often normal. If a patient has pulmonary hypertension secondary to COPD, the P wave is tall (P pulmonale), and there may be a right bundle branch block and evidence of right ventricular hypertrophy (see p. 1055).
- **Echocardiography** is useful to assess cardiac function where there is disproportionate dyspnoea.
- **\( \alpha_1 \)-Antitrypsin** levels and genotype are worth measuring in premature disease or life-long non-smokers.

Management
See Fig. 28.23 for management strategies.

Smoking cessation
The single most useful measure is to persuade the patient to stop smoking. Even in advanced disease, this may slow down the rate of deterioration and prolong the time before disability and death occur (see Fig. 28.22). Smoke from burning biomass fuels in poorly ventilated homes should also be reduced.

Drug therapy
This is used both for the short-term management of exacerbations and for the long-term relief of symptoms. Many of the drugs used are similar to those employed in asthma (see p. 952).

### Box 28.23 Classification of airflow limitation severity in COPD (based on post-bronchodilator FEV\(_1\))

</tbody>
</table>

(From Global Initiative for Chronic Obstructive Lung Disease (GOLD), 2016; www.goldcopd.com)

**Bronchodilators**
- **\( \beta \)-Adrenoceptor agonists.** Many patients with mild COPD feel less breathless after inhaling a \( \beta \)-adrenergic agonist such as salbutamol (200\,\mu g every 4–6 h). In more severe airway limitation (moderate and severe COPD) a long-acting \( \beta_2 \) agonist should be used.
- **Antimuscarinic drugs.** Regular use of a LAMA (such as inhaled tiotropium) improves lung function, symptoms of dyspnoea and quality of life. Use of a LAMA does not prevent the decline in FEV\(_1\).
- **Theophyllines.** Long-acting preparations of theophylline are of little benefit in COPD.

**Phosphodiesterase type 4 inhibitors**
Roflumilast is a phosphodiesterase inhibitor with anti-inflammatory properties. It is used as an adjunct to bronchodilators for maintenance treatment in those patients with an FEV\(_1\) of less than 50% and chronic bronchitis.

**Corticosteroids**
Inhaled corticosteroids are recommended in patients with frequent exacerbations or a FEV\(_1\) of less than 50% predicted. Demonstration of a blood eosinophilia may identify patients who are more likely to have a beneficial response to inhaled corticosteroid therapy. High-dose inhaled steroids are not advised, as their use is linked to increased rates of pneumonia.

Oral corticosteroids are prescribed in the context of an acute exacerbation.

**Antibiotics**
Prompt antibiotic treatment shortens exacerbations and should always be given in acute episodes, as it may prevent hospital admission and further lung damage. Patients can be given antibiotics to keep at home, starting them as soon as their sputum turns yellow or green.

In patients who experience frequent exacerbations, long-term treatment with macrolide antibiotics such as azithromycin has been shown to reduce exacerbations and improve quality of life.

**Mucolytic agents**
These reduce sputum viscosity and can reduce the number of acute exacerbations. A meta-analysis showed that mucolytics such as carbocysteine are useful in preventing COPD exacerbations in those who experience them frequently.

**Oxygen therapy**
Two controlled trials (chiefly in males) have shown improved survival with continuous administration of oxygen at 2 L/min via nasal prongs to achieve an oxygen saturation of more than 90% for large proportions of the day and night. Survival curves from these two studies are shown in Fig. 28.24. Only 30% of those not receiving long-term
oxygen therapy survived for more than 5 years. A fall in pulmonary artery pressure was achieved if oxygen was given for 15 hours daily, but substantial improvement in mortality was achieved only by the administration of oxygen for 19 hours daily. These results suggest that long-term continuous domiciliary oxygen therapy will benefit patients who have:

- $P_{aO_2}$ of <7.3 kPa (55 mmHg) when breathing air; measurements should be taken on two occasions at least 3 weeks apart after appropriate bronchodilator therapy (Box 28.24)
- $P_{aO_2}$ of <8 kPa with secondary polycythaemia, nocturnal hypoxaemia, peripheral oedema or evidence of pulmonary hypertension
- carboxyhaemoglobin of <3% (i.e. patients who have stopped smoking).

Domiciliary oxygen is best provided via an oxygen concentrator.

Pulmonary rehabilitation

Pulmonary rehabilitation courses are an essential part of management in COPD, and randomized control trials have shown them to improve symptoms of fatigue and dyspnoea, as well as exercise tolerance.

Additional measures

- **Vaccines.** Patients with COPD should receive a single dose of the polyvalent pneumococcal polysaccharide vaccine and yearly influenza vaccinations.

- **α1-Antitrypsin replacement.** Weekly or monthly infusions of α1-antitrypsin have been recommended for patients with serum levels <310 mg/L and abnormal lung function. Whether this modifies long-term progression remains to be determined.

- **Heart failure.** This should be treated (see p. 1073).
Box 28.24 Guidelines for home oxygen use in adults (British Thoracic Society guidelines, June 2015)

- Chronic obstructive pulmonary disease with a $P_aO_2 < 7.3$ kPa when breathing air during a period of clinical stability.
- Chronic obstructive pulmonary disease with a $P_aO_2$ 7.3–8 kPa in the presence of secondary polycythemia, nocturnal hypoxaemia, peripheral oedema or evidence of pulmonary hypertension.
- Severe chronic asthma with a $P_aCO_2 < 7.3$ kPa or persistent disabling breathlessness.
- Diffuse lung disease with a $P_aO_2 < 8$ kPa and patients with $P_aO_2 > 8$ kPa with disabling dyspnoea.
- Cystic fibrosis when a $P_aO_2 < 7.3$ kPa or if $P_aCO_2$ 7.3–8 kPa in the presence of secondary polycythemia, nocturnal hypoxaemia, pulmonary hypertension or peripheral oedema.
- Pulmonary hypertension without parenchymal lung involvement when $P_aO_2 < 8$ kPa.
- Obstructive sleep apnoea despite continuous positive airways pressure therapy, after specialist assessment.
- Pulmonary malignancy or other terminal disease with disabling dyspnoea.
- Heart failure with a daytime $P_aO_2 < 7.3$ kPa (on air) or with nocturnal hypoxaemia.

- **Secondary polycythemia.** This requires venesection if the packed cell volume is >55%.
- **Sensation of breathlessness.** Short-acting sedation such as sublingual lorazepam or opiates may be a helpful palliative measure for intractable dyspnoea. Other useful adjuncts include breathing techniques and fan therapy.
- **Air travel.** Commercial aircraft are pressurized to the equivalent of 2000–2400 m altitude. In healthy people, this causes a $P_aO_2$ to fall from 13.5 to 10 kPa, leading to a trivial 3% drop in oxygen saturation, but patients with moderate COPD may desaturate significantly. The desaturation associated with air travel can be simulated by breathing 15% oxygen at sea level. Patients whose saturation drops below 85% within 15 minutes should be advised to contact their airline to request supplemental oxygen during their flight.
- **Surgery.** Some patients have large emphysematous bullae that reduce lung capacity. Surgical bullectomy can enable adjacent areas of collapsed lung to re-expand, thereby restoring function. In addition, carefully selected patients with severe COPD (FEV$_1 < 1$ L) have been treated with lung volume reduction surgery. Initial studies suggested that ventilation was improved and patients felt less breathless, although mortality was unchanged. However, a controlled trial in severe emphysema found increased mortality and no improvement in the patient’s condition.
- **Single lung transplantation** (see p. 994) is used for end-stage emphysema.
- **Endobronchial valves.** These occlude airways of hyperinflated emphysematous lungs and effectively achieve lung volume reduction. In selected patients, studies have shown an improvement in quality of life and exercise tolerance.

**COPD exacerbation**

Acute exacerbations may be precipitated by a viral or bacterial infection. Patients may have symptoms of cough, acute bronchospasm and dyspnoea. Type I and type II respiratory failure may occur as a consequence of a COPD exacerbation.

**Management** consists of the following measures:

- **Airway, breathing and circulation.** These should be assessed (see Ch. 10).
- **Oxygen therapy.** COPD is by far the most common cause of respiratory failure. In managing respiratory failure, the main goal is to improve the $P_aO_2$ by continuous oxygen therapy. A fixedpercentage mask (Venturi mask, Fig. 28.25) is used to deliver controlled concentrations of oxygen. Initially, 24% oxygen is given, and the concentration of inspired oxygen can be gradually increased, provided the $P_aCO_2$ does not rise unacceptably. In type II respiratory failure, the $P_aCO_2$ is elevated and the patient is dependent on hypoxic drive. In this setting, giving additional oxygen will nearly always cause a further rise in $P_aCO_2$. Patients at risk of hypercapnia should be managed with oxygen therapy to maintain the saturations within a target range of 88–92%. It is important to monitor arterial blood gases closely if there is any risk of decompensated type II respiratory failure. If there is evidence of respiratory acidosis (pH $< 7.35$ with an elevated $P_aCO_2$), despite medical management, the patient should be considered for non-invasive ventilation unless there are any contraindications (Fig. 28.26).
- **Corticosteroids, antibiotics and bronchodilators.** These should be administered in the acute phase of an exacerbation but decisions on long-term use should wait until the patient has recovered (see earlier).
- **Removal of retained secretions.** Patients should be encouraged to cough up secretions. Physiotherapy is helpful in achieving adequate chest clearance.

**Fig. 28.25** ‘Fixed-performance’ device for administration of oxygen to spontaneously breathing patients (Venturi mask). Oxygen is delivered through the injector of the Venturi mask at a given flow rate. A proportionate amount of air is entrained and the inspired oxygen can be predicted accurately. Masks are available that deliver 24%, 28% and 95% oxygen.

**Type II respiratory failure in COPD**

- **Respiratory support** (see p. 227). Non-invasive ventilation should be offered if a patient has a persistent respiratory acidosis with a pH of $< 7.35$. Randomized controlled trials have demonstrated that non-invasive ventilation (NIV) reduces the need for intubation and lowers mortality. Indications and contraindications are shown in Boxes 28.25 and 28.26. Assisted ventilation with an endotracheal tube is occasionally necessary for patients with COPD who have severe respiratory failure but only when there is a clear precipitating factor and the overall prognosis is reasonable. Assessing the likelihood of reversibility in an acute setting can present a difficult ethical problem.

**Prognosis of COPD**

Predictors of a poor prognosis are increasing age and worsening airflow limitation: that is, decreasing FEV$_1$. A predictive index...
Acute exacerbation of COPD

Assess airway, breathing and circulation

Heart failure – follow resuscitation guidelines

CXR

Pneumothorax

Chest drain (may require CT guidance if complex bullous disease)

Pneumonia

Antibiotics

Sit up

Measure saturations – if necessary targeted oxygen therapy to maintain saturations at preferred target range

For those at risk of hypercapnic respiratory failure – target range 88–92%

Oral or intravenous corticosteroids

Nebulized bronchodilators – salbutamol and ipratropium

Chest physiotherapy if difficulty clearing secretions

Controlled oxygen therapy with a Venturi mask to maintain target saturations according to prescribed target range

88–92% if risk of hypercapnia

Repeat ABG if increasing oxygen requirements, increasing breathlessness

Repeat ABG – If pH <7.35 with $P_aCO_2 > 6.5$ kPa – NIV should be considered if clinically appropriate (see acute NIV section) – refer to senior

Review and discuss ceiling of care

Obstructive sleep apnoea

Obstructive sleep apnoea (OSA) is a form of sleep-disordered breathing that is characterized by upper airway collapse resulting in obstructive apnoeas and hypopnoeas with desaturation. The prevalence of this condition is 3–5% of the population and it occurs most often in overweight, middle-aged men. The prevalence of OSA increases with

(BODE, body mass index, degree of airflow obstruction, dyspnoea and exercise capacity) is shown in Box 28.27. A patient with a BODE index of 0–2 has a 4-year mortality rate of 10%, compared with 80% in someone with a BODE index of 7–10. This scoring tool may be useful in determining timing of referral for transplant consideration.
Respiratory rate >23 breaths/min – obesity, acromegaly, enlarged tonsils.

Pathophysiology

During sleep, activity of the respiratory muscles is reduced, especially during rapid eye movement (REM) sleep when the diaphragm is virtually the only active muscle. Apnoeas occur when the airway at the back of the throat is sucked closed when breathing in during sleep. When the person is awake, this tendency is overcome by the action of opening muscles of the upper airway (the genioglossus and palatal muscles), but these become hypotonic during sleep (Fig. 28.27). Partial narrowing results in snoring, complete occlusion causes apnoea and critical narrowing causes hypopnoeas. Apnoea leads to hypoxia and increasingly strenuous respiratory efforts until the patient overcomes the resistance. The combination of central hypoxic stimulation and the effort to overcome obstruction wakes the patient from sleep. These awakenings are so brief that patients remain unaware of them but may be woken hundreds of times per night, leading to sleep deprivation with consequent daytime sleepiness and impaired intellectual performance.

Correctable factors occur in about one-third of cases and include:

- **encroachment on pharynx** – obesity, acromegaly, enlarged tonsils
- **nasal obstruction** – nasal deformities, rhinitis, polyps, adenoids
- **respiratory depressant drugs** – alcohol, sedatives, strong analgesics

Diagnosis

Relatives often provide a good history of the snore–silence–snore cycle. Individuals may complain of poor concentration and of waking feeling unrefreshed. The Epworth Sleepiness Scale (Box 28.29) is a measure of excessive daytime sleepiness and may prompt investigation. The STOP BANG tool (Box 28.30) is also a useful screening tool and should flag appropriate patients to refer for further investigation. It may help discriminate OSA from simple snoring.

Investigations

If the diagnosis is suspected, further investigation is necessary to determine if there is sleep-disordered breathing. Many of these investigations can be performed at home, using overnight pulse oximetry, and monitoring the pulse and the oxygen level. Oximetry
Respiratory disease

### Box 28.29 Epworth sleepiness scale

How likely are you to doze off or fall asleep in the following situations, in contrast to just feeling tired? This refers to your usual way of life in recent times. Even if you have not done some of these things recently, try to work out how they would have affected you. Use the following scale to choose the most appropriate number for each situation.

**Normal <9**

**Excessive daytime somnolence >9** – causes include obstructive sleep apnoea. Other conditions causing excessive daytime somnolence include narcolepsy, restless leg syndrome and periodic limb movement disorder.

will demonstrate desaturations in a cyclical manner, which will give a typical sawtooth appearance. The oximetry desaturation index (ODI) measures the number of desaturations per hour, which can determine the severity of sleep apnoea and correlates with the apnoea–hypopnoea index (see later).

Overnight oximetry will not differentiate between central and obstructive apnoeas. Multichannel sleep studies (nocturnal polygraphy), which measure body posture and movements, breathing rate and electroencephalography alongside pulse oximetry, are used where the diagnosis is uncertain.

Severity is defined by the number of episodes of apnoea or hypopnoea per hour, which is known as the **apnoea–hypopnoea index (AHI):**

- AHI <5: normal
- AHI 5–15: mild OSA
- AHI 15–30: moderate OSA
- AHI >30: severe OSA.

### Management

Management consists of correction of treatable factors, including encouraging weight loss and alcohol reduction. Patients who have OSA with associated daytime somnolence should be offered continuous positive airway pressure (CPAP) during sleep. CPAP splits the upper airway such that it cannot occlude. It improves symptoms, quality of life, daytime alertness and survival.

### Chronic ventilatory failure

Ventilatory failure, also known as type II respiratory failure (see p. 224), is a failure of alveolar ventilation with associated hypercapnia. This can be the sequela of a number of conditions that result in an imbalance of the respiratory load in the lungs (Box 28.31). Symptoms of hypercapnia include morning headaches, daytime somnolence, confusion, memory impairment and unsteadiness.

- Motor neurone disease
- Myotonic dystrophy

#### Central causes
- Brain injury
- Multiple system atrophy

### Domiciliary non-invasive ventilation

Home mechanical ventilation can be considered if a patient has persistent hypercapnia due to one of the conditions above. Patients typically use a portable ventilator overnight, which provides positive pressure support at different levels during inspiration and expiration. Home mechanical ventilation has been shown to improve survival in COPD patients who have persistent type II respiratory failure following an acute admission. There are no randomized trials of NIV in kyphoscoliosis; however, survival curves show improved survival where NIV is offered. In patients with neuromuscular disorders, home NIV has been shown to improve quality of life and prolong survival.

### Further reading

- https://www.catestonline.org, COPD Assessment Test (CAT).
Prevalence
Cigarette smoking is declining in the Western world but remains a leading cause of preventable death. The World Health Organization (WHO) predicts that tobacco is responsible for the death of 7 million people each year. In 1974 in the UK, 51% of men and 41% of women smoked cigarettes – nearly half the adult population – whereas the annual population survey of 2015 showed that 17.2% of adults in the UK smoked.

Toxic effects
Cigarette smoke contains polycyclic aromatic hydrocarbons and nitrosamines, which are potent carcinogens. Smokers have an increase in neutrophils and macrophages in the airways. These inflammatory cells release proteases that are capable of destroying elastin and lead to lung damage. Pulmonary epithelial permeability increases, even in symptomless cigarette smokers, and correlates with the concentration of carboxyhaemoglobin in blood. This altered permeability may allow easier access into blood for carcinogens.

Dangers
Cigarette smoking is addictive and harmful to health (Box 28.32). Smoking 20 cigarettes daily for 20 years increases the lifetime risk of lung cancer by about ten times, compared to the risk in a life-long non-smoker. Smoking and asbestos exposure are synergistic risk factors for lung cancer, with a combined risk about 90 times that of unexposed non-smokers.

Environmental tobacco smoke ('passive smoking') has been shown to increase the frequency and severity of asthma attacks in children and may also raise the incidence of asthma. It is also associated with a small but definite increase in lung cancer. Worldwide, second-hand smoke was estimated to affect 40% of children, 33% of non-smoking males and 35% of non-smoking females in 2004. This caused 1% of all deaths worldwide and 0.7% of the total worldwide burden of disease in disability-adjusted life years (DALYs).

Smoking cessation
If the entire population could be persuaded to stop smoking, the effect on healthcare use would be enormous. National campaigns, bans on advertising and a substantial increase in the cost of cigarettes are the best ways of achieving this at the population level. Smoking bans in workplaces and public spaces have also helped. Meanwhile, active encouragement to stop smoking remains a useful approach for individuals. Smokers who want to quit should have access to smoking cessation clinics for behavioural support. Nicotine replacement therapy (NRT) and bupropion are effective aids to smoking cessation in those smoking more than 10 cigarettes per day. Both should be used only in smokers who commit to a target stop date, and the initial prescription should be for 2 weeks beyond the target stop date. NRT is the preferred choice; there is no evidence that combined therapy offers any advantage. Therapy should be changed after 3 months if abstinence is not achieved.

Varenicline is an oral partial agonist on the \( \alpha_4\beta_2 \) subtype of the nicotinic acetylcholine receptor. It stimulates the nicotine receptor and reduces withdrawal symptoms and also the craving for cigarettes. A 12-week course doubles the chances of smoking cessation. Electronic cigarettes (battery-operated vaporizers, e-cigarettes) are useful alternatives to tobacco smoking and there is evidence that they may be helpful in smoking cessation, although evidence regarding the long term safety of vaping is awaited.

### BOX 28.32 DANGERS OF CIGARETTE SMOKING

**General**
- Lung cancer
- Chronic obstructive pulmonary disease (COPD)
- Carcinoma of the oesophagus
- Ischaemic heart disease
- Peripheral vascular disease
- Bladder cancer
- An increase in abnormal spermatozoa
- Memory problems

**Maternal smoking**
- A decrease in birth weight of the infant
- An increase in fetal and neonatal mortality
- An increase in asthma

**Passive smoking**
- Risk of asthma, pneumonia and bronchitis in infants of smoking parents
- An increase in cough and breathlessness in smokers and non-smokers with COPD and asthma
- An increase in cancer risk

### RESPIRATORY INFECTION

#### Pneumonia

Pneumonia is defined as inflammation of the substance of the lungs. It is usually caused by bacteria but can also be caused by viruses and fungi. Clinically, it usually presents as an acute illness with cough, purulent sputum, breathlessness and fever, together with physical signs or radiological changes compatible with consolidation of the lung (Fig. 28.28). However, it can present with more subtle symptoms, particularly in the elderly.

Pneumonia is usually classified by the setting in which the patient has contracted the infection, for example:
- **Community-acquired pneumonia** in a person with no underlying immunosuppression or malignancy
- **Hospital-acquired pneumonia** (sometimes called ‘healthcare-associated pneumonia’, reflecting the role of other institutions such as nursing homes)
- **Aspiration pneumonia**, associated with the aspiration of food material or stomach contents into the lungs, and caused by impaired swallowing
- **Pneumonia in immunocompromised patient**, acquired through either a genetic defect, immunosuppressive medication or acquired immunodeficiency, as in human immunodeficiency virus (HIV) infection
- **Ventilator-acquired pneumonia**, acquired through mechanical ventilation on a critical care unit.

#### Community-acquired pneumonia

Community-acquired pneumonia (CAP) occurs across all ages but is more common at the extremes of age. *Streptococcus pneumoniae*...
is the most common cause overall; however, in 30–50% of cases no organism is identifiable, while in about 20% more than one organism is present. Infection can be localized, when the whole of one or more lobes is affected (‘lobar pneumonia’), or diffuse, when the lobules of the lung are mainly affected, often due to infection centred on the bronchi and bronchioles (‘bronchopneumonia’). Factors that increase the risk of developing CAP are shown in Box 28.33.

Clinical features
The clinical presentation varies according to the immune state of the patient and the infecting agent. Features include:
- **a dry or productive cough**, sometimes with haemoptysis
- **breathlessness**
- **fevers**, which, if swinging, may indicate empyema (see p. 965)
- **chest pain** may be experienced, commonly pleuritic in nature and due to inflammation of the pleura; a pleural rub may be heard early on in the illness
- **extrapulmonary features** (Box 28.34).

In the elderly, CAP can present with confusion or non-specific symptoms such as recurrent falls. CAP should always be considered in the differential diagnosis of sick elderly patients, given their frequently atypical presentation.

Initial assessment
The type and extent of investigations depend on the severity of the illness, which also guides where the patient should be managed and predicts their outcome. Diagnostic microbiological tests are not needed in mild infection, which should be treated at home with standard oral antibiotics (amoxicillin, or clarithromycin for those with a history of penicillin allergy). Where patients have mild disease, chest X-ray is not routinely recommended unless they fail to improve after 48–72 hours.

Severity is commonly assessed by the CURB-65 or the CRB-65 score; the CRB-65 score is used in the community where the serum urea level is not usually available (Box 28.35). These give a guide to the likely risk of fatal outcome but antibiotic choice must always be tempered by clinical assessment and judgement, taking into account other factors associated with increased rates of mortality (see Box 28.27).

Investigations
All patients admitted to hospital with suspected CAP should have a chest X-ray, blood tests and microbiological tests.

Chest X-ray
Radiological abnormalities can lag behind clinical signs. A normal chest X-ray on presentation should be repeated after 2–3 days if CAP is suspected clinically. The chest X-ray must be repeated 6
weeks later to rule out an underlying bronchial malignancy causing pneumonia due to bronchial obstruction.

**Blood tests**

Full blood count, serum creatinine and electrolytes, biochemistry and C-reactive protein (CRP) are helpful.

- **Strep. pneumoniae.** White cell count is usually >15 x 10⁹/L (90% leucocytosis neutrophils). Inflammatory markers are significantly elevated: erythrocyte sedimentation rate (ESR) >100 mm/h; CRP >100 mg/L.
- **Mycoplasma.** White cell count is usually normal. In the presence of anaemia, haemolysis should be ruled out (direct Coombs’ test and measurement of cold agglutinins, see p. 965).
- **Legionella.** There is lymphopenia without marked leucocytosis, hyponatraemia, hyperalbuminaemia and high serum levels of liver aminotransferases.

**Other tests**

- **Sputum culture and blood cultures** are required for all patients who have moderate to severe CAP, ideally before antibiotics are administered. In Strep. pneumoniae infection, positive blood cultures indicate more severe disease with greater mortality.
- **Arterial blood gas analysis** is necessary if oxygen saturation is <94%.
- **An HIV test** should be offered to all patients with pneumonia since it is a common initial presenting illness in previously undiagnosed HIV infection.

**General management**

Initial management and assessment should follow the guidelines for management of sepsis (see p. 157), particularly when a patient appears to have a moderate to severe pneumonia. In general:

- **Oxygen.** Supplemental oxygen should be administered to maintain saturations between 94% and 98% (provided the patient is not at risk of carbon dioxide retention, due to loss of hypoxic drive in COPD). In patients with known COPD, oxygen saturations should be maintained between 88% and 92%.
- **Intravenous fluids.** These are required in hypotensive patients showing any evidence of volume depletion and hypotension.
- **Antibiotics.** The first dose of antibiotic should be administered within 1 hour of identifying any high-risk criteria and treatment should not be delayed while investigations are awaited. Parenteral antibiotics should be switched to oral once the temperature has settled for a period of 24 h, provided there is no contraindication to oral therapy. If patients fail to respond to initial treatment, microbiological advice should be sought and alternative diagnoses considered. The antibiotic regimen should be adjusted specifically once culture and sensitivity results are available (Fig. 28.29).
- **Thromboprophylaxis.** If the patient is admitted for >12h, subcutaneous low-molecular-weight heparin should be prescribed and thromboembolus deterrent (TED) stockings should be fitted, unless contraindications exist.
- **Physiotherapy.** Chest physiotherapy is not needed unless sputum retention is an issue.
- **Nutritional supplementation.** Need is assessed by a dietician, particularly in severe disease.
- **Analgesia.** Simple analgesics, such as paracetamol or an NSAID, helps treat pleuritic pain, thereby reducing the risk of further complications due to restricted breathing because of pain (e.g. sputum retention, atelectasis or secondary infection). Causes of a slow-resolving pneumonia are outlined in Box 28.36.

**Complications of pneumonia**

See Box 28.37.

**Parapneumonic effusion and empyema**

Pleural effusions are common with pneumonia and complicate around one-third to one-half of cases of CAP. The majority of these are simple exudative effusions but empyema may also develop (purulent fluid in the pleural space). Early indications of empyema are ongoing fever and rising or persistently elevated inflammatory markers, despite appropriate antibiotic therapy.

Pleural aspiration should be performed under ultrasound guidance to make a diagnosis and fluid sent for Gram stain, culture, fluid protein, glucose and LDH (with comparison to serum levels). Light’s criteria (see p. 973) can be applied to assess whether an effusion is transudative or exudative. An exudative effusion with pleural fluid pH of <7.2 is strongly suggestive of empyema. Pathogens are often detectable; sensitivity analysis will help guide antimicrobial therapy.

If an empyema develops, the fluid should be urgently drained to prevent further complications, such as development of a thick
pleural rind or prolonged hospital admission. The presence of empyema further increases mortality risk. The duration of antibiotic administration will usually need to be extended. Whenever possible, the choice of antimicrobial should be guided by the results of cultures. Thoracic surgical intervention is necessary in severe cases.

**Lung abscess**

This term is used to describe severe localized suppuration within the lung associated with cavity formation visible on the chest X-ray or CT scan, often with a fluid level (which always indicates an air-liquid interface). There are several causes of lung abscess (Box 28.38). Clinical features usually include persisting or worsening pneumonia associated with the production of large quantities of sputum, which is often foul-smelling owing to the growth of anaerobic organisms. There is usually a swinging fever; malaise and weight loss frequently occur. There may be few signs on physical examination, although clubbing occurs in chronic suppuration. Patients have a normocytic anaemia and raised inflammatory markers (ESR/CRP). CT scanning is essential and bronchoscopy can be undertaken to obtain samples or remove foreign bodies. Treatment should be guided by available culture results or clinical judgement, and is often prolonged (4–6 weeks). Surgical drainage is sometimes necessary.

### Pneumonia in other settings

#### Hospital-acquired pneumonia

Hospital-acquired pneumonia (HAP) is defined as new onset of cough with purulent sputum, along with a compatible X-ray demonstrating consolidation, in patients who are beyond 2 days of their

---

**Fig. 28.29** Algorithm for the assessment and treatment of community-acquired pneumonia. CRB, confusion, respiratory rate, blood pressure (CURB includes urea); ITU, intensive treatment unit; PCR, polymerase chain reaction.
**Box 28.38 Causes of lung abscess and causative organisms**

**Causes**
- Aspiration pneumonia
- Tuberculosis
- Staphylococcus aureus or Klebsiella pneumoniae
- Septic emboli usually containing staphylococci
- Inadequately treated community-acquired pneumonia
- Spread from an amoebic liver abscess
- Bronchial obstruction by an endoluminal cancer
- Foreign body inhalation

**Common causative organisms**
- Klebsiella pneumoniae
- Staphylococcus aureus
- Gram-negative enteric bacilli
- Mycobacterium tuberculosis
- Streptococcus milleri
- Anaerobic bacteria (post aspiration)
- Haemophilus influenzae

**Box 28.39 Organisms implicated in hospital-acquired pneumonia**

- Gram-negative bacteria (*Pseudomonas* spp., *Escherichia* spp., *Klebsiella* spp.)
- Anaerobic bacteria (*Enterobacter* spp.)
- *Staphylococcus aureus* (including meticillin-resistant *Staph. aureus*)
- *Acinetobacter* spp.

initial admission to hospital or who have been in a healthcare setting within the last 3 months (including nursing or residential homes, as well as acute care facilities such as hospitals). HAP is the second most common form of hospital-acquired infection after urinary tract infections and carries a significant mortality risk, particularly in the elderly or those with co-morbidities such as stroke, respiratory disease or diabetes. In HAP, the causative organisms differ from those causing CAP (Box 28.39). Viral or fungal pathogens only affect immunocompromised hosts.

**Ventilator-associated pneumonia**

This occurs in the context of mechanical ventilation in a critical care setting. Often multidrug-resistant Gram-negative organisms (such as *Acinetobacter baumannii*) are responsible, requiring careful selection of an appropriate antibiotic in association with a clinical microbiologist.

**Aspiration pneumonia**

Acute aspiration of gastric contents into the lungs can produce an extremely severe and sometimes fatal illness owing to the intense destructiveness of gastric acid. This can complicate anaesthesia, particularly during pregnancy (Mendelson’s syndrome). Because of the bronchial anatomy, the most usual sites for aspirated material to end up are the right middle lobe and the apical or posterior segments of the right lower lobe. Persistent pneumonia is often due to anaerobes and may progress to lung abscess or even bronchiectasis if protracted. It is vital to identify any underlying problem, as aspiration will recur without appropriate corrective measures.

**Treatment** should be directed specifically against positive cultures if available. If not, then co-amoxiclav is used for mild to moderate disease, which covers Gram-negative and anaerobic bacteria. Treatment needs to be escalated when there is a lack of response or cases are severe.

**Pneumonia in immunocompromised patients**

Patients who are immunosuppressed (either iatrogenically or due to a defect in host defences) are at risk not only from all the usual organisms that can cause pneumonia but also from opportunistic pathogens that would not be expected to cause disease. These opportunistic pathogens can be commonly occurring microorganisms (that are ubiquitous in the environment) or bacteria, viruses and fungi that are less common (see Box 37.21). The symptom pattern may resemble CAP or be more non-specific. A high degree of clinical suspicion is therefore necessary when assessing an ill patient who is immunocompromised.

**Pneumocystis jirovecii pneumonia**

*Pneumocystis* pneumonia is one of the most common opportunistic infections encountered in clinical practice. It affects patients on immunosuppressant therapy, such as long-term corticosteroids, monoclonal antibodies or methotrexate for autoimmune disease; those on anti-rejection medication after a solid organ or haemopoietic stem cell transplantation; and those infected with HIV. Individuals with CD4 counts of less than 200/mm³ are at particular risk. *Pneumocystis jirovecii* is found in the air, and pneumonia arises from re-infection rather than reactivation of persisting organisms acquired in childhood.

Clinically, the pneumonia is associated with a high fever, breathlessness and dry cough. A characteristic feature on examination is rapid desaturation on exercise or exertion. The typical radiographic appearance is one of diffuse bilateral alveolar and interstitial shadowing beginning in the perihilar regions and spreading out in a butterfly pattern. Other chest X-ray appearances include localized infiltration, nodules, cavitation or a pneumothorax. Empirical treatment is justified in very sick high-risk patients; wherever possible, however, the diagnosis should be confirmed by indirect immunofluorescence on induced sputum or bronchoalveolar lavage fluid. First-line treatment of *Pneumocystis* pneumonia is with high-dose co-trimoxazole (see p. 1443), with adjunctive corticosteroids in patients with HIV infection.

**Further reading**

**Tuberculosis**

Tuberculosis (TB) is one of the world’s most common infectious diseases. It is caused by the bacterium *Mycobacterium tuberculosis*, which comes from the large *Mycobacteriaceae* family, members of which include *M. leprae*. It is estimated that one-third of the world’s population is infected with tuberculosis (see also p. 503), with the majority of cases (around 65%) seen in Africa and Asia. There is
Respiratory disease

Box 28.40 Factors affecting prevalence and risk of developing tuberculosis in the developed world

**Contact with high-risk groups**
- Origin from a high-incidence country (defined as >40/100,000)
- Frequent travel to high-incidence areas

**Immune deficiency**
- HIV infection
- Corticosteroids or immunosuppressant therapy
- Chemotherapeutic drugs
- Nutritional deficiency (vitamin D)
- Diabetes mellitus
- Chronic kidney disease
- Malnutrition/body weight >10% below ideal body weight

**Lifestyle factors**
- Drug/alcohol misuse
- Homelessness/hostels/overcrowding
- Prison inmates

**Genetic susceptibility**
- Twin studies of gene polymorphisms

Pathogenesis

*M. tuberculosis* is an aerobic, intracellular pathogen. Due to their relative impermeability to acid-based dyes in the laboratory, these organisms are often termed ‘acid-fast bacilli’. TB is an airborne infection spread by coughing via respiratory droplets. Only a small number of bacteria need to be inhaled for infection to develop, but not all those who are infected develop active disease.

Primary tuberculosis

‘Primary TB’ describes the first infection with TB. When the bacteria reach the alveolar macrophages, they are ingested and the subsequent inflammatory reaction results in tissue necrosis and formation of a granuloma. These granulomatous lesions consist of a central area of necrotic material called caseation, surrounded by epithelioid cells and Langhans giant cells.

Subsequently, the caseated areas heal completely and many become calcified. Some of these calcified nodules contain bacteria, which are contained by the immune system (and the hypoxic acidic environment created within the granuloma) and are capable of lying dormant for many years. This is known as the primary focus or the ‘Ghon focus’ of the disease. On a chest X-ray, the Ghon focus can be evident as a small, calcified nodule.

On initial contact with infection, less than 5% of patients develop active disease. This increases to 10% within the first year of exposure.

Reactivation tuberculosis

In the majority of people who are infected by *Mycobacterium* spp., the immune system contains the infection and the patient develops cell-mediated immune memory of the bacteria. This is termed ‘latent TB’. The majority of active TB cases are due to reactivation of latent infection, where the initial contact usually occurred many years or decades earlier. Most patients are young and previously healthy but may have one or more of risk factors implicated in the development of active disease (Box 28.41). In patients with HIV infection, newly acquired TB is also common. The majority of active TB occurs in the lung, but extrapulmonary infection occurs with spread to the lymph nodes, particularly the cervical and intrathoracic chains, where it causes active disease in 20–25% (UK figures) and also via the bloodstream to more distant sites such as the brain, bones and skin.

Clinical features and diagnosis

The cardinal symptoms of TB are cough, haemoptysis and the systemic symptoms of fevers, night sweats and weight loss. However, in extrapulmonary sites, respiratory symptoms are often absent, and the systemic symptoms are often ignored by patients and medical practitioners alike.

In all cases of suspected TB, it is essential, depending on the site of disease, to obtain sputum, biopsy samples or fluid for microscopy, smear and culture, to obtain information on sensitivities. Tissue samples should also be sent for histopathological examination, either dry or in saline.

Pulmonary TB

Patients are frequently symptomatic with a productive cough and, occasionally, haemoptysis, along with systemic symptoms. Where there is laryngeal involvement, a hoarse voice and a severe cough are found. If disease involves the pleura, then pleuritic pain is a frequent presenting complaint.

The chest X-ray (Fig. 28.30) can show consolidation with or without cavitation, pleural effusion, or thickening or widening of the mediastinum caused by hilar or paratracheal adenopathy.
Serial sputum samples should be collected on at least three occasions (ideally, first thing in the morning); if the patient is unable to produce sputum, it may be necessary to organize an induced sputum or perform bronchoscopy to obtain samples.

Patients whose sputum is smear-positive for TB are considered to be infectious and should be isolated in hospital. Those who are smear-negative but subsequently culture-positive are less infectious and generally so not need to be isolated, although care should be taken when contacts include immunocompromised individuals.

Lymph node TB
The lymph nodes are the second most commonly affected organs. Extrathoracic nodes are more commonly involved than intrathoracic or mediastinal. Usually, presentation is with firm, non-tender enlargement of a cervical or supraclavicular node. The node becomes necrotic centrally and can liquefy and be fluctuant if peripheral. The overlying skin is frequently indurated or there can be sinus tract formation with purulent discharge, but characteristically there is no erythema (‘cold abscess’ formation). Nodes can typically be enlarged for several months prior to diagnosis. On CT imaging, the central area appears necrotic (Box 28.42). Samples should be obtained via either ultrasound-guided fine needle aspiration (FNA), core biopsy or, if necessary, removal of a whole node. All samples must be sent for AFB smear and culture, and cancer should be excluded on cytology. EBUS can be used to biopsy intrathoracic nodes.

Other forms of TB
Gastrointestinal TB
See page 455 and 484.

TB of bone and spine
See pages 455 and 484.

Miliary TB
Miliary disease occurs through haematogenous spread of the bacilli to multiple sites, including the central nervous system (CNS) in 20% of cases. It often presents with systemic symptoms and the chest X-ray demonstrates multiple nodules, which appear like millet seeds: hence the term ‘miliary’.

Other findings are liver and splenic microabscesses with deranged liver enzymes, cholestasis and gastrointestinal symptoms. All patients should have brain imaging (MRI), to look for evidence of cerebral disease, which can present as an asymptomatic brain tuberculoma.

Central nervous system TB
See page 870.

Pericardial TB
See page 1126.

Skin
See page 671.

Microbiological diagnosis
Once samples have been taken, the rapid identification of the presence of mycobacterium by stains is essential and should be performed within 24 hours; culture of the sample allows determination of the antibiotic sensitivity of the infecting strain.

Stains
Auramine–rhodamine staining is more sensitive (though less specific) than Ziehl–Neelsen; as a result, it is more widely used. It requires fluorescence microscopy and highlights bacilli as yellow–orange on a green background.

Culture
The majority of the developed world uses liquid/broth culture of mycobacteria in addition to solid media (Lowenstein–Jensen slopes or Middlebrook agar), as time to culture is shorter than for solid culture (1–3 weeks compared with 3–8 weeks). Using liquid culture in the presence of antimycobacterial drugs (usually first-line therapy) establishes the drug sensitivity for that strain and usually takes approximately 3 weeks.

Nucleic acid amplification and polymerase chain reaction
Nucleic acid amplification testing (NAAT) is increasingly used for rapid identification of MTb complex and is useful in differentiating between M. tuberculosis complex and non-tuberculous mycobacteria, as well as identifying TB in smear-negative sputum specimens. It works by using the polymerase chain reaction (PCR) to replicate and then identify mycobacterium DNA. Culture and staining are still necessary and should not be replaced by PCR. PCR is useful only at the initial stage of diagnosis, as it frequently remains positive despite treatment, due to the detection of dead organisms.

The identification of mycobacterial DNA is useful in facilitating rapid commencement of treatment and also rapid identification of drug resistance. Genetic mutations in bacterial DNA conferring rifampicin resistance are highly predictive of multidrug resistance. The development of a highly specific probe designed to detect this mutation thereby allows efficient identification of resistant disease and commencement of appropriate therapy sooner than waiting for cultures to complete (which may take up to 8 weeks).

Commercial kits, such as GeneXpert, are available that can reliably perform molecular testing in the field and take less than 2 hours to complete; they are now widely used in low- and middle-income countries to detect genetic mutations associated with rifampicin resistance.

More recently, in the UK, whole-genome sequencing (WGS) has begun to be used on a routine basis to identify different strains of mycobacterium and also detect drug resistance. This will start to replace routine culture and phenotypic testing in the near future.

Management
All patient should have routine blood tests and a viral hepatitis screen, and be offered an HIV test before treatment. Patients with active viral hepatitis are much more likely to develop a fatal drug-induced hepatitis and need careful monitoring and counselling. Those with fully sensitive TB require 6 months of treatment; the exception is TB infection of the CNS, for which the recommended duration is at least 12 months. Isoniazid, rifampicin, pyrazinamide and ethambutol are the first-line TB drugs, known as quadruple therapy. In CNS and pericardial disease, corticosteroids are used as an adjunct at treatment initiation to reduce long-term complications. Box 28.43 summarizes the standard recommended regimens.

Enhanced case management, together with directly observed therapy (DOT), is recommended where there are concerns about adherence to treatment or difficulties in taking medication (Box 28.44).

| **Pulmonary, pleural and laryngeal TB** | Smear and culture of:  
Sputum (≥2 samples increase diagnostic yield)  
Induced sputum (inhaled hypertonic saline, which induces coughing):  
diagnostic yield comparable to bronchoscopic samples  
Bronchoalveolar lavage fluid if cough unproductive and induced sputum not possible  
Aspiration of pleural fluid and pleural biopsy  
Gastric aspirates – can be useful in paediatric disease  
Nasoendoscopic or bronchoscopic examination/biopsy of vocal cords with biopsy for smear/culture and histology in laryngeal disease |
| **Miliary TB** | Blood cultures  
Bronchoalveolar lavage fluid (usually smear-negative but culture-positive)  
MRI head followed by lumbar puncture should be performed in all cases, unless contraindicated, to assess for central nervous system involvement (affects treatment duration), and sampling of other involved organs is often necessary |
| **Central nervous system TB** | Ensure that patient and scans are discussed at neurology/neurosurgery MDT  
Consider brain biopsy if concerns about diagnosis  
Lumbar puncture if no contraindication – characteristics:  
CSF protein may be very high (usually >2–3 g/L)  
CSF glucose <½ blood glucose  
CSF lymphocytosis |
| **Lymph node TB** | All samples should be sent for histocytological examination as well as culture and smear:  
Fine needle aspiration or biopsy of an involved lymph node, usually under radiological guidance  
Mediastinal nodal sampling (endobronchial ultrasound transbronchial needle aspiration, mediastinoscopy/mediastinotomy) |

CSF, cerebrospinal fluid; MDT, multidisciplinary team meeting.
Unwanted effects of drug treatment

The most common side-effects of quadruple TB therapy are nausea, vomiting, rash and itching. An antiemetic or antihistamine can be prescribed to alleviate these symptoms, although in some cases treatment may need to be interrupted. This is a particular problem when liver function tests become deranged and there is concern about a drug-induced hepatitis, in which case it is often necessary to stop all four drugs and re-introduce one at a time. The drug should be stopped only if the serum bilirubin becomes elevated or if transferases are more than three times elevated.

Isoniazid can cause a polyneuropathy due to $B_6$ deficiency, as isoniazid interacts with pyridoxal phosphate; vitamin $B_6$, pyridoxine 10–25 mg daily, should be prescribed concomitantly to prevent this. Occasionally, isoniazid gives rise to allergic reactions, such as a skin rash and fever. Hepatitis occurs in less than 1% of cases but may lead to liver transplantation or death if the drug is continued.

Rifampicin induces liver enzymes, which may be transiently elevated in the serum of many patients. This also means that concomitant drug treatment may be made less effective and a careful review of a patient’s therapy will need to be undertaken, particularly with antidepressants, anticoagulants and antiepileptics (see p. 259). Oral contraception will not be effective, so alternative birth-control methods should be used. Rifampicin stains body secretions red/pink and patients should be warned of the change in colour of their urine, tears (affecting contact lenses) and sweat. Thrombocytopenia has been reported.

Pyrazinamide may cause hepatic toxicity but its most common side-effects are itching, rash and arthralgia; pyrazinamide reduces the renal excretion of urate and may precipitate hyperuricaemic gout.

Ethambutol can cause a dose-related optic retrobulbar neuritis that presents with colour blindness for green, reduction in visual acuity and a central scotoma. Patients should have their visual acuity and colour vision checked prior to treatment using Snellen and Ishihara charts. This condition usually reverses, provided the drug is stopped when symptoms develop; patients should therefore be warned of its effects. All patients prescribed the drug should be seen by an ophthalmologist prior to treatment and doses of 15 mg/kg should be used, with a maximum dose of 1.2 g.

Drug resistance

Mono- or multidrug resistance arises due to incomplete or incorrect drug treatment (acquired) and can be spread from person to person. Isoniazid monoresistance occurs in approximately 10% of TB cases in the UK. A risk assessment for drug resistance should be routinely performed (Box 28.45). The incidence of multidrug resistance in TB (resistance to both rifampicin and isoniazid, termed MDR-TB) is relatively low in developed countries (around 1%). Extremely drug-resistant disease (XDR-TB) is defined as high-level resistance to rifampicin, isoniazid, fluoroquinolones and at least one injectable agent such as amikacin, capreomycin or kanamycin.

TB in special situations

Mycobacterium bovis infection

Mycobacterium bovis infection occurs in humans who have consumed unpasteurized milk, farmers working with infected cows, and abattoir workers. TB due to $M. bovis$ does not differ from ordinary TB in the chest but extrapulmonary sites of infection, such as lymph nodes, are more frequently involved. Lymphadenitis is common in children. Immunosuppression is also a risk factor. The tuberculin test is positive. Treatment is with isoniazid, rifampicin, fluoroquinolones and at least one injectable agent such as amikacin, capreomycin or kanamycin.

HIV co-infection

The increase in TB seen over recent decades has occurred to a considerable extent in association with the incidence of HIV infection, with high levels seen in Africa (particularly sub-Saharan), the Indian subcontinent and parts of Eastern Europe and Russia. The incidence of HIV infection in TB worldwide is around 10% and TB is responsible for about one-quarter of acquired immunodeficiency syndrome (AIDS)-related deaths.

Alongside the increased morbidity and mortality of co-infection, there are specific issues relating to the treatment of TB in HIV: namely, the incidence of drug interactions and intolerability, the increased risk of treatment toxicity and the higher incidence of drug resistance. TB/HIV infection should be managed by experts
in TB (respiratory or infectious disease physicians) alongside HIV specialists.

**Latent TB infection**

Latent TB infection (LTBI) is diagnosed by demonstrating immune memory to mycobacterial proteins. Two types of test are available.

In the *tuberculin skin test* (*Mantoux test*) a positive result is indicated by a delayed hypersensitivity reaction evident 48–72 hours after the intradermal injection of purified protein derivative (PPD), resulting in a raised, indurated lesion. False-negative (anergic) tuberculin skin tests (TSTs) are common in patients with immunosuppression due to HIV infection (CD4+ <200/mm³), those taking immunosuppressant medications (chemotherapy, anti-TNF therapy, steroids), those at the extremes of age and those with active disease. False-positives occur due to cross-reactivity with non-tuberculous mycobacteria and bacille Calmette–Guérin (BCG) vaccination.

*Interferon-gamma release assays (IGRAs)* detect T-cell secretion of IFN-γ following exposure to *M. tuberculosis*-specific antigens (ESAT-6, CFP-10). Where a person has been previously infected or is currently infected with TB, activated T cells within their extracted whole blood secrete quantifiable levels of IFN-γ in response to re-exposure to TB-specific antigens. The test does not differentiate between active and latent infection. However, it is highly specific compared with the TST, with similar or better sensitivity, and requires only a single patient visit.

In certain groups with LTBI, *chemoprophylaxis* is offered to reduce the risk of active infection:

- household and close workplace contacts of patients with pulmonary and laryngeal TB
- health workers
- recent new migrant entrants from high-risk countries
- patients who are immunocompromised, such as those with HIV infection
- those about to commence treatment with biologic agents (such as infliximab)
- those due to have stem cell or solid organ transplants.

**LTBI treatment** is either with isoniazid and rifampicin for 3 months or with isoniazid monotherapy for 6 months.

**BCG vaccination**

BCG is a live attenuated vaccine derived from *M. bovis* that has lost its virulence. It has variable efficacy but is still recommended in certain situations in developed countries (but not the USA), though it is no longer offered routinely to all due to the lack of cost efficacy. In the UK it is still offered to all neonates in high-risk areas such as inner cities, although there are safety concerns in babies with HIV.

**Non-tuberculous mycobacterial infection**

Non-tuberculous mycobacteria (NTM) occur in soil and water, and are not usually pathogenic due to their lack of virulence. However, where there is a breach of the normal host defence mechanisms, certain strains have the potential to become pathogenic (Box 28.46). Factors associated with an increased risk of pulmonary NTM infection include structural lung disease such as COPD, bronchiectasis and cystic fibrosis, and immunosuppressive states such as HIV infection (see Box 37.21). Treatment is suggested if there is a compatible clinical picture, the organism is isolated from an invasive sample or an NTM is isolated from more than one sputum sample obtained at different times.

**PLEURAL DISEASE**

**Pleural effusion**

A pleural effusion is an excessive accumulation of fluid in the pleural space. It can be detected on X-ray when 300mL or more of fluid is present, and clinically when there is 500mL or more. The chest X-ray appearances (Fig. 28.31) range from obliteration of the costophrenic angle to dense homogeneous shadows occupying part or all of the hemithorax. Fluid below the lung (a subpulmonary effusion) can simulate a raised hemidiaphragm. Fluid in the fissures may resemble an intrapulmonary mass. The physical signs are are described in Box 28.8.

**Diagnosis**

This is by pleural aspiration (see p. 944), usually done under ultrasound guidance. The fluid that accumulates may be a transudate or an exudate (Box 28.47).
Transudates
Effusions that are transudates can be bilateral but are often larger on the right side. The protein content is less than 30 g/L, the LDH is less than 200 IU/L and the fluid to serum LDH ratio is below 0.6. Causes include:
- heart failure
- hypoproteinaemia (e.g. nephrotic syndrome)
- constrictive pericarditis
- hypothyroidism
- ovarian tumours producing right-sided pleural effusion – Meigs’ syndrome.

Exudates
The protein content of exudates is over 30 g/L and the LDH is more than 200 IU/L. Causes include:
- bacterial pneumonia (common)
- carcinoma of the bronchus – fluid may be blood-stained (common)
- pulmonary infarction
- TB
- autoimmune rheumatic diseases
- post-myocardial infarction syndrome (rare)
- acute pancreatitis (high amylase content) (rare)
- mesothelioma
- sarcoidosis (very rare)
- yellow-nail syndrome (effusion due to lymphoedema) (very rare)
- familial Mediterranean fever (very rare).

Pleural biopsy (see p. 944) may be necessary if the diagnosis has not been established by simple aspiration.

Management is of the underlying condition unless the fluid is purulent (empyema), in which case drainage is mandatory.

Management of malignant pleural effusions
Malignant pleural effusions that reaccumulate and are symptomatic can be aspirated to dryness followed by the instillation of a sclerosing agent such as tetracycline or talc. Effusions should be drained slowly since rapid shift of the mediastinum causes severe pain and occasionally shock. This treatment produces only temporary relief.

Chylothorax
This is caused by accumulation of lymph in the pleural space, usually resulting from leakage from the thoracic duct following trauma or infiltration by carcinoma.

Empyema
The presence of pus in the pleural space can be a complication of pneumonia. It requires urgent drainage (see p. 965).

Pneumothorax
‘Pneumothorax’ means air in the pleural space. Primary spontaneous pneumothoraces occur predominantly in young people. Traditionally, patients are tall, thin and male but shape, size and gender often do not follow this rule. Primary pneumothoraces are usually caused by rupture of a pleural bleb, usually apical, and are thought to be due to congenital defects in the connective tissue of the alveolar walls. Both lungs are affected with equal frequency.

Secondary pneumothoraces occur in conjunction with pre-existing lung disease such as COPD, infection and cystic fibrosis. Iatrogenic pneumothoraces are caused by instrumentation to the thorax, such as central venous line insertion, percutaneous or tranbronchial lung biopsy, or trauma.
Clinical features
Patients commonly present with sudden onset of chest drain and breathlessness. On careful questioning, they may be discovered to have had a milder version of these symptoms in the past but not sought medical attention. In tension pneumothorax they may become shocked, and emergency decompression of the pneumothorax may be necessary using a 14–16 gauge needle in the second rib space in the mid-clavicular line.

Investigations
Plain chest X-ray is the baseline investigation and the size of pneumothorax should be recorded. There are several ways to measure: in North America the apex to cupola distance tends to be used, while UK guidelines recommend the pleura to edge of lung distance. If a patient’s first pneumothorax resolves and there is no recurrence, cross-sectional imaging with a CT chest is unnecessary. However, if the chest is abnormal on resolution, a scan should be requested. With the common use of cannabis and other recreational drugs, bullae and associated emphysema are being more commonly seen in young people.

Management
Pneumothoraces can be managed in a number of ways (Fig. 28.32), depending on the cause and the severity of symptoms on presentation. Treatment includes simple observation, pleural aspiration, intercostal drain and surgical management, both in the more acute situation or electively.
Simple aspiration of pneumothorax

1. Explain the nature of the procedure and obtain consent.
2. Infiltrate 2% lidocaine down to the pleura in the second intercostal space in the mid-clavicular line.
3. Push a 3–4 cm 16-gauge cannula through the pleura.
4. Connect the cannula to a three-way tap and a 50 mL syringe.
5. Aspirate up to 2.5 L of air. Stop if resistance to suction is felt or the patient coughs excessively.
6. Repeat the chest X-ray (in expiration) in the X-ray department.

Observation: For patients with mild symptoms and a pneumothorax of <2 cm simple observation is enough. Patients can be discharged from the emergency department with instructions to return if their symptoms become worse. They should be advised not to fly until the pneumothorax has completely resolved and never to scuba dive unless they have had surgical pleurodesis (Box 28.48). They have a 30% chance of a recurrent pneumothorax. Patients often ask about sport and exercise, and while there are no real restrictions, apart from diving, they should generally rest for a few days before exercising in moderation and should avoid contact sports for a week or two. Outpatient follow-up should be arranged within 10 days.

Aspiration: This can be considered in symptomatic patients with a pneumothorax of >2 cm, or 1 cm in a secondary pneumothorax. It is undertaken using a 16 French gauge needle attached to a three-way tap and a 50 mL syringe (Box 28.49). Generally, aspiration should not be attempted in most cases of traumatic pneumothorax. It should be followed by a repeat chest X-ray, discharge advice (as described) and outpatient follow-up.

Pleural intercostal drain: If aspiration fails to inflate the lung satisfactorily, the patient is very breathless on admission, there is evidence of a tension pneumothorax or the cause is related to trauma, an intercostal drain should be inserted, normally in the mid-axillary line 4th intercostal space. The tube should be connected to an underwater drain and bottle, which are kept below the level of the patient’s chest. It should be checked daily for evidence of infection at the insertion site and for kinks and leaks along its course.

Surgical pleurodesis and bleb resection: An open surgical pleurodesis via thoracotomy or VATS procedure should be considered when the lung fails to re-inflate, or offered to patients electively.

Smoking: Patients should be strongly advised to stop smoking both tobacco and recreational drugs. Cannabis, in particular, can cause marked emphysematous changes in younger people, which leads to subcutaneous blebs and bullae.

Psychological effects: Medical staff underestimate the concern that patients often feel, knowing that they have a medical condition that can potentially recur at any time. Some become very anxious and often request surgical pleurodesis after their second or third recurrence.

TUMOURS OF THE RESPIRATORY TRACT

Malignant tumours

Bronchial carcinoma

Bronchial carcinoma is the most common malignant tumour worldwide, causing around 1.76 million deaths annually. It is the fifth most frequent cause of death in the UK and is now the most common cause of cancer-related death in both men and women.

Cigarette smoking (including passive smoke exposure) accounts for 80% and 90% of lung cancer in men and women, respectively. There remains a higher incidence of bronchial carcinoma in urban compared with rural areas, even when allowance is made for cigarette smoking. Other aetiological factors include:

- Environmental: radon exposure, asbestos, polycyclic aromatic hydrocarbons and ionizing radiation; occupational exposure to arsenic, chromium, nickel, petroleum products and oils.
- Host factors: pre-existing lung disease such as pulmonary fibrosis; HIV infection; genetic factors.

Legislative control over smoking in public places in many parts of the world has been introduced to reduce ill health related to cigarette smoke.

Pathophysiology

Historically, lung cancers have been broadly divided into small-cell carcinoma and non-small-cell carcinoma, based on the histological appearances of the cells seen within the tumour. This distinction is necessary with respect to the behaviour of the tumour, providing prognostic information and determining best treatment. Non-small-cell carcinoma is further divided into a number of cell types (adenocarcinoma, squamous cell carcinoma, large-cell carcinoma (Box 28.50)). A number of molecular characteristics have been described in the subtypes of cancer, which confer potential prognostic benefit and may result in the ability to deliver a more personalized therapy with targeted agents. The most common of these are activating mutations within epidermal growth factor receptor (EGFR), most commonly encountered in non-smokers, females and those of Asian origin, and the presence of anaplastic lymphoma kinase (ALK) fusion oncogene, again more commonly found in non-smokers or ex-smokers and younger patients (see p. 119).

Clinical features

The presentation and clinical course vary between the different cell types (see Box 28.50). Symptoms and signs may be different, depending on the extent and site of disease.

Common presenting features can be divided into those caused by direct/local tumour effects, metastatic spread and non-metastatic extrapulmonary features.

Local effects

- Cough. This is the most commonly encountered symptom in lung cancer. Because evidence suggests that this symptom is neglected by both patients and healthcare professionals, campaigns in the UK have highlighted the ‘3-week cough’ as a symptom that merits a chest X-ray.

</table>

- **Breathlessness.** Central tumours occlude large airways, resulting in lung collapse and breathlessness on exertion. Many patients with lung cancer have coexistent COPD, which is also a cause of breathlessness. Patients may also develop a pleural effusion due to metastatic involvement of the pleura.
- **Haemoptysis.** Fresh or old blood is coughed up because of the tumour bleeding into an airway.
- **Chest pain.** Peripheral tumours invade the chest wall or pleura (both well innervated), resulting in sharp pleuritic pain. Large-volume mediastinal nodal disease often results in a characteristic dull central chest ache.
- **Wheeze.** This is monophonic when due to partial obstruction of an airway by tumour.
- **Hoarse voice.** Mediastinal nodal or direct tumour invasion of the mediastinum results in compression of the left recurrent laryngeal nerve.
- **Nerve compression.** Pancoast tumours in the apex of the lung invade the brachial plexus, causing C8/T1 palsy with small muscle wasting in the hand and weakness, as well as pain, radiating down the arm. An associated Horner’s syndrome also occurs, caused by compression of the sympathetic chain, with classic features of miosis, ptosis and anhidrosis.
- **Recurrent infections.** Tumour causing partial obstruction of an airway results in post-obstructive pneumonia.
- **Direct invasion of the phrenic nerve.** Bronchial carcinoma invading the phrenic nerve causes paralysis of the ipsilateral hemidiaphragm. It can involve the oesophagus, producing progressive dysphagia, and the pericardium, resulting in pericardial effusion and malignant dysrhythmias.
- **Superior vena caval obstruction.** See page 117.
- **Tracheal tumours.** These present with progressive dyspnoea and stridor. Flow–volume curves show dramatic reductions in inspiratory flow (see Fig. 28.6C).

**Metastatic spread**

Bronchial carcinoma commonly spreads to mediastinal, cervical and even axillary or intra-abdominal nodes. In addition, the liver, adrenal glands, bones, brain and skin are frequent sites for metastases:
- **Liver.** Common symptoms are anorexia, nausea and weight loss. Right upper quadrant pain radiating across the abdomen is associated with liver capsular pain.
- **Bone.** Bony pain and pathological fractures occur as a result of tumour spread. If the spine is involved, there is a risk of spinal cord compression (see p. 878), which requires urgent treatment.
- **Adrenal glands.** Metastases to the adrenals do not usually result in adrenal insufficiency and are generally asymptomatic.
- **Brain.** Metastases present as space-occupying lesions with subsequent mass effect and signs of raised intracranial pressure. Less common presentations include carcinomatous meningitis with cranial nerve deficits, headache and confusion.
- **Malignant pleural effusion.** This presents with breathlessness and is commonly associated with pleuritic pain.

**Non-metastatic extrapulmonary manifestations of bronchial carcinoma**

discussed later Minor haematological extrapulmonary manifestations of lung cancer, such as normocytic anaemia and thrombocytosis, are reasonably common. Apart from finger clubbing and hypertrophic pulmonary osteoarthropathy (HPOA), most other non-metastatic complications are relatively rare. Approximately 10% of small-cell tumours produce ectopic hormones, giving rise to paraneoplastic syndromes (see Box 6.9).

**Investigations**

Investigations are necessary to:
- stage the extent of disease
- make a tissue diagnosis (to differentiate small-cell from non-small-cell lung cancer, as well as to detail the molecular characteristics – increasingly relevant with newer targeted biologic agents and immunotherapy)
- assess fitness to undergo treatment.

**Staging and diagnosis**

**Chest X-ray**

Plain chest X-rays may show obvious evidence of lung cancer or non-specific appearances (Box 28.51). In some cases the initial film is normal, either because the lesion is small or because disease is confined to central structures.

**Computed tomography**

CT indicates the extent of disease. Imaging should include the liver and adrenal glands, which are common sites for metastases. The

</table>
| ![Image](mass-lesion.png) | **Mass lesion**  
Lesions visible if >1 cm in diameter. Spiculated, cavitating or smooth-edged. Often an incidental finding, usually asymptomatic if small. By the time symptoms are present, chest X-ray is almost always abnormal. |
| ![Image](pleural-effusion.png) | **Pleural effusion**  
Usually unilateral; can obscure an underlying mass or pleural tumour. Mesothelioma and metastatic disease from other tumour sites are in the differential diagnosis. |
| ![Image](mediastinal-widening.png) | **Mediastinal widening or hilar adenopathy**  
Lymphadenopathy evident on the plain film, manifested by splayed carina, hilar enlargement or paratracheal shadowing. |
| ![Image](Collapse.png) | **Collapse**  
Endoluminal tumour causes complete collapse of a lung and associated mediastinal shift, or collapse of a lobe or segment, resulting in volume loss on the affected side with raised hemidiaphragm/deviated trachea. |
| ![Image](Reticular-shadowing.png) | **Reticular shadowing**  
Carcinoma spreads through the lymphatic channels of the lung to give rise to lymphangitis carcinomatosa; in bronchial carcinoma this is usually unilateral and associated with striking dyspnoea. Bilateral lymphangitis should prompt investigation for a primary site other than lung, such as breast, stomach or colon. |
| ![Image](Normal.png) | **Normal**  
A normal film does not rule out an underlying tumour. A minority of tumours are confined to the central airways and mediastinum without obvious change on plain chest X-ray. Although investigation of isolated haemoptysis with a normal chest X-ray is often negative, a normal chest X-ray should not discourage further investigation, especially in smokers over the age of 40 years. |
Box 28.52 Non-metastatic extrapulmonary manifestations of bronchial carcinoma

**Metabolic (universal at some stage)**
- Loss of weight
- Lassitude
- Anorexia

**Endocrine (10%) (usually small-cell carcinoma)**
- Ectopic adrenocorticotropic hormone syndrome
- Syndrome of inappropriate secretion of antidiuretic hormone (SIADH)
- Hypercalcaemia (usually squamous cell carcinoma)
- Rarer: hyperglycaemia, thyrotoxicosis, gynaecomastia

**Neurological (2–16%)**
- Encéphalopathies – including subacute cerebellar degeneration
- Myelopathies – motor neurone disease
- Neuropathies – peripheral sensorimotor neuropathy
- Muscular disorders – polymyopathy, myasthenic syndrome (Eaton–Lambert syndrome)

**Vascular and haematological (rare)**
- Thrombophlebitis migrans
- Non-bacterial thrombotic endocarditis
- Microcytic and normocytic anaemia
- Disseminated intravascular coagulopathy
- Thrombotic thrombocytopenic purpura
- Haemolytic anaemia

**Skeletal**
- Clubbing (30%)
- Hypertrophic osteoarthropathy (± gynaecomastia) (3%)

**Cutaneous (rare)**
- Dermatomyositis
- Acanthosis nigricans
- Herpes zoster

Percentage of all cases.

International Association for the Study of Lung Cancer (IASLC) has devised the most widely used staging definitions, based on CT imaging of tumour size (T), nodal involvement (N) and metastases (M), along with prognostic data (Box 28.53).

Using CT criteria, lymph nodes that are less than 1 cm in diameter are not classed as being enlarged, yet they can still contain malignant cells. With increasing size, the positive predictive value of CT in detecting malignant nodes grows; however, it cannot be assumed that enlarged nodes are definitely malignant and further staging tests should be performed if there are no distant metastases, and the primary tumour is thought to be eligible for curative treatment. These tests include direct sampling of affected nodes and PET-CT to assess distant spread of cancer.

If cerebral metastases are suspected, CT imaging of the brain should be performed.

**PET-CT**
See page 941.

**Other imaging modalities**
MRI is not useful for the diagnosis of primary lung tumours other than Pancoast tumours with nerve invasion or the assessment of chest wall involvement prior to surgery. MRI spine is required if there is any clinical suspicion of spinal cord compression. MRI brain may also be required to assess cerebral metastases.

Bone is a common site for metastatic deposits, and CT imaging of the primary tumour may demonstrate bony metastases. If the patient is describing bony pain that is not included in the CT imaging field, a bone scan may be helpful to demonstrate bony deposits. If these are identified, local radiotherapy may be helpful in controlling local symptoms such as pain.

**Obtaining histology and cytology**
Investigations for this purpose are listed in Box 28.54.

**Other investigations**
These include a full blood count for the detection of anaemia, and biochemistry to assess for liver involvement, hypercalcaemia and hyponatraemia. Investigations for non-metastatic extrapulmonary manifestations of cancer may be indicated (Box 28.52).

**Assessing fitness for treatment**
The Eastern Cooperative Oncology Group (ECOG) performance status should be recorded for all patients with suspected malignancy (Box 28.55). Before radical treatment, an assessment of fitness for treatment should be carried out. This work-up should include full lung function testing with transfer capacity, and if cardiovascular disease is present, cardiopulmonary exercise testing, stress echo or, occasionally, preoperative angiography may be required.

**Management**
Treatment of lung cancer (see also p. 119) involves several different modalities and should be planned by a multidisciplinary team. In the UK, approximately 75% of patients will have advanced lung cancer at the stage of presentation; hence radical treatment is not an option. Patient co-morbidities may also preclude radical treatment. Box 28.56 shows the mean survival based on tumour stage for non-small-cell lung cancer (NSCLC), including squamous cell carcinoma: only 25–30% of patients are still alive 1 year after diagnosis and only 6–8% after 5 years. Small-cell carcinoma is staged as limited or extensive disease. The treatment and prognosis differ from those of NSCLC.

**Surgery**
Surgery is performed in early-stage NSCLC (stages I, II and selected IIIA) with curative intent. Many patients with stage III disease are treated with chemoradiation with a view to downstaging disease and rendering it amenable to surgical resection. Where surgical staging of resected lung cancer demonstrates nodal involvement, patients require adjuvant chemotherapy.

**Radiation therapy with curative intent**
In selected patients with adequate lung function and early-stage NSCLC, high-dose radiotherapy or continuous hyperfractionated accelerated regimens (CHART) provide a good alternative to surgical resection with almost comparable outcomes. It is the treatment of choice if surgery is not possible due to co-morbidities. Radiation pneumonitis (defined as an acute infiltrate precisely confined to the radiation area and occurring within 3 months of radiotherapy) develops in 10–15% of cases. Radiation fibrosis, a fibrotic change occurring within a year or so of radiotherapy and not precisely confined to the radiation area, occurs to some degree in all cases.

In patients with significant cardiovascular or respiratory co-morbidities and early stage I disease, stereotactic ablative radiotherapy (SABR) can be used. In the same patient group, radiofrequency ablation is used: this is an image-guided technique that uses heat to destroy small peripheral tumours. Data regarding long-term outcomes are unavailable as yet.

**Palliative radiation treatment**
Radiation therapy has a role in palliation of symptoms from lung cancer. Bone and chest wall pain from metastases or direct invasion, haemoptysis, occluded bronchi and superior vena caval obstruction...
### Notation and Description

**Notation** | **Description**
--- | ---
TX | Primary tumour cannot be assessed, or tumour proven by the presence of malignant cells in sputum or bronchial washings, but not visualized by imaging or bronchoscopy
T0 | No evidence of primary tumour
Tis | Carcinoma *in situ*[^a]
T1 | Tumour 3 cm or less in greatest dimension, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus (i.e. not in the main bronchus); subtypes mi, a, b and c exist according to the tumour size.
T2 | Tumour more than 3 cm but not more than 5 cm; or tumour with any of the following features:[^b]
  - Involves main bronchus, regardless of distance to the carina but without involvement of the carina
  - Invades visceral pleura
  - Associated with atelectasis or obstructive pneumonitis that extends to the hilar region involving either part of or the entire lung
T2a | Tumour more than 3 cm but not more than 4 cm in greatest dimension
T2b | Tumour more than 4 cm but not more than 5 cm in greatest dimension
T3 | Tumour more than 5 cm but not more than 7 cm in greatest dimension or one that directly invades any of the following: parietal pleura, chest wall (including superior sulcus tumours), phrenic nerve, parietal pericardium; or tumour nodule(s) in the same lobe as the primary
T4 | Tumour more than 7 cm or of any size that invades any of the following: diaphragm, mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, oesophagus, vertebral body, carina; separate tumour nodule(s) in a different ipsilateral lobe to the primary

**N – regional lymph nodes**

| Notation | Description |
--- | ---
NX | Regional lymph nodes cannot be assessed
N0 | No regional lymph node metastasis
N1 | Metastasis *in* ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension
N2 | Metastasis *in* ipsilateral mediastinal and/or subcarinal lymph node(s)
N3 | Metastasis *in* contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)

**M – distant metastasis**

| Notation | Description |
--- | ---
M0 | No distant metastasis
M1 | Distant metastasis
M1a | Separate tumour nodule(s) in a contralateral lobe; tumour with pleural nodules or malignant pleural or pericardial effusion[^c]
M1b | Single extrathoracic metastasis *in* a single organ[^d]
M1c | Multiple extrathoracic metastasis *in* a single or multiple organs

**Resultant stage groupings**

| Stage | T | N | M |
--- | --- | --- | ---
Occult carcinoma | TX | N0 | M0
Stage 0 | Tis | N0 | M0
Stage IA[^a] | T1 | N0 | M0
Stage IB | T2a | N0 | M0
Stage IIA | T2b | N0 | M0
Stage IIB | T1, T2a, b | N1 | M0
  | T3 | N0 | M0
  | T4 | N0, N1 | M0
Stage IIIA | T1, T2a, b | N2 | M0
  | T3 | N1 | M0
  | T4 | N0, N1 | M0
Stage IIIB | T1, T2a, b | N3 | M0
  | T3, T4 | N2 | M0
  | T3 | N3 | M0
Stage IV | Any T | Any N | M1
Stage IVA | Any T | Any N | M1a, M1b
Stage IVB | Any T | Any N | M1c

[^a]: Tis includes adenocarcinoma *in situ* and squamous carcinoma *in situ*.
[^b]: T2 tumours with these features are classified T2a if 4 cm or less or if size cannot be determined, and T2b if greater than 4 cm but not larger than 5 cm.
[^c]: Most pleural (pericardial) effusions with lung cancer are due to tumour. In a few patients, however, multiple microscopic examinations of pleural (pericardial) fluid are negative for tumour, and the fluid is non-bloody and is not an exudate. Where these elements and clinical judgement dictate that the effusion is not related to the tumour, the effusion should be excluded as a staging descriptor.
[^d]: This excludes involvement of a single non-regional node.

respond favourably to irradiation in the short term. Radiotherapy is also given at the end of chemotherapy to consolidate treatment in small-cell lung cancer.

Chemotherapy, targeted therapy and immunotherapy

This is discussed on page 119–120. Adjunct chemotherapy with radiotherapy improves response rate and extends median survival in NSCLC.

Targeted agents against EGFRs, tyrosine kinases and anaplastic lymphoma kinase (ALK) in NSCLC (in particular, adenocarcinoma) offer better outcomes in selected patients and can also be used where intravenous chemotherapy offers unacceptable toxicity or as second-line chemotherapy. Immunotherapy with checkpoint inhibitors and PDL-1 inhibitors modulates the immune response and offers another treatment option in appropriate patient groups. This is an emerging field and may have an impact on the prognosis of all types of lung cancer.

Laser therapy, cryotherapy and tracheobronchial stents

These techniques are used in the palliation of inoperable lung cancer in selected patients with tracheobronchial narrowing from intraluminal tumour, or extrinsic compression causing disabling breathlessness, intractable cough and complications including infection, haemoptysis and respiratory failure.

A neodymium-Yag (Nd-Yag) laser passed through a fibreoptic bronchoscope can be used to vaporize inoperable fungating intraluminal carcinoma involving short segments of trachea or main bronchi. Benign tumours, strictures and vascular lesions can also be treated effectively with immediate relief of symptoms.

Cryotherapy is an endobronchial technique by which a cryoprobe is passed through the bronchoscope. The cryoprobe repeatedly freezes and thaws the tumour, which enables parts of it to be excised, restoring airway patency without causing bleeding. The excised tissue can be sent for histological analysis.

Tracheobronchial stents made of silicone or in the form of expandable metal springs are available for insertion into strictures caused by tumour, external compression, or weakening and collapse of the tracheobronchial wall.

Palliative care

Patients dying of cancer of the lung need attention to their overall wellbeing (see Ch. 7). Much can be done to render the individual’s remaining life symptom-free and as active as possible. Patient and relatives both require psychological and emotional support, a task that should be shared between the respiratory team, oncology team, primary care team and nurses, social workers, hospital chaplains and doctors who together make up the palliative care team.

Mesothelioma

Mesothelioma describes a malignant tumour arising from the parietal or visceral mesothelial lining of the lung. These tumours are almost always related to asbestos exposure (see p. 996), and mesothelioma typically develops from pre-existing pleural plaque disease.

The number of cases of mesothelioma has increased progressively since the mid-1980s and has now reached 2500 deaths per year in the UK, which has the highest per capita death rate from this condition.

The most common presentation of mesothelioma is a pleural effusion, typically with persistent chest wall pain, which should raise the index of suspicion even if the initial pleural fluid or biopsy samples are non-diagnostic. CT/ultrasound-guided biopsy or VATS pleural biopsy is often needed to obtain sufficient tissue for diagnosis. Clinical trials of chemotherapy, sometimes combined with surgery, are under way but the outlook for most patients remains very limited.

Secondary tumours

Metastases in the lung are very common. They are usually detected on chest X-ray or CT in patients already diagnosed as having
carcinoma but can be the first presentation. Typical sites for the primary tumour include the kidney, prostate, breast, bone, gastrointestinal tract, cervix or ovary.

Carcinoma, particularly of the stomach, pancreas and breast, can involve mediastinal glands and spread along the lymphatics of both lungs, leading to progressive and severe breathlessness (lymphangitis carcinomatosis). On the chest X-ray, bilateral lymphadenopathy is seen, together with streaky basal shadowing fanning out over both lung fields.

Single pulmonary metastases can be removed surgically but, as CT scans usually show the presence of small metastases undetected on chest X-ray, detailed imaging, including PET scanning and assessment, is essential before undertaking surgery.

Solitary pulmonary nodules

A solitary pulmonary nodule is defined as a discrete lesion of less than 3 cm in diameter. The differential diagnoses for a solitary pulmonary nodule are:

- primary bronchial carcinoma
- pulmonary metastases
- inflammatory lesions, e.g. rounded pneumonia or abscess
- granuloma
- benign tumour of the lung, e.g. hamartoma
- rheumatoid nodules
- hydatid cyst.

With the increased use of CT scanning for other conditions, there has been greater incidental detection of asymptomatic, small, sub-centimetre nodules. The majority of these are benign; however, radiological follow-up should be arranged at intervals in line with recommended guidelines, determined by the size of the nodule in millimetres and the risk of developing malignancy. Scoring tools such as the Brock score are useful in assessing the risk of malignancy based on nodule characteristics and size.

Screening for lung cancer

A large trial carried out in the USA has demonstrated a 20% mortality benefit from low-dose helical CT screening for lung cancer in high-risk populations of smokers and ex-smokers between the ages of 55 and 74. A similar trial has been undertaken in the Netherlands and the UK. It is likely that low-dose CT screening will be employed in the future to detect cancer at an earlier stage so that curative treatment may be offered.

Fig. 28.33 Bronchoscopic view of a bronchial carcinoma obstructing a large bronchus.

Fig. 28.34 Lymph node stations commonly involved in lung cancer. These nodes are sampled during staging investigations.
Bronchial carcinoid tumours

These rare tumours are typically slow-growing, low-grade malignant neoplasms. They arise from neuroendocrine tumours and account for approximately 1% of all bronchial tumours. Many of these may be asymptomatic. Some patients will present with symptoms related to obstruction, recurrent infection or haemoptysis. The histological appearance may range from low-grade typical tumours to atypical tumours. Surgery is usually the treatment of choice, although patients will require long-term surveillance. As foetal derivatives, bronchial carcinoids produce adrenocorticotropic hormone (ACTH) but do not usually produce the 5-hydroxytryptamine that is seen in midgut or hindgut carcinoid tumours. Staging of carcinoid tumours is the same as for NSCLC.

Benign tumours

**Pulmonary hamartoma**

This is the most common benign tumour of the lung and is usually seen on X-ray as a very well-defined round lesion 1–2 cm in diameter in the periphery of the lung. Growth is extremely slow but the tumour can reach several centimetres in diameter.Rarely, it arises from a major bronchus and causes obstruction.

**Bronchial adenoma**

This diverse group of benign tumours arises from mucus glands and ducts of the windpipe.

**Cylindroma, chondroma and lipoma**

These extremely rare tumours grow in the bronchus or trachea, causing obstruction.

**Tracheal tumours**

Benign tumours include squamous papilloma, leiomyoma and haemangiomias.

Field JK, Duffy SW, Baldwin DR et al. UK Lung Cancer RCT Pilot Screening Trial: baseline findings from the screening arm provide evidence for the potential implementation of lung cancer screening. Thorax 71:161–170.

BRONCHIECTASIS

Bronchiectasis describes abnormal and permanently dilated airways. The disease is characterized by a vicious circle of neutrophilic inflammation, recurrent infection and damage to the airway. This further impairs mucociliary clearance, and persistent inflammation leads to impairment of immunity.

Bronchiectasis is associated with a number of diseases but a cause will only be found in around 50% of cases. Little is known about the epidemiology and there is a wide variation in reported incidence. Bronchiectasis related to cystic fibrosis (see p. 983) is generally considered a separate entity.

**Aetiology**

The causes of bronchiectasis are listed in Box 28.57. Globally, TB is the leading cause. Bronchiectasis associated with other lung diseases – in particular, COPD – is becoming increasingly recognized.

**Clinical features**

These are shown in Box 28.58.

**Investigations**

The aims of investigation are to confirm the diagnosis, rule out an underlying cause, look for reversible factors and exclude complications.

- **HRCT scanning** is the investigation of choice. Characteristically, non-tapering ‘tram track’ airways and an increased bronchoarterial ratio termed the “signet ring” sign can be seen (Fig. 28.35).
- **Chest X-ray** may often be normal but tram track airways, ring shadows and cysts may be seen.
- **Sputum examination** is useful for a focused antibiotic treatment plan, as well as the exclusion of non-tuberculous mycobacterial disease. Extended microbiological culture is often required and needs to be specifically requested.
- **Immune assessment** would include immunoglobulins and responses to Hib, tetanus and pneumococcal vaccines as baseline tests. Second-line immunological investigation by an immunologist may be necessary.
- **Sweat test and cystic fibrosis genetic assessment** (see p. 984) should be carried out for all patients under 40, but also for patients at any age where there is a high index of suspicion.
- **Nasal nitric oxide** is a useful test for screening for primary ciliary dyskinesia (PCD). It is very low in PCD. Further ciliary investigation in a specialist centre may be required.
- **Total IgE and Aspergillus-specific IgE or Aspergillus skin-prick testing** should be done to exclude allergic bronchopulmonary aspergillosis.

**Management**

Therapy can broadly be divided into airway clearance, anti-inflammatories, and treatment of infection and complications.

**Airway clearance**

Daily airway clearance therapies are advised. The activated cycle of breathing technique, *autogenic (self-)drainage* and postural drainage are popular modalities. A number of devices are available to assist, such as the Flutter or Acapella, which provide positive expiratory pressure with or without airway oscillation. Nebulized hypertonic saline is also approved for use in bronchiectasis; it works as a mucoactive agent.

**Anti-inflammatories**

Long-term azithromycin has an immunomodulatory effect and has been demonstrated to reduce exacerbation frequency. Inhaled corticosteroids are beneficial to some patients.

**Treatment of infection**

Treatment of exacerbations usually lasts 2 weeks and is based on previously obtained microbiological information. When
Bronchiectasis

Pseudomonas aeruginosa is being treated, dual therapy is often used where there are multi-resistant pathogens and where multiple antibiotic courses would be expected. High-dose ciprofloxacin (750mg twice daily) is a useful oral drug for treatment of Pseudomonas. H. influenzae infection is common in bronchiectasis and usually responds to oral antibiotics such as amoxicillin, co-amoxiclav or doxycycline. Some multi-resistant species need intravenous cephalosporin treatment.

Experience in cystic fibrosis has promoted the use of aggressive antibiotic strategies in bronchiectasis, with eradication therapy and chronic suppressive nebulized therapy with colistimethate or an aminoglycoside for P. aeruginosa (see p. 984).

Rotating oral antibiotic regimes are no longer recommended routinely. Long-term quinolones should be avoided.

Treatment of complications

- Pulmonary rehabilitation should be offered to patients with a reduced exercise capacity and breathlessness.
- Massive haemoptysis is a life-threatening medical emergency; treatment is resuscitation with airway protection until bronchial artery embolization can be performed to control the bleeding. If this is not successful, surgery may be required.
- Treatment of Aspergillus lung disease and non-tuberculous mycobacteria is covered on page 993.
- Respiratory failure should be treated with oxygen and non-invasive ventilation. Suitable patients should be referred to a transplant centre.
- Surgery is used for localized disease.

Prognosis

Prognosis is undefined and obviously quite variable, depending on disease severity. A low FEV₁ and infection with P. aeruginosa are associated with a poorer outcome.

Cystic fibrosis

Cystic fibrosis (CF) is an autosomal recessive condition. In the UK the birth prevalence is 1 in 2500 and the carrier rate is 1 in 25. Prevalence is a little lower in North America, rates being much lower in the non-Caucasian population. CF no longer causes most patients to die in childhood: survival has improved dramatically. The current expected median survival is now around 47 years. CF is a multisystem disease, although respiratory problems are usually the most prominent. A vicious circle of mucus stasis, inflammation and infection leads to respiratory failure and death in the majority of patients. Most individuals with CF also have pancreatic insufficiency.
Pathogenesis
The CF gene is located on the long arm of chromosome 7 at position 31.2 (see p. 18). Mutations lead to abnormalities in the production of the cystic fibrosis transmembrane conductance regulator (CFTR) protein. This protein is expressed in the apical membrane of epithelial cells and acts as a chloride channel. Over 1000 mutations have been identified, most of them rare. The F508del mutation is the most common, accounting for around 70% of cases. Mutations have been divided into different classes, depending on their effect on CFTR (Box 28.59). This classification is used therapeutically, with new CF treatments aimed at improving CFTR function. Ivacaftor was the first drug available for CF that improves CFTR function.

In the lungs, CFTR dysfunction leads to dehydrated airway surface liquid, mucus stasis, airway inflammation and recurrent infection. This process originates in the small airways, leading to progressive airway obstruction and bronchiectasis (Fig. 28.36).

Clinical features and complications
CF is a multisystem disease but in 90% of cases the eventual cause of death is related to respiratory disease. Pancreatic insufficiency occurs in the majority of patients and CF-related diabetes is becoming increasingly common as survival improves, occurring in up to 50% of older adults with CF. Liver disease occurs in around 20% of the CF population and can lead to cirrhosis in around 2%. Clinical manifestations and complications are summarized in Box 28.60.

Diagnosis
Most new CF diagnoses are currently made at newborn screening. The test involves measuring immunoreactive trypsinogen at the time of the neonatal heel-prick test. If the concentration is raised, formal testing is performed.

Aside from newborn screening, diagnosis for children and adults is based on a combination of:
- Common clinical features (see Box 28.60).
- CFTR functional testing. The sweat test (pilocarpine iontophoresis) measures chloride concentration and is the test routinely performed. The normal range is <30 mmol/L, with borderline cases at 30–60 mmol/L. These cases often represent patients with a milder ‘atypical’ phenotype. In difficult cases, nasal potential difference can be measured.
- Confirmatory genetic testing.

Management
Patients with CF should be managed in a specialist centre by a multidisciplinary group of experienced healthcare professionals. They should be seen at least every 3 months and have an annual review. Lung function (FEV₁) and body mass index (BMI) should be recorded at every appointment, as they have prognostic importance.

Pulmonary disease
The aim of chronic pulmonary therapies is to reduce FEV₁, decline, daily symptoms and exacerbation frequency.
- Airway clearance techniques are a vital part of CF treatment regimens, taught to patients and their caregivers by specialist respiratory physiotherapists. Techniques include percussion, vibration, deep breathing and forced coughing; there is no consensus on the best type and patient choice is the main factor.
- Nebulized therapy:
  - Recombinant human DNase (rhDNase) works by lysing bacterial DNA and reducing sputum viscosity; it is advised for routine treatment from early childhood (regardless of disease status). There is clear evidence of improvement in lung disease and therapy may influence survival.
  - Hypertonic saline works as an osmotic agent to draw water to the cell surface and reduce sputum viscosity.
  - Inhaled mannitol also increases mucociliary clearance.
- Anti-inflammatory treatment with long-term azithromycin is widely used in CF and has an immunomodulatory effect.

Respiratory infection
Spread of respiratory infection is a great threat to CF patients. Clinics are microbiologically coherded, patients are managed in single rooms and no patient social events are organized.
P. aeruginosa infection is common in patients with CF and is associated with accelerated lung function decline. Eradication is the treatment aim. A combination of nebulized colistimethate and oral ciprofloxacin, or inhaled tobramycin, can be given. Long-term nebulized suppression therapy with these medications is also used to improve respiratory health.

Other organisms, such as Burkholderia cepacia, meticillin-resistant Staph. aureus (MRSA) and Stenotrophomonas maltophilia, have been associated with worsening respiratory outcomes and so eradication regimes for these bacteria are being used. Non-tuberculous mycobacterial disease, in particular M. abscessus, can be associated with a rapid decline and active infection may preclude transplantation.

In exacerbations, intravenous antibiotic therapy is based on previous infection history. For Pseudomonas, a combination of a β-lactam antibiotic such as ceftazidime with an aminoglycoside such as tobramycin would be the first-line choice. In vitro sensitivities are less useful in CF. Many CF patients have a permanently implanted venous access device for delivery of intravenous therapy.

**Advanced disease**

Respiratory failure should be treated with oxygen and NIV. Patients should be referred for consideration for lung transplantation when FEV₁ falls to around 30% predicted. In end-stage disease, palliative care is an essential part of management. This can be challenging when patients are on an active waiting list for a lung transplant.

**Non-respiratory complications**

Pancreatic enzymes and vitamin supplements are used to treat patients with pancreatic insufficiency. Close attention is paid to diet and calorie supplementation. Overnight gastric feeding may be required to maintain BMI in some patients.

CF-related diabetes will often require treatment with insulin and is screened for at annual review. It is distinct from type 1 and type 2 diabetes. Osteoporosis is screened for and treated. Fertility treatment is available for men with CF who are infertile. Women with CF who become pregnant should be monitored very closely and deliver in a recognized CF centre.

**The future**

CFTR modulation has proved to be a major therapeutic advance, and studies of therapies for the F508del mutation are ongoing. Recently, lumacaftor (a CFTR corrector) in combination with ivacaftor has been shown to be beneficial in patients with P.Phe508del CFTR mutation. It is now widely available in the USA but not NICE-approved in UK, where it is given only as compassionate use. Trials are ongoing of triple therapy (using lumacaftor, ivacaftor and another agent that also improves CFTR function), which shows initial promise.

**INTERSTITIAL LUNG DISEASES**

This heterogeneous group of conditions are also referred to as **diffuse parenchymal lung diseases** and account for about 15% of respiratory clinical practice. They are characterized by varying degrees of inflammation and fibrosis, initially affecting the interstitium of the lung and typically presenting with exertional dyspnoea, with or without cough. A classification is shown in **Fig. 28.37**.

### Sarcoidosis

Sarcoidosis is a multisystem granulomatous disorder; it commonly affects young adults and typically presents with bilateral hilar lymphadenopathy, pulmonary infiltration and skin or eye lesions.

**Epidemiology and aetiology**

Sarcoidosis is a common disease of unknown aetiology that is often detected on routine chest X-ray. It is most common in Northern Europe (annual incidence 5–40/100,000) but uncommon in Japan (incidence 1–2/100,000). It occurs more frequently in Afro-Caribbean patients, who are also more likely to develop extrapulmonary or chronic disease. There is a female preponderance with a peak incidence in the third and fourth decades. There is no relation to any histocompatibility antigen but first-degree relatives (particularly Caucasians) have an increased risk of developing sarcoidosis.

**Immunopathology**

- Typical sarcoid granulomas consist of focal accumulations of epitheloid cells, macrophages and lymphocytes, mainly T cells.
- There is depressed cell-mediated reactivity to tuberculin; the Mantoux test is usually negative. There is overall lymphopenia; circulating T lymphocytes are low but B cells are slightly increased.
- Bronchoalveolar lavage shows a great increase in the overall number of cells; a lymphocytosis (particularly CD4⁺ T-helper cells) is common.
- Transbronchial biopsies show infiltration of the alveolar walls and interstitial spaces with leucocytes, mainly T cells, prior to granuloma formation.

**Clinical features**

Sarcoidosis can affect any organ (**Box 28.61**) but has a predilection for the lungs (involvement in up to 90%). Presentation may be with respiratory symptoms but it is not unusual for the diagnosis to be made incidentally on chest X-ray. Common extrathoracic manifestations include eye, skin or lymph node involvement, and constitutional upset with fatigue is a frequent and often refractory symptom.

A typical combination of bilateral hilar lymphadenopathy, erythema nodosum, arthralgia and fever is known as Löfgren’s syndrome and usually resolves spontaneously without the need for treatment.

In less classic presentations, HRCT may initially suggest sarcoidosis but tissue biopsy of an affected organ is often sought for definitive diagnosis (the presence of non-caseating granulomas being diagnostic). Skin biopsy is comparatively non-invasive, and careful examination for infiltration of scars and tattoos amenable to sampling should be undertaken.

**Pulmonary manifestations**

Although pulmonary involvement may be an incidental finding, cough, exertional breathlessness and vague chest discomfort are common presentations. Even in symptomatic individuals the chest is often clear to auscultation, although wheeze may be evident if there is significant involvement of the airways with endobronchial disease. There are four radiological stages of lung involvement, which help inform prognosis:

- **Stage 1:** bilateral hilar lymphadenopathy alone (BHL) – 55–90% spontaneous remission.
Stage 2: pulmonary infiltrates with BHL – 40–70% spontaneous remission.
Stage 3: pulmonary infiltrates without BHL – 10–20% spontaneous remission.
Stage 4: fibrosis.

Patients may present with any stage of disease and do not necessarily progress through the stages sequentially. Moreover, the extent of disease on chest X-ray does not correlate with the degree of impairment on pulmonary function testing.

Bilateral hilar lymphadenopathy
Symmetrical BHL is a characteristic feature of sarcoidosis and is usually asymptomatic. Occasionally, it is associated with a dull ache in the chest, malaise and a mild fever. The differential diagnosis of BHL includes:
- Lymphoma: this rarely affects the hilar lymph nodes in isolation.
- Pulmonary TB: hilar lymph nodes are usually enlarged asymmetrical.
- Carcinoma of the bronchus with malignant spread to the hilar lymph nodes: again, this is rarely symmetrical.

Pulmonary infiltration
Although the lung fields may appear normal on plain chest X-ray, the lung parenchyma is frequently involved, as shown by CT scanning (Fig. 28.38), transbronchial biopsy and bronchoalveolar lavage. Symptoms may be minimal (or even absent), despite quite marked radiographic abnormalities. Progressive disease may lead to irreversible fibrosis in up to 20% of cases. The principal differential diagnoses are TB, pneumoconiosis, idiopathic pulmonary fibrosis and hypersensitivity pneumonitis.

Extrapulmonary manifestations
Sarcoidosis can affect any organ. Cutaneous sarcoidosis and ocular sarcoidosis are the most common extrapulmonary presentations but cardiac and CNS involvement are the most important clinically.

Skin lesions
These occur in 10–30% of cases. Sarcoidosis is the most common cause of erythema nodosum (see p. 678). Lupus pernio (indurated
erythematous or violaceous papules or plaques, **Fig. 28.39** may be seen over the face and ears.

**Eye lesions**

In 5% of patients, anterior or, less commonly, posterior uveitis presents with misting of vision, a painful, red eye or progressive loss of vision. Asymptomatic uveitis may be found in up to 25% of patients with sarcoidosis and ophthalmological assessment should be considered in all patients with a new diagnosis of sarcoidosis. Keratoconjunctivitis sicca and lacrimal gland enlargement also occur.

**Metabolic manifestations**

Hypercalcaemia and hypercalciuria can lead to the development of renal calculi, nephrocalcinosis and, ultimately, renal failure.

**Central nervous system**

CNS involvement is rare (2%) but can lead to severe neurological disease (see p. 868).

**Bone and joint involvement**

Arthralgia without erythema nodosum is seen in 5% of cases. Bone cysts with associated swelling, particularly affecting the digits, may be seen on X-ray.

**Hepatosplenomegaly**

Mild derangement of liver function tests is common and granulomas are seen in the majority of biopsy specimens, although these findings are rarely of clinical consequence. Progression to portal hypertension or liver failure is uncommon.

**Renal involvement**

Sarcoidosis classically causes a granulomatous tubulointerstitial nephritis, although kidney damage secondary to hypercalcaemia and stone formation may also be seen.

**Cardiac involvement**

Ventricular dysrhythmias, conduction defects and cardiomyopathy with congestive cardiac failure are rare (3%). Severity ranges from benign rhythm disturbance to sudden cardiac death. All patients with sarcoidosis should have an ECG at presentation.

**Investigations**

- **Imaging.** Chest X-ray is the initial modality for staging, followed by HRCT for assessment of parenchymal involvement. This may show nodules of up to 10 mm diameter that form a characteristic ‘beading’ appearance along airways, vessels and fissures; nodules may aggregate into larger nodules or masses of up to 3 cm; there may be increased reticulation due to septal thickening; in severe cases fibrotic honeycombing is seen.
- **Full blood count.** There may be a mild normochromic, normocytic anaemia with raised ESR.
- **Biochemistry.** Renal involvement is occasionally found and may require renal biopsy and first-line treatment. Hypercalcaemia occurs in 10–20% and hypercalciuria in 30–50%. Activated macrophages in lung and lymph nodes are able to hydroxylate vitamin D directly (independent of parathyroid hormone levels), leading to increased intestinal absorption of dietary calcium. Measurement of 24-hour urinary calcium excretion should be performed at presentation.
- **Serum ACE level.** This is elevated in over 75% of patients with untreated sarcoidosis. Raised (but lower) levels are also seen in patients with lymphoma, pulmonary TB, asbestosis and silicosis, limiting the diagnostic value of the test. The utility of serum ACE in monitoring disease activity and response to treatment is contentious.
• **Cardiac tests.** ECG and echocardiogram should be performed at presentation. If these raise concern about underlying cardiac sarcoidosis, then further investigation is with cardiac MRI.

• **Bronchoscopy.** Bronchoalveolar lavage typically shows a lymphocytosis with raised CD4:CD8 ratio. Transbronchial biopsy of the lung parenchyma is positive in up to 90% of cases of pulmonary sarcoidosis. Pulmonary non-caseating granulomas are found in approximately 50% of patients with extrapulmonary sarcoidosis who have a normal chest X-ray. If, in addition, endobronchial biopsy (EBUS) of thoracic lymph nodes is performed, this may significantly increase the yield, even if the macroscopic appearances are normal.

• **Lung function tests.** These show a restrictive lung defect with reduced gas transfer in patients with parenchymal infiltration or fibrosis. However, an obstructive defect may be seen in endobronchial disease and a mixed pattern is also possible. Lung function is usually normal in patients with isolated hilar adenopathy or extrapulmonary disease.

### Prognosis and management
The natural history of sarcoidosis is unpredictable and varies from spontaneous remission to inexorable progression and death in a small number (1–5%). Even once remission has been achieved, relapses are common. Worse outcomes are seen in patients of Afro-Caribbean and Asian descent, and those presenting with extrathoracic disease. Systemic treatment is indicated for hypercalcaemia and extrathoracic major organ involvement, particularly neurological, cardiac or ocular disease resistant to topical therapy. Treatment of pulmonary sarcoidosis is less clear-cut, as spontaneous resolution is frequently seen, typically within the first 6 months. Moreover, although corticosteroids improve radiographic appearances, this is not consistently reflected in improved lung function tests. Treatment is therefore reserved for patients with troublesome symptoms, deteriorating lung function or radiological evidence of disease progression. First-line treatment is with prednisolone (or equivalent) 0.5 mg/kg for 4–6 weeks, gradually tapering to a maintenance dose for at least 12 months. Alternative immunosuppressants, including methotrexate, azathioprine and hydroxychloroquine, have been used in place of, or in addition to, prednisolone. Relapses are common on withdrawal of therapy. Lung transplantation should be considered for suitable patients with stage IV disease and respiratory failure.

### Idiopathic interstitial pneumonias
The terminology used to describe the idiopathic interstitial pneumonias can be confusing but a distinction must be made between subgroups, as there are significant differences in terms of prognosis and treatment options. Clinical patterns usually link to particular histological subtypes; their classification is shown in Box 28.62.

### Idiopathic pulmonary fibrosis
Idiopathic pulmonary fibrosis (IPF) is the most common of the idiopathic interstitial pneumonias. It is a progressive and ultimately fatal disease of unknown cause. There is significant worldwide variation in reported prevalence but the incidence appears to be increasing (6.8–8.8/100000 in the USA). The onset is usually in the patient's sixties and is rare below the age of 50. Males are twice as likely to be affected.

### Pathology
Usual interstitial pneumonia (UIP) is the histological finding in IPF. The key feature is a heterogenous appearance with areas of normal lung punctuated by areas of marked fibrosis, honeycombing mainly in subpleural areas and fibroblastic foci (dense proliferations of fibroblasts and myofibroblasts). The terms IPF and UIP are often used interchangeably but they are not synonymous, as UIP is also the primary histological finding in several other diffuse parenchymal lung diseases (e.g. pulmonary autoimmune rheumatic disease).

### Pathogenesis
It is thought that repetitive injury to the alveolar epithelium, caused by currently unidentified environmental stimuli, leads to the activation of several pathways responsible for repair of the damaged tissue. However, in IPF, the wound healing mechanisms become uncontrolled, leading to over-production of fibroblasts and deposition of increased extracellular matrix in the interstitium with little inflammation. The structural integrity of the lung parenchyma is therefore disrupted: there is loss of elasticity and the ability to perform gas exchange is impaired, leading to progressive respiratory failure.

### Clinical features
Patients typically present with insidious onset of progressive dyspnoea that may be accompanied by cough, with or without sputum production. Examination of the chest shows bi-basal end-inspiratory crackles and therefore it is not uncommon for patients to be mistakenly treated for heart failure or recurrent chest infections before the diagnosis of IPF is made. Finger clubbing is seen in 25–50% of cases. Progressive respiratory failure may be complicated by pulmonary hypertension. Stepwise deterioration can occur due to pneumothorax, pulmonary embolism or intercurrent infection, but acute exacerbations with no identifiable cause are well recognized and are associated with increased mortality. An acute form (also known as Hamman–Rich syndrome) occasionally occurs and has a particularly poor prognosis.

### Investigations
- **Respiratory function tests** usually show a restrictive pattern (FEV₁/FVC ratio >70%) with reduced lung volumes and gas transfer. However, spirometry may be normal in early disease and lung volumes can be preserved in the presence of coexisting emphysema.
• **Blood tests**, including antinuclear antibodies (ANA) and rheumatoid factor (RF), are performed to exclude autoimmune rheumatic disease but there is no specific serological test for IPF.
• **Chest X-ray** shows small-volume lungs with increased reticular shadowing at the bases but may be normal in early disease.
• **HRCT** is the imaging modality of choice. A confident diagnosis of IPF may be made in patients with:
  • **Basal distribution**: abnormalities are more pronounced at the bases.
  • **Subpleural reticulation**: reticulation is most evident in the lung peripheries.
  • **Traction bronchiectasis**: the fibrotic process distorts the normal lung architecture, pulling the airways open and causing bronchiectasis.
  • **Honeycombing**: there are basal layers of small, cystic airspaces with irregularly thickened walls composed of fibrous tissue (Fig. 28.40).
• **Bronchoalveolar lavage** is necessary only if an infective or malignant cause is suspected. A differential cell count may lend support to an alternative diagnosis: a lymphocytosis is suggestive of hypersensitivity pneumonitis, whereas a neutrophilic pattern (neutrophils >3%) is commonly seen in IPF.
• **Histological confirmation** is necessary in some patients. Surgical lung biopsy, usually via VATS, is the most reliable method for obtaining diagnostic histological samples; transbronchial biopsy can be undertaken bronchoscopically but only obtains small samples.

**Differential diagnosis**
The main differential diagnosis for IPF is an alternative interstitial lung disease. Other differentials for the chest X-ray appearances include interstitial pulmonary oedema, infection and lymphangitis carcinomatosa.

**Prognosis and management**
The median survival time for patients with IPF is 2–5 years. Serial lung function testing is used to monitor disease progression and a 10% decline in FVC or 15% decline in gas transfer (TLCO) in the first 6–12 months confers a worse prognosis. Periods of stability may be interspersed with spells of more accelerated decline but failure to recover back to baseline following these episodes is common. Mortality is increased following acute exacerbations. Immunosuppression is generally avoided in IPF and steroids are no longer recommended in confirmed disease.

**Pirfenidone**, an antifibrotic agent, has been shown to slow the rate of FVC decline, with the most common side-effects being a reversible photosensitive rash and gastrointestinal disturbance. Other treatments include **nintedanib**, an intracellular inhibitor of tyrosine kinases.

Gastro-oesophageal reflux disease should be treated if symptomatic.

Even with treatment, IPF is a life-limiting disease and transplant assessment should be undertaken in accordance with local guidelines. All patients should have their need for supportive care evaluated with respect to oxygen therapy, pulmonary rehabilitation and palliative care input.

**Other idiopathic interstitial pneumonias**
These are described in **Box 28.63**.

---

**Hypersensitivity pneumonitis**

Hypersensitivity pneumonitis (HP) is caused by an allergic reaction affecting the small airways and alveoli in response to an inhaled antigen or occasionally following ingestion of a causative drug. Common antigens are illustrated in **Box 28.64**.

One of the most common causes worldwide is farmer’s lung, which can affect up to 9% of farmers in humid climates. Cigarette smokers have a lower risk of developing HP due to decreased antibody reaction to the antigen, but once established, smoking may lead to a more chronic or severe disease course.

**Pathogenesis**

Histological features include chronic inflammatory infiltrates and poorly defined interstitial granulomas, together with interstitial fibrosis and honeycomb change in chronic disease.

The allergic response to the inhaled antigen involves both cellular immunity and deposition of immune complexes, causing foci of inflammation through activation of complement via the classical pathway.

**Clinical features**

HP can be categorized according to the time course of symptoms, as determined by duration and intensity of exposure. Symptoms include weight loss, malaise, dyspnoea and cough. Auscultation reveals inspiratory squeaks due to bronchiolitis, and bilateral fine crackles. Wheeze is uncommon.

• **Acute**: symptom onset 4–6 h following exposure. Fever is common and patients may be mistakenly diagnosed with a chest infection. Resolution occurs 24–48 h following removal from the inciting antigen.
• **Subacute**: usually occurs with intermittent or lower-level exposure. Improvement is seen in weeks to months following removal from exposure.
• **Chronic**: usually no history of preceding acute symptoms. Insidious onset of respiratory and constitutional symptoms is typical. Finger clubbing may be present. Progression to irreversible fibrosis is associated with increased mortality.

Investigations
A diagnosis can often be made by maintaining a high index of suspicion and taking a detailed exposure history. Identification of a culprit antigen in the context of typical clinical and radiological findings often makes lung biopsy unnecessary.

- **Chest X-ray** may be normal in acute and subacute disease. When present, abnormalities include diffuse small nodules and increased reticular shadowing.
- **HRCT** shows nodules with ground-glass opacity and evidence of air trapping. Increased reticulation and honeycomb change
are seen in advanced disease. Abnormalities are most marked in the mid or upper zones.

- **Lung function tests** are not diagnostic. A restrictive ventilatory defect with decreased carbon monoxide gas transfer is seen in chronic disease.

- **Precipitating antibodies** are present in the serum. One-quarter of pigeon fanciers have precipitating IgG antibodies against pigeon protein and droppings in their serum, but only a small proportion have lung disease. Precipitating antibodies are therefore evidence of exposure, not disease.

- **Bronchoalveolar lavage** shows a lymphocytosis. A low CD4:CD8 ratio can help differentiate HP from sarcoidosis.

- **Lung biopsy** demonstrates a lymphocyte-rich infiltrate with varying degrees of fibrosis, depending on chronicity of disease.

**Differential diagnosis**

Although HP due to inhalation of the spores of *Micropolyspora faeni* is common among farmers (farmer's lung), it is probably more usual for these individuals to suffer from asthma related to inhalation of antigens from a variety of mites that infest stored grain and other vegetable material, such as *Lepidoglyphus domesticus*, *L. destructor* and *Acarus siro*.

**Management**

The key to successful treatment is avoidance of exposure to the inciting antigen (if known) and this may be achieved by changes in work practice. Pigeon fancier's lung is more difficult to control, as affected individuals remain strongly attached to their hobby. Prednisolone should be initiated in patients whose symptoms persist despite withdrawal from the causative antigen, and in severe disease. Established fibrosis will not resolve and, in some patients, the disease may progress inexorably to respiratory failure despite intensive therapy. Farmer's lung is a recognized occupational disease in the UK and sufferers are entitled to compensation, depending on their degree of disability.

**Rare interstitial lung diseases**

**Langerhans cell histiocytosis**

This rare disease is characterized histologically by proliferation of Langerhans cells. There is a wide variation in clinical presentation, from isolated lytic bone lesions to multisystem disease involving skin, lymph nodes and major organs (more commonly seen in young children). Pulmonary involvement occurs in 10% of cases and is strongly associated with cigarette smoking. Recurrent spontaneous pneumothorax is seen in up to 25% and is a common mode of presentation. HRCT shows characteristic interstitial thickening, nodules, cysts and honeycomb ing with mid and upper zone predominance, and this may be sufficient for diagnosis in a young smoker (typical age 20–40 years). Smoking cessation is essential. Various treatment strategies, including corticosteroids, chemotherapy agents and the purine analogue cladribine, have been used with variable success. Lung transplantation may be considered in advanced disease. Outcome varies from spontaneous remission to progressive end-stage fibrosis but overall 5-year survival is 75%.

**Pulmonary lymphangioleiomyomatosis**

Pulmonary lymphangioleiomyomatosis (LAM) is a rare disorder of premenopausal women, causing hamartomatous smooth muscle infiltration of the lungs. Extrapulmonary involvement, especially with renal angiomyolipomas (hamartomas), is common. Some 15% of patients with pulmonary LAM have tuberous sclerosis. Presentation is with dyspnoea, chylous pleural effusions and pneumothorax. HRCT shows diffuse thin-walled cysts scattered throughout the lungs. Treatment with hormonal manipulation or oophorectomy has shown a variable response. Sirolimus (rapamycin) can be effective but lung transplantation may be necessary.

**Pulmonary alveolar proteinosis**

In this rare disease lipoproteinaceous material accumulates within the alveoli. It can be congenital but most cases are acquired and appear to have an autoimmune basis, with antibodies directed against the cytokine granulocyte-macrophage colony-stimulating factor (GM-CSF). The disease mostly affects men and presents with progressive exertional dyspnoea and cough. Inspiratory crackles are present in 50%. Diagnosis is made by bronchoalveolar lavage, which reveals a milky appearance and many large, foamy macrophages but few other inflammatory cells. Initial therapy is with whole-lung lavage.

**Small-vessel vasculitides**

The vasculitides are a group of autoimmune diseases that cause inflammation of the large, medium and small blood vessels. The small-vessel vasculitides associated with **anti-neutrophil cytoplasmic antibody (ANCA)** include granulomatosis with polyangiitis (GPA, formerly referred to as Wegener’s granulomatosis), microscopic polyangiitis (MPA) and eosinophilic granulomatosis with polyangiitis (EGPA, formerly called Churg–Strauss syndrome). Staining for ANCA shows either a diffuse pattern (c-ANCA) with antibodies directed against proteinase 3 (PR3), or a perinuclear pattern (p-ANCA) with antibodies to myeloperoxidase (MPO) (see also p. 416). The respiratory tract and kidneys are frequently involved and the ESR is often markedly elevated (>100 mm/h).

**Granulomatosis with polyangiitis**

GPA typically affects older adults and is more common in Caucasians. The c-ANCA is usually positive with elevated PR3 antibodies. The ears and upper respiratory tract are frequently affected with bloody nasal discharge, crusting and destruction, sinusitis and otorrhea media. Evidence of glomerulonephritis should be sought on urinalysis (see p. 1352). Respiratory symptoms include cough, dyspnoea and pleuritic chest pain. Diffuse alveolar haemorrhage occurs in up to 45% and haemoptysis can be life-threatening. Thoracic imaging characteristically shows multiple nodules that often cavitate, areas of consolidation and ground-glass opacification (which may be due to pulmonary haemorrhage). Diagnosis should be confirmed with biopsy of the active site but it is sometimes necessary to initiate empirical treatment in acutely unwell patients. Initial immunosuppressant therapy is with a combination of glucocorticoids and cyclophosphamide, rituximab or methotrexate.

**Microscopic polyangiitis**

MPA is primarily associated with p-ANCA positivity. Presentation and treatment are similar to those of granulomatosis with polyangiitis. It is diagnosed on tissue biopsy, where the absence of granuloma formation differentiates it from GPA.

**Eosinophilic granulomatosis with polyangiitis**

EGPA classically presents in early adulthood with allergic rhinitis, asthma that is often difficult to control, and peripheral blood eosinophilia (>10%); it is ANCA-positive in up to 60% (usually p-ANCA). Systemic vasculitis subsequently develops, sometimes
many years later. Involvement of skin (tender subcutaneous nodules, petechiae or purpuric lesions), peripheral nerves (mononeuritis multiplex), heart, kidneys and gastrointestinal tract may occur. The chest X-ray shows migratory patchy opacities that may be accompanied by nodules and pleural effusions. EGPA generally responds well to corticosteroids, although additional immunosuppressants are required for severe or refractory disease. Occasionally, EGPA is ‘unmasked’ when oral steroids are withdrawn in patients being treated for asthma.

**Anti-glomerular basement membrane disease (Goodpasture’s syndrome)**

Anti-glomerular basement membrane (anti-GBM) disease is characterized by the triad of pulmonary haemorrhage, glomerulonephritis, and the presence of circulating antibodies directed against an antigen intrinsic to the basement membrane of both kidney and lung. Respiratory symptoms may precede the onset of glomerulonephritis by weeks or months. The chest X-ray shows transient patchy shadows due to intrapulmonary haemorrhage, although haemoptysis can vary from negligible to life-threatening. The carbon monoxide gas transfer is increased due to the presence of haemoglobin in the alveoli. The extent of renal recovery depends on early detection and treatment. Treatment is with plasmapheresis to remove circulating antibodies and immunosuppression (prednisolone and cyclophosphamide) to prevent further antibody production.

**Diffuse alveolar haemorrhage**

Bleeding into the alveolar spaces is associated with certain drugs, infections and autoimmune rheumatic diseases, including vasculitis, but can also occur without an identifiable precipitating cause. Haemoptysis may be minimal (or even absent), despite significant blood loss into the lungs. It is one of the relatively few causes of raised carbon monoxide gas transfer (KCO, see p. 943). Gas exchange is impaired due to the presence of blood in the alveoli and patients may present with severe respiratory failure requiring intensive care support. Treatment is directed at the underlying cause, if known.

**Pulmonary manifestations of autoimmune rheumatic diseases**

**Rheumatoid disease**

The lungs can be affected by rheumatoid arthritis (RA) and also by some of the drugs used in its treatment (Fig. 28.41; see also Box 18.32).

- **Pleural effusions** are often unilateral and tend to be chronic. Low glucose content is typical but not specific.
- **Pulmonary fibrosis** occurring in RA has similar clinical features to the idiopathic form of the disease but often follows a more chronic course (see p. 443). In patients taking methotrexate, it is often impossible to determine whether fibrosis is due to the drug or the underlying disease; either way, methotrexate should be substituted for an alternative agent.
- **Rheumatoid nodules** appearing on the chest X-ray may be single or multiple, ranging in size from a few millimetres to a few centimetres. The nodules frequently cavitate. They usually produce no symptoms but can give rise to a pneumothorax or pleural effusion.
- **Obliterative bronchiolitis** causing concentric narrowing of the bronchioles is a rare disorder characterized by progressive breathlessness and irreversible airflow limitation. Response to immunosuppressive therapy is generally poor but macrolide antibiotics may have a role.
- **Cricoarytenoid joint involvement** in RA gives rise to dyspnoea, stridor and hoarseness. Occasionally, severe obstruction necessitates tracheostomy.
- **Caplan’s syndrome** is due to occupational dust inhalation in patients with RA; it occurs particularly in coal worker’s pneumoconiosis but can by caused by exposure to other dusts, such as silica and asbestos. Typically, the chest X-ray shows rounded nodules 0.5–5.0 cm in diameter but progressive fibrosis can sometimes occur. These lesions may precede the development of arthritis. Rheumatoid factor is positive in the majority of patients.
- **Drugs** used in the treatment of RA can cause pulmonary problems, e.g. pneumonitis with methotrexate, gold and NSAIDs; fibrosis with methotrexate; bronchospasm with NSAIDs; infections with corticosteroids and methotrexate; and reactivation of TB with anti-TNF therapy.

**Systemic lupus erythematosus**

The most common respiratory manifestation is pleurisy, occurring in up to two-thirds of cases, with or without an effusion (see also p. 458), which is usually small and bilateral. Pneumonia also occurs, either because of infection or because of the disease process itself. In contrast to RA, diffuse pulmonary fibrosis is uncommon.

**Systemic sclerosis**

Some degree of lung involvement is present in the majority of cases of systemic sclerosis, and pulmonary complications are the leading cause of death (see p. 462). Interstitial fibrosis and pulmonary arterial hypertension are the most common pathologies. Serial lung function testing can aid early detection. Other complications include bronchiectasis and aspiration pneumonitis secondary to oesophageal dilation.
Pulmonary infiltration with eosinophilia

This is a group of allergic respiratory conditions, often directed against helminths or drugs; common types and characteristics are shown in Box 28.65. They range from simple pulmonary eosinophilia to the often fatal hypereosinophilic syndrome. **Simple pulmonary eosinophilia** is a relatively mild illness, with a slight fever and cough, and usually lasts for less than 2 weeks. If symptoms become more prolonged and there is an eosinophilia in the blood, it is then called **prolonged pulmonary eosinophilia**. In both conditions the chest X-ray shows either localized or diffuse opacities. The simple form is probably due to a transient allergic reaction in the alveoli. Many allergens have been implicated, including *Ascaris lumbricoides*, *Ancylostoma*, *Trichuris*, *Trichinella*, *Taenia* and *Strongyloides*. Drugs such as aspirin, penicillin, nitrofurantoin and sulphonamides have also been implicated. Often, however, no allergen is identified. The disease is self-limiting and no treatment is required, apart from withdrawing the identified cause. In the more chronic form, all unnecessary treatment should be withdrawn and corticosteroid therapy is indicated, with resolution of the disease over the ensuing weeks.

**Asthmatic bronchopulmonary eosinophilia** is characterized by the presence of asthma, transient fleeting shadows on the chest X-ray, and blood or sputum eosinophilia. By far the most common cause worldwide is allergy to *Aspergillus fumigatus* (see later), although *Candida albicans* and other mycoses may be the inciting allergen in a small number of patients. In many, no allergen can be identified. Whether these cases are intrinsic or driven by an unidentified extrinsic factor is uncertain. **Tropical pulmonary eosinophilia** is the term reserved for an allergic reaction to microfilaria from *Wuchereria bancrofti*.

**Hypereosinophilic syndrome** is characterized by eosinophilic infiltration in various organs, sometimes associated with an eosinophilic arteritis. The heart muscle is particularly involved, but pulmonary involvement in the form of a pleural effusion or interstitial lung disease occurs in about 40% of cases.

### Diseases caused by *Aspergillus fumigatus*

The various types of lung disease caused by *A. fumigatus* are illustrated in Fig. 28.42. The spores (diameter 5 mm) are readily inhaled and are present in the atmosphere throughout the year. *Aspergillus* can be grown from sputum in up to 15% of patients with chronic lung disease, in whom it does not produce active fungal disease. They are a cause of extrinsic asthma in atopic individuals.

**Allergic bronchopulmonary aspergillosis (asthmatic pulmonary eosinophilia)**

This rare disease is caused by a hypersensitivity reaction when the bronchi are colonized by *Aspergillus*. It can complicate asthma and cystic fibrosis. Proximal bronchiectasis occurs.

Episodes of eosinophilic pneumonia present with a wheeze, cough, fever and malaise, associated with expectoration of firm sputum plugs containing the fungal mycelium. Occasionally, large mucus plugs obliterate the bronchial lumen, causing collapse of the lung. Left untreated, repeated episodes of eosinophilic pneumonia can result in progressive pulmonary fibrosis that usually affects the upper zones.
### Drug- and radiation-induced respiratory reactions

Drugs affecting the respiratory system are shown in Box 28.66, together with the types of reaction they produce. Pulmonary infiltrates with fibrosis may result from a number of cytotoxic drugs used in the treatment of cancer. The most common cause of these reactions is bleomycin, in which case the pulmonary damage is dose-related. The most sensitive test is a decrease in carbon monoxide gas transfer, and therefore gas transfer should be measured repeatedly during treatment with the drug. The use of corticosteroids may help resolution.

**Irradiation** of the lung during radiotherapy can cause a radiation pneumonitis. Patients experience breathlessness and a dry cough. Radiation pneumonitis results in a restrictive lung defect. Corticosteroids should be given in the acute stage.

### LUNG AND HEART–LUNG TRANSPLANTATION

#### Indications and donor selection

The main diseases treated by transplantation are:

- pulmonary fibrosis
- primary pulmonary hypertension
- cystic fibrosis
- bronchiectasis
- emphysema – particularly that caused by α₁-antitrypsin inhibitor deficiency
- Eisenmenger’s syndrome.

Patients selected for transplantation are usually under 60 years and have a life expectancy of less than 18 months, with no underlying cancer and no serious systemic disease.

Organs are taken from donors under 40 years, with good cardiac and lung function, and chest measurements slightly smaller than those of the recipient. Matching for ABO blood group is essential but Rhesus blood group compatibility is not necessary. Since donor material is limited, single-lung transplantation is preferred to double-lung or heart–lung transplantation; this can be successfully undertaken in pulmonary fibrosis, pulmonary hypertension and emphysema. Bilateral lung transplantation is needed in infective conditions to prevent spillover of bacteria from the diseased lung to a single transplanted lung. Eisenmenger’s syndrome requires heart-lung transplant.

**Immunosuppression** is with ciclosporin (the inhaled formulation has shown benefit) or tacrolimus, azathioprine or mycophenolate mofetil, and prednisolone.

#### Complications and their treatment

- **Early post-transplant pulmonary oedema** requires diuretics and ventilatory support.

---

### Box 28.66 Some drug-induced respiratory reactions

**Bronchospasm**

- Penicillins, cephalosporins
- Sulphonamides
- Aspirin/NSAIDs
- Monoclonal antibodies, e.g. infliximab
- Iodine-containing contrast media
- β-Adrenoceptor blocking drugs (e.g. propranolol)
- Non-depolarizing muscle relaxants
- Intravenous thiamine
- Adenosine

**Interstitial lung disease and/or fibrosis**

- Amiodarone
- Anakinra (IL-1 receptor antagonist)
- Nitrofurantoin
- Paraquat (weedkiller)
- Continuous oxygen
- Cytotoxic agents (many, particularly busulfan, CCNU, bleomycin, methotrexate)

**Pulmonary eosinophilia**

- Antibiotics:
  - Penicillin
  - Tetracycline
- Sulphonamides, e.g. sulfasalazine
- NSAIDs
- Cytotoxic agents

**Acute lung injury**

- Paraquat

**Pulmonary hypertension**

- Fenfluramine, dexfenfluramine, phentermine

**SLE-like syndrome including pulmonary infiltrates, effusions and fibrosis**

- Hydralazine
- Procainamide
- Isoniazid
- Phenytoin
- ACE inhibitors
- Monoclonal antibodies

**ACE**, angiotensin-converting enzyme; **CCNU**, chloroethyl-cyclohexyl-nitrosourea (lomustine); **IL-1**, interleukin 1; **NSAIDs**, non-steroidal anti-inflammatory drugs; **SLE**, systemic lupus erythematosus.

The peripheral blood eosinophil count is usually raised and total levels of IgE are usually extremely high, at more than 1000 ng/mL (both that specific to Aspergillus and non-specific). Sputum may show eosinophils and mycelia. Treatment is with prednisolone 30 mg daily, which causes rapid clearing of the pulmonary infiltrates. Antifungal agents should be used in patients on high doses of steroids. The asthma component responds to inhaled corticosteroids, although these do not influence the occurrence of pulmonary infiltrates.

**Aspergilloma and invasive aspergillosis**

Aspergilloma is the growth of *A. fumigatus* within previously damaged lung tissue, where it forms a ball of mycelium within lung cavities. Typically, the chest X-ray shows a round lesion with an air ‘halo’ above it. The aspergilloma itself causes little trouble, though occasionally massive haemoptysis may occur, requiring resection of the area of damaged lung containing the aspergilloma. Treatment is with oral antifungal agents, although invasive aspergillosis is a well-recognized complication of immunosuppression and often requires intravenous antifungal therapy.
Infections are common, particularly within the first 3 months, and need prompt treatment:
- bacterial pneumonia – antibiotics
- cytomegalovirus infection – ganciclovir or valganciclovir (often given as prophylaxis in the early post-transplantation period)
- herpes simplex virus – aciclovir
- Pneumocystis jirovecii – co-trimoxazole (often given as prophylaxis).

Rejection:
- Early (first few weeks) – high-dose intravenous corticosteroids.
- Late (after 3 months) – often produces the histological pattern of obliterative bronchiolitis. High-dose intravenous corticosteroids are sometimes effective in obliterative bronchiolitis.

Post-transplant lymphoproliferative disease refers to a range of lymphomas seen in recipients of solid organ transplants; they may respond to rituximab, an anti-B-cell monoclonal antibody, or other forms of chemotherapy.

Prognosis
Several studies show a major improvement in overall quality of life after transplantation. One-year survival rates are around 80%, with a yearly mortality rate thereafter of about 10%. Death is due mainly to obliterative bronchiolitis. Overall survival varies with the original diagnosis but median survival is approximately 4 years.

OCCUPATIONAL LUNG DISEASE

Exposure to dusts, gases, vapours and fumes at work can cause several different types of lung disease:
- acute bronchitis and even pulmonary oedema from irritants such as sulphur dioxide, chlorine, ammonia or the oxides of nitrogen
- pulmonary fibrosis caused by mineral dust
- occupational asthma (see Box 28.18), now the most common industrial lung disease in the developed world
- hypersensitivity pneumonitis (see Box 28.64)
- bronchial carcinoma due to industrial agents (e.g. asbestos, polycyclic hydrocarbons, radon in mines).

The degree of fibrosis that follows inhalation of mineral dust varies. While iron (siderosis), barium (baritosis) and tin (stannosis) lead to dramatic, dense, nodular shadowing on the chest X-ray, their effect on lung function and symptoms is minimal. In contrast, exposure to silica or asbestos leads to extensive fibrosis and disability. Coal dust has an intermediate fibrogenic effect and used to account for 90% of all compensated industrial lung diseases in the UK.

Box 28.67 outlines how to take an occupational history in lung disease.

Coal-worker’s pneumoconiosis
This disease is caused by coal dust particles approximately 2–5μm in diameter that are retained in the small airways and alveoli of the lung. The incidence is related to total dust exposure, which is highest at the coal face, particularly if ventilation and dust suppression are poor. Improved ventilation and working conditions have reduced the risk of this disease.

Two very different syndromes result from the inhalation of coal.

Simple pneumoconiosis
This simply reflects the deposition of coal dust in the lung, which produces fine micronodular shadowing on the chest X-ray. It is graded on the chest X-ray appearance according to standard categories set by the International Labour Office:
- Category 1: small round opacities definitely present but few in number
- Category 2: numerous small round opacities but normal lung markings still visible
- Category 3: very numerous small round opacities and normal lung markings partly or totally obscured.

There is considerable dispute about the effects of simple pneumoconiosis on respiratory function and symptoms. In many cases, symptoms may be due to COPD related to coexisting cigarette smoking but this is not always the case. Changes to UK workers’ compensation legislation means that coal miners who develop COPD are compensated for their disability, regardless of their chest X-ray appearance.

Simple pneumoconiosis can progress to the development of progressive massive fibrosis (see next section). The latter virtually never occurs on a background of category 1 simple pneumoconiosis but does arise in about 7% of those with category 2 disease and in 30% of those with category 3 disease. Miners with category 1 pneumoconiosis are unlikely to receive compensation unless they also have evidence of COPD. Those with more extensive radiographic changes are compensated solely on the basis of their X-ray appearances.

Progressive massive fibrosis
In progressive massive fibrosis (PMF), patients develop round, fibrotic masses several centimetres in diameter, almost invariably situated in the upper lobes and sometimes having necrotic central cavities. Rheumatoid factor and antinuclear antibodies are both often present in the serum of patients with PMF, and also in those suffering from asbestosis or silicosis. Pathologically, there is apical destruction and disruption of the lung, resulting in emphysema and airway damage. Lung function tests show a mixed restrictive and obstructive ventilatory defect with loss of lung volume, irreversible airflow limitation and reduced gas transfer.

The patient with PMF suffers considerable effort dyspnoea, usually with a cough. The sputum may be black. The disease can progress (or even develop) after exposure to coal dust has ceased and may lead to respiratory failure.

Silicosis
Silicosis is caused by the inhalation of silica (silicon dioxide). While uncommon, it may still be encountered in stonemasons, sand-blasters, pottery and ceramic workers, and foundry workers involved in fettling (removing sand from metal castings made in
sand-filled moulds). The dust is highly fibrogenic; a coal miner can remain healthy with 30 g of coal dust in the lungs but 3 g of silica is sufficient to kill. Silica seems particularly toxic to alveolar macrophages and readily initiates fibrogenesis. The chest X-ray appearances and clinical features of silicosis are similar to those of PMF but distinctive thin streaks of calcification may be seen around the hilar lymph nodes (‘eggshell’ calcification).

**Diseases caused by asbestos**

Asbestos is a mixture of silicates of iron, magnesium, nickel, cadmium and aluminium, and has the unique property of occurring naturally as a fibre. It is remarkably resistant to heat, acid and alkali, and has been widely used for roofing, insulation and fireproofing. Asbestos has been mined in southern Africa, Canada, Australia and Eastern Europe. Several different types of asbestos are recognized: about 90% of asbestos is chrysotile, 6% crocidolite and 4% amosite.

**Chrysotile (white asbestos)** is the softest asbestos fibre. Each fibre is often as long as 2 cm but only a few microns thick. It is less fibrogenic than crocidolite.

**Crocidolite (blue asbestos)** is particularly resistant to chemical destruction and exists in straight fibres up to 50 cm in length and 1–2 μm in width. Crocidolite is the type of asbestos most likely to produce asbestosis and mesothelioma.

**Amosite (brown asbestos)** was used in cement and pipe insulation and has sharp, needle-like fibres; exposure creates a higher risk of cancer in comparison with common chrysotile asbestos.

Exposure to asbestos occurred particularly in shipbuilding yards and in power stations, but it was used so widely that low levels of exposure were very common. There is a considerable time lag between exposure and development of disease, particularly mesothelioma (20–40 years). Regulations in the UK now prohibit the use of crocidolite and severely restrict the use of chrysotile. Careful dust control measures are enforced, which should eventually abolish the problem.

The risk of primary lung cancer (usually adenocarcinoma) is increased in people exposed to asbestos, even non-smokers. This risk is about 5–7-fold greater in those who have parenchymal asbestosis and about 1.5-fold in those with pleural plaques without parenchymal fibrosis. A synergistic relationship exists between asbestosis and cigarette smoking, the risk of bronchial carcinoma being about fivefold the risk attributable to smoking alone.

Diseases caused by asbestos are summarized in **Box 28.68**. Bilateral diffuse pleural thickening, asbestosis, mesothelioma (see p. 980) and asbestos-related carcinoma of the bronchus are all eligible for industrial injuries benefit in the UK.

**Asbestosis**

Asbestosis is defined as fibrosis of the lungs caused by asbestos dust, which may or may not be associated with fibrosis of the parietal or visceral layers of the pleura. It is a progressive disease characterized by breathlessness and accompanied by finger clubbing and bilateral basal end-inspiratory crackles. Minor degrees of fibrosis that are not seen on chest X-ray are often revealed on HRCT scan. No treatment is known to alter progress, though corticosteroids are often prescribed.

**Byssinosis**

This disease is caused by cotton dust; it occurs worldwide but is declining rapidly in areas where the number of people employed in cotton mills is falling. Typically, symptoms start on the first day back at work after a break (Monday sickness), with improvement as the week progresses. Tightness in the chest, cough and breathlessness occur within the first hour in dusty areas of the mill.

The exact nature of the disease and its aetiology remain disputed. Pure cotton does not cause the disease, and cotton dust has some effect on airflow limitation in all those exposed. Individuals with asthma are particularly badly affected by exposure to cotton dust. The most likely aetiology is constriction of the airways of the lung caused by endotoxins from bacteria present in raw cotton. There are no changes on the chest X-ray.

Berylliosis
Beryllium–copper alloy has a high tensile strength and is resistant to metal fatigue, high temperature and corrosion. It is used in the aerospace industry, atomic reactors and many electrical devices. When beryllium is inhaled, it can cause a systemic illness with a clinical picture similar to that of sarcoidosis. Clinically, there is progressive dyspnoea with pulmonary fibrosis. However, strict control of levels in the working atmosphere has made this disease a rarity.

Further reading

Lung cysts
These can be congenital, bronchogenic or the result of a seques-
trated pulmonary segment. Lung cysts therefore have a wide dif-
erential diagnosis, informed by the clinical presentation. Causes include:
- hydatid disease, which causes fluid-filled cysts
- lung abscesses (thin-walled cysts, found particularly in staphy-
lococcal pneumonia)
- cavitating tuberculosis
- septic pulmonary infarction
- primary bronchogenic carcinoma or cavitating metastatic neo-
plasms
- paragonimiasis caused by the lung fluke Paragonimus westermani
- systemic conditions such as Birt–Hogg–Dubé syndrome.

Trauma
Trauma to the thoracic wall can cause penetrating wounds and lead to pneumothorax or haemothorax.

Rib fractures
Rib fractures are caused by trauma or coughing (particularly in the elderly), and can occur in patients with osteoporosis. Pathological rib fractures are due to metastatic spread (most often from carci-
noma of the bronchus, breast, kidney, prostate or thyroid). Ribs can also become involved by a mesothelioma. Fractures may not be readily visible on a postero-anterior chest X-ray and so lateral X-rays and oblique views may be necessary.

Pain prevents adequate chest expansion and coughing, and this can lead to pneumonia.

Treatment is with adequate oral analgesia, or by local infiltration or an intercostal nerve block.

Two fractures in one rib can lead to a flail segment with paradoxical movement: that is, part of the chest wall moves inwards during inspiration. This can produce inefficient ventilation and may require intermittent positive-pressure ventilation, especially if several ribs are similarly affected.

Rupture of the trachea or a major bronchus
Rupture of the trachea or a major bronchus can occur during decel-
eration injuries, leading to pneumothorax, surgical emphysema, pneumomediastinum and haemoptysis. Surgical emphysema is caused by air leaking into the subcutaneous connective tissue; this can also arise after insertion of an intercostal drainage tube. A pneumomediastinum occurs when air leaks from the lung inside the parietal pleura and extends along the bronchial walls.

Rupture of the oesophagus
Rupture of the oesophagus (see p. 1170) leads to mediastinitis, usually with mixed bacterial infection. This is a serious complication of external injury, endoscopic procedures, bougienage or necrotic carcinoma, and requires broad-spectrum antibiotics.

Lung contusion
This causes widespread fluffy shadows on the chest X-ray owing to intrapulmonary haemorrhage. It may give rise to acute respiratory distress syndrome (see p. 232).

Kyphoscoliosis
Kyphoscoliosis may be congenital, due to disease of the verte-
brae such as TB or osteomalacia, or due to neuromuscular disease such as Friedreich’s ataxia or poliomyelitis. The respiratory effects of severe kyphoscoliosis are often more pronounced than might be expected and respiratory failure and death often occur in the fourth or fifth decade. The abnormality should be corrected at an early stage if possible. Positive airway pressure ventilation delivered through a tightly fitting nasal mask is the treatment of choice for respiratory failure (see p. 229).

Ankylosing spondylitis
Limitation of chest wall movement is often well compensated by diaphragmatic movement and so the respiratory effects of this disease are relatively mild (see also p. 448). It is occasionally associated with upper lobe fibrosis.

Pectus excavatum and pectus carinatum
Pectus excavatum causes few problems other than embarrassment about the deep vertical furrow in the chest, which can be corrected surgically. The heart is seen to lie well to the left on the chest X-ray. Pectus carinatum (pigeon chest) is often the result of rickets but is rarely seen in the West. No treatment is required.

Pleurisy
Pleurisy is pain arising from any disease of the pleura. The local-
ized inflammation produces sharp localized pain, which is worse on deep inspiration, coughing and occasionally on twisting and bending movements. Common causes are pneumonia, pulmonary infarct and carcinoma. Rarer causes include rheumatoid arthritis and systemic lupus erythematosus.

Epidemic myalgia (Bornholm disease) is caused by infection with Coxsackie B virus. This illness is common in young adults in the late summer and autumn, and is characterized by an upper respiratory tract illness followed by pleuritic pain in the chest and upper abdomen with tender muscles. The chest X-ray remains normal and the illness clears within a week.

DISORDERS OF THE DIAPHRAGM

Diaphragmatic fatigue
The diaphragm can become fatigued if the force of contraction dur-
ing inspiration exceeds 40% of the force it can develop in a maximal
static effort. When this occurs acutely, in patients with exacerbations of COPD or cystic fibrosis, or in quadriplegics, positive-pressure ventilation is required. Further rehabilitation requires exercises to increase the strength and endurance of the diaphragm by breathing against resistance for 30 minutes a day.

**Unilateral diaphragmatic paralysis**
This is common and symptomless. The affected diaphragm is usually elevated and moves paradoxically on inspiration. It can be diagnosed by ultrasound when a sniff causes the paralysed diaphragm to rise and the unaffected diaphragm to descend. Causes include:
- surgery
- carcinoma of the bronchus with involvement of the phrenic nerve
- neurological disease, including poliomyelitis and herpes zoster
- trauma to the cervical spine, birth injury or subclavian vein puncture
- infection, such as TB, syphilis or pneumonia.

**Bilateral diaphragmatic weakness or paralysis**
This causes breathlessness in the supine position and may lead to sleep apnoea, with daytime headaches and somnolence. Tidal volume is decreased and respiratory rate increased. Vital capacity is substantially reduced when lying down and sniffing causes a paradoxical inward movement of the abdominal wall, best seen in the supine position. Causes include viral infections, multiple sclerosis, motor neurone disease, poliomyelitis, Guillain–Baré syndrome, quadriplegia after trauma, and rare muscle diseases. Treatment is either diaphragmatic pacing or night-time assisted ventilation.

**Complete eventration of the diaphragm**
This is a congenital condition (invariably left-sided) in which muscle is replaced by fibrous tissue. It presents as marked elevation of the left hemidiaphragm, sometimes associated with gastrointestinal symptoms. Partial eventration, usually on the right, causes a hump (often anteriorly) on the diaphragmatic shadow on X-ray.

**Diaphragmatic hernias**
These are most commonly through the oesophageal hiatus but occasionally occur anteriorly, through the foramen of Morgagni, posterolaterally through the foramen of Bochdalek, or at any site following traumatic tears.

**Hiccups**
Hiccups are due to involuntary diaphragmatic contractions with closure of the glottis and are extremely common. Occasionally, patients present with persistent hiccups. This can be as a result of diaphragmatic irritation (e.g. subphrenic abscess) or may have a metabolic cause (e.g. uraemia). Treatment for persistent hiccups is with gabapentin 300mg or pregabalin 50mg three times daily. The underlying cause should be treated, if known.

**Further reading**

---

**MEDIASTINAL LESIONS**

The mediastinum is defined as the region between the pleural sacs. It is additionally divided as shown in Fig. 28.43. Tumours affecting the mediastinum are rare. Masses are detected very accurately on CT, as well as on MRI scan (Fig. 28.44), and can be localized to the anterior, middle or posterior mediastinum. The position and characteristics of the lesion will help to determine the underlying aetiology.

**Anterior mediastinum**

**Retrosternal or intrathoracic thyroid**
The most common mediastinal mass is a retrosternal or intrathoracic thyroid, which is nearly always an extension of the thyroid present in the neck. Enlargement of the thyroid by a colloid goitre or malignant disease, or, rarely, in thyrotoxicosis, can cause displacement of the trachea and oesophagus to the opposite side. Symptoms of compression develop insidiously before producing the cardinal feature of dyspnoea. Flow–volume loops are useful to assess the physiological impact. Very occasionally, an intrathoracic...
thyroid may cause dysphagia or hoarseness and vocal cord paralysis due to stretching of the recurrent laryngeal nerve. The treatment is surgical removal.

**Thymic tumours (thymomas)**

The thymus is large in childhood and occupies the superior and anterior mediastinum. It involutes with age but may be enlarged by cysts, which are rarely symptomatic, or by tumours, which may cause myasthenia gravis or compress the trachea or, rarely, the oesophagus. Surgery is the treatment of choice. Approximately half of the patients presenting with a thymic tumour have myasthenia gravis. Good’s syndrome, a combined defect of humoral and cellular immunity, is seen in 10% of thymomas.

**Middle mediastinum**

- **Bronchogenic cyst** is a benign growth that is an embryological remnant.
- **Mediastinal lymphadenopathy** may be due to a number of conditions, including metastatic lesions, primary lung cancer, sarcoid, and infection such as tuberculosis. Lymphoma commonly presents with enlargement of the middle mediastinal nodes, and may represent both Hodgkin or non-Hodgkin disease (see pp. 399 and 401).
- **Pericardial cysts**, which may be up to 10 cm in diameter, are filled with clear fluid. Some 70% of them are situated anteriorly in the cardiophrenic angle on the right side. Infection is rare and malignant change does not occur. The diagnosis may be made on MRI but needle aspiration may be required if there is any diagnostic uncertainty. No treatment is required but patients should be followed up, as an increase in cyst size suggests an alternative pathology and surgical excision is then advisable.
- **Vascular abnormalities** include aortic aneurysm and aortic dissection.
- **Tracheal tumours** were discussed earlier.

**Posterior mediastinum**

- **Embryological remnants** include neurogenic and neuroenteric cysts.
- **Oesophageal abnormalities**, e.g. oesophageal tumours and hiatus hernias, are seen here.

INTRODUCTION

Pulmonary embolism (PE) is the third most common cause of cardiovascular death after acute myocardial infarction and stroke. As well as leading to PE, deep vein thrombosis (DVT) and/or pulmonary embolism (PE), and is frequently recurrent. Patients with a suspected episode of VTE may present to their GP or directly to the hospital emergency department, or VTE may occur while care is being given to inpatients for other medical problems. Many clinical teams may therefore be involved in the initial diagnosis and management, but most commonly it is acute physicians who play a leading role. Haematologists often provide advice on acute management and frequently oversee long-term treatment, while some chest physicians have a particular interest in the management and long-term complications of PE.

• It is a significant cause of morbidity: long-term sequelae are frequent and significantly impair quality of life.

PATHOGENESIS OF THROMBOSIS

Thrombosis is the pathological process by which a localized solid mass of blood constituents (a blood clot or thrombus) forms within a blood vessel, mostly as a result of fibrin formation with a variable contribution from platelets and other cells. This differentiates it from physiological haemostasis, the process in which a fibrin-rich blood clot occurs outside the vessel-wall lining (or endothelium) as a result of injury. Thrombi form on, and are attached to, the vessel wall but fragments (emboli) may break off and occlude vessels downstream.

Arterial and venous thrombosis

Thrombosis can occur in both arteries and veins (for example, the usual cause of myocardial infarction is thrombosis within a coronary artery). The pathogenesis of thrombosis in these two sites is different, reflecting the different shear stresses in arteries and veins, and the contribution that rupture of atheromatous plaques makes to the initiation of arterial thrombosis. Arterial clots are described as white thrombi and venous clots as red thrombi, reflecting the contribution that platelets, as well as fibrin, make to the former, and fibrin and red
Venous thromboembolic disease

Factors influencing thrombosis

Thrombosis is considered to arise from the interplay between the three factors that make up Virchow’s triad:
- changes in blood flow (stasis or turbulence)
- vessel wall dysfunction
- changes in blood components, leading to hypercoagulability.

The importance of the individual components of Virchow’s triad varies between arterial and venous thrombosis:
- **Turbulence and vessel-wall dysfunction** caused by atheromatous plaques are factors in arterial thrombosis.
- **Stasis and hypercoagulability** are more relevant in the pathogenesis of venous thrombosis.

Further reading

DEFINITIONS

Most often, venous thrombosis originates in the deep veins of the leg: hence the term deep vein thrombosis. It is thought that the process starts within the pocket of one of the valves that line the veins, where flow may be turbulent and localized hypoxia may develop, resulting in endothelial dysfunction. The thrombus may remain localized to the leg veins or may embolize through the circulation to result in a pulmonary embolus. A minority (about 10%) of episodes of venous thrombosis arise in other sites, such as the upper limb, the cerebral venous sinuses and the splanchnic veins (hepatic, portal and mesenteric veins). Apart from upper limb venous thrombosis, these unusual-site thromboses are described further in relevant specialty-specific chapters.

If confined to the calf veins, the thrombus is called a calf or distal DVT. Untreated, the thrombus may extend proximally and, when it reaches the popliteal vein or above, is called a proximal DVT. Thrombi at this level are larger, and may be more likely to embolize and be transported with blood flow through the large veins of the pelvis and abdomen to the right atrium and ventricle. From there, they are pumped into the pulmonary arteries, which progressively divide into smaller arteries as they course through the lungs to supply the alveoli. The emboli stop in the pulmonary arteries, where they are no longer physically able to progress, and, in so doing, obstruct the flow of blood distally. It is thought to take at least several days for venous thrombi to become clinically evident.

EPIEDEMOLOGY AND RISK FACTORS

The annual incidence of VTE within the community is estimated at around 1 per 1000 per year overall and is age-dependent. VTE is uncommon in childhood, affects around 1 per 10 000 young adults per year and 1 per 1000 middle-aged adults per year, and approaches an incidence of 1 in 100 elderly adults per year. Historical autopsy data suggest that about 10% of patients who died in hospital did so from PE. Over 5% of people will develop one or more episodes of VTE during their lifetime. Clinically, about 60% of episodes of VTE present with DVT and the other 40% with PE, with or without accompanying features of DVT.

Risk factors for VTE are shown in Box 29.1. They can be divided into transient provoking factors (such as major surgery) and longer-term predisposing factors (such as obesity or heritable thrombophilias).

- **Transient**
  - Surgery, especially major, lower limb/pelvis or cancer-related
  - Trauma, especially lower limb/pelvis
  - Active cancer
  - Acute medical admission
  - Immobilization (bed rest >3 days)
  - Plaster cast
  - Pregnancy/puerperium
  - Oestrogen administration (combined hormonal contraception, oral hormone therapy)
  - Recent long-haul travel (>4 h)
  - Central venous catheter
  - Heparin-induced thrombocytopenia
  - Superficial vein thrombosis

- **Persistent**
  - Increasing age
  - Body mass index >30 kg/m²
  - Ethnicity
  - Previous episode of venous thromboembolism
  - Inflammatory conditions, e.g. inflammatory bowel disease, systemic lupus erythematosus, Behçet’s syndrome
  - Nephrotic syndrome
  - Lower limb paresis, e.g. after stroke
  - Heritable thrombophilia (factor V Leiden, prothrombin gene mutation, deficiencies of antithrombin, protein C or protein S)
  - Antiphospholipid syndrome
  - Myeloproliferative neoplasms

CLINICAL FEATURES

The typical features of DVT include pain and swelling in one leg. The leg may be red and warm to the touch. There may also be
tenderness along the course of the deep veins and dilation of the superficial veins.

**PE** presents:
- In about 65% of cases, with pleuritic chest pain and breathlessness, sometimes accompanied by haemoptysis. Tachypnoea and tachycardia are typically present. Crackles and a pleural rub over a localized area of pulmonary infarction may be evident on auscultation.
- In another 25%, with isolated breathlessness, sometimes only evident on exertion.
- In the remaining 10%, with more severe features, including syncope episodes, systolic hypotension or shock, and myocardial ischaemia with associated central chest pain. With this more severe presentation the patient is tachypnoeic, and has a tachycardia with peripheral shutdown, a raised jugular venous pulse (JVP) with a prominent α-wave, right ventricular heave, gallop rhythm and a widely split second heart sound. Cardiac arrest may occur, typically with pulseless electrical activity. The severity of presentation depends on both the thrombus burden and the individual’s cardiopulmonary reserve.

At least one-third of patients presenting with DVT have clinically silent pulmonary emboli. About 70% of people presenting with symptomatic PE have an associated DVT that is symptomatic in about a quarter of cases.

**DIAGNOSIS**

Unfortunately, the differential diagnosis of suspected DVT or PE is very wide (Box 29.2), and most patients (>80%) who present with suspected VTE have the diagnosis excluded rather than confirmed. The clinical features are often non-specific and the majority of people who die from PE probably do so because earlier warning signs were missed rather than because of sudden collapse and death, or failure of treatment.

The challenge in the diagnostic investigation of suspected DVT and PE is therefore to identify, rapidly and accurately, when urgent treatment is required, and to distinguish these patients from those who do not have the condition, in whom unnecessary investigation and treatment would be potentially harmful.

**Initial investigations**

The initial investigations that might be undertaken because of chest pain or breathlessness are often non-diagnostic in patients with PE:
- **ECG (Fig. 29.1):** A right ventricular strain pattern may be seen, with T wave inversion in the inferior (II, III, AVF) and right precordial (V1–V6) leads. The classical ECG is of an ‘S1Q3T3’ pattern, with a prominent S wave in lead I and a prominent Q wave and inverted T wave in lead III, but this is present in only a minority of patients. It is more common to see a sinus tachycardia.
- **Chest X-ray:** This may be normal but more often shows non-specific abnormalities, including atelectasis, parenchymal abnormalities, cardiomegaly, elevation of the hemidiaphragm or a pleural effusion.
- **Arterial blood gas analysis:** Blood gases typically show hypoxia and hypocapnia, but again these are non-specific findings and are not always present.
- **Biomarkers of cardiac injury:** Plasma levels of brain natriuretic peptide (BNP) or its precursor, amino-terminal pro-BNP, may be elevated because of stretching of the right ventricle, and troponin may be increased because of right ventricular injury due to strain, but once again these findings are non-specific.

**Fig. 29.1 Acute pulmonary embolism shown on a 12-lead ECG.** There is an S wave in lead I, a Q wave in lead III and an inverted T wave in lead III (the S1, Q3, T3 pattern). There is sinus tachycardia (160 beats/min) and an incomplete right bundle branch block pattern (an R wave in AVR and V1 and an S wave in V3).
Diagnosis of DVT and PE

For patients in the UK, other than those with shock or hypotension due to suspected PE, the approach to the diagnosis of VTE recommended by the National Institute for Health and Care Excellence (NICE) is generally used.

Risk scoring

The diagnostic process starts with assessment of the clinical probability using a clinical prediction score that takes account of the individual patient’s clinical features, the presence or absence of risk factors for VTE, and whether an alternative diagnosis is likely to explain the symptoms and signs. There are a number of clinical prediction scores available, and NICE recommends the modified two-level Wells score for DVT (Box 29.3) and the two-level Wells score for PE (Box 29.4); these categorize patients into groups that are likely or unlikely to have DVT or PE, respectively. Clinical prediction scores standardize clinical assessment and increase reproducibility among less experienced clinicians. However, in themselves, they do not confirm or exclude the diagnosis of VTE and further assessment is necessary.

Measurement of D-dimer

In those considered unlikely to have VTE based on the Wells score, the next step is D-dimer testing. D-dimer is a fibrin degradation product that can be measured quantitatively in plasma by highly sensitive laboratory tests, or qualitatively by point-of-care testing of whole blood. Raised levels indicate activation of the coagulation system but are not specific for VTE, as they are also seen, for example, with advanced age, infection, inflammation, postoperatively, in cancer and during pregnancy.

The value of D-dimer in VTE diagnosis is based on its high negative predictive value: that is, VTE is very unlikely in a patient who has a low pre-test probability of VTE or PE by the Wells score and in whom D-dimer, measured by a sensitive assay, falls below a pre-defined cut-off (typically quoted as ‘normal’). Such patients do not need further diagnostic testing for VTE. With this approach it must be borne in mind that there is a small failure rate (<2% within 3 months) and that it does not absolutely exclude VTE.

In contrast, patients whose Wells score indicates that VTE is unlikely but whose D-dimer is raised (lies above the cut-off value) require formal radiological imaging to confirm or exclude VTE. Similarly, imaging is also required for all patients whose Wells score indicates that VTE is likely.

Imaging for DVT

The diagnosis of DVT is generally confirmed by ultrasonography of the deep venous system, which has long replaced the historical gold standard of venography, as it is quicker and non-invasive. At a minimum, ultrasonography involves examination of the proximal venous system. Typically, this includes compression of the popliteal and femoral veins by the ultrasound probe to determine whether the vein is compressible or not. This is usually supplemented by direct thrombus imaging with vein enlargement and assessment of blood flow by Doppler. Ultrasonography is very sensitive for proximal DVTs (>95%) but less so for distal DVTs (70%). In general terms, a positive scan will confirm the diagnosis. However, in those with a Wells score indicating that a DVT is likely, a negative scan, if limited to the proximal venous system, does not exclude the diagnosis, as it will not identify a proportion of patients who have a distal DVT. Further assessment of these patients is required (Fig. 29.2).

Alternatively, whole-leg ultrasonography can be performed. This avoids the need for repeat scanning but is more time-consuming and requires greater expertise.

The diagnosis of DVT in those with a prior event is often problematic because of the presence of residual vein occlusion, and expert radiological advice should be sought.

Imaging for PE

The approach to the diagnosis of PE is similar in principle (Fig. 29.3). When the Wells score indicates that a PE is unlikely, a negative D-dimer excludes the diagnosis without further investigation.

(From Wells PS, Anderson DR, Rodger M et al. Derivation of a simple clinical model to categorize patients probability of pulmonary embolism: increasing the models utility with the SimpliRED D-dimer. Thromb Haemost 2000; 83:416–420.)
However, imaging is essential in those who either have a raised D-dimer level or are categorized as likely to have a PE based on their Wells score.

The most common imaging technique is computed tomographic pulmonary angiography (CTPA) (Fig. 29.5), which is widely available and sensitive, and can provide an alternative diagnosis when PE is excluded. The alternative is ventilation-perfusion (V/Q) isotope lung scanning, (Fig. 29.6). This test is performed in two stages:

- **a perfusion phase**, in which technetium-labelled albumin aggregates are injected intravenously and blood flow to the lungs is assessed
- **a ventilation phase**, in which patients inhale radiolabelled xenon or technetium to assess air delivery to the lungs.

A diagnosis of PE is made if there are mismatched defects in the perfusion scan, indicating impaired blood flow to the lungs, but normal ventilation because air entry to the lungs is normal. A normal V/Q scan excludes the diagnosis of PE. This technique has the advantage of a lower radiation dose and is preferred in those with renal impairment and allergies to intravenous contrast agents. The disadvantages are that it is less readily available and the results are often non-diagnostic because other lung pathology can cause matched or smaller mismatched defects.

**Timescale of investigation**

Diagnostic testing for VTE should be performed urgently and completed within 24 hours of initial presentation. When imaging is required, a first dose of anticoagulant should be given if it is anticipated that it will take more than 1 hour to investigate a suspected PE and 4 hours for a suspected DVT.

The approaches described apply only to patients presenting to primary care or emergency departments. Inpatients and pregnant women should be regarded as high-risk and require appropriate imaging if DVT or PE is suspected (see p. 1457).

**Emergency presentations**

In the minority of patients with suspected PE who present with hypotension, mortality is high and prompt diagnosis is essential. If an urgent CTPA is not possible, a bedside trans-thoracic echocardiogram may be diagnostic, showing acute pulmonary hypertension and right ventricular dysfunction (see Fig. 29.4).

![Suspected DVT](image-url)

**Fig. 29.2** Investigation of suspected DVT.
**Upper limb DVT**

The diagnostic algorithm for suspected upper limb venous thrombosis is less well established and patients with suggestive clinical features of arm pain and swelling typically require ultrasound imaging.

**Further reading**

**MANAGEMENT**

Anticoagulant therapy is the standard treatment for VTE. It is traditionally divided into three phases:

- the acute phase, lasting 5–10 days
- a maintenance phase, lasting a minimum of 3 months
- a long-term phase beyond this.

The aim of treatment in the initial phase is to prevent thrombus extension and hence reduce the risk of embolization; the goal thereafter is to prevent thrombus recurrence.

**Initial treatment**

**Traditional management**

The long-established initial treatment of VTE involves a **parenteral anticoagulant**, most commonly subcutaneous low-molecular-weight heparin (LMWH); alternatively, intravenous unfractionated heparin (UFH) or subcutaneous fondaparinux may be used. In addition, an **oral vitamin K antagonist**, such as warfarin, is given.

Parenteral anticoagulants are used initially, as they provide almost immediate anticoagulant activity, whereas warfarin needs at least 5 days to provide therapeutic anticoagulation, as judged by its impact on the **International Normalized Ratio** (INR). Heparin or fondaparinux can be stopped and warfarin continued alone once the INR is 2.0 or more on 2 consecutive days, indicating that the vitamin K antagonist is now providing sufficient anticoagulation.

Anticoagulant agents are described on pages 1014–1016.
Direct oral anticoagulants

The introduction of the direct oral anticoagulants (DOACs) into clinical practice around 2010 has had a major impact on the management of VTE. Four DOACs are currently licensed for VTE treatment: three direct factor Xa inhibitors (apixaban, edoxaban and rivaroxaban) and one direct thrombin inhibitor (dabigatran). There are differences between them in the timing of their introduction, based on the large randomized clinical trials that led to approval for their use.

- **Edoxaban and dabigatran** are preceded by parenteral anticoagulation (such as LMWH) for 5 days prior to starting the DOAC alone: that is, there is a straight switch from LMWH to edoxaban or dabigatran on day 6 with no overlap.
- **Apixaban and rivaroxaban** do not require parenteral anticoagulation and the DOAC is used alone from the outset, albeit at a higher initial dose, for 7 and 21 days, respectively.

The different treatment models are shown in Fig. 29.7 and the drugs are described further on pages 1014–1016.

Ambulatory care

Many patients with DVT can be managed on an outpatient basis, admission being reserved for those with a complex presentation or significant co-morbidities. Increasingly, too, low-risk PE can be managed on an outpatient basis or with early discharge after 24–48 hours. Low-risk patients can be identified using the Pulmonary Embolism Severity Index (PESI) or simplified PESI (Box 29.5); management as an outpatient or with early discharge might be considered for this group. Higher-risk patients need admission for close observation and administration of high-flow oxygen.

Special circumstances

A minority of patients warrant a different initial approach.

Pregnant women

Warfarin and the DOACs cross the placenta and should not be used in pregnancy, when LMWH is the treatment of choice. Warfarin causes embryopathy between the 6th and 12th weeks of pregnancy, with skeletal abnormalities including nasal hypoplasia and stippled epiphyses; later in pregnancy it causes bleeding in the fetus, with neurological abnormalities and a significant risk of intrauterine death. However, in women who become pregnant while taking warfarin, the drug is safe until the 6th week; it is therefore important to recognize pregnancy early and to switch by the 6th week to LMWH, which does not cross the placenta and is safe for...

the fetus. The consequence of exposure of the fetus to the DOACs is uncertain at this time. See page 1456 for further details of anticoagulation in pregnancy.

**Breast-feeding mothers**

Both warfarin and LMWH are safe for breast-feeding women but this has not been established for the DOACs, which should therefore be avoided (see also p. 1457).

**Patients with cancer**

Trials have shown that LMWH is more effective than warfarin in the treatment of VTE in patients with active cancer, who have a particularly high risk of recurrent thrombosis. Therefore, for many years LMWH has been the treatment of choice for cancer-associated thrombosis. Recent trial data suggest that, in the cancer setting, DOACs may be at least as effective as LMWH in preventing recurrent thrombosis but may increase the risk of bleeding.

**Role of thrombolysis**

Anticoagulants help prevent thrombus extension and recurrence but do not dissolve blood clots, in contrast to thrombolytic agents. The latter are seldom used in the treatment of VTE because they carry a higher risk of major bleeding than anticoagulation, including a 2% risk of intracranial haemorrhage. However, in patients presenting with massive PE characterized by systolic hypotension (blood pressure ≤90 mmHg) there is a high risk of early death, and systemic thrombolysis administered intravenously, or occasionally by catheter infusion directly into the thrombus, may be life-saving by rapidly restoring pulmonary perfusion.

The role of thrombolysis in the management of intermediate-risk PE – that is, without systolic hypotension but with evidence of right ventricular dysfunction and raised pro-BNP or troponin levels – remains controversial. Thrombolysis – either systemic, catheter-directed or pharmaco-mechanical – is occasionally used in the rare setting of management of limb-threatening ilio-femoral vein thrombosis. Local thrombolysis is also sometimes used in non-limb-threatening ilio-femoral vein thrombosis in an attempt to reduce symptoms and prevent the post-thrombotic syndrome, although there is limited evidence of long-term benefit.

**Interventional approaches**

**Surgical embolectomy**

When patients present with massive PE and thrombolysis is contraindicated, emergency pulmonary embolectomy can be life-saving.

**Inferior vena cava filters**

Occasionally, patients with newly diagnosed VTE have a contraindication to anticoagulation – for example, active bleeding – or a major bleeding risk, such as the need for urgent surgery. In such settings an inferior vena cava (IVC) filter can be inserted by an interventional radiologist to prevent emboli from the deep veins in the leg reaching the lungs. Contraindications to anticoagulation are usually temporary, and anticoagulant treatment should be started as soon as it is safe to do so because filters do not entirely prevent pulmonary emboli and are independently associated with an increased risk of DVT. IVC filters do not reduce the risk of recurrent PE compared to anticoagulation alone. As IVC filters can give rise to complications that include migration and embolization, retrievable filters are preferred over permanent ones and they should be removed as soon as anticoagulation has been safely established.

**Treatment duration**

Anticoagulation needs to continue for a minimum of 3 months in all patients with proximal DVT or PE because earlier discontinuation is associated with a higher risk of recurrence. After 3 months, the decision as to whether to stop treatment or to continue anticoagulation long-term for secondary prevention should be made on an individual patient basis, taking account of the risks of recurrent thrombosis, bleeding and the person’s own views.

Anticoagulants reduce the relative risk of recurrent thrombosis by 80–90% but carry a 1–3% absolute risk per year of major bleeding. Both recurrent thrombotic episodes and anticoagulant-associated
major bleeding carry a significant risk of morbidity and mortality. Therefore, the benefits of long-term anticoagulation potentially outweigh the risks of major bleeding in those at higher risk of recurrent thrombosis, whereas in others the risks of long-term treatment potentially outweigh the benefits.

Across all patients receiving anticoagulation for VTE, if anticoagulation is stopped after a minimum of 3 months, the risk of recurrent thrombosis is about 5% in the next year. It has been suggested that if the recurrence risk is greater than this, continuation of anticoagulation should be considered, whereas if the recurrence risk is less, anticoagulation should stop. As long as anticoagulation has been continued for at least 3 months, a longer duration of treatment does not appear to reduce the risk of recurrent thrombosis further on stopping anticoagulation.

INR, International Normalized Ratio; LMWH, low-molecular-weight heparin.](image)
Risk of recurrence

Higher recurrence risks are seen in patients with unprovoked VTE episodes (about 10% at 1 year and 30% at 5 years) and in those with persisting risk factors. Lower recurrence risks are seen in those with transient provoking risk factors, and the stronger the transient provoking factor, the lower the recurrence risk (providing the transient provoking factor is no longer present). Recurrence risks are higher in males than in females, in those with second events, and in those with PE or proximal DVT as opposed to distal DVT. The risk of recurrent PE is higher in those whose initial presentation is with PE rather than with DVT. Since the case fatality of PE is higher than that of DVT, this suggests that the threshold for continuing anticoagulation might be lower in patients presenting with PE. Also relevant is the individual patient’s cardiopulmonary reserve, since those with impaired reserve are less able to compensate for the acute circulatory effects of PE.

Accurate prediction of risk

A number of prediction rules have been devised to assist in the determination of risk of VTE recurrence in those with unprovoked VTE. These take into account a number of clinical features, and often the measurement of D-dimer 1 month after discontinuation of warfarin. Prediction rules for risk of major bleeding have been less well developed. Moreover, the VTE recurrence threshold for considering long-term anticoagulation may be different in patients on DOACs than those on warfarin.

Broadly, the approach in the UK for the treatment of unprovoked VTE is as outlined in NICE guidelines. These recommend consideration of long-term anticoagulation in those with unprovoked proximal DVT, and the offer of long-term anticoagulation to patients presenting with unprovoked PE.

Patients with persisting risk factors for recurrence should be considered for continuation of anticoagulation as long as the risk factor persists. For example, the risk of recurrent thrombosis is very high in patients with cancer-associated thrombosis as long as the cancer remains active. After a minimum of 6 months and once the cancer is in remission, anticoagulation can typically be discontinued.

In contrast, the risk of recurrence is lower following isolated calf vein thrombosis. In practice, most symptomatic distal DVTs are treated for 3 months and anticoagulation is then stopped. In those with a low risk of recurrence due, for example, to a transient provoking factor that has now resolved, it may be reasonable to reduce this duration to 6 weeks.

Treatment of upper limb DVT follows the same principles as for leg vein thrombosis. Many such episodes are associated with the presence of indwelling central venous lines; anticoagulation should generally continue for a minimum of 3 months, and longer if the line remains in situ.

COMPLICATIONS

Mortality

Once VTE is diagnosed and treatment commenced, the short-term mortality rate is lower in patients presenting with DVT than with PE.

In those presenting with PE, the mortality rate by 1 month is around 5%, although at least half of these deaths are due to associated comorbidities rather than being directly caused by PE. Nevertheless, compared to those without VTE, mortality remains elevated in both the short and longer term, with observed mortality rates of 10–20% at 1 year; cancer is the leading cause of death.

Associated cancer

Cancer-associated thrombosis, the initial description of which is often attributed to Trousseau in the 19th century (Trousseau’s syndrome), is common and 10–20% of all episodes of VTE are diagnosed in people with cancer. The pathogenesis is multifactorial and includes:
- hypercoagulability resulting directly from the cancer
- the added impact of surgery and/or chemotherapy
- reduced mobility
- use of indwelling central venous catheters that cause local catheter-associated thrombosis.

The combination of cancer and thrombosis carries a particularly poor prognosis. Up to 5% of patients who present with a seemingly unprovoked episode of VTE are diagnosed with cancer within 12 months.

Post-thrombotic syndrome

For many patients, quality of life after the diagnosis and initial treatment of VTE is adversely affected in the long term by development of the post-thrombotic syndrome (PTS). This occurs in about 40% of people following a proximal DVT. It causes symptoms of variable severity in the affected leg, including pain, swelling, heaviness, venous claudication on exercise, itching and discolouration. The symptoms may be persistent or intermittent, and reduce physical functioning and mobility. At its most severe, it leads to permanent skin damage with redness, hyperpigmentation, venous ectasia and skin fibrosis (lipodermatosclerosis), and 5–10% of patients develop leg ulceration that is difficult to treat and tends to recur (Fig. 29.8).

PTS results from:
- proximal venous occlusion with outflow obstruction
- damage to the venous valves that normally allow blood flow from superficial to deep and distal to proximal
- development of a collateral circulation
- venous hypertension
- capillary leakage
- localized inflammation.

The role of knee-length, graduated compression stockings, providing at least 24 mmHg support at the ankle, in the reduction of risk of PTS remains controversial. Those who develop PTS sometimes benefit symptomatically from graduated compression stockings, whereas others find them difficult to put on and uncomfortable to wear.

A multidisciplinary approach is necessary in patients who develop venous ulceration. With residual ilio-femoral vein occlusion, a vascular surgery opinion should be sought, as some patients may benefit from venous stent insertion.

Pulmonary hypertension

Following PE, up to 5% of patients remain persistently breathless due to chronic thromboembolic pulmonary hypertension (CTEPH). In this condition there is incomplete resolution of pulmonary emboli. The diagnosis should be suspected in those with persisting symptoms supported by follow-up perfusion lung scanning, CTPA showing evidence of residual occlusion, and echocardiography suggesting pulmonary hypertension. Assessment is undertaken by respiratory specialists and a proportion of patients can be successfully treated surgically with a pulmonary endarterectomy.
can be divided into mutations that cause either gain of function of procoagulants or loss of function of anticoagulants.

**Gain of function of procoagulants**

**Factor V Leiden** results from a mutation in clotting factor V that causes activated clotting factor V (factor Va) to be resistant to inactivation by activated protein C, and thereby leads to an increase in thrombin generation. Heterozygous factor V Leiden is present in about 5% of individuals of European or Mediterranean origin but is not found in other ethnic groups such as those from eastern Asia. It increases the risk of VTE fivefold throughout life, and interacts synergistically with acquired risk factors such as combined hormonal contraceptives and pregnancy. Thus, the risk of thrombosis is increased about 30-fold in heterozygous V Leiden carriers on the combined oral contraceptive pill compared to non-carriers who are not on the combined oral contraceptive pill. However, because the absolute risk of VTE is low in young women, even a 30-fold increase in risk remains significantly below 0.5% per year for any single individual. Overall, factor V Leiden is present in about 20% of cases of VTE. Individuals who are homozygous for factor V Leiden are much less common but have a higher risk of thrombosis (about a 10-fold increase) than those who are heterozygous.

**A mutation in the 3′ untranslated region of the prothrombin gene** (G20210A) causes levels of prothrombin to rise and increases the risk of VTE 2–3-fold throughout life. It is present in about 2% of Caucasians and in about 5% of people with VTE.

**Loss of function of anticoagulants**
The sites of action of the naturally occurring anticoagulants are shown in Fig. 29.9.

**Antithrombin** is a serine protease inhibitor (serpin) that functions as an anticoagulant by inhibiting predominantly thrombin and factor Xa reactions that are catalysed by heparin. Reduced antithrombin activity therefore leads to increased thrombin generation and activity, and thereby a predisposition to thrombosis. Heterozygous antithrombin deficiency is rare in the population but increases the risk of VTE about 10-fold. The disorder is identified by measurement of antithrombin activity rather than by genetic testing because multiple genetic mutations have been described. Some of these reduce synthesis of the antithrombin molecule, while others reduce the function of the synthesized protein due to conformational changes. Laboratory diagnosis is not straightforward because low antithrombin levels can also be acquired, for example, after acute illness, after surgery, with heparin therapy, in liver disease and in other disorders such as the nephrotic syndrome. Those with antithrombin deficiency often present at a young age and are more likely to have recurrent events. Because antithrombin is required for the action of heparin, those with antithrombin deficiency may be relatively resistant to heparin.

**Protein C and protein S** are vitamin K-dependent, naturally occurring anticoagulants. Together, they inhibit the activated forms of the clotting system co-factors, factor Va and factor; deficiency leads to an increase in thrombin generation and a predisposition to thrombosis. Heterozygous deficiencies of protein C and protein S are uncommon in the population and increase the risk of venous thrombosis at least fivefold. As with antithrombin deficiency, multiple genetic mutations have been described that affect either the synthesis or the function of the proteins. Diagnosis is therefore based on measurement of the activity or concentration of the proteins, and is often difficult because reduced levels can also be acquired due to, for example, acute illness, liver disease, warfarin or vitamin K deficiency, or, in the case of protein S, due to pregnancy

---

**INVESTIGATION OF NEWLY DIAGNOSED VENOUS THROMBOSIS**

**General investigations**

All patients with newly diagnosed unprovoked VTE should undergo a physical examination and have the following general tests:

- full blood count
- renal and liver function tests, including serum calcium
- clotting screen
- chest X-ray
- urinalysis.

Further assessment may be required, depending on the results of the initial assessment. In view of the frequency with which cancer is subsequently diagnosed in people with unprovoked VTE, the current recommendation from NICE is that, in patients aged over 40 years with unprovoked VTE, consideration should be given to further assessment, including a CT scan of the abdomen and pelvis and, in females, a mammogram. The benefit of this additional investigation is uncertain, however, as it has not been established that it improves survival.

**Thrombophilia testing**

Thrombophilia testing is often considered in patients with VTE but the indications remain controversial. In this context the term thrombophilia applies to a thrombotic tendency that can be identified in the laboratory. Thrombophilic tendencies can be either heritable or acquired.

**Heritable thrombophilias**

Heritable thrombophilias can be identified in about 20% of cases of VTE but do not play a significant role in arterial thrombosis. They...
Management of heritable thrombophilias

In general, the more common heritable defects cause a milder clinical picture than those that are rare, such as antithrombin deficiency. The acute management of VTE is not affected by the presence or absence of heritable thrombophilia, and diagnosis of antithrombin, protein C and protein S deficiencies is problematic in the setting of acute VTE because levels of these proteins are often reduced either by the thrombosis itself or by the anticoagulants used in treatment. Moreover, for the most part, identification of a heritable thrombophilic defect does not influence the long-term management, since most defects do not influence the risk of recurrent VTE. Therefore, if a heritable thrombophilia is to be sought, it should preferably be once the acute stage is over and when the patient has completed a minimum of 3 months’ anticoagulation, and their course of treatment either has finished or can be safely interrupted to allow measurement of naturally occurring anticoagulant levels. Testing for heritable thrombophilias might be considered in:

- those with unprovoked VTE who are planning to stop anticoagulation, particularly if they have a family history
- those who present with VTE under 50 years
- women of child-bearing age, for assistance with the management of future pregnancies
- those with unusual-site thromboses.

Acquired thrombophilia

Many risk factors for thrombosis cause an acquired hypercoagulable state, but in practice, from a laboratory angle, the main acquired thrombophilia is the antiphospholipid syndrome. Heparin-induced thrombocytopenia (HIT) is considered on page 1014.

Antiphospholipid syndrome

The antiphospholipid syndrome (APS) is an acquired prothrombotic disorder that has specific clinical and laboratory features. See page 459 for a full description, including diagnostic testing.

The diagnosis of APS should be considered in patients presenting with:

- **VTE at a young age** (<50 years), particularly if unprovoked or provoked by a minor risk factor.
- **Unusual-site venous thrombosis.**
- **Recurrent episodes of venous thrombosis,** particularly if anticoagulants are being given.
- **Arterial thrombosis** at a young age (<50 years) that is otherwise unexplained.
- **Pregnancy-related morbidity** – the loss of three or more embryos before the 10th week of gestation after exclusion of other causes such as chromosomal abnormalities, and/or one or more otherwise unexplained fetal deaths beyond the 10th week of gestation, and/or the premature birth of a morphologically normal neonate before the 34th week of gestation because of eclampsia, severe pre-eclampsia or placental insufficiency.
- **Incidentally detected abnormalities of clotting screens** performed for other reasons. The activated partial thromboplastin time (APTT) is typically prolonged; less often, the prothrombin time is. Although this would suggest a bleeding tendency, in practice it is a thrombotic tendency that is observed.

Recognition of APS in patients with VTE is associated with an increased risk of recurrent episodes. This may influence decisions on the duration of anticoagulation after an episode of VTE. There is emerging evidence that the DOACs may be less effective than warfarin in the prevention of recurrent thrombosis in APS.

Management of APS presenting with arterial thrombosis is controversial and there is ongoing debate as to whether the best approach is anticoagulation with warfarin, at either standard...
intensity (INR 2.0–3.0) or higher intensity (INR 3.0–4.0), and/or anti-
platelet therapy.

Women with obstetric APS are generally managed throughout preg-
nancy with low-dose aspirin and a prophylactic dose of
LMWH.

PREVENTION

Between a third and a half of all episodes of VTE are provoked by
surgery and/or admission to hospital, and mostly diagnosed in the
three months after discharge. Studies in certain groups of patients,
such as those undergoing major orthopaedic or cancer surgery,
where routine postoperative screening for venous thrombosis has
been undertaken, have reported incidences of asymptomatic DVT
as high as 50%. As already stated, PE is the most common prevent-
able cause of hospital-related death. Clinical trials have shown the
benefit and cost-effectiveness of thromboprophylaxis in preventing
symptomatic VTE in patients undergoing major surgery and in high-
risk medical inpatients.

All adults admitted to hospital require formal assessment of their
risks of VTE and of bleeding. The factors included in the UK Depart-
ment of Health risk assessment tool are shown in Box 29.6.

Prophylactic measures can be considered as mechanical or
pharmacological. Patients considered at risk of VTE who do not
also have a bleeding risk are considered for pharmacological pro-
phylaxis, with or without additional mechanical measures. Those
who have a bleeding risk may be deemed unsuitable for pharma-
cological prophylaxis but may be considered for mechanical
prophylaxis.

Mechanical prophylaxis

Measures include:
• early mobilization
• elevation of the legs
• use of anti-embolic stockings of knee or thigh length; these
  should not be used in peripheral arterial disease, stroke or situa-
  tions where they could result in skin damage
• intermittent compression devices that can be applied to patients
during surgery or on bed rest and aim to improve blood flow.

Pharmacological prophylaxis

This involves the prescription of anticoagulants in lower doses than
those used in treatment. Most often, LMWH is used during hospital
admission, and in some groups – for example, those undergoing
major abdominal surgery for cancer – this is continued for a period
following discharge. DOACs in low dose have been approved for
VTE prevention following major hip and knee replacement surgery,
and again these are continued for 2–5 weeks after surgery. Though
traditionally not thought to be of benefit in VTE, aspirin has also
been found to reduce the risk of venous thrombosis after major joint
replacement surgery.

ANTICOAGULANT AGENTS

The physiological purpose of the coagulation system is to generate,
rapidly and locally, the enzyme (or serine protease) thrombin, which
converts soluble circulating plasma fibrinogen into insoluble fibrin in
response to vascular injury, and thereby helps secure haemostasis.
Venous thromboembolic disease

This is achieved through a complex series of reactions on exposed cell surfaces and activated platelets, in which inactive circulating clotting factors become locally activated in a coordinated and sequential manner. Initiation follows the binding of circulating factor VII to tissue factor, a receptor expressed on subendothelial and adventitial cells, and leads to the generation of activated factor X (traditionally referred to as the extrinsic system, see p. 371). This, in turn, results in initial thrombin generation and subsequent amplification of the process through activation of the intrinsic system, leading to further activation of factor X and thrombin generation.

Venous thrombosis is characterized by the pathological formation of a localized fibrin-rich clot. Anticoagulants work by inhibiting the generation and/or activity of thrombin in different ways (Figs 29.10 and 29.11).

Parenteral anticoagulants

The main pharmacological properties of the parenteral anticoagulants used in the treatment and prevention of VTE are summarized in Box 29.7.

Heparin

Heparin is not a pure substance but a mixture of polysaccharides of different molecular weights of biological origin. In the UK, all heparins are derived from processed porcine gut mucosa. Heparins are destroyed in the stomach and must be administered parenterally. Heparin is an indirect anticoagulant because it does not work directly, but by binding through a specific pentasaccharide sequence to naturally occurring antithrombin in plasma, and inducing a conformational change that increases the inhibitory activity of antithrombin at least 1000-fold. The result is more rapid inhibition of several of the activated serine protease coagulation factors, particularly thrombin (factor IIa) and factor Xa. Heparins are classed as unfractionated heparin (UFH) or as low-molecular-weight heparin (LMWH).

Unfractionated (standard) heparin

For many years, UFH was the only form of heparin available for the treatment and prevention of VTE. In VTE treatment it is usually administered as an immediate-acting bolus injection, followed by an initially weight-based intravenous infusion. It is difficult to use in practice because it is necessary to monitor its effect on the APTT regularly and to adjust the rate of infusion to maintain the APTT ratio (APTT of patient sample compared to mid-point of the normal range) within a target range: typically, an APTT ratio of 1.5–2.5. UFH has a short half-life of 1 hour and, if necessary, can be rapidly reversed with a specific antidote, protamine sulphate. It is not excreted through the kidneys. It carries a small but significant risk of major bleeding, and of an uncommon but important immunologically mediated, prothrombotic adverse drug reaction, heparin-induced thrombocytopenia (HIT, see later). Its use nowadays in the treatment of VTE is largely restricted to particular high-risk settings where its short half-life, reversibility and lack of renal excretion are advantageous properties. UFH is rarely used for thromboprophylaxis because its short half-life means that it needs to be given two or three times daily by subcutaneous injection.

Low-molecular-weight heparin

LMWHs are the main type of heparin given nowadays because their favourable pharmacokinetic properties facilitate their use in clinical practice. LMWH is produced by the chemical or enzymatic degradation of unfractionated heparin, and results in polysaccharide chains of shorter length and molecular weight than UFH. Since long chains with at least 18 saccharides are required for inhibition of thrombin by antithrombin, whereas factor Xa is inhibited by shorter chains, the consequence is that, compared to UFH, the LMWHs inhibit factor Xa to a greater degree than thrombin. LMWH is administered by subcutaneous injection and peak activity is seen by 4 hours. The half-life of LMWH is longer than that of UFH at 4 hours. LMWH is excreted through the kidneys and caution is required in patients with renal impairment. Because of its better bioavailability than UFH, it has the major advantage of fixed, weight-based dosing, without the need for laboratory monitoring. As a result, the majority of patients with DVT and many with PE can be treated as outpatients without hospital admission. Further advantages of LMWH over UFH are that it is at least as safe and effective, and carries a lower risk of HIT. However, LMWH is only partially reversed by protamine sulphate.

In VTE treatment, standard practice for many years has been to give an initial subcutaneous injection of LMWH while awaiting confirmation of the radiological diagnosis of DVT or PE, and then continuing it with warfarin until the latter, with its slower onset of action, is providing sufficient anticoagulation for the LMWH to be stopped, a process that takes at least 5 days. During this time, LMWH is administered, often by the patients themselves, by subcutaneous injection once or twice daily. In certain groups, longer-term LMWH is preferred over oral anticoagulants:

- In pregnant women, LMWH is used throughout because it does not cross the placenta.
- In patients with cancer-associated thrombosis, LMWH is more effective than warfarin.

LMWH is also widely used as thromboprophylaxis in patients admitted to hospital or undergoing surgery, and has the advantages over UFH of once-daily administration and lower risk of HIT. LMWH (or an alternative anticoagulant) also may be used to reduce morbidity and mortality in acute coronary syndrome, where it is usually given twice daily.

Heparin-induced thrombocytopenia

An uncommon but important adverse effect of heparin administration in some patients is heparin-induced thrombocytopenia (HIT). Thrombocytopenia typically causes a bleeding tendency but that...
seen in HIT is associated with a strong prothrombotic tendency due to activation of both platelets and the coagulation system. The disorder usually occurs 5–14 days after heparin exposure, with a greater than 30% fall in platelet count occurring over 1 or 2 days. The thrombocytopenia is usually mild to moderate and it is rare for the platelet count to fall below $20 \times 10^9/L$. HIT is immunologically mediated, with the development by the patient of immunoglobulin G (IgG) antibodies to a complex of heparin and platelet factor 4 (PF4) that is found in, and released from, platelet granules. Without prompt diagnosis and treatment, the risk of thrombosis, which can be either venous or arterial, is 50% over the next few days. The diagnosis is based on the clinical features, supplemented by laboratory confirmation of IgG antibodies to the heparin/PF4 complex.

If HIT is suspected and/or confirmed:
- Specialist advice should be sought.
- All heparin should be discontinued (including that used, for example, to flush indwelling lines).
- The allergic reaction should be noted on the drug chart.
- An alternative, non-heparin anticoagulant should be administered in view of the high rate of thrombosis.

The most common alternative anticoagulants used in this setting are danaparoid (a heparinoid), argatroban (an intravenously administered direct thrombin inhibitor) and fondaparinux. Patients who develop HIT should not be re-exposed to heparin in future.

**Fondaparinux**

Unlike heparins, fondaparinux is a synthetic pentasaccharide. It binds to antithrombin, and because of its short chain length it inhibits only factor Xa and not thrombin. It is administered by subcutaneous injection and has a longer half-life than heparin at around 18 hours. It is renally excreted and cannot be used in those with significant renal impairment. Its effect is not reversed by protamine sulphate.

**Oral anticoagulants**

**Vitamin K antagonists**

These agents are indirect anticoagulants that inhibit the final stage of the synthesis of vitamin K-dependent proteins in the liver: namely, clotting factors II (prothrombin), VII, IX and X, and
1016  Venous thromboembolic disease

the naturally occurring anticoagulants, protein C and protein S. The main vitamin K antagonist used in the UK is warfarin. The full anticoagulant effect of warfarin takes at least 5 days because it affects only synthesis of new proteins; those already circulating or fully formed in hepatocytes are unaffected and decline as a function of their half-lives, which vary from 6 hours (factor VII) to 60 hours (prothrombin). Therefore, in the setting of VTE treatment, where an immediate anticoagulant effect is desired, it is necessary to commence with a quick-acting anticoagulant such as heparin, and to continue the latter until warfarin is providing sufficient anticoagulation on its own.

The anticoagulant effect of vitamin K antagonists is measured using the prothrombin time (PT), which measures the extrinsic and common pathways of the coagulation system. Because different laboratories use different reagents with different sensitivities and normal ranges to measure the PT, a system has been devised to standardize assessment of the degree of anticoagulation by the vitamin K antagonists. In this system the PT for each patient test (in comparison to the normal PT of the general population not on anticoagulants) is converted to a standardized ratio, the International Normalized Ratio (INR), and this enables comparison between results in different laboratories and target ranges defined in clinical trials to be adopted in routine clinical practice. The higher the INR is, the greater the intensity of anticoagulation. For most patients on warfarin for VTE treatment, the target INR is 2.0–3.0. A small proportion of patients – for example, those who have a recurrent VTE episode while the INR is in the target range – need to be more intensively anticoagulated and the new target range may be set at 3.0–4.0, reflecting greater prolongation of the PT.

Warfarin is metabolized in the liver and has a half-life of about 36 hours. It has a narrow therapeutic index and a wide range of interactions with dietary factors, alcohol and other drugs. Drug interactions can be either pharmacokinetic or pharmacodynamic. The former are represented by drugs that either induce or inhibit the metabolism of warfarin by the cytochrome P450 system, and thereby reduce or increase warfarin levels and the resulting INR. The latter are exemplified by aspirin and clopidogrel, which do not affect warfarin levels, but further increase the bleeding risk of warfarin through their antiplatelet effects. For reasons that are partly genetic, there is considerable variation between individuals in the dose of warfarin required for the same effect on the INR.

Monitoring warfarin therapy

The consequence of this is that, during the initial period of anticoagulation with warfarin and heparin, it is necessary to measure the INR frequently (almost daily) so that the dose of warfarin can be adjusted and heparin can be discontinued when the INR is in the target range for 2 consecutive days. Following this initial period, the frequency of INR monitoring can be reduced, but it remains necessary on a long-term basis at least every 8–12 weeks in patients whose INR control is stable, and more frequently in those with unstable INRs in order to allow appropriate dose adjustment: that is, a dose increase if the INR is below target and a dose reduction and/or omission if the INR is too high.

This process of INR monitoring is usually done either in hospital-based anticoagulant clinics or in general practice. A small number of motivated and trained patients self-test their INRs at home using point-of-care coagulometers. Patients starting warfarin must be fully counselled, and this should include information about the need to inform clinicians in advance of invasive procedures. This enables steps to be taken where necessary to interrupt warfarin several days beforehand (to allow for its long half-life), and consideration to be given to covering the period off warfarin with, for example, LMWH, which can be stopped closer to the time of the procedure in view of its shorter half-life.

Pregnancy and breast-feeding

In general, warfarin should not be used in pregnancy because it crosses the placenta and is teratogenic between the 6th and 12th weeks of pregnancy, as well as causing fetal bleeding later in pregnancy. It does not cross into breast milk and therefore is safe during breast-feeding.

Risks of warfarin therapy

The main risk of warfarin is bleeding. Most bleeds are not major but can be a considerable nuisance for the patient. The risk of major bleeding is around 2% per year, and about 0.25% patients per year will have a fatal bleed, usually due to intracranial haemorrhage. Most bleeds occur when the INR is within the therapeutic range, but the higher the INR is, the greater the risk of a major bleed. Management of high INRs and of bleeding on warfarin is shown in Box 29.8.

Direct oral anticoagulants

DOACs, also called NOACs (non-vitamin K antagonist oral anticoagulants), are a class of anticoagulants that have been transforming clinical practice since their introduction around 2010. In view of their increasing use, the clinician should be aware of their pharmacological properties, which are very different to those of warfarin (Box 29.9). Four DOACs are currently licensed for treatment of VTE in the UK: three (apixaban, edoxaban and rivaroxaban) are inhibitors of factor Xa and one ( dabigatran) is an inhibitor of factor IIa (thrombin). Unlike heparin and warfarin, they directly inhibit their target substrates. All are administered orally and peak levels are seen about 2 hours after ingestion.

- They have a wider therapeutic index than warfarin.
- There is no interaction with dietary factors or alcohol.
- There is limited interaction (compared to warfarin) with other drugs.
- They can be given in a fixed dose with no monitoring – a major clinical advantage.
- They are variably eliminated through the kidneys and have a half-life of around 12 hours.

Clinical trials have shown they are as effective as heparin and warfarin in the treatment and secondary prevention of VTE. Overall, they carry a similar or lower risk of major bleeding, with a reduced risk of intracranial haemorrhage, partly offset by an increased risk of gastrointestinal haemorrhage.

Their use in the acute treatment of VTE has already been outlined. The combination of efficacy, safety, simplified dosing and avoidance of monitoring has led to a rapid increase in use of DOACs for VTE treatment and secondary prevention.

Special circumstances

DOACs cross the placenta and should not be used by pregnant women or those trying to conceive. Neither should they be used during breast-feeding. The Xa inhibitors are licensed for VTE treatment down to a creatinine clearance of 15 mL/min, although data are still limited in patients with a creatinine clearance of less than 30 mL/min, the lower limit for dabigatran. Significant interactions with certain drugs such as protease inhibitors and many antiepileptics preclude their use in some patients. They are also contraindicated in those with mechanical heart valve replacements, or moderate or severe mitral stenosis. Recent trials suggest that the DOACs are as effective as LMWH in the treatment of cancer-associated thrombosis. However, they increase the risk of gastrointestinal bleeding and LMWH remains the preferred option in patients with cancers where this is a risk.

Management of bleeding on DOACs

In the event of major bleeding on DOACs, management should, in general, follow established principles:
- The DOAC should be stopped.
- Supportive therapy, e.g. intravenous fluids and blood components, should be administered as appropriate.
- Consideration should be given to specialty-specific intervention, e.g. endoscopy.

In the event of life-threatening bleeding, specific antidotes are emerging as additional options. In the case of dabigatran, a monoclonal antibody, idarucizumab, which rapidly binds to and completely reverses dabigatran, is now widely available. An antidote to the inhibitors of factor Xa, andexanet alfa, is currently undergoing clinical evaluation.

Heart disease remains the most common cause of death in the developed world and the third most common in low-income countries. Reducing this burden requires close collaboration between general practitioners, public health doctors, hospital specialists and allied health care professionals, with interventions including reducing smoking rates, encouraging healthy eating choices, promoting aerobic exercise, and targeting hypertension (Ch. 31) and dyslipidaemia (Ch. 24).

In the outpatient setting, patients with stable cardiac symptoms (e.g. exertional chest pain, palpitations or peripheral oedema) are evaluated, and those with established cardiological disease are followed up in order to optimize lifestyle factors and titrate medications.

Most cardiologists are trained in various interventional techniques (e.g. direct current cardioversion, coronary angiography or implantation of cardiac rhythm devices) and work closely with cardiac surgeons. Cardiologists also look after patients with emergency cardiac presentations (e.g. acute coronary syndromes or heart block), often on coronary care units.

Key skills in cardiology include:

- becoming familiar with the management of cardiac emergencies, including acute coronary syndrome and life-threatening rhythm disorders
- understanding cardiovascular risk reduction, and the management of chronic cardiological conditions such as heart failure and atrial fibrillation
- confidently interpreting electrocardiograms (ECGs) and echocardiogram reports, and understanding the role of different forms of invasive cardiac intervention.

Cardiology can be best learned by observing cardiology outpatient clinics, attending ward rounds on the coronary care unit, observing invasive procedures such as coronary angiography or DC cardioversion, and seeing patients in the community with general practitioners or specialist heart failure nurses.
CLINICAL SKILLS FOR CARDIOLOGY

History

A full cardiological history covers the relevant symptoms and risk factors for cardiac disease in detail and is focused on establishing the cause of symptoms. Is this patient’s chest pain likely to originate in the heart? Is their breathlessness more likely to be due to heart failure, lung disease or something else? A fuller description of cardiac history-taking begins on page 1028 but Box 30.1 provides a suggested structure to ensure that the relevant material is covered systematically.

Box 30.1 History-taking in cardiac disease

Symptoms

Chest pain
Think anatomically, about the type of pain caused by disease in different structures within the chest:
• Heart – central, squeezing or crushing in nature, radiation to left arm or jaw, with associated sweating or nausea
• Pericardium – central, sharp in character, retrosternal, may radiate to back, worse sitting upright, associated viral symptoms or causative medication
• Oesophagus – central, burning or tight in nature, worse on lying flat, worse after eating, with associated burping, epigastric discomfort or altered taste
• Pleural – localized and often peripheral, sharp in nature, worse on deep inspiration or coughing, with associated cough, breathlessness or haemoptysis
• Musculoskeletal – often localized, intermittent and related to movement; possible trigger event (e.g. abnormal activity); reproducible on palpation or movement

Breathlessness
Identify severity (see Box 30.23) and likely cause:
• Heart disease – worse on lying flat, episodes of paroxysmal nocturnal dyspnoea, peripheral oedema
• Lung disease – associated respiratory symptoms, e.g. cough, wheeze, pleuritic pain or haemoptysis

Palpitations
These are usually episodic. Identify:
• Nature of symptoms – fast or slow, feelings of ‘missing a beat’, associated chest pain or tightness, breathlessness and dizziness
• Pattern of symptoms – duration of problem, frequency of attacks, associations with exercise, caffeine or alcohol intake
• Severity of symptoms – dizziness, pre-syncope or loss of consciousness

Dizziness or collapse
A full event history is required, ideally correlated by an eye-witness if there was a loss of consciousness, to try to diagnose the likely cause:
• Possible vasovagal syncope – intercurrent illness or dehydration, antihypertensive medication, emotion or physical exertion, preceding presyncopal symptoms, rapid recovery
• Possible cardiac cause (malignant dysrhythmia or valve disease) – preceding chest pain or palpitations, sudden loss of consciousness, lack of alternative explanation, family history of collapse or sudden death
• Possible neurological cause – neurological aura, abnormal movements, urinary incontinence, tongue-biting, post-ictal phase

Risk factors
• Previous cardiovascular disease – enquire about or look up previous investigations and interventions
• Smoking – quantified in pack years
• Diabetes – time since diagnosis, degree of glycaemic control
• Hypertension – time since diagnosis, degree of control, number of drugs required to control blood pressure
• Hyperlipidaemia
• Chronic inflammatory disorders
• Family history of early-onset cardiovascular disease
• Cocaine use

Functional baseline and disability
• Accommodation – where the patient lives and with whom
• Physical activity – fully active, limited by symptoms, house- or chair-bound
• Symptom-related disability – exertional chest pain or breathlessness (try to quantify – how far can they walk? Can they climb a flight of stairs?)
• Level of care – ranging from full functional independence to carer visits or full residential or nursing care

Examination

Many features of cardiovascular disease can be elicited on physical examination (see figure opposite). They include:
• Evidence of life-threatening cardiac disease requiring emergency resuscitation: shock, dysrhythmias, pulmonary oedema
• Evidence of underlying conditions that contribute to cardiovascular disease (eg hyperlipidaemia or Marfan’s syndrome)
• Evidence of heart failure
• Murmurs and specific signs associated with particular forms of valvular heart disease

ECG interpretation

The ECG is an essential bedside test in the investigation of all patients with cardiac disease. A full guide to understanding the science behind it and its interpretation begins on page 1033 but Box 30.2 offers a systematic approach to ensure that abnormalities are not missed.

Step 1: Preliminaries
• Correct patient?
• Correct date and time?
• Standard speed (25 mm/sec)?
• Standard amplitude (10 mm/mV)?

Step 2: Heart structure
• Axis (left axis deviation if <-30 degrees, right axis deviation if >90 degrees)?
• Left ventricular hypertrophy (various criteria, see Fig. 30.79)?
• Evidence of atrial enlargement?

Step 3: Rate and rhythm
• Heart rate?
• Regular or irregular?
• Sinus rhythm (P–QRS–T)?
• Atrioventricular node delay (PR duration should be 120–200 ms)?
• Intraventricular conduction delay (QRS duration should be <120 ms)?
• Repolarization delay (QTc should be <450 ms)?

Step 4: Ischaemia
• Features include:
  – Q waves
  – ST elevation or depression
  – T-wave inversion
• Anatomical regions:
  – Anterior (V1-V3)
  – Septal (V4-V6)
  – Lateral (V5-V6)
  – Inferior (II, III, AVF)
  – High lateral (II, AVL)

Step 5: Global features
• Pericarditis (global saddle-shaped ST elevation)?
• Electrolyte abnormalities, eg hyperkalaemia (peaked T waves)?
• Pre-excitation (upstroke before QRS complexes)?
• Rarer causes of global abnormalities include hypothyroidism, thyroid disease and drug effects.
Examination

**General**
- Breathless
- Position - sitting up?
- Colour - cyanosed (central)
- pale
- malar flush (mitral stenosis)
- Pain
- Obesity/cachexia
- Signs of other conditions, e.g. Marfan’s
- Temperature
- Sweating

**Mouth**
- Oral hygiene
- Poor dentition

**Precordium**
- Inspect - look for scars
- Palpate - apex beat
- - thrills
- - ventricular heaves
- Auscultate
- - added sounds
- - murmurs

**Chest**
- Basal crackles

**Abdomen**
- Hepatomegaly (pulsatile in tricuspid incompetence)
- Ascites
- Aortic aneurysm

**Legs**
- Oedema
- Feel for peripheral pulses

**Feet**
- Look for ischaemia
- - Feel for pulses
- - Temperature
- Vasculitis rash

**Infective endocarditis, septic embolization**

ANATOMY, PHYSIOLOGY AND EMBRYOLOGY OF THE HEART

Myocardial cells constitute 75% of the heart mass but only about 25% of the cell number. They are designed to perform two fundamental functions: initiation and conduction of electrical impulses and contraction. Although most myocardial cells are able to perform both these functions, the vast majority are predominantly contractile cells (myocytes) and a small number are specifically designed as electrical cells. The latter, collectively known as the conducting system of the heart, are not nervous tissue but modified myocytes lacking in myofibril components. They have the ability to generate electrical impulses, which are then conducted to the myocytes, leading to contraction by a process known as excitation–contraction coupling. The rate of electrical impulse generation and the force of myocardial contraction are modified by numerous factors, including autonomic input and stretch.

Three epicardial coronary arteries supply blood to the myocardium, and a more complex network of veins is responsible for drainage. In the face of continuous arterial pressure fluctuations, blood vessels, especially in the cerebral circulation, maintain constant tissue perfusion by a process known as autoregulation; blood vessel control is, however, complex, involving additional local and central mechanisms.

Conduction system of the heart
Sinus node (sinoatrial node)
The sinus node is a complex, spindle-shaped structure that lies in the lateral and epicardial aspects of the junction between the superior vena cava and the right atrium (Fig. 30.1). Physiologically, it generates impulses automatically by spontaneous depolarization of its membrane at a rate quicker than any other cardiac cell type. It is therefore the natural pacemaker of the heart.

A number of factors are responsible for the spontaneous decay of the sinus node cell membrane potential (‘pacemaker potential’), the most significant of which is a small influx of sodium ions into the cells. This small sodium current has two components: the background inward ($I_{Na}$) current and the ‘funny’ ($I_{f}$) current (pacemaker current) (Fig. 30.2). The term ‘funny’ current denotes ionic flow through channels activated in hyperpolarized cells (−60 mV or greater), unlike other time- and voltage-dependent channels activated by depolarization. The rate of depolarization of the sinus node membrane potential is modulated by autonomic tone (i.e. sympathetic and parasympathetic input), stretch, temperature, hypoxia and blood pH, and responds to other hormonal influences (e.g. tri-iodothyronine and serotonin).

Atrial and ventricular myocyte action potentials
Action potentials in the sinus node trigger depolarization of the atrial myocytes and subsequently the ventricular ones. These cells have a different action potential from that of sinus node cells (see Fig. 30.2). Their resting membrane potential is a consequence of a small flow of potassium ions into the cells through open ‘inward rectifier’ channels ($I_{K1}$); at this stage, sodium and calcium channels are closed. The arrival of adjacent action potentials triggers the opening of voltage-gated, fast, self-inactivating sodium channels, resulting in a sharp depolarization spike. This is followed by a partial repolarization of the membrane due to activation of ‘transient outward’ potassium channels.

The plateau phase that follows is unique to myocytes and results from a small but sustained inward calcium current through L-type calcium channels ($I_{CaL}$) lasting 200–400 ms. This calcium influx is caused by a combined increase in permeability of the cell, especially the sarcolemmal membranes to calcium (Fig. 30.3). This plateau (or refractory) phase in myocyte action potential prevents early reactivation of the myocytes and directly determines the strength of contraction. The gradual inactivation of the calcium channels activates delayed rectifier potassium current ($I_{K(D)}$), repolarizing the membrane. Atrial tissue is activated like a ‘forest fire’, but the activation peters out when the insulating layer between the atrium and the ventricle – the annulus fibrosus – is reached. Controversy exists about whether impulses from the sinoatrial (SA) node travel over specialized conducting ‘pathways’ in the atrium or over ordinary atrial myocardium.

Atrioventricular node, His bundle and Purkinje fibres
The depolarization continues to conduct slowly through the atrioventricular (AV) node. This is a small, bean-shaped structure that lies beneath the right atrial endocardium within the lower interatrial septum. The AV node continues as the His bundle, which penetrates the annulus fibrosus and conducts the cardiac impulse rapidly towards the ventricle. The His bundle reaches the crest of the interventricular septum and divides into the right bundle branch and the main left bundle branch.

The right bundle branch continues down the right side of the interventricular septum to the apex; from here, it radiates and divides to form the Purkinje network, which spreads throughout the subendocardial surface of the right ventricle. The main left bundle branch is a short structure, which fans out into many strands on the left side of the interventricular septum. These strands can be grouped into an anterior superior division (the anterior hemi-bundle) and a posterior inferior division (the posterior hemi-bundle). The anterior hemi-bundle supplies the subendocardial Purkinje network of the anterior and superior surfaces of the left ventricle, and the inferior hemi-bundle...
Impulse conduction through the AV node is slow and depends on action potentials, largely produced by slow transmembrane calcium flux. In the atria, ventricles, and His–Purkinje system, conduction is rapid and is due to action potentials generated by rapid transmembrane sodium diffusion.

**Cellular basis of myocardial contraction–excitation–contraction coupling**

Each myocyte, approximately 100 μm long, branches and interdigitates with adjacent cells. An intercalated disc permits electrical conduction to adjacent cells. Myocytes contain bundles of parallel myofibrils. Each myofibril is made up of a series of sarcomeres (Fig. 30.4). A sarcomere (the basic unit of contraction) is bound by two transverse Z lines, to each of which is attached a perpendicular filament of the protein actin. The actin filaments from each of the two Z bands overlap with thicker parallel protein filaments known as myosin. Actin and myosin filaments are attached to each other by cross-bridges that contain adenine triphosphatase (ATPase), which breaks down adenosine triphosphate (ATP) to provide the energy for contraction.

Two chains of actin molecules form a helical structure with another molecule, tropomyosin, in the grooves of the actin helix; a further molecule, troponin, is attached to every seven actin molecules. During cardiac contraction, the length of the actin and myosin monofilaments does not change. Rather, the actin filaments slide between the myosin filaments when ATPase splits a high-energy bond of ATP. To supply the ATP, the myocyte (which cannot stop for a rest) has a very high mitochondrial density (35% of the cell volume). As calcium ions bind to troponin C, the activity of troponin I is inhibited, which induces a conformational change in tropomyosin.
This event unlocks the active site between actin and myosin, enabling contraction to proceed.

Calcium is made available during the plateau phase of the action potential when calcium ions enter the cell and are mobilized from the sarcoplasmic reticulum (SR) through the ryanodine receptor (RyR2) calcium-release channel (see p. 1121). RyR2 activity is regulated by the protein calstabin 2 and nitric oxide. The force of cardiac muscle contraction (‘inotropic state’) is thus regulated by the influx of calcium ions into the cell through calcium channels (see Fig. 30.3). T (transient) calcium channels open when the muscle is more depolarized, whereas L (long-lasting) calcium channels require less depolarization. The extent to which the sarcomere can shorten determines the stroke volume of the ventricle. It is maximally shortened in response to powerful inotropic drugs or severe exercise.

Starling’s law of the heart

The contractile function of an isolated strip of cardiac tissue can be described by the relationship between the velocity of muscle contraction, the load that is moved by the contracting muscle, and the extent to which the muscle is stretched before contracting. As with all other types of muscle, the velocity of contraction of myocardial tissue is reduced by increasing the load against which the tissue must contract. However, in the non-failing heart, pre-stretching of cardiac muscle improves the relationship between the force and velocity of contraction (Fig. 30.5).

This phenomenon was described in the intact heart as an increase of stroke volume (ventricular performance) with an enlargement of the diastolic volume (preload), and is known as ‘Starling’s law of the heart’ or the ‘Frank–Starling relationship’. It has been transcribed into more clinically relevant indices. Thus, stroke work (aortic pressure × stroke volume) is increased as ventricular end-diastolic volume is raised. Alternatively, within certain limits, cardiac output rises as pulmonary capillary wedge pressure increases. This clinical relationship is described by the ventricular function curve (see Fig. 30.5), which also shows the effect of sympathetic stimulation.

Nerve supply of the myocardium

Adrenergic nerves supply atrial and ventricular muscle fibres, as well as the conduction system. Beta_1-receptors predominate in the heart, with both adrenaline (epinephrine) and noradrenaline (norepinephrine) having positive inotropic and chronotropic effects. Cholinergic nerves from the vagus supply mainly the SA and AV nodes via M_2 muscarinic receptors. The ventricular myocardium is sparsely innervated by the vagus. Under basal conditions, vagal inhibitory effects predominate over the sympathetic excitatory effects, resulting in a slow heart rate.

Adrenergic stimulation and cellular signalling

Beta_1-adrenergic stimulation enhances Ca^{2+} flux in the myocyte and thereby strengthens the force of contraction (see Fig. 30.3). Binding of catecholamines, such as noradrenaline, to the myocyte beta_1-adrenergic receptor stimulates membrane-bound adenylyl kinases. These enzymes enhance production of cyclic adenosine monophosphate (cAMP), which activates intracellular protein kinases; these, in turn, phosphorylate cellular proteins, including L-type calcium channels within the cell membrane. Beta_1-adrenergic stimulation of the myocyte also enhances myocyte relaxation.

The return of calcium from the cytosol to the SR is regulated by phospholamban (PL), a low-molecular-weight protein in the SR membrane. In its dephosphorylated state, PL inhibits Ca^{2+} uptake by the SR ATPase pump (see Fig. 30.3). However, beta_1-adrenergic activation of protein kinase phosphorylates PL and blunts its inhibitory effect. The subsequently greater uptake of Ca^{2+} ions by the SR hastens Ca^{2+} removal from the cytosol and promotes myocyte relaxation.

The increased cAMP activity also results in phosphorylation of troponin I, an action that inhibits actin–myosin interaction and further enhances myocyte relaxation.

Cardiac cycle

The cardiac cycle (Fig. 30.6) consists of precisely timed rhythmic electrical and mechanical events that propel blood into the systemic and pulmonary circulations. The first event in the cardiac cycle is atrial depolarization (a P wave on the surface ECG), followed by right atrial and then left atrial contraction. Ventricular activation (the QRS complex on the ECG) follows after a short interval (the PR interval). Left ventricular contraction starts and, shortly thereafter, right ventricular contraction begins. The increased ventricular pressures exceed the atrial pressures and close first the mitral and then the tricuspid valves.

Until the aortic and pulmonary valves open, the ventricles contract with no change of volume (isovolumetric contraction). When ventricular pressures rise above the aortic and pulmonary artery
pressures the pulmonary valve and then the aortic valve open and ventricular ejection occurs. As the ventricles begin to relax, their pressures fall below the aortic and pulmonary arterial pressures, and aortic valve closure is followed by pulmonary valve closure. Isovolumetric relaxation then occurs. After the ventricular pressures have fallen below the right atrial and left atrial pressures, the tricuspid and mitral valves open. The cardiac cycle can be depicted graphically as the relationship between the pressure and volume of the ventricle (Fig. 30.7), illustrating the changing pressure–volume relationships in response to increased contractility and to exercise.

Coronary circulation
The coronary arterial system (Fig. 30.8) consists of the right and left coronary arteries. These arteries branch from the aorta, arising immediately above two cusps of the aortic valve. The right and left coronary arteries are unique in that they fill during diastole, when not occluded by valve cusps and when not squeezed by myocardial contraction. The right coronary artery arises from the right coronary sinus and courses through the right side of the AV groove, giving off vessels that supply the right atrium and the right ventricle. The vessel usually continues as the posterior descending coronary artery, which runs in the posterior interventricular groove and supplies the posterior part of the interventricular septum and the posterior left ventricular wall.

Within 2.5 cm of its origin from the left coronary sinus the left main coronary divides into the left anterior descending artery and the circumflex artery. The left anterior descending artery runs in the anterior interventricular groove and supplies the anterior septum and the anterior left ventricular wall. The left circumflex artery travels along the left AV groove and gives off branches to the left atrium and the left ventricle (margin branches).

The sinus node and the AV node are supplied by the right coronary artery in about 60% and 90% of people, respectively. Therefore, disease in this artery may cause sinus bradycardia and AV nodal block. The majority of the left ventricle is supplied by the left coronary artery and disease in this vessel can cause significant myocardial dysfunction.

Some blood from the capillary beds in the wall of the heart drains directly into the cavities of the heart via tiny veins but the majority returns by veins that accompany the arteries, to empty into the right atrium via the coronary sinus. An extensive lymphatic system drains into vessels that travel along the coronary vessels and then into the thoracic duct.
Blood vessel control and functions of the vascular endothelium

In functional terms the tunica intima with the vascular endothelium and the smooth-muscle-cell-containing tunica media are the main constituents of blood vessels. These two structures are closely linked by a variety of mechanisms to regulate vascular tone. The central control of blood vessels is achieved via the neuroendocrine system. Sympathetic vasoconstrictor and parasympathetic vasodilator nerves regulate vascular tone in response to daily activity. Where neural control is impaired or in various pathological states, such as haemorrhage, endocrine control of blood vessels, mediated through adrenaline (epinephrine), angiotensin and vasopressin, takes over.

At a local level, tissue perfusion is maintained automatically and by the effect of various factors synthesized and/or released in the immediate vicinity. In the face of fluctuating arterial pressures, blood vessels vasoconstrict independently of nervous input when blood pressure drops, and vice versa. This process of autoregulation is a consequence of:

- the Bayliss myogenic response – the ability of blood vessels to constrict when distended
- the vasodilator washout effect – the vasoconstriction triggered by a decrease in the concentration of tissue metabolites.

The vascular endothelium is a cardiovascular endocrine organ, which occupies a strategic interface between blood and other tissues. It produces various compounds (e.g. nitric oxide (NO), prostacyclin (PGI₂), endothelin, endothelial-derived hyperpolarizing factor (EDHF), adhesion molecules, vascular endothelial growth factor (VEGF)), and has enzymes located on the surface, controlling the levels of circulating compounds such as angiotensin, bradykinin and serotonin. It has many regulatory roles.

**Vasomotor control**

- **Nitric oxide** is a diffusible gas with a very short half-life; it is produced in endothelial cells from the amino acid l-arginine via the action of the enzyme NO synthase (NOS), which is controlled by cytoplasmic calcium/calmodulin (Fig. 30.9). It is produced in response to various stimuli (Box 30.4), triggering vascular smooth muscle relaxation through activation of guanylate cyclase; this leads to an increase in the intracellular levels of cyclic 3,5-guanine monophosphate (cGMP). Its cardiovascular effects protect against atherosclerosis, high blood pressure, heart failure and thrombosis. NO is also the neurotransmitter in various ‘nitrergic’ nerves in the central and peripheral nervous systems and may play a role in the central regulation of vascular tone. The class of drugs used to treat erectile dysfunction, the phosphodiesterase (PDE₅) inhibitors, prevent the breakdown of cGMP and promote vasodilation.
- **PGI₂** is synergistic to NO and also plays a role in the local regulation of vasomotor tone.

| P, L, E selectins ICAM, VCAM, PECAM | Margination of white blood cells Binding and diapedesis of WBCs into vessel wall | Inflammatory mediators: histamine, thrombin, TNF, IL-6 |
| Vascular endothelial growth factor (VEGF) | Angiogenesis Vasodilation Increase in vascular permeability | Pregnancy Hypoxia Inflammation, e.g. rheumatoid arthritis Trauma Tumours |

ICAM, intracellular adhesion molecule; IL, interleukin; PECAM, platelet/endothelial cell adhesion molecule; TNF, tumour necrosis factor; VCAM, vascular cell adhesion molecule; WBC, white blood cell.
• **Endothelin** is a 21-amino-acid peptide that counteracts the effects of NO. Its production is inhibited by shear stress – i.e. the stress exerted on the vessel wall by the flowing blood – and it causes profound vasoconstriction and vascular smooth muscle hypertrophy. It is thought to play a role in the genesis of hypertension and atheroma.

• **Angiotensin-converting enzyme (ACE)**, located on the endothelial cell membrane, converts circulating angiotensin I (synthesized by the action of renin on angiotensinogen) to angiotensin II, which has vasoconstrictor properties and leads to aldosterone release (see Fig. 30.6). Aldosterone promotes sodium absorption from the kidney and, together with the angiotensin-induced vasoconstriction, provides haemodynam-ic stability.

• **Other factors** that influence vasomotor tone include histamine (released by mast cells), bradykinin (synthesized from kininogen by the action of coagulation factor XIIa) and serotonin (released by platelets).

### Anti- and prothrombotic mechanisms

PGI₂, produced from arachidonic acid in the endothelial cell membrane by the action of the enzyme cyclo-oxygenase, inhibits platelet aggregation. Low-dose aspirin prevents activation of the cyclo-oxygenase pathway in platelets but only to a degree that does not affect PGI₂ synthesis, unlike higher doses. Other antithrombotic agents, such as clopidogrel (an adenosine diphosphate (ADP) receptor antagonist) and glycoprotein IIb/IIIa inhibitors, achieve their effects by acting directly on platelet receptors. The antithrombotic effect of PGI₂ is aided by NO, affecting platelets via activation of guanylate cyclase. The endothelial cell membrane also produces other anticoagulant molecules, such as thrombomodulin, heparin sulphate and various fibrinolytic factors. Clinically used, fast-acting heparin preparations are identical to this naturally occurring molecule.

In addition to their ability to prevent clotting, endothelial cells also aid thrombosis. They are responsible for the production of von Willebrand factor through a unique organelle called the Weibel–Palade body, which not only acts as a carrier for factor VIII but also promotes platelet adhesion by binding to exposed collagen (see p. 367).

### CLINICAL APPROACH TO THE PATIENT WITH HEART DISEASE

#### Clinical features of heart disease

The following symptoms occur with heart disease:

- chest pain
- dyspnoea (breathlessness)
- palpitations
- syncope
- fatigue
- peripheral oedema.

The severity of cardiac symptoms or fatigue is classified according to the New York Heart Association (NYHA) grading of cardiac status (see Box 30.23). The differential diagnosis of chest pain is given in Box 30.5.

#### Non-cardiac

- Pulmonary embolism
- Esophageal disease (see Box 32.11)
- Mediastinitis
- Costochondritis (Tietze disease)
- Trauma (soft tissue, rib)

### Central chest pain

This is the most common symptom associated with heart disease. The pain of angina pectoris and myocardial infarction is due to myocardial hypoxia.

Types of pain include:

- a retrosternal heavy or gripping sensation with radiation to the left arm or neck that is provoked by exertion and eased with rest or nitrates – *angina* (see p. 1081)
- similar pain at rest – *acute coronary syndrome* (see p. 1084)
- severe, tearing chest pain radiating through to the back – *aortic dissection* (see p. 1130)
- sharp, central chest pain that is worse with movement or respiration but relieved with sitting forward – *pericarditis pain* (see p. 1125)
- sharp, stabbing, left submammary pain associated with anxiety – *da Costa’s syndrome*.

#### Dyspnoea

Left ventricular failure causes dyspnoea due to oedema of the pulmonary interstitium and alveoli. This makes the lungs stiff (less compliant), thus increasing the respiratory effort required to ventilate them. *Tachypnoea* (increased respiratory rate) is often present owing to stimulation of pulmonary stretch receptors.

*Orthopnoea* refers to breathlessness on lying flat. Blood is redistributed from the legs to the torso, leading to an increase in central and pulmonary blood volume. The patient uses an increasing number of pillows to sleep.

*Paroxysmal nocturnal dyspnoea (PND)* is when a patient is woken from sleep fighting for breath. It is caused by the same mechanisms as orthopnoea. However, as sensory awareness is reduced during sleep, the pulmonary oedema can become quite severe before the patient is woken.

*Hyperventilation* with alternating episodes of apnoea (*Cheyne-Stokes respiration*) occurs in severe heart failure.

If hypopnoea occurs rather than apnoea, the phenomenon is termed ‘periodic breathing’, but the two variations are known together as *central sleep apnoea syndrome (CSAS)*. This occurs due to malfunctioning of the respiratory centre in the brain, caused by poor cardiac output with concurrent cerebrovascular disease. The symptoms of CSAS, such as daytime somnolence and fatigue, are similar to those of obstructive sleep apnoea syndrome (OSAS, see p. 960) and there is considerable overlap with the symptoms of heart failure. CSAS is believed to lead to myocardial hypertrophy and fibrosis, deterioration in cardiac function and complex arrhythmias,
including non-sustained ventricular tachycardia, hypertension and stroke. Patients with CSAS have a worse prognosis than similar patients without CSAS.

**Palpitations**
These represent an increased awareness of the normal heart beat or the sensation of slow, rapid or irregular heart rhythms. The most common arrhythmias felt as palpitations are premature ectopic beats and paroxysmal tachycardias. A useful trick is to ask patients to tap out the rate and rhythm of their palpitations, as the different arrhythmias have different characteristics:

- **Premature beats (ectopics)** are felt by the patient as a pause followed by a forceful beat. This is because premature beats are usually followed by a pause before the next normal beat, as the heart resets itself. The next beat is more forceful, as the heart has had a longer diastolic period and therefore is filled with more blood before this beat.

- **Paroxysmal tachycardias** (see p. 1057) are felt as a sudden, racing heart beat.

- **Bradycardias** (see p. 1052) may be appreciated as slow, regular, heavy or forceful beats. Most often, however, they are simply not sensed. All palpitations can be graded by the NYHA cardiac status (see Box 30.23).

**Syncope**
Syncope is a transient loss of consciousness due to inadequate cerebral blood flow. The cardiovascular causes are listed in Box 30.6.

**Vascular**

- A **vasovagal attack** is a simple faint and is the most common cause of syncope. The mechanism begins with peripheral vasoconstriction and venous pooling of blood, leading to a reduction in the amount of blood returned to the heart. The near-empty heart responds by contracting vigorously, which, in turn, stimulates mechanoreceptors (stretch receptors) in the inferoposterior wall of the left ventricle. These, in turn, trigger reflexes via the central nervous system, which act to reduce ventricular stretch (i.e. further vasoconstriction and sometimes profound bradycardia), but this causes a drop in blood pressure and therefore syncope. These episodes are usually associated with a prodrome of dizziness, nausea, sweating, tinnitus, yawning and a sinking feeling. Recovery occurs within a few seconds, especially if the patient lies down.

- A **postural (orthostatic) hypotension** is a drop in systolic blood pressure of 20 mmHg or more on standing from a sitting or lying position. Usually, reflex vasoconstriction prevents a drop in pressure, but if this is absent or the patient is fluid-depleted or on vasodilating or diuretic drugs, hypotension occurs.

- **Pulmonary hypertension**/embolism
- **Atrial myxoma/thrombus**
- **Defective prosthetic valve**

**Arrhythmias**

- **Rapid tachycardias**
- **Profound bradycardias (Stokes–Adams)**
- **Significant pauses (in rhythm)**
- **Artificial pacemaker failure**

**Obstructive**

- **Aortic stenosis**
- **Hypertrophic cardiomyopathy**
- **Pulmonary stenosis**
- **Tetralogy of Fallot**

- **Postprandial hypotension** is a drop in systolic blood pressure of 20 mmHg or more, or the systolic blood pressure drops from over 100 mmHg to below 90 mmHg within 2 hours of eating. The mechanism is unknown but may involve pooling of blood in the splanchnic vessels. In normal people, this elicits a homeostatic response via activation of baroreceptors and the sympathetic system, peripheral vasoconstriction and an increase in cardiac output.

- **Micturition syncope** refers to loss of consciousness while passing urine.

- **Carotid sinus syncope** occurs when there is an exaggerated vagal response to carotid sinus stimulation, provoked by wearing a tight collar, looking upwards or turning the head.

**Obstructive**
The obstructive cardiac causes listed in Box 30.6 all lead to syncope due to restriction of blood flow from the heart into the rest of the circulation, or between the different chambers of the heart.

**Arrhythmias**

- **Stokes–Adams attacks** (see p. 1055) are a sudden loss of consciousness unrelated to posture and caused by intermittent high-grade AV block, profound bradycardia or ventricular standstill. The patient falls to the ground without warning, and is pale and deeply unconscious. The pulse is usually very slow or absent. After a few seconds the patient flushes brightly and recovers consciousness as the pulse quickens. Often there are no sequelae but patients may injure themselves during falls. Occasionally, a generalized convolution may occur if the period of cerebral hypoxia is prolonged, leading to a misdiagnosis of epilepsy.

**Fatigue**
Fatigue may be a symptom of inadequate systemic perfusion in heart failure. Other contributing factors may include:

- poor sleep
- side-effects of medication, particularly beta-blockers
- electrolyte imbalance caused by diuretic therapy
- a systemic manifestation of infection, such as endocarditis.

**Peripheral oedema**
Heart failure results in salt and water retention due to renal underperfusion and consequent activation of the renin–angiotensin–aldosterone system (see p. 1346). This leads to dependent pitting oedema.

Splinter haemorrhages are small, subungual linear haemorrhages that are frequently due to trauma but also seen in infective endocarditis.

Cyanosis is a dusky blue discoloration of the skin (particularly at the extremities) or of the mucous membranes when the capillary oxygen saturation is below 85%. Central cyanosis (see p. 937) is seen with shunting of deoxygenated venous blood into the systemic circulation, as in the presence of a right-to-left heart shunt. Peripheral cyanosis is seen in the hands and feet, which are cold. It occurs in conditions associated with peripheral vasoconstriction and stasis of blood in the extremities, leading to increased peripheral oxygen extraction. Such conditions include congestive heart failure, circulatory shock, exposure to cold temperatures and abnormalities of the peripheral circulation, such as Raynaud’s (see p. 1131).

**Arterial pulse**

The first pulse to be examined is the right radial pulse. A delayed femoral pulsation occurs because of a proximal stenosis, particularly of the aorta (coarctation).

**Rate**

The pulse rate should be between 60 and 80 beats per minute (b.p.m.) when an adult patient is lying quietly in bed.

**Rhythm**

The rhythm is regular, except for a slight quickening in early inspiration and a slowing in expiration (sinus arrhythmia).

- Premature beats occur as occasional or repeated irregularities superimposed on a regular pulse rhythm. Similarly, intermittent heart block is revealed by occasional beats dropped from an otherwise regular rhythm.

- Atrial fibrillation produces an ‘irregularly irregular’ pulse. This irregular pattern persists when the pulse quickens in response to exercise, in contrast to pulse irregularity due to ectopic beats, which usually disappears on exercise.

**Character**

- Carotid pulsations are not normally apparent on inspection of the neck but may be visible (Corrigan’s sign) in conditions associated with a large-volume pulse, including high-output states (such as thyrotoxicosis, anaemia or fever), and in aortic regurgitation.

- A ‘collapsing’ or ‘water hammer’ pulse (Fig. 30.10) is a large-volume pulse characterized by a short duration with a brisk rise and fall. This is best appreciated by palpating the radial artery with the palmar aspect of four fingers while elevating the patient’s arm above the level of the heart. A collapsing pulse is characteristic of aortic valvular regurgitation or a persistent ductus arteriosus.

- A small-volume pulse is seen in cardiac failure, shock and obstructive valvular or vascular disease. It may also be present during tachyarrhythmias.

- A plateau pulse (see Fig. 30.10) is small in volume and slow in rising to a peak; it is due to aortic stenosis.

- An alternating pulse (pulsus alternans) (see Fig. 30.10) is characterized by regular alternate beats that are weak and strong. It is a feature of severe myocardial failure and is due to the prolonged recovery time of damaged myocardium; it indicates a very poor prognosis. It is easily noticed when taking the blood pressure because the systolic pressure may vary from beat to beat by as much as 50 mmHg.

- A bigeminal pulse (pulsus bigeminus) (see Fig. 30.10) is caused by a premature ectopic beat following every sinus beat. The rhythm is not regular because every weak pulse is premature.

- Pulsus bisferiens (see Fig. 30.10) is found in hypertrophic cardiomyopathy and in mixed aortic valve disease (regurgitation combined with stenosis). The first systolic wave is the ‘percussion’ wave, produced by transmission of the left ventricular pressure in early systole. The second peak is the ‘tidal’ wave, caused by recoil of the vascular bed. This normally happens in diastole (the dicrotic wave), but when the left ventricle empties slowly or is obstructed and cannot empty completely, the tidal wave occurs in late systole. The result is a palpable double pulse.

- A dicrotic pulse (see Fig. 30.10) results from an accentuated dicrotic wave. It occurs in sepsis and hypovolaemic shock, and after aortic valve replacement.

- Paradoxical pulse is a misnomer, as it is actually an exaggeration of the normal pattern. In normal subjects, the systolic pressure and the pulse pressure (the difference between the systolic and diastolic blood pressures) fall during inspiration. The normal fall of systolic pressure is less than 10 mmHg, and this can be measured using a sphygmomanometer. It is due to increased pulmonary intravascular volume during inspiration. In severe airflow limitation (especially severe asthma), there is an increased negative intrathoracic pressure on inspiration, which enhances the normal fall in blood pressure. In patients with cardiac tamponade, the fluid in the pericardium increases the intrapericardial pressure, thereby impeding diastolic filling of the heart. The normal inspiratory increase in venous return to the right ventricle is at the expense of the left ventricle, as both ventricles are confined by the accumulated pericardial fluid within the pericardial space. Paradox can occur via a similar mechanism in constrictive pericarditis but is less common.
Box 30.7 Taking the blood pressure

Use a properly calibrated machine.
1. Take the blood pressure in the (right) arm with the patient relaxed and comfortable.
2. Wrap the sphygmomanometer cuff around the upper arm and place the inflation bag over the brachial artery.
3. Inflate the cuff until the pressure exceeds the arterial pressure – when the radial pulse is no longer palpable.
4. Position the diaphragm of the stethoscope over the brachial artery just below the cuff.
5. Slowly reduce the cuff pressure until sounds (Korotkoff sounds) can be heard (phase 1). This is the systolic pressure.
6. Allow the pressure to fall further until the Korotkoff sounds suddenly become muffled (phase 4).
7. Allow the pressure to fall still further until the sounds disappear (phase 5).
8. The diastolic pressure is usually taken as phase 5 because this phase is more reproducible and nearer to the intravascular diastolic pressure.

Blood pressure
The peak systemic arterial blood pressure is produced by transmission of left ventricular systolic pressure. Vascular tone and an intact aortic valve maintain the diastolic blood pressure. Instructions for taking the blood pressure are outlined in Box 30.7.

Jugular venous pressure
There are no valves between the internal jugular vein and the right atrium. Observation of the column of blood in the internal jugular system is therefore a good measure of right atrial pressure. The external jugular cannot be relied on because of its valves and because it may be obstructed by the fascial and muscular layers through which it passes; it can be used only if typical venous pulsation is seen, indicating no obstruction to flow.

Measurement of jugular venous pressure
See Box 30.8.

Elevation of the jugular venous pressure (JVP) occurs in heart failure. An elevated JVP also occurs in:
- constrictive pericarditis and cardiac tamponade (increases in inspiration – Kussmaul’s sign)
- renal disease with salt and water retention
- over-transfusion or excessive infusion of fluids
- congestive cardiac failure
- superior vena cava obstruction.

A reduced JVP occurs in hypovolaemia.

Jugular venous pressure wave
This consists of three peaks and two troughs (Fig. 30.11). The peaks are described as a, c and v waves and the troughs are known as x and y descents:
- The a wave is produced by atrial systole and is increased with right ventricular hypertrophy secondary to pulmonary hypertension or pulmonary stenosis. Giant cannon waves occur in complete heart block and ventricular tachycardia.
- The x descent occurs when atrial contraction finishes.
- The c wave occurs during the x descent and is due to transmission of right ventricular systolic pressure before the tricuspid valve closes.
- The v wave occurs with venous return filling the right atrium. Giant v waves occur in tricuspid regurgitation.

Box 30.8 Measurement of jugular venous pressure (JVP)

- The patient is positioned at about 45 degrees to the horizontal (between 30 and 60 degrees), wherever the top of the venous pulsation can be seen in a good light.
- The JVP is measured as the vertical distance between the manubriosternal angle and the top of the venous column.
- The normal JVP is usually <3 cmH₂O, which is equivalent to a right atrial pressure of 8 cmH₂O when measured with reference to a point midway between the anterior and posterior surfaces of the chest.
- The venous pulsations are not usually palpable (except for the forcible venous distension associated with tricuspid regurgitation).
- Compression of the right upper abdomen causes a temporary increase in venous pressure and makes the jugular venous pulse more visible (hepatojugular reflux).

![Fig. 30.11 Jugular venous waveforms.](image)

- The y descent follows the v wave when the tricuspid valve opens. A steep y descent is seen in constrictive pericarditis and tricuspid incompetence.

Precordium
- With the patient at 45 degrees, the cardiac apex is located in the fifth intercostal space mid-clavicular line. Left ventricular dilation will displace the apex downwards and laterally. It may be palpable in patients with emphysema, obesity, or pericardial or pleural effusions.
- A tapping apex is a palpable first sound and occurs in mitral stenosis.
- A vigorous apex may be present in diseases with volume overload, e.g. aortic regurgitation.
- A heaving (sustained) apex may occur with left ventricular hypertrophy – aortic stenosis, systemic hypertension and hypertrophic cardiomyopathy.
- A double pulsation may occur in hypertrophic cardiomyopathy.
- A sustained left parasternal heave occurs with right ventricular hypertrophy or left atrial enlargement.
- A palpable thrill may be felt overlying an abnormal cardiac valve, e.g. systolic thrill with aortic stenosis.
Auscultation

The bell of the stethoscope is used for low-pitched sounds (heart sounds and mid-diastolic murmur in mitral stenosis). The diaphragm is used for high-pitched sounds (systolic murmurs, aortic regurgitation, ejection clicks and opening snaps). The areas of auscultation are shown in Fig. 30.12. Left-sided valve murmurs may be more prominent in expiration and right-sided in inspiration. Mitral murmurs may be more audible with the patient reclining to the left.

First heart sound (S1)

This is due to mitral and tricuspid valve closure. A loud S1 occurs in thin people, hyperdynamic circulation, tachycardias and mild to moderate mitral stenosis. A soft S1 occurs in obesity, emphysema, pericardial effusion, severe calcific mitral stenosis, mitral or tricuspid regurgitation, heart failure, shock, bradycardias and first-degree block.

Second heart sound (S2)

This is due to aortic and pulmonary valve closure. Physiological splitting of S2 occurs during inspiration in children and young adults.

Third and fourth heart sounds

These are pathological:

- **A third heart sound (volume overload)** is due to rapid ventricular filling and is present in significant heart failure.
- **A fourth heart sound (pressure overload)** occurs in late diastole and is associated with atrial contraction. Causes include aortic stenosis, severe systemic hypertension and left ventricular outflow obstruction, as in hypertrophic cardiomyopathy, i.e. causes of significant left ventricular hypertrophy.
  Singly or together, they will produce a gallop rhythm.

Heart murmurs

These are due to turbulent blood flow and occur in hyperdynamic states or with abnormal valves. (Listen online on Student Consult.)

Cardiac investigations

Blood tests

These include:

- routine haematology
- serum creatinine and electrolytes
- liver biochemistry
- cardiac enzymes (troponin; creatine kinase, aspartate aminotransferase (AST) and lactate dehydrogenase (LDH) may also be elevated)
- thyroid function
- B-type natriuretic peptides (BNP).

Chest X-ray

Ideally, this is taken in the postero-anterior (PA) direction at maximum inspiration with the heart close to the X-ray film to minimize magnification with respect to the thorax. The cardiac structures and great vessels that can be seen are indicated in Fig. 30.13. An anteroposterior (AP) view is often taken in the emergency setting.
Heart size
Heart size can be reliably assessed only from the PA chest film. The maximum transverse diameter of the heart is compared with the maximum transverse diameter of the thorax measured from the inside of the ribs (the cardiothoracic ratio, CTR). The CTR is usually less than 50%, except in neonates, infants, athletes and patients with skeletal abnormalities such as scoliosis and funnel chest. A transverse cardiac diameter of more than 15.5 cm is abnormal. Pericardial effusion or cardiac dilation causes an increase in the ratio.

A pericardial effusion produces a globular heart (see Fig. 30.121). This enlargement may occur quite suddenly and, unlike in heart failure, there is no associated change in the pulmonary vasculature. The echocardiogram is more specific (see Fig. 30.121).

Certain patterns of specific chamber enlargement may be seen on the chest X-ray:

- **Left atrial dilation** leads to prominence of the left atrial appendage and a straightening or convex bulging of the upper left heart border, a double atrial shadow to the right of the sternum, and splaying of the carina because a large left atrium elevates the left main bronchus (Fig. 30.14). On a lateral chest X-ray, an enlarged left atrium bulges backwards, impinging on the oesophagus.
- **Left ventricular enlargement** causes an increase in the CTR and smooth elongation and increased convexity of the left heart border.
- **Right atrial enlargement** results in projection of the right border of the heart into the right lower lung field.
- **Right ventricular enlargement** causes an increase in the CTR and upward displacement of the apex of the heart because the enlarging right ventricle pushes the left ventricle leftwards, upwards and eventually backwards. Differentiation of left from right ventricular enlargement may be difficult using the shape of the left heart border alone, but the lateral view shows enlargement anteriorly for the right ventricle and posteriorly for the left ventricle.
- **Ascending aortic dilation or enlargement** is seen as a prominence of the aortic shadow to the right of the mediastinum between the right atrium and superior vena cava.

- **Dissection of the ascending aorta** is seen as a widening of the mediastinum on chest X-ray but an ultrasound/magnetic resonance imaging (MRI) should be performed.
- **Enlargement of the pulmonary artery** in pulmonary hypertension, pulmonary artery stenosis and left-to-right shunts produces a prominent bulge on the left-hand border of the mediastinum below the aortic knuckle.

**Calcification**
Calcification in the cardiovascular system occurs because of tissue degeneration. Calcification is visible on a lateral or a penetrated PA film but is best studied with computed tomography (CT) scanning.

**Lung fields**
- **Pulmonary plethora** results from left-to-right shunts (e.g. atrial or ventricular septal defects). It is seen as a general increase in the vascularity of the lung fields and as an increase in the size of hilar vessels (e.g. in the right lower lobe artery), which normally should not exceed 16 mm in diameter.
- **Pulmonary oligoemia** is a paucity of vascular markings and a reduction in the width of the arteries. It occurs in situations where there is reduced pulmonary blood flow, such as pulmonary embolism, severe pulmonary stenosis and Fallot’s tetralogy.
- **Pulmonary hypertension** may result from pulmonary embolism, chronic lung disease or chronic left heart disease, e.g. left ventricular failure or mitral valve disease such as shunts due to a ventricular septal defect or mitral valve stenosis. In addition to the X-ray features of these conditions, the pulmonary arteries are prominent close to the hila but are reduced in size (pruned) in the peripheral lung fields. This pattern is usually symmetrical. Normal pulmonary capillary pressure is 5–14 mmHg at rest. Mild pulmonary capillary hypertension (15–20 mmHg) produces isolated dilation of the upper zone vessels.
- **Interstitial oedema** occurs when the pressure is between 21 and 30 mmHg. This manifests as fluid collections in the interlobar fissures, interlobular septa (Kerley B lines) and pleural spaces. This gives rise to indistinctness of the hilar regions and haziness of the lung fields.
- **Alveolar oedema** occurs when the pressure exceeds 30 mmHg, appearing as areas of consolidation and mottling of the lung fields (Fig. 30.15) and pleural effusions. Patients with longstanding elevation of the pulmonary capillary pressure have reactive thickening of the pulmonary arteriolar intima, which protects the alveoli from pulmonary oedema. Thus, in these patients, the pulmonary venous pressure may increase to well above 30 mmHg before frank pulmonary oedema develops.

**Electrocardiography**
The ECG is a recording of the electrical activity of the heart. It is the vector sum of the depolarization and repolarization potentials of all myocardial cells (see Fig. 30.2). At the body surface, these generate potential differences of about 1 mV, and fluctuations in these potentials create the familiar P–QRS–T pattern. At rest, the intracellular voltage of the myocardium is polarized at −90 mV compared with that of the extracellular space. This diastolic voltage difference occurs because of the high intracellular potassium concentration, which is maintained by the sodium–potassium pump despite the free membrane permeability to potassium. Depolarization of cardiac cells occurs when there is a sudden increase in the permeability of the membrane to sodium. Sodium rushes into the cell and the negative resting voltage is lost (phase 0 on Fig. 30.38). The depolarization of a myocardial cell causes the depolarization of adjacent cells and, in the healthy heart, the entire myocardium is depolarized.
in a coordinated fashion. During repolarization, cellular electrolyte balance is slowly restored (phases 1, 2 and 3). Slow diastolic depolarization (phase 4) follows until the threshold potential is reached. Another action potential then follows.

The ECG is recorded from two or more simultaneous points of skin contact (electrodes). When cardiac activation proceeds towards the positive contact, an upward deflection is produced on the ECG. Correct representation of a three-dimensional spatial vector requires recordings from three mutually perpendicular (orthogonal) axes. The shape of the human torso does not make this easy, so the practical ECG records 12 projections of the vector, called ‘leads’ (Fig. 30.16).
Six of the leads are obtained by recording voltages from the limbs (I, II, III, AVR, AVL and AVF). The other six leads record potentials between points on the chest surface and an average of the three limbs: RA, LA and LL. These are designated V₁–V₆ and aim to select activity from the right ventricle (V₁–V₂), interventricular septum (V₃–V₄) and left ventricle (V₅–V₆). Note that leads AVR and V₁ are oriented towards the cavity of the heart, leads II, III and AVF face the inferior surface, and leads I, AVL and V₆ face the lateral wall of the left ventricle. A V₄ on the right side of the chest (V₄R) is occasionally useful (e.g. for the diagnosis of right ventricular infarction).

Most ECG machines are simultaneous three-channel recorders, with output given either as a continuous strip or with automatic channel switching. Many ECG machines also analyse the recordings and print the analysis on the record. Usually, the machine interpretation is correct but many arrhythmias still defy automatic analysis.

ECG waveform

The shape of the normal ECG waveform (Fig. 30.17) has similarities, whatever the orientation. The first deflection is caused by atrial depolarization; it is a low-amplitude, slow deflection called a P wave. The QRS complex reflects ventricular activation or depolarization, and is sharper and larger in amplitude than the P wave. An initial downward deflection is called the Q wave. An initial upward deflection is called an R wave. The S wave is the last part of ventricular activation. The T wave is another slow and low-amplitude deflection that results from ventricular repolarization.

The PR interval is the length of time from the start of the P wave to the start of the QRS complex. It is the time taken for activation to pass from the sinus node, through the atrium, AV node and His–Purkinje system, to the ventricle.

The QT interval extends from the start of the QRS complex to the end of the T wave. This interval represents the time taken to depolarize and repolarize the ventricular myocardium. The QT interval varies greatly with heart rate and is often represented as a corrected QT interval (or QTc) for a given heart rate. There are a number of formulae for derivation of QTc, but the most widely accepted are Bazett’s formula and Fridericia’s correction (Box 30.9).

An abnormally prolonged QTc can predispose to a risk of dangerous ventricular arrhythmias. Prolongation of the QT interval may be congenital or can occur in many acquired conditions (see Box 30.18).

The ST segment is the period between the end of the QRS complex and the start of the T wave. In the normal heart, all cells are depolarized by this phase of the ECG: that is, the ST segment represents ventricular repolarization.

A normal 12-lead ECG is shown in Fig. 30.18, and the normal values for the electrocardiographic intervals are indicated in Box 30.9. Leads that face the lateral wall of the left ventricle have predominantly positive deflections, and leads looking into the ventricular

![Fig. 30.18 A normal 12-lead electrocardiogram.](image)
cavity are usually negative. Detailed patterns depend on the size, shape and rhythm of the heart and the characteristics of the torso.

**Cardiac vectors**

At any point in time during depolarization and repolarization, electrical potentials are being propagated in different directions. Most of these cancel each other out and only the net force is recorded. This net force in the frontal plane is known as the cardiac vector.

The mean QRS vector can be calculated from the six standard leads (Fig. 30.19):

- **Normal**: between −30° and +90°
- **Left axis deviation**: between −30° and −90°
- **Right axis deviation**: between +90° and +150°

Calculation of this vector is useful in the diagnosis of some cardiac disorders.

**Exercise electrocardiography**

This is less used than previously because of its low sensitivity. The ECG is recorded while the patient walks or runs on a motorized treadmill. The test is based on the principle that exercise increases myocardial demand on coronary blood supply, which may be inadequate during exercise, and at peak stress can result in relative myocardial ischaemia. Most exercise tests are performed according to a standardized method, such as the Bruce protocol. Normally, there is little change in the T wave or ST segment during exercise.

The patient’s exercise capacity (the total time achieved) will depend on many factors; however, individuals who can exercise for less than 6 minutes generally have a poorer prognosis.

Myocardial ischaemia provoked by exertion results in ST segment depression (>1 mm) in leads facing the affected area. The form of ST segment depression provoked by ischaemia is characteristic: it either is planar or shows down-sloping depression (Fig. 30.20). Up-sloping depression is a non-specific finding. The degree of ST segment depression is positively correlated to the degree of myocardial ischaemia.

ST segment elevation during an exercise test is induced much less frequently than ST depression. When it does occur, it reflects transmural ischaemia caused by coronary spasm or critical stenosis.

Although most abnormalities are detected in lead V₅ (anterior and lateral ischaemia) or AVF (inferior ischaemia), it is best to record a full 12-lead ECG. During an exercise test the blood pressure and rhythm responses to exercise are also assessed. Exercise normally causes an increase in heart rate and blood pressure. A sustained fall in blood pressure usually indicates severe coronary artery disease. A slow recovery of the heart rate to basal levels has also been reported to be a predictor of mortality.

Frequent premature ventricular depolarizations during the test are associated with a long-term increase in the risk of death from cardiovascular causes, and further testing is required in these patients.
Clinical approach to the patient with heart disease

Twenty-four-hour ambulatory taped electrocardiography

This records transient changes, such as a brief paroxysm of tachycardia, an occasional pause in the rhythm or intermittent ST segment shifts (Fig. 30.21). A conventional 12-lead ECG is recorded in less than a minute and usually samples fewer than 20 complexes. In a 24-hour period, over 100,000 complexes are recorded. Such a large amount of data must be analysed by automatic or semi-automatic methods. This technique is called Holter electrocardiography after its inventor.

Event recording is another technique that is used to record less frequent arrhythmias. The patient is provided with a pocket-sized device that can record and store a short segment of the ECG. The device may be kept for several days or weeks until the arrhythmia is recorded. Most units of this kind will also allow transtelephonic ECG transmission so that the physician can determine the need for treatment or the continued need for monitoring.

A very small event recorder, known as an implantable loop recorder (ILR), can also be implanted subcutaneously, triggered by events or a magnet, and interrogated by the physician.

Other tests

Non-invasive methods that make use of digitalized Holter recordings to identify an increased risk of ventricular arrhythmias include...
assessment of heart rate variability, signal-averaged ECG and T wave alternans.

- **Heart rate variability (HRV)** can be assessed from a 24-hour ECG. HRV is decreased in some patients following myocardial infarction and represents an abnormality of autonomic tone or cardiac responsiveness. Low HRV is a major risk factor for sudden death and ventricular arrhythmias in patients discharged from hospital following myocardial infarction.

- **Signal-averaged ECG (SAECG)** is a technique that requires amplification and averaging of abnormal low-amplitude signals that occur beyond the end of the QRS complex and extend well into the ST segment. These signals are therefore also known as late potentials and are too small to be detected on a surface ECG. They arise in areas of slow conduction in the myocardium, such as the border zone of an infarct, where re-entrant ventricular arrhythmias can originate.

- **T wave alternans (TWA)** is a valuable technique used as a non-invasive marker of susceptibility to ventricular arrhythmias and sudden cardiac death. TWA represents microvolt level changes in the morphology of the T waves in every other beat and can be detected during acute myocardial ischaemia using amplification techniques. Visible TWA on an ordinary surface ECG is quite a rare phenomenon, except in patients with long QT syndromes, particularly during emotion or exercise.

### Tilt testing

Patients with suspected neurocardiogenic (vasovagal) syncope should be investigated by upright tilt testing. The patient is secured to a table that is tilted to +60 degrees to the vertical for 45 minutes or more. The ECG and blood pressure are monitored throughout. If neither symptoms nor signs develop, isoprenaline may be slowly infused or glyceryl trinitrate inhaled and the tilt repeated. A positive test results in hypotension, sometimes bradycardia (Fig. 30.22) and pre-syncpe/syncpe, and supports the diagnosis of neurocardiogenic syncope. If symptoms and signs appear, placing the patient flat can quickly reverse them. The effect of treatment can be evaluated by repeating the tilt test but it is not always reproducible. The overall sensitivity, specificity and reproducibility are low.

### Carotid sinus massage

Carotid sinus massage (Box 30.10) may lead to asystole (>3 sec) and/or a fall in systolic blood pressure (>50 mmHg). This hypersensitive response occurs in many of the normal (especially elderly) population but may also be responsible for loss of consciousness in some patients with carotid sinus syndrome (see p. 1052). In one-third of cases, carotid sinus massage is positive only when the patient is standing. Atherosclerosis can cause narrowing and stenosis of carotid arteries. Carotid sinus massage should thus be avoided in patients with carotid bruits.

### Echocardiography

Echocardiography is a non-invasive diagnostic technique that is widely employed in clinical cardiology. It involves the use of ultrasound (either alone or with a contrast agent) to assess cardiac structure and function. A physician or technician performs the studies and a comprehensive examination takes 15–45 minutes. The ultrasound machines are either mobile on wheels or handheld.

### Physics

Echocardiography uses transmitted ultrasound wavelengths of 1 mm or less, which correspond to frequencies of approximately 2 MHz or more (2 million cycles per second or more). At such high frequencies, the ultrasound waves can be focused into a ‘beam’ and aimed at a particular region of the heart. The waves are generated in very short bursts or pulses a few microseconds long by a crystal transducer, which also detects returning echoes and converts them into electrical signals.

When the handheld crystal transducer is placed on the body surface, the emitted ultrasound pulses encounter interfaces between various body tissues as they pass through the body. In crossing each interface, some of the wave energy is reflected, and if the beam path is approximately at right angles to the plane of the interface, the reflected waves return to the transducer as an echo. Since the velocity of sound in body tissues is almost constant (1550 m/s), the time delay for the echo to return measures the distance of the reflecting interface. Thus, if a single ultrasound pulse is transmitted, a series of echoes return, the first of which is from the closest interface.

### Echocardiographic modalities

#### M-mode and two-dimensional echocardiography

M-mode echocardiography is a technique that details the changing motion of structures along the ultrasound beam with time. Thus, the motion of the interventricular septum during the cardiac cycle (either towards or away from the transducer placed on the chest wall) can be assessed and quantified. Stationary structures...
Thus generate horizontal straight lines; the distances of these lines from the top of the screen indicate the depth of the structures, and movements, such as those of heart valves, are indicated by zigzag lines (Fig. 30.23C). Alternatively, a series of views from different positions can be obtained in the form of a two-dimensional image (cross-sectional 2-D echocardiography; Fig. 30.23A,B). This method is useful for delineating anatomical structures and for quantifying volumes of the cardiac chambers. M mode can be used to estimate left ventricular (LV) systolic function by comparing end-diastolic and end-systolic dimensions. For example, the percentage reduction in the left ventricular cavity size (fractional shortening, FS) is given by:

$$FS = \frac{LVDD - LVSD}{LVDD} \times 100\%$$

where LVDD is left ventricular diastolic diameter and LVSD is left ventricular systolic diameter, at the base of the heart. The normal range is 30–45%.

This method is easy to perform but is an inaccurate measure of ejection fraction (EF) because it does not take account of reduced regional function of the mid or apical myocardium – due to infarction, for example. For this reason, estimation of EF based on the difference in LV volumes from systole to diastole, derived from planimetered measurements of LV area in at least two planes, is more accurate. A normal EF is over 55%. This method is helpful in assessing the response of the patient with heart failure to therapy. It also permits estimation of LV mass.

**Three-dimensional echocardiography**

Three-dimensional echocardiography is a novel development in cardiac imaging in which a volumetric dataset is acquired using a multiplane probe rotating around a fixed axis. Clinical uses include accurate volumetric assessment of ventricular function and mass, assessment of mitral and aortic valve disease, and assessment of adult congenital heart disease (Fig. 30.24).

**Doppler echocardiography**

Echocardiography imaging utilizes echoes from tissue interfaces. Using high amplification, it is also possible to detect weak echoes scattered by small targets, including those from red blood cells. Blood velocity in the heart chambers is typically much more rapid (>1 m/s) than the movement of myocardial tissue. If the blood is moving in the same direction as the direction of the ultrasound beam, the frequency of the returning echoes will be changed according to the Doppler phenomenon. The Doppler shift frequency is directly proportional to the blood velocity. Blood velocity data can be acquired and displayed in several ways.

**Pulsed-wave (PW) Doppler** extracts velocity data from the pulse echoes used to form a two-dimensional image and gives useful qualitative information. PW echoes can be specified from...
locations within an image identified by a sample volume cursor placed on the screen. Such information from the left ventricular outflow tract (LVOT) and right ventricular outflow tract provides the stroke distance, and is used to estimate cardiac output (CO) and also to quantify intracardiac shunts. Cardiac output can then be derived using the formula:

\[ \text{CO} = \text{stroke volume} \times \text{heart rate} \]

Stroke volume is the stroke distance multiplied by the area of the LVOT, which can also be measured echocardiographically. PW Doppler of the flow across the mitral valve and into the left atrium through the pulmonary veins can be used as an element of the estimation of left ventricular filling pressure.

**Colour flow Doppler imaging** uses one colour for blood flowing towards the transducer and another colour for blood flowing away. This technique allows the direction, velocity and timing of the flow to be measured with a simultaneous view of cardiac structure and function. Colour flow Doppler is used to help assess valvular regurgitation (Fig. 30.25) and may be helpful in the assessment of coronary blood flow.

**Continuous-wave (CW) Doppler** collects all the velocity data from the path of the beam and analyses it to generate a spectral display. This is unlike PW Doppler, which provides information from a particular sample volume at one location along a line. Thus, CW Doppler does not provide any depth information.

The outline of the envelope of the spectral display is used to estimate the value of peak velocity throughout the cardiac cycle. CW Doppler is typically used to assess valvular obstruction, which then causes increased velocities. For example, normal flow velocities are of the order of 1 m/s across the normal aortic valve, but if there is a severe obstructive lesion, such as a severely stenotic aortic valve, velocities of 4 m/s or more can occur. These velocities are generated by the pressure gradient that exists across the lesion.

According to the Bernoulli equation, the pressure difference between two chambers is calculated as: 4 multiplied by the square of the CW Doppler velocity between chambers. Thus a velocity of 5 m/s across the aortic valve suggests a peak gradient of \(4 \times 5^2 = 100\text{mmHg}\) between the ascending aorta and the left ventricle. This equation has been validated in a wide variety of clinical situations, including valve stenoses, ventricular septal defects and intraventricular obstruction (as in hypertrophic cardiomyopathy). It is often clinically unnecessary to resort to invasive methods such as cardiac catheterization to measure intracardiac pressure gradients.

Similarly, pulmonary artery (PA) systolic pressure and right ventricular diastolic pressure can be calculated using the Bernoulli equation. In this case, CW Doppler tracing of the tricuspid regurgitant jet is used to estimate the pressure gradient between the right ventricle and the right atrium. The PA systolic pressure is then calculated by adding the estimated right atrial pressure to the pressure gradient between the right ventricle and the right atrium.

**Tissue Doppler** is similar to PW Doppler. It measures myocardial tissue velocities within a particular sample volume placed on the image. Such velocities are of the order of 1 cm/s. Currently, tissue Doppler of the mitral annulus is used as part of the estimation of left ventricular filling pressure.

**Other ultrasound modalities** include harmonic power Doppler, pulse inversion Doppler and ultraharmonics, which are used to detect and amplify microsphere-specific signals as part of the echocardiographic assessment of myocardial perfusion.

**Transoesophageal echocardiography**

In transoesophageal echocardiography (TOE, see Fig. 30.80), a transducer mounted on a flexible tube is placed into the oesophagus. This involves the use of local anaesthesia and, sometimes, intravenous sedation. High-resolution images can be obtained because of the close proximity of the heart to the transducer in the oesophagus, and also because of the higher frequencies that are used relative to transthoracic imaging. TOE is most commonly used to assess valve structure and function (for reparability of mitral valve prolapse), the features and complications of infective endocarditis, and the aorta (for aortic dissection); it is also useful for seeking a cardiac source of embolus.

**Wall motion stress echocardiography**

Echocardiography can be used clinically to evaluate the patient for the presence of myocardial scars and reversible ischaemia. Since ultrasound cannot directly detect red blood cells in capillaries, myocardial wall motion is used as a surrogate for perfusion. Myocardial segments that demonstrate a change in function (defined as a change or reduction in thickening) from rest to stress can be assumed to be supplied by a flow-limiting stenosis in the epicardial artery or graft.
Stress for this indication needs to be inotropic to induce true ischaemia. Physiological stress includes treadmill exercise, which is complicated by the difficulty in obtaining reliable images rapidly as the patient comes off the treadmill, before heart rate reduces back to submaximal levels. Alternatively, pharmacological stress can be induced with dobutamine at graded doses. This is relatively safe but complications such as ventricular arrhythmia have been reported. This technique can also assess viability of the myocardium, and hibernating or stunned myocardium (see p. 1075).

**Myocardial perfusion echocardiography**

In order to assess myocardial perfusion by echocardiography (MPE), microspheres of similar size to red blood cells are used as an intravenous contrast agent. Microsphere-specific ultrasound modes, such as harmonic power Doppler, can be used for detection. MPE involves the use of intravenous contrast infusion to fill the myocardium. A pulse of ultrasound destroys microspheres within the capillaries (and not the left ventricular cavity), and the time taken to replenish the capillaries is a measure of myocardial blood flow. The time taken to fill should be significantly shorter at stress than at rest.

**Contrast echo for left ventricular opacification**

Intravenous contrast agents opacify the left ventricle and can define the endocardial border. Their clinical utility has reduced with the advent of harmonic imaging, which has improved image quality in patients who were previously ‘difficult to image’.

**Intravascular (coronary) ultrasound**

Intravascular (coronary) ultrasound probes can be used to obtain images of proximal coronary arteries as part of a percutaneous transluminal coronary angioplasty (PTCA) procedure: for example, to assess adequacy of deployment of intracoronary stents.

**Nuclear imaging**

Nuclear imaging is used to detect myocardial infarction or to measure myocardial function, perfusion or viability, depending on the radiopharmaceutical and the imaging technique chosen. These data are particularly valuable when used in combination. All involve a significant radiation dose (see later).

**Image type**

Gamma cameras produce a planar image in which structures are superimposed, as in a standard X-ray. Single-photon emission computed tomography (SPECT) imaging uses similar raw data to construct tomographic images, just as a CT image is reconstructed from X-rays. This gives finer anatomical resolution but is technically demanding. These methods may be used with any of the radiopharmaceuticals.

**Myocardial perfusion and viability**

Thallium-201 is rapidly taken up by the myocardium, so an image taken immediately after injection reflects the distribution of blood flow to the myocardium. Areas of ischaemia or infarction receive less $^{201}\text{Tl}$ and appear dark. Between 2 and 24 hours after injection, $^{201}\text{Tl}$ is redistributed so that all cardiac myocytes contain a comparable concentration. Images obtained at this time show dark areas where the myocardium has infarcted but normal density in ischaemic areas. Comparison of early and late images is one method of predicting whether an ischaemic area of myocardium contains enough viable tissue to justify coronary bypass or angioplasty. Technetium-99-labelled tetrofosmin (Fig. 30.26) is also taken up rapidly by cardiac myocytes but does not undergo redistribution. When this substance is injected during exercise, its distribution in the myocardium reflects the distribution of blood at the time of the exercise, even if the image is taken several hours later. This is a sensitive method of detecting myocardial viability. Images produced following injection of $^{99m}\text{Tc}$ tetrofosmin during exercise can be compared to images produced following injection at rest to decide which areas of ischaemia are reversible (see p. 1075). In patients unable to exercise the heart can be stressed with drugs, such as dipyridamole or dobutamine.

**Infarct imaging**

Perfusion images produced using compounds labelled with $^{201}\text{Tl}$ or $^{99m}\text{Tc}$ sestamibi show a myocardial infarction as a perfusion defect or ‘cold spot’. These methods are sensitive for detecting and localizing the infarct but give no information about its age. $^{99m}\text{Tc}$ Pyrophosphate is preferentially taken up by myocardium that has undergone infarction within the previous few days. Images are difficult to interpret because the isotope is also concentrated by bone and cartilage.

**Cardiac computed tomography**

Computed tomography (CT) is useful for assessment of the thoracic aorta and mediastinum. The development of 512-slice multidetector CT (MDCT) scanners has enabled accurate non-invasive imaging of the coronary arteries.

**Coronary artery calcification**

Calcium is absent in normal coronary arteries but is present in atherosclerosis and increases with age. Studies have demonstrated a positive correlation between calcification and the presence of coronary artery stenoses, although the relationship is non-linear. Electron beam CT (EBT) and MDCT scanners are used to obtain multiple thin axial slices through the heart and then the calcium score is calculated. The calcium score is based on the X-ray attenuation coefficient or CT number measured in Hounsfield units. Meta-analyses have demonstrated that a higher calcium score is associated with a higher event rate and higher relative risk ratios, although no study to date has shown a net effect on health outcomes of calcium scoring. The current National Institute for Health and Care Excellence (NICE) chest pain guidelines recommend the use of CT calcium scoring in patients with chest pain and a 10–29% likelihood of coronary artery disease (see p. 1082).

**CT coronary angiography**

CT coronary angiography (CTCA) is performed with a supine patient connected to a three-lead ECG for cardiac synchronisation. The 64-slice MDCT scanners have a temporal resolution of 165–210 ms; image quality is optimal with a slow and steady heart rate (<65–70 b.p.m.), which can be obtained with the use of oral or intravenous beta-blockers. Sublingual nitroglycerin (0.4–0.8 mg dose) may improve visualization of the coronary artery lumen. A volume dataset containing the whole heart is acquired during a single breath-hold with the injection of 60–80 mL of iodinated contrast agent at 4–6 mL/sec. The radiation dose during the scan is 11–22 mSv but this can be reduced to 7–11 mSv with ECG-controlled dose modulation; this compares with 2.5–5.0 mSv for diagnostic coronary angiography and 15–20 mSv for SPECT. The volume dataset is then analysed with multiplanar reformatting for the presence of coronary artery stenoses (Fig. 30.27). Studies
have reported high sensitivity (>85%) and specificity (>90%) for the detection of coronary artery disease, with a very high negative predictive value (>95%). CTCA may become part of an acute chest pain service in the emergency medicine department to exclude aortic dissection, pulmonary embolism and coronary artery disease. However, this technique does expose the patient to ionizing radiation.

Cardiovascular magnetic resonance (CMR)
Cardiovascular magnetic resonance (CMR), a non-invasive imaging technique that does not involve harmful radiation, is increasingly used in the investigation of patients with cardiovascular disease. CMR is usually performed with multiple breath-holds to minimize respiratory motion artefacts and cardiac gating to reduce blurring during the cardiac cycle. Several different sequences provide anatomical and functional information. Most sequences do not require a contrast agent but intravenous gadolinium may be needed for magnetic resonance angiography, myocardial perfusion, infarct and fibrosis imaging. The major contraindications are permanent pacemaker or defibrillator, intracerebral clips and significant claustrophobia. Patients with coronary stents and prosthetic valves can be safely scanned.

Clinical use
The current indications for CMR are summarized in Box 30.11.

Congenital heart disease
CMR provides additional and complementary information to echocardiography in patients with congenital heart disease. Cine-imaging can accurately assess systemic and non-systemic ventricular function and mass. Extracardiac conduits, anomalous pulmonary venous return and aortic coarctations before and after repair can be studied by CMR, and the studies repeated for long-term follow-up without the risk of ionizing radiation.

Cardiomyopathies, pericardial disease and cardiac masses
In hypertrophic cardiomyopathy, CMR accurately defines the extent and distribution of myocardial hypertrophy and can be used in patients with suboptimal echocardiograms. Intravenous gadolinium can be
Clinical approach to the patient with heart disease

utilized to demonstrate regional myocardial fibrosis, which is associated with an adverse prognosis. In patients with suspected arrhythmogenic right ventricular cardiomyopathy, CMR is the imaging investigation of choice to detect global and regional wall motion abnormalities of the right ventricle and right ventricular outflow tract, and to detect fatty or fibro-fatty infiltration of the right and left ventricles. In constrictive pericarditis and restrictive cardiomyopathy, CMR can demonstrate the effects of the impaired ventricular filling common to both conditions (dilated right atrium and inferior vena cava) and can also determine the thickness of the pericardium (usually 4 mm in normal individuals) (Fig. 30.28). In patients with dilated cardiomyopathy, CMR can accurately quantify biventricular function and, with gadolinium, can demonstrate myocardial fibrosis. In inflammatory and infiltrative conditions of the myocardium, such as myocarditis, sarcoidosis and amyloidosis (see p. 1357), CMR is increasingly used as a diagnostic investigation due to the different patterns of signal enhancement seen with gadolinium. In patients with thalassaemia, CMR can detect iron deposition within the myocardium and guide chelation therapy. CMR can be useful in patients with cardiac masses to differentiate benign from malignant tumours and to identify thrombus not visualized on echocardiography.

Diseases of the aorta

CMR is an excellent technique for assessing patients with aortic dissection and can detect the clinical features of an aortic dissection: the intimal flap, thrombosis in a false lumen, aortic regurgitation, pericardial effusion and aortic dilation. As it does not involve radiation or need contrast, CMR is an ideal method of surveillance of patients with dilated thoracic aortas or repaired coarctation.

Valvular heart disease

Valvular stenosis produces signal void on gradient-echo CMR. CMR can quantify the velocity across a stenosed valve using phase-contrast velocity mapping. Valvular regurgitation can be accurately quantified using phase-contrast velocity mapping across the valve, or by calculating the stroke volumes of the left and right ventricles, which are equal in the absence of significant regurgitation. However, in most patients, transthoracic and transoesophageal echocardiography should provide sufficient information.

Coronary artery disease

CMR can be used to evaluate coronary artery anatomy, left ventricular function, myocardial perfusion and viability in a ‘one-stop’ approach to the assessment of patients with coronary artery disease. Coronary artery anatomy and stenoses can be identified with ultra-fast breath-hold or respiratory-gated sequences with high accuracies. Global left ventricular function and wall motion abnormalities can be detected with cine-imaging performed at rest and during dobutamine stress. Myocardial perfusion can be assessed with gadolinium and first-pass imaging; ischaemia can be demonstrated with adenosine for coronary vasodilation. Myocardial viability can be determined using gadolinium and ‘delayed enhancement’ images. With these techniques, CMR is increasingly used to assess...
both ischaemia in patients with suspected coronary disease, and myocardial viability prior to revascularization in individuals with impaired cardiac function (Figs 30.29 and 30.30).

**Pulmonary vessels**

Magnetic resonance angiography (MRA) with gadolinium can provide high-quality images of the pulmonary veins, which can be fused with electrical data during pulmonary vein isolation for the treatment of atrial fibrillation.

**Positron emission tomography**

Positron emission tomography (PET) is based on detection of high-energy emissions caused by annihilation of positrons released from unstable isotopes. PET has several advantages over other techniques, such as improved spatial resolution, accurate quantification, and use of biological isotopes of carbon, nitrogen and oxygen. However, it is expensive and requires a cyclotron to produce the short-lived tracers. PET/CT has become a useful investigation in the detection of viable myocardium in patients who are suitable for revascularization.

Myocardial perfusion and ischaemia can be determined using PET with $^{15}$N-ammonia or $^{15}$Oxygen with greater sensitivity than SPECT. Myocardial metabolism and viability can be detected with the use of $^{18}$F-fluorodeoxyglucose (FDG), which the cardiac myocyte utilizes for energy production in the presence of reduced oxygen supply and blood flow. There may be reduced perfusion to infarcted or fibrotic myocardium, but also reduced FDG uptake. In hibernating myocardium, with viable but dysfunctional myocardium, PET can demonstrate reduced myocardial perfusion but with preserved or increased FDG uptake.

**Cardiac catheterization**

Cardiac catheterization is the introduction of a thin radio-opaque tube (catheter) into the circulation. The right heart is catheterized by introducing the catheter into a peripheral vein (usually the right femoral or internal jugular vein) and advancing it through the right atrium and ventricle into the pulmonary artery. The pressures in the right heart chambers and in the pulmonary artery can be measured directly. An indirect measure of left atrial pressure can be obtained by ‘wedging’ a balloon-tipped catheter into the distal pulmonary artery (see Fig. 10.15). In this position the pressure from the right ventricle is obstructed by the catheter, and only the pulmonary venous and left atrial pressures are recorded. Left heart catheterization is usually performed via the right femoral or radial artery. A pigtail catheter is advanced up the aorta and manipulated through the aortic valve into the left ventricle. Pressure tracings are taken from the left ventricular cavity. The end-diastolic pressure is invariably elevated in patients with left ventricular dysfunction. A power injection of radio-opaque contrast material opacifies the left ventricular cavity (left ventriculography) and thereby assesses left ventricular systolic function. The catheter is then withdrawn across the aortic valve into the aorta and the ‘pullback’ gradient across the valve is measured. Aortography (a power injection into the aortic root) can be performed to assess the aortic root and the presence and severity of aortic regurgitation. Specifically designed catheters are then used to engage the left and right
coronary arteries selectively, and contrast cine-angiograms are taken in order to define the coronary circulation and identify the presence and severity of any coronary artery disease. During the procedure, intracoronary nitrate or adenosine may be used to dilate the coronary arteries. During cardiac catheterization, blood samples may be withdrawn to measure the oxygen content. These estimations are used to quantify intracardiac shunts and measure cardiac output.

Further reading

Cardiac resuscitation
Each year in the UK, there are approximately 100,000 unexpected deaths occurring within 24 hours of the development of cardiac symptoms. About half of these deaths are almost instantaneous. Most deaths are due to ventricular fibrillation or rapid ventricular tachycardia; a small proportion are caused by severe bradyarrhythmias. Coronary artery disease accounts for approximately 80% of sudden cardiac deaths in Western society. Transient ischaemia is suspected of being the major trigger factor; however, only a small proportion of survivors have clinical evidence of acute myocardial infarction.

When cardiac arrest occurs, basic life support must be started immediately. The longer the period of respiratory and circulatory arrest, the lower is the chance of restoring healthy life. The chain of survival (Fig. 30.31) includes:
• early recognition of cardiac arrest
• early activation of emergency services
• early cardiopulmonary resuscitation (CPR)
• early defibrillation and early advanced life support
• high-quality post-resuscitation care.

Basic life support
The first step in basic life support (BLS) is to ensure the safety of the victim and rescuer. The next is to ascertain that the victim is unresponsive by shaking them and shouting into one ear. If no response is obtained, help should be sought immediately prior to commencement of BLS. If the victim has absent or abnormal breathing, then cardiac arrest is confirmed and BLS should be started (Box 30.12).

Airway
Debris (e.g. blood and mucus) in the mouth and pharynx should be removed, as should loose or ill-fitting dentures. The airway should be opened gently by flexing the patient’s neck and extending the
**Head ('sniffing the morning air' position).** This manoeuvre is not recommended if a cervical spine injury is suspected. Any obstruction deep in the oral cavity or upper respiratory tract may need to be removed using abdominal and/or chest thrusts (Heimlich manoeuvre, see Box 28.16).

**Circulation**
Most adult cardiac arrest is due to a primary cardiac disorder, such as acute coronary syndrome, and results in circulatory collapse. Pulse detection can be difficult, and if the victim is unresponsive, with absent or abnormal breathing, external chest compression should be started immediately. The heel of one hand is placed over the centre of the patient’s chest and the heel of the second hand is placed over the first with the fingers interlocked. The arms are kept straight and the sternum is rhythmically depressed by 5–6 cm at a rate of approximately 100–120 per minute, allowing for complete recoil between compressions. Chest compressions do not massage the heart. The thorax acts as a pump and the heart provides a system of one-way valves to ensure forward circulation. Respiratory and circulatory support is continued by providing two effective breaths for every 30 cardiac compressions (30:2 for one or two persons, 15:2 in paediatric patients). It is easier for the lay public to give compressions without interruption (‘hands only CPR’). This maintains adequate cerebral and coronary perfusion pressures. The initiation of CPR by the lay public at the site of the arrest saves lives. There is evidence to suggest that if the person performing compressions tires, the quality of resuscitation deteriorates. Mechanical CPR devices are available but not yet widely used.

**Breathing**
After 30 compressions the rescuer opens the victim’s airway by tilting the head backwards (head lift) and pulling the chin forwards (chin lift or jaw thrust). The rescuer then pinches the victim’s nostrils firmly, takes a deep breath and seals their lips around the mouth of the victim. Two effective breaths are given, each over 1 second. In paediatric patients, respiratory arrests are more common and patients should be given rescue breaths and a minute of CPR before a sole rescuer leaves the victim to seek help. CPR should not be interrupted to reassess the victim unless they start to show signs of life and begin to breathe normally.

**Advanced cardiac life support**
By the time effective life support has been established, more help should have arrived and advanced cardiac life support (ACLS) can begin. This consists of ECG monitoring, advanced airway management (endotracheal intubation or supraglottic airway tube) and establishment of an intravenous infusion in a large peripheral or central vein (an intraosseous needle may be used if intravenous...
access is not possible). As soon as feasible, the cardiac rhythm should be established, as this determines which pathway of the European Resuscitation Council and the Resuscitation Council UK ACLS algorithm is followed (Fig. 30.32). This can be determined with an automated external defibrillator (AED), or the paddles or limb leads of a standard defibrillator.

If the ECG shows a shockable rhythm – ventricular fibrillation or pulseless ventricular tachycardia – then an unsynchronized shock of 150–200 J biphasic (360 J monophasic) is delivered without delay via paddles or self-adhesive pads, followed immediately by 2 minutes of CPR. For a non-shockable rhythm – asystole or pulseless electrical activity – minutes of CPR is delivered with 1 mg of intravenous adrenaline (epinephrine).

For both sides of the algorithm, it is vital to maintain CPR, ensure oxygenation and exclude or treat reversible causes – the ‘four Hs and four Ts’:

- **Hypoxia** should be minimized by ventilating the patient with oxygen and a bag-valve mask or advanced airway (endotracheal intubation or supraglottic airway tube), ensuring that there is bilateral air entry and chest expansion. With an advanced airway,
CPR should continue, with a ventilation rate of 10 per minute without interrupting cardiac massage.

- **Hypovolaemia** is a frequent cause of pulseless electrical activity due to haemorrhage. Intravenous volume should be replaced.
- **Hyper- or hypokalaemia** may cause ECG abnormalities and should be detected by biochemical testing. Intravenous calcium chloride may be helpful in hyperkalaemia or hypocalcaemia. Acidosis should be managed with effective ventilation.
- **Hypothermia** should be excluded with a low-reading thermometer and treated with external or internal warming.
- **Thromboembolism** and massive pulmonary embolism may cause pulseless electrical activity and patients should be considered for intravenous thrombolysis.
- **Tension pneumothorax** may occur during central venous cannulation or following chest trauma. Clinical diagnosis (deviated trachea, hyper-resonant chest, absent breath sounds, ultrasound) and needle thoracocentesis or thoracostomy may be required.
- **Tamponade** should be excluded with echocardiography; if present, it should be treated with pericardiocentesis.
- **Toxins** may have been ingested by accident or deliberate self-harm, and specific antidotes should be used in appropriate patients.

**Defibrillation**

This technique is used to convert ventricular fibrillation to sinus rhythm. When the defibrillator is discharged, a high-voltage field envelops the heart, depolarizing the myocardium and allowing an organized heart rhythm to emerge. Electrical energy is discharged through two paddles with gel pads or adhesive pads placed on the chest wall.

The paddles are placed in one of two positions:
- One paddle is placed to the right of the upper sternum and the other over the cardiac apex.
- One paddle is placed under the tip of the left scapula and the other over the anterior wall of the left chest.

All personnel should stand clear of the patient. The person performing defibrillation has responsibility for ensuring the safety of the patient and of the other people present. Conventional defibrillators employ a damped monophasic waveform. Biphasic defibrillators, which require less energy, are increasingly common. AEDs, which recognize ventricular fibrillation automatically, deliver a shock if indicated. These are available in some public places (in the UK, their location is signalled by a specific sign, Fig. 30.33). It is the responsibility of all healthcare practitioners to be familiar with the range of defibrillators they may be called on to use in their workplace.

**Post resuscitation – therapeutic hypothermia**

Early studies suggested that therapeutic hypothermia (32–34°C for 12–24h) might improve outcomes in unconscious adult patients with spontaneous circulation after an out-of-hospital cardiac arrest due to ventricular fibrillation. A subsequent multinational study from 2013 demonstrated similar outcomes with therapeutic hypothermia at 33°C, compared to a targeted temperature of 36°C. In a French study from 2019, moderate hypothermia (33°C) was associated with improved neurological outcomes (but not mortality) when compared with targeted normothermia (37°C) in a group of out-of-hospital cardiac arrest survivors presenting with non-shockable rhythms. Thus, the value of hypothermia is unclear.

Neurological recovery appears to be more favourable in patients with purposeful movements and electroencephalogram activity within 3 days of a cardiac arrest.

**Direct current cardioversion**

Tachyarrhythmias that do not respond to medical treatment or are associated with haemodynamic compromise (e.g. hypotension, worsening heart failure) may be converted to sinus rhythm by the use of a transthoracic electric shock. A short-acting general anaesthetic is used. Muscle relaxants are not usually given.

When the arrhythmia has definite QRS complexes, delivery of the shock should be timed to coincide with the downstroke of the QRS complex (synchronization, Fig. 30.34). The machine being used to perform the direct current cardioversion (DCC) will do this automatically if the appropriate button is pressed. There is a
Therapeutic procedures

crucial difference between defibrillation and cardioversion: a non-synchronized shock is used to defibrillate. Accidental defibrillation of a patient who does not require it may itself precipitate ventricular fibrillation.

Typical indications for DCC include:

- atrial fibrillation
- atrial flutter
- sustained ventricular tachycardia
- junctional tachyarrhythmias.

If atrial fibrillation or flutter has been present for more than 48 hours, it is necessary to anticoagulate the patient adequately for 3 weeks before elective cardioversion to reduce the risk of embolization. The duration of anticoagulation after successful cardioversion for atrial fibrillation is a complex issue and depends on a number of factors: it should be given for at least 4 weeks after the procedure and may well be given for much longer.

Digoxin toxicity may lead to ventricular arrhythmias or asystole following cardioversion. Therapeutic digitalization does not increase the risks of cardioversion, but it is conventional to omit digoxin several days prior to elective cardioversion in order to be sure that toxicity is not present.

Cardiac enzyme levels may rise after a cardioversion.

Temporary pacing

Therapeutic cardiac pacing is employed in any patient with sustained symptomatic or haemodynamically compromising bradycardia. Bradycardias may be due to either a slow intrinsic heart rate (e.g. sinus node dysfunction) or AV block. Prophylactic cardiac pacing is employed in asymptomatic patients with either bradycardia or conduction abnormalities, as the risk of progression to symptomatic bradycardia justifies such a strategy.

Transvenous pacing is the preferred method in patients with symptomatic bradycardias. In summary, a thin (French gauge 5 or 6), bipolar pacing electrode wire is inserted via an internal jugular vein, a femoral vein or a subclavian vein and is positioned at the right ventricular apex using cardiac fluoroscopy. The energy needed for successful pacing (the pacing threshold) is assessed by reducing the energy until the pacemaker fails to stimulate the tissue (loss of capture). The output energy is then set at three times the threshold value to prevent inadvertent loss of capture. If the threshold increases above 5V, the pacemaker wire should be resited. A temporary pacemaker unit (Fig. 30.35A) is almost always set to work ‘on demand’ – to fire only when a spontaneous beat has not occurred. The rate of temporary pacing is usually 60–80 per minute.

Transcutaneous pacing is the preferred method in selected patients with asymptomatic bradycardia or conduction abnormalities, and may be life-saving when a cardiac arrest is precipitated by bradycardia. In this method the myocardium is depolarized by current flow between two large adhesive electrodes positioned anteriorly and posteriorly on the chest wall. Transcutaneous pacing is uncomfortable for the conscious patient but can usually be tolerated until a temporary transvenous pacemaker is inserted.

Permanent pacing

Permanent pacemakers are fully implanted in the body and connected to the heart by one or two electrode leads (Fig. 30.35B). The pacemaker is powered by solid-state lithium batteries, which usually last 5–10 years. Pacemakers are ‘programmable’, in that their operating characteristics (e.g. the pacing rate) can be changed by a programmer that transmits specific electromagnetic signals through the skin. The pacemaker leads are passed transvenously to the right heart chambers. Leadless pacemakers have been developed but are not recommended by NICE unless implanted as part of a research study.

Pacemakers are designed both to pace and to sense either the ventricles, the atria or, more commonly, both chambers. A single-chamber ventricular pacemaker is described as a ‘VVI’ unit because it paces the ventricle (V), senses the ventricle (V) and is inhibited (I) by a spontaneous ventricular signal. Occasionally (e.g. in symptomatic sinus bradycardia), an atrial pacemaker (AAI) may be implanted. Pacemakers that are connected to both the right atrium and ventricle (‘dual-chamber’ pacemakers) are used to simulate the natural
A pericardial effusion is an accumulation of fluid between the parietal and visceral layers of pericardium. Fluid is removed for relief of symptoms that are due to haemodynamic embarrassment or for diagnostic purposes. This can be a technically difficult procedure, particularly in the acute setting, and should be performed in a cardiac laboratory. In an emergency, it can be performed at the bedside.

Pericardiocentesis (Fig. 30.36) is performed by inserting a needle into the pericardial space, usually via a subxiphisternal route under ultrasound guidance. Certain effusions, particularly posterior ones, require surgical drainage under general anaesthetic. If a large volume of fluid is to be removed, a wide-bore needle and cannula are inserted. The needle may be removed and the cannula left in situ to drain the fluid. Fluid that is removed is sent for chemical analysis, microscopy, including cytology, Gram stain and culture. If a reaccumulation of pericardial fluid is anticipated, the cannula may be left in place for several days, or an operation can be performed to cut a window in the parietal pericardium (fenestration) or to remove a large section of the pericardium.

Right-heart bedside catheterization

Bedside catheterization (see Fig. 10.15) of the pulmonary artery with a pulmonary artery balloon flotation catheter (Swan–Ganz catheter) is now rarely performed routinely, but may be required in patients with:

- cardiac failure
- pulmonary arterial hypertension
- septic shock
- cardiogenic shock
- doubtful fluid status.

Intra-aortic balloon pumping

This technique is used to assist the failing left ventricle temporarily. A catheter with a long, sausage-shaped balloon at its tip is introduced percutaneously into the femoral artery and manipulated subxiphisternally in front of the pectoral muscle. Following surgery, which usually takes 60–90 minutes, the patient rests in bed for 6–12 hours before being discharged. Patients may not drive for at least 1 week after implantation, and must inform the licensing authorities and their motor insurers.

Complications are few but can prove to be very difficult to manage, and patients should be referred to the pacemaker clinic. They include the following:

- infection
- erosion
- pocket haematoma
- lead displacement
- electromagnetic interference.

Pericardiocentesis

A pericardial effusion is an accumulation of fluid between the parietal and visceral layers of pericardium. Fluid is removed for relief of symptoms that are due to haemodynamic embarrassment or for diagnostic purposes. This can be a technically difficult procedure, particularly in the acute setting, and should be performed in a cardiac laboratory. In an emergency, it can be performed at the bedside.

Pericardiocentesis or pericardiocentesis (Fig. 30.36) is performed by inserting a needle into the pericardial space, usually via a subxiphisternal route under ultrasound guidance. Certain effusions, particularly posterior ones, require surgical drainage under general anaesthetic. If a large volume of fluid is to be removed, a wide-bore needle and cannula are inserted. The needle may be removed and the cannula left in situ to drain the fluid. Fluid that is removed is sent for chemical analysis, microscopy, including cytology, Gram stain and culture. If a reaccumulation of pericardial fluid is anticipated, the cannula may be left in place for several days, or an operation can be performed to cut a window in the parietal pericardium (fenestration) or to remove a large section of the pericardium.

Right-heart bedside catheterization

Bedside catheterization (see Fig. 10.15) of the pulmonary artery with a pulmonary artery balloon flotation catheter (Swan–Ganz catheter) is now rarely performed routinely, but may be required in patients with:

- cardiac failure
- pulmonary arterial hypertension
- septic shock
- cardiogenic shock
- doubtful fluid status.
with severe aortic regurgitation, aortic dissection and severe peripheral vascular disease.

Complications of balloon pumping occur in about 20% of patients and include aortic dissection, leg ischaemia, emboli from the balloon, and balloon rupture. Embolic complications are reduced by anticoagulation with heparin.

CARDIAC ARRHYTHMIAS

An abnormality of the cardiac rhythm is called a cardiac arrhythmia. Arrhythmias may cause sudden death, syncope, heart failure, chest pain, dizziness, palpitations or no symptoms at all. There are two main types of arrhythmia:

- **Bradycardia**: the heart rate is slow (<60 b.p.m. during the day or <50 b.p.m. at night).
- **Tachycardia**: the heart rate is fast (>100 b.p.m.).

Tachycardias are more symptomatic when the arrhythmia is fast and sustained. Tachycardias are subdivided into **supraventricular tachycardias**, which arise from the atrium or the AV junction, and **ventricular tachycardias**, which arise from the ventricles.

Some arrhythmias occur in patients with apparently normal hearts; in others, arrhythmias originate from diseased tissue, such as scar, as a result of underlying structural heart disease. When myocardial function is poor, arrhythmias are more symptomatic and are potentially life-threatening.

### Sinus node function

The normal cardiac pacemaker is the sinus node (see p. 1023) and, like most cardiac tissue, it depolarizes spontaneously.

The rate of sinus node discharge is modulated by the autonomic nervous system. Normally, the parasympathetic system predominates, resulting in slowing of the spontaneous discharge rate from approximately 100 to 70 b.p.m. A reduction of parasympathetic tone or an increase in sympathetic stimulation leads to tachycardia; conversely, increased parasympathetic tone or decreased sympathetic stimulation produces bradycardia. The sinus rate in women is slightly faster than in men. Normal sinus rhythm is characterized by P waves that are upright in leads I and II of the ECG (see Fig. 30.18) but inverted in lead AVR.

### Sinus arrhythmia

Fluctuations of autonomic tone result in phasic changes of the sinus discharge rate. During inspiration, parasympathetic tone falls and the heart rate quickens; on expiration, the heart rate falls. This variation is normal, particularly in children and young adults. Typically, sinus arrhythmia results in predictable irregularities of the pulse.

### Sinus bradycardia

A sinus rate of less than 60 b.p.m. during the day or <50 b.p.m. at night is known as sinus bradycardia. It is usually asymptomatic unless the rate is very slow. Sinus bradycardia is normal in athletes owing to increased vagal tone. Other causes may be divided into systemic or cardiac, and are discussed on page 1052.

### Sinus tachycardia

Sinus rate acceleration to more than 100 b.p.m. is known as sinus tachycardia. Again, causes may be divided into systemic or cardiac, and are discussed on page 1057.

### Mechanisms of arrhythmia production

Abnormalities of automaticity, which could arise from a single cell, and abnormalities of conduction, which require abnormal interaction between cells, account for both bradycardia and tachycardia. Sinus bradycardia is a result of abnormally slow automaticity while bradycardia due to AV block is caused by abnormal conduction within the AV node or the intraventricular conduction system. The mechanisms generating tachycardia are shown in Fig. 30.38.

### Accelerated automaticity

The normal mechanism of spontaneous cardiac rhythmicity is slow depolarization of the transmembrane voltage during diastole until the threshold potential is reached and the action potential of the pacemaker cells takes off. This mechanism may be accelerated by increasing the rate of diastolic depolarization or changing the threshold potential (Fig. 30.38A). For example, sympathetic stimulation releases adrenaline (epinephrine), which enhances automaticity. Such changes are thought to produce sinus tachycardia, escape rhythms and accelerated AV nodal (junctional) rhythms.
The mechanism of re-entry (Fig. 30.38C) occurs when a ‘ring’ of cardiac tissue surrounds an inexcitable core (e.g. in a region of scarred myocardium). Tachycardia is initiated if an ectopic beat finds one limb refractory (α), resulting in unidirectional block, and the other limb excitable. Provided conduction through the excitable limb (β) is slow enough, the other limb (α) will have recovered and will allow retrograde activation to complete the re-entry loop. If the time to conduct around the ring is longer than the recovery times (refractory periods) of the tissue within the ring, circus movement will be maintained, producing a run of tachycardia. The majority of regular paroxysmal tachycardias are produced by this mechanism.

### BRADYCARDIAS AND HEART BLOCK

Bradycardias may be due to failure of impulse formation (sinus bradycardia) or failure of impulse conduction from the atria to the ventricles (atrioventricular block).

### Sinus bradycardia

Sinus bradycardia is due either to extrinsic factors that influence a relatively normal sinus node, or to intrinsic sinus node disease. The mechanism can be acute and reversible, or chronic and degenerative.

- **Common extrinsic causes** of sinus bradycardia include:
  - hypothermia, hypothyroidism, cholestatic jaundice and raised intracranial pressure
  - drug therapy with beta-blockers, digitals and other antiarrhythmic drugs
  - neurally mediated syndromes (see next section).

- **Common intrinsic causes** include:
  - acute ischaemia and infarction of the sinus node (as a complication of acute myocardial infarction)
  - chronic degenerative changes, such as fibrosis of the atrium and sinus node (sick sinus syndrome).

**Sick sinus syndrome or sinoatrial disease** is usually caused by idiopathic fibrosis of the sinus node. Other causes of fibrosis, such as ischaemic heart disease, cardiomyopathy or myocarditis, can also cause the syndrome. Patients develop episodes of sinus bradycardia or sinus arrest (Fig. 30.39B), and commonly experience paroxysmal atrial tachyarrhythmias (tachy–brady syndrome) owing to diffuse atrial disease.

### Neuromediated syndromes

Neurally mediated syndromes are due to a reflex (Bezold–Jarisch) that may result in both bradycardia (sinus bradycardia, sinus arrest and AV block) and reflex peripheral vasodilation. These syndromes usually present as syncope or pre-syncope (dizzy spells).

- **Carotid sinus syndrome** occurs in the elderly and mainly leads to bradycardia. Syncope occurs (see p. 1029).
- **Neurocardiogenic (vasovagal) syncope** usually presents in young adults but may present for the first time in elderly patients (see p. 1029). It results from a variety of situations (physical and emotional) that affect the autonomic nervous system. The eff erent output may be predominantly bradycardic, predominantly vasodilatory or mixed.
- **Postural orthostatic tachycardia syndrome (POTS)** is a sudden and significant increase in heart rate associated with normal or mildly reduced blood pressure and produced by standing. The underlying mechanism is a failure of the peripheral vasculature to constrict appropriately in response to orthostatic stress, which is compensated by an excessive increase in heart rate. Many medications, such as antihypertensives, tricyclic antidepressants and neuroleptics, can be the cause of syncope, particularly in the elderly. Careful dose titration and avoidance of...
combination of two agents with the potential to cause syncope help to prevent iatrogenic syncope.

**Management**

The management of sinus bradycardia is first to identify and then, if possible, remove any extrinsic causes. Temporary pacing may be employed in patients with reversible causes until a normal sinus rate is restored, and in individuals with chronic degenerative conditions until a permanent pacemaker is implanted.

Chronic symptomatic sick sinus syndrome may require permanent pacing (DDD), with additional antiarrhythmic drugs (or ablation therapy) to manage any tachycardic element.

Patients with carotid sinus hypersensitivity (asystole >3 sec), especially if symptoms are reproduced by carotid sinus massage and life-threatening causes of syncope have been excluded, may benefit from pacemaker implantation.

Treatment options in vasovagal attacks include avoidance, if possible, of situations known to cause syncope in a particular patient, and sitting/lying down and applying counter-pressure manoeuvres (pushing the palms together or crossing the legs) if an attack threatens. Increased salt intake, compression of the lower legs with compression stockings, and drugs such as beta-blockers, alpha-agonists (e.g. midodrine) or myocardial negative inotropes (e.g. disopyramide) may be helpful.

In selected patients with ‘malignant’ neurocardiogenic syncope (syncope associated with injuries and demonstrated asystole), permanent pacemaker therapy is helpful. These patients benefit from dual-chamber pacemakers with a feature called ‘rate drop response’, which, once activated, paces the heart at a fast rate for a set period of time in order to prevent syncope.

**Heart block**

Heart block or conduction block may occur at any level in the conducting system. Block in either the AV node or the His bundle results in AV block, whereas block lower in the conduction system produces bundle branch block.

### Atrioventricular block

There are three forms.

#### First-degree AV block

This is simple prolongation of the PR interval to more than 0.20 sec. Every atrial depolarization is followed by conduction to the ventricles but with delay (Fig. 30.40).

#### Second-degree AV block

This occurs when some P waves conduct and others do not. There are several forms (Fig. 30.41):

- **Mobitz I block** (Wenckebach block phenomenon) is progressive PR interval prolongation until a P wave fails to conduct. The PR interval before the blocked P wave is much longer than the PR interval after the blocked P wave.
- **Mobitz II block** occurs when a dropped QRS complex is not preceded by progressive PR interval prolongation. Usually, the QRS complex is wide (>0.12 sec).
- **2:1 or 3:1 (advanced) block** occurs when every second or third P wave conducts to the ventricles. This form of second-degree block is neither Mobitz I nor Mobitz II.

**Wenckebach AV block** in general is due to block in the AV node, whereas Mobitz II block signifies block at an infranodal level, such as the His bundle. The risk of progression to complete heart block is greater and reliability of the resultant escape rhythm is less with Mobitz II block. Therefore, pacing is usually indicated in Mobitz II block, whereas patients with Wenckebach AV block are usually monitored.

**Acute myocardial infarction** may produce second-degree heart block. In inferior myocardial infarction, close monitoring and transcutaneous temporary back-up pacing are all that is required. In anterior myocardial infarction, second-degree
Fig. 30.41 Three varieties of second-degree atrioventricular (AV) block. (A) Wenckebach (Mobitz type I) AV block. The PR interval gradually prolongs until the P wave does not conduct to the ventricles (arrowed). (B) Mobitz type II AV block. The P waves that do not conduct to the ventricles (arrowed) are not preceded by gradual PR interval prolongation. (C) Two P waves to each QRS complex. The PR interval prior to the dropped P wave is always the same. It is not possible to define this type of AV block as type I or type II Mobitz block and it is, therefore, a third variety of second-degree AV block (arrows show P waves).
Bradycardias and heart block

Heart block is associated with a high risk of progression to complete heart block, and temporary pacing followed by permanent pacemaker implantation is usually indicated. Block either in the AV node or at an infranodal level may cause 2:1 heart block. Management depends on the clinical setting in which it occurs.

**Third-degree (complete) AV block**

Complete heart block occurs when all atrial activity fails to conduct to the ventricles (Fig. 30.42). In patients with complete heart block, the aetiology needs to be established (Box 30.13). In this situation, life is maintained by a spontaneous escape rhythm.

A **narrow-complex escape rhythm** (<0.12 sec QRS complex) originates from the His bundle and therefore implies that the region of block lies more proximally in the AV node. The escape rhythm occurs with an adequate rate (50–60 b.p.m.) and is relatively reliable. Treatment depends on the aetiology. Recent-onset, narrow-complex AV block that has transient causes may respond to intravenous atropine but temporary pacing facilities should be available for the management of these patients. Chronic narrow-complex AV block requires permanent pacing (dual-chamber; see p. 1049) if it is symptomatic or associated with heart disease. Pacing is also advocated for isolated, congenital AV block, even if asymptomatic.

A **broad-complex escape rhythm** (>0.12 sec) implies that the escape rhythm originates below the His bundle and therefore that the region of block lies more distally in the His–Purkinje system. The resulting rhythm is slow (15–40 b.p.m.) and relatively unreliable. Dizziness and blackouts (Stokes–Adams attacks) often occur. In the elderly it is usually caused by degenerative fibrosis and calcification of the distal conduction system (Lev’s disease). In younger individuals a proximal progressive cardiac conduction disease due to an inflammatory process is known as Lenegre’s disease. Sodium channel abnormalities have been identified in both syndromes. Broad-complex AV block may also be caused by ischaemic heart disease, myocarditis or cardiomyopathy. Permanent pacemaker implantation (see p. 1049) is indicated, as pacing considerably reduces the mortality. Because ventricular arrhythmias are not uncommon, an implantable cardioverter–defibrillator (ICD) may be indicated in those with severe left ventricular dysfunction (>0.30 sec duration).

**Box 30.13 Causes of complete heart block**

- **Congenital**
  - Autoimmune (e.g. maternal SLE)
  - Structural heart disease (e.g. transposition of great vessels)
- **Idiopathic fibrosis**
  - Lev’s disease (progressive fibrosis of distal His–Purkinje system in elderly patients)
  - Lenegre’s disease (proximal His–Purkinje fibrosis in younger patients)
- **Ischaemic heart disease**
  - Acute myocardial infarct
  - Ischaemic cardiomyopathy
- **Non-ischaemic heart disease**
  - Calcific aortic stenosis
  - Idiopathic dilated cardiomyopathy
  - Infiltrations (e.g. amyloidosis, sarcoidosis, neoplasia)
- **Cardiac surgery**
  - e.g. Following aortic valve replacement, CABG, VSD repair
- **Iatrogenic**
  - Radiofrequency AV node ablation and pacemaker implantation
- **Drug-induced**
  - e.g. Digoxin, beta-blockers, non-dihydropyridine calcium-channel blockers, amiodarone
- **Infections**
  - Endocarditis
  - Lyme disease
  - Chagas’ disease
- **Autoimmune rheumatic disease**
  - e.g. SLE, rheumatoid arthritis
- **Neuromuscular diseases**
  - e.g. Duchenne muscular dystrophy

AV, atrioventricular; CABG, coronary artery bypass graft surgery; SLE, systemic lupus erythematosus; VSD, ventricular septal defect.

**Bundle branch block**

The His bundle gives rise to the right and left bundle branches. The left bundle subdivides into the anterior and posterior divisions of the left bundle. Various conduction disturbances can occur.
Bundle branch conduction delay
This produces slight widening of the QRS complex (up to 0.12 sec). It is known as incomplete bundle branch block.

Complete block of a bundle branch
This is associated with a wider QRS complex (≥0.12 sec). The shape of the QRS depends on whether the right or the left bundle is blocked.

Right bundle branch block (Fig. 30.43A) produces late activation of the right ventricle. This is seen as deep S waves in leads I and V6, and as a tall late R wave in lead V1 (late activation moving towards right-sided leads and away from left-sided leads).

Left bundle branch block (Fig. 30.44) produces the opposite: a deep S wave in lead V6 and a tall late R wave in leads I and V6. Because left bundle branch conduction is normally responsible for the initial ventricular activation, left bundle branch block also produces abnormal Q waves.

Hemiblock
Delay or block in the divisions of the left bundle branch produces a swing in the direction of depolarization (electrical axis) of the heart. When the anterior division is blocked (left anterior hemiblock), the left ventricle is activated from inferior to superior. This produces a superior and leftward movement of the axis (left axis deviation). Delay or block in the postero-inferior division swings the QRS axis inferiorly to the right (right axis deviation).

Bifascicular block
Bifascicular block (see Fig. 30.43B) is a combination of a block of any two of the following: the right bundle branch, the left antero-superior division and the left postero-inferior division. Block of the remaining fascicle will result in complete AV block.

Clinical features of heart blocks
Bundle branch blocks are usually asymptomatic. Right bundle branch block causes wide but physiological splitting of the second heart sound. Left bundle branch block may cause reverse splitting of the second sound. Patients with intraventricular conduction disturbances may complain of syncope. This is due to intermittent complete heart block or to ventricular tachyarrhythmias. ECG monitoring and electrophysiological studies are needed to determine the cause of syncope in these patients.
Aetiology
Right bundle branch block occurs as an isolated congenital anomaly, present in 5% of healthy individuals, or is associated with cardiac or pulmonary conditions. Conditions commonly associated with right bundle branch block include congenital cardiac disorders, such as atrial and ventricular septal defects, pulmonary stenosis and Fallot’s tetralogy, pulmonary embolism, pulmonary hypertension, myocardial infarction, fibrosis of conduction tissue and Chagas’ disease. Block in the right bundle alone does not tend to alter the electrical axis of the heart unless accompanied by right ventricular hypertrophy (RV overload) or coexistent fascicular block. The combination of right bundle branch block with left axis deviation is seen in patients with ostium primum atrial septal defects but more often signifies diffuse conduction tissue disease affecting the right bundle and the left anterior fascicle. Complete left bundle branch block is often associated with extensive left ventricular disease. The most common causes include aortic stenosis, hypertension, myocardial infarction and severe coronary disease, similar to the causes of complete heart block.

Supraventricular tachycardias (SVTs) arise from the atrium or the atrioventricular junction. Conduction is via the His–Purkinje system; therefore, the QRS shape during tachycardia is usually similar to that seen in the same patient during baseline rhythm. A classification of supraventricular tachycardia is given in Box 30.14. Some of these tachycardias are discussed in more detail in the sections that follow.

Atrioventricular junctional tachycardias
AV nodal re-entrant and AV re-entrant tachycardias are usually referred to as paroxysmal SVTs and are often seen in young patients with no or little structural heart disease, although congenital heart abnormalities can coexist in a small proportion of patients with these arrhythmias. The first presentation is commonly between ages 12 and 30, and the prevalence is approximately 2.5/1000. In these tachycardias the AV node is an essential component of the re-entry circuit.

Atrioventricular nodal re-entrant tachycardia
Atrioventricular nodal re-entrant tachycardia (AVNRT) is twice as common in women. Clinically, the tachycardia often strikes suddenly without obvious provocation, but exertion, emotional stress, coffee, tea and alcohol may aggravate or induce it. An attack may stop spontaneously or may continue indefinitely until medical intervention.

In AVNRT, there are two functionally and anatomically different pathways predominantly within the AV node: one is characterized by a short effective refractory period and slow conduction, and the other has a longer effective refractory period and conducts faster. In sinus rhythm the atrial impulse that depolarizes the ventricles usually conducts through the fast pathway. If the atrial impulse (e.g. an atrial premature beat) occurs early when the fast pathway is still refractory, the slow pathway takes over in propagating the atrial impulse to the ventricles. It then travels back through the fast pathway, which has already recovered its excitability, thus initiating the most common ‘slow–fast’, or typical, AVNRT.

Inappropriate sinus tachycardia
Inappropriate sinus tachycardia is a persistent increase in resting heart rate unrelated to, or out of proportion with, the level of physical or emotional stress. It is found predominantly in young women. Sinus tachycardia due to intrinsic sinus node abnormalities, such as enhanced automaticity, or abnormal autonomic regulation of the heart with excess sympathetic and reduced parasympathetic input, is extremely rare.

In general, sinus tachycardia is a secondary phenomenon and the underlying causes need to be actively investigated. Depending on the clinical setting, acute causes include exercise, emotion, pain, fever, infection, acute heart failure, acute pulmonary embolism and hypovolaemia. Chronic causes include pregnancy, anaemia, hyperthyroidism and catecholamine excess. The underlying cause should be found and treated, rather than treating the compensatory physiological response. If necessary, beta-blockers may be used to slow the sinus rate – in hyperthyroidism, for example (see Box 21.30); ivabradine, an If (pacemaker current) blocker, may be useful when beta-blockade cannot be tolerated.
The rhythm is recognized on ECG from normal regular QRS complexes, usually at a rate of 140–240/min (Fig. 30.45A). Sometimes, the QRS complexes will show typical bundle branch block. P waves either are not visible or are seen immediately before or after the QRS complex because of simultaneous atrial and ventricular activation. It is less common (5–10%) to observe a tachycardia when the atrial impulse conducts anterogradely through the fast pathway and returns through the slow pathway, producing a long RP′ interval (‘fast–slow’ or long RP′ tachycardia).

Atrioventricular re-entrant tachycardia
This large circuit comprises the AV node, the His bundle, the ventricle and an abnormal connection of myocardial fibres from the ventricle back to the atrium. It is called an accessory pathway or bypass tract and results from an incomplete separation of the atria and the ventricles during fetal development.

In contrast to AVNRT, atrioventricular re-entrant tachycardia (AVRT) is due to a macro re-entry circuit and each part of the circuit is activated sequentially. As a result, atrial activation occurs after ventricular activation and the P wave is usually seen clearly between the QRS and T waves (Fig. 30.45B).

Accessory pathways are most commonly situated on the left but may occur anywhere around the AV groove. The most common accessory pathways, known as Kent bundles, are in the free wall or septum. In about 10% of cases, multiple pathways occur. Mahaim fibres are atriofascicular or nodofascicular fibres that enter the ventricular myocardium in the region of the right bundle branch. Accessory pathways that conduct from the ventricles to the atria only are not visible on the surface ECG during sinus rhythm and are therefore ‘concealed’. Accessory pathways that conduct bidirectionally usually are manifest on the surface ECG. If the accessory pathway conducts from the atrium to the ventricle during sinus rhythm, the electrical impulse can conduct quickly over this abnormal connection to depolarize part of the ventricles abnormally (pre-excitation). A pre-excited ECG is characterized by a short PR interval and a wide QRS complex that begins as a slurred part known as the δ wave (Fig. 30.45C). Patients with a history of palpitations and a pre-excited ECG have a condition known as Wolff–Parkinson–White (WPW) syndrome.

During AVRT, the AV node and ventricles are activated normally (orthodromic AVRT), usually resulting in a narrow QRS complex.
Less commonly, the tachycardia circuit can be reversed, with activation of the ventricles via the accessory pathway, and atrial activation via retrograde conduction through the AV node (antidromic AVRT). This results in a broad-complex tachycardia. These patients are also prone to atrial fibrillation.

During atrial fibrillation, the ventricles may be depolarized by impulses travelling over both the abnormal and the normal pathways. This results in pre-excited atrial fibrillation, a characteristic tachycardia that is typified by irregularly irregular broad QRS complexes (Fig. 30.45D). If an accessory pathway has a short antegrade effective refractory period (<250 ms), it may conduct to the ventricles at an extremely high rate and may cause ventricular fibrillation. The incidence of sudden death is 0.15–0.39% per patient-year and it may be a first manifestation of the disease in younger individuals. Verapamil and digoxin may allow a higher rate of conduction over the abnormal pathway and precipitate ventricular fibrillation. Therefore, neither verapamil nor digoxin should be used to treat atrial fibrillation associated with the WPW syndrome.

Clinical features of AVNRT and AVRT

The leading symptom of most SVTs, in particular AVNRT and AVRT, is rapid regular palpitations, usually with abrupt onset and sudden termination, which can occur spontaneously or be precipitated by simple movements. A common feature is termination by Valsalva manoeuvres. In younger individuals with no structural heart disease the rapid heart rate can be the main pathological finding. Irregular palpitations may be due to atrial premature beats, atrial flutter with varying AV conduction block, atrial fibrillation or multifocal atrial tachycardia. In patients with depressed ventricular function, uncontrolled atrial fibrillation can reduce cardiac output and cause hypotension and congestive heart failure.

Other symptoms may include anxiety, dizziness, dyspnoea, neck pulsation, central chest pain and weakness. Polyuria may occur because of the release of atrial natriuretic peptide in response to increased atrial pressures during the tachycardia, especially during AVNRT and atrial fibrillation. Prominent jugular venous pulsations due to atrial contractions against closed AV valves may be observed during AVNRT.

Syncopa has been reported in 10–15% of patients, usually just after initiation of the arrhythmia or in association with a prolonged pause following its termination. It is more common if the person is standing. However, in older patients with concomitant heart disease, such as aortic stenosis, hypertrophic cardiomyopathy and cerebrovascular disease, significant hypotension and syncope may result from moderately fast ventricular rates.

Management of AVNRT and AVRT

Acute management

In an emergency, distinguishing between AVNRT and AVRT may be difficult but is usually not critical, as both tachycardias respond to the same treatment. Patients presenting with SVTs and haemodynamic instability (e.g. hypotension, pulmonary oedema) require emergency cardioversion. If the patient is haemodynamically stable, vagal manoeuvres, including right carotid massage (see Box 30.10), the Valsalva manoeuvre and facial immersion in cold water, can be successfully employed.

If physical manoeuvres have not been successful, intravenous adenosine (initially 6 mg by i.v. push, followed by 12 mg if needed) should be tried. Adenosine is a very short-acting (half-life <10 sec), naturally occurring purine nucleoside that causes complete heart block for a fraction of a second following intravenous administration. It is highly effective at terminating AVNRT and AVRT or unmasking underlying atrial activity, but rarely affects ventricular tachycardia. The side-effects of adenosine are very brief but may include chest pain, sense of impending doom, bronchospasm, flushing or heaviness of the limbs. Adenosine should be used with caution in patients with a history of asthma. An alternative treatment is verapamil 5–10 mg i.v. over 5–10 min or beta-blockers (esmolol, propranolol, metoprolol). Verapamil must not be given after beta-blockers or if the tachycardia presents with broad (>0.12 sec) QRS complexes.

Long-term management

Patients with suspected cardiac arrhythmias should always be referred to a cardiologist for electrophysiological evaluation and long-term management, as both pharmacological and non-pharmacological treatments, including ablation of an accessory pathway, are readily available. Verapamil, diltiazem and beta-blockers have proven efficacy in 60–80% of patients. Sodium-channel blockers (flecainide and propafenone), potassium repolarization current blockers (sotalol, dofetilide, azimilide) and the multichannel blocker amiodarone may also prevent the occurrence of tachycardia.

Refinement of catheter ablation techniques has rendered many AV junctional tachycardias entirely curable. Modification of the slow pathway is successful in 96% of patients with AVNRT, although a 1% risk of AV block is present. In AVRT, the target for catheter ablation is the accessory pathway(s). The success rate of ablation of a single accessory pathway is approximately 95%, with a recurrence rate of 5%, requiring a repeat procedure.

Atrial tachyarrhythmias

Atrial tachyarrhythmias, including atrial fibrillation, atrial flutter, atrial tachycardia and atrial ectopic beats, all arise from the atrial myocardium. They share similar aetiologies, of which the most commonly encountered in clinical practice are increasing age, myocardial infarction, hypertension, obesity, diabetes mellitus, hypertrophic cardiomyopathy, heart failure, valvular heart disease, myocarditis, pericarditis, cardiothoracic surgery, electrolyte imbalance, alcohol use, obstructive airway disease, chest infections and hyperthyroidism.

Atrial fibrillation

This is a common arrhythmia, occurring in 1–2% of the general population and 5–15% of patients over 75 years of age. It also occurs, particularly in a paroxysmal form, in younger patients. Any condition resulting in raised atrial pressure, increased atrial muscle mass, atrial fibrosis, or inflammation and infiltration of the atrium may cause atrial fibrillation.

Although rheumatic heart disease, alcohol intoxication and thyrotoxicosis are the ‘classic’ causes of atrial fibrillation, hypertension and heart failure are the most common causes in the developed world. Hyperthyroidism may provoke atrial fibrillation, sometimes as virtually the only feature of the disease, and thyroid function tests are mandatory in any patient with atrial fibrillation that is unaccounted for. Atrial fibrillation occurs in one-third of patients after cardiac surgery.

In some patients no cause can be found and this group is labelled as having ‘lone’ atrial fibrillation. The pathogenesis of ‘lone’, or ‘idiopathic’, atrial fibrillation is unknown but genetic predisposition or even specific genetically predetermined forms of the arrhythmia have been proposed. About 30–40% of patients with atrial fibrillation,
especially those who present at a young age, have at least one parent with the arrhythmia, and genes associated with the sodium channel, the potassium channel, gap junction proteins and right–left isomerism have been implicated. Gene defects linked to chromosomes 10, 6, 5 and 4 have been associated with familial atrial fibrillation.

Atrial fibrillation is maintained by continuous, rapid (300–600/min) activation of the atria by multiple meandering re-entry wavelets, often driven by rapidly depolarizing automatic foci, located predominantly within the pulmonary veins. The atria respond electrically at this rate but there is no coordinated mechanical action and only a proportion of the impulses are conducted to the ventricles. The ventricular response depends on the rate and regularity of atrial activity, particularly at the entry to the AV node, the refractory properties of the AV node itself, and the balance between sympathetic and parasympathetic tone.

**Clinical features**

Symptoms attributable to atrial fibrillation are highly variable. In some patients (about 30%) it is an incidental finding, while others attend hospital as an emergency with rapid palpitations, dyspnoea and/or chest pain following the onset of atrial fibrillation. Most patients with on-going atrial fibrillation experience some deterioration of exercise capacity or wellbeing, but this may be appreciated only once sinus rhythm is restored. When caused by rheumatic mitral stenosis, the onset of atrial fibrillation results in considerable worsening of cardiac failure.

The patient has an ‘irregularly irregular’ pulse, as opposed to a basically regular pulse with an occasional irregularity (e.g. extrasystoles) or recurring irregular patterns (e.g. Wenckebach block). The irregular nature of the pulse in atrial fibrillation is maintained during exercise.

The ECG shows fine oscillations of the baseline (so-called fibrillation or f waves) and no clear P waves (Fig. 30.46A). The QRS rhythm is rapid and irregular. Untreated, the ventricular rate is usually 120–180/min but it slows with treatment.

The clinical classification of atrial fibrillation includes:

- first detected – irrespective of duration or severity of symptoms
- paroxysmal – stops spontaneously within 7 days

![Twelve-lead ECGs showing atrial fibrillation and atrial flutter. (A) Atrial fibrillation. Note the absolute rhythm irregularity. The ECG shows fine oscillations of the baseline (so-called fibrillation or f waves) and no clear P waves. (B) Atrial flutter, showing regular sawtooth-like atrial flutter waves (F waves) between QRS complexes. The flutter frequency is 300/min. Every fourth flutter wave is transmitted to the ventricles and the ventricular rate is therefore 75/min.](image)
• persistent – continuous >7 days
• longstanding persistent – continuous >1 year
• permanent – continuous, with a joint decision between the patient and the physician to cease further attempts to regain sinus rhythm.

The classification is helpful in choosing between rhythm restoration and rate control. Atrial fibrillation may be asymptomatic and the ‘first detected episode’ should not necessarily be regarded as the true onset.

Management
Acute management
When atrial fibrillation is due to an acute precipitating event, such as alcohol toxicity, chest infection or hyperthyroidism, the provoking cause should be treated. Strategies for the acute management of atrial fibrillation are:

• **Ventricular rate control**, achieved by drugs that block the AV node (see later).
• **Cardioversion**, achieved electrically by DC shock (see p. 1048), or medically by intravenous infusion of an antiarrhythmic drug such as flecainide, propafenone, vernakalant or amiodarone. Cardioversion can also be achieved by giving an oral agent (flecainide or propafenone) previously tested in hospital and found to be safe in a particular patient (‘pill-in-pocket’ approach). The choice depends on:
  • how well the arrhythmia is tolerated (is cardioversion urgent?)
  • whether anticoagulation is required before considering elective cardioversion
  • whether spontaneous cardioversion is likely (previous history? reversible cause?).

Conversion to sinus rhythm can be achieved by electrical DC cardioversion in about 80% of patients. Biphasic waveform defibrillation is more effective than conventional (monophasic) defibrillation, and biphasic defibrillators are now standard. To minimize the risk of thromboembolism associated with cardioversion, patients are fully anticoagulated with warfarin (International Normalized Ratio (INR) 2.0–3.0) or with a direct acting oral anticoagulant agent (DOAC) for 3 weeks before cardioversion (unless atrial fibrillation is of less than 48 hours’ duration) and at least 4 weeks after the procedure. The patient is then assessed for the necessity for long-term anticoagulation based on their thromboembolic risk score (see later). If cardioversion is urgent and the patient is not on any anticoagulation, transoesophageal echocardiography is used to exclude the presence of atrial thrombus.

Long-term management
Two strategies are available:

• ‘rate control’ (AV nodal slowing agents **plus oral anticoagulation**)
• ‘rhythm control’ (antiarrhythmic drugs plus DC cardioversion **plus oral anticoagulation**).

Major randomized studies in patients predominantly over the age of 65 years (AFFIRM) or in patients with heart failure (AF-CHF) have shown that there is no net mortality or symptom benefit to be gained from one strategy compared with the other. Which strategy to adopt needs to be assessed for each individual patient. Factors to consider include the likelihood of maintaining sinus rhythm and the safety/tolerability of antiarrhythmic drugs in a particular patient.

Rhythm control
This is advocated for younger, symptomatic and physically active patients. **Recurrent paroxysms** may be prevented with oral medication. In general, patients with no significant heart disease can be treated with any class Ia, Ic or III antiarrhythmic drug, although it is recommended that amiodarone (because of its substantial extracardiac adverse effect profile) should be reserved until other drugs have failed. For patients with **heart failure or left ventricular hypertrophy** only amiodarone is recommended. Patients with **coronary artery disease** may be treated with sotalol or amiodarone. Patients with **paroxysmal atrial fibrillation** or with early **persistent atrial fibrillation** (little left atrial dilation) may be treated with left atrial ablation. The ectopic triggers for atrial fibrillation are generally found in the pulmonary veins, which can be isolated from the atria using radiofrequency or cryothermal energy. Occasionally, more extensive ablation within the left atrium is needed. These techniques are more successful than antiarrhythmic drugs and may represent a ‘cure’ in some patients. However, the procedure is invasive and carries some risk of serious complications such as stroke, and bleeding in about 2% of cases. In the long term, recurrence is not uncommon and an apparently successful ablation does not remove the obligation for appropriate anticoagulation. Ablation has not been shown to improve long-term cardiovascular outcome but it does successfully treat symptoms due to atrial fibrillation.

**Rate control**
As a primary strategy, this is appropriate in patients who:

• have the permanent form of the arrhythmia associated with symptoms that can be further improved by slowing heart rate, or are older than 65 years with recurrent atrial tachyarrhythmias (‘accepted’ atrial fibrillation)
• have persistent tachyarrhythmias and have failed cardioversion(s) and serial prophylactic antiarrhythmic drug therapy, and in whom the risk/benefit ratio from using specific antiarrhythmic agents is shifted towards increased risk.

Rate control is usually achieved with a combination of **digoxin**, **beta-blockers** or **non-dihydropyridine calcium-channel blockers** (verapamil or diltiazem). Digoxin monotherapy may be sufficient for elderly, non-ambulant patients. In younger patients the effect of catecholamines easily overwhelms the vagotonic effect of digoxin and additional AV nodal slowing agents are needed. The ventricular rate response is generally considered to be controlled if the resting heart rate is below 110 b.p.m. but stricter control, between 60 and 80 b.p.m. at rest and below 110 b.p.m. during moderate exercise, may be needed if symptoms persist. To assess the adequacy of rate control, an ECG rhythm strip may be sufficient in an elderly patient but ambulatory 24-hour Holter monitoring and an exercise stress test (treadmill) are needed in younger individuals. Older patients with poor rate control despite optimal medical therapy should be considered for AV node ablation and pacemaker implantation (**ablate and pace’ strategy**). These patients usually experience a marked symptomatic improvement but require life-long anticoagulation because of the on-going risk of thromboembolism.

**Anticoagulation**
A scoring system known as **CHA2DS2-VASc** is used (Box 30.15) as the first step in determining the need for anticoagulation.

Long-term prophylaxis against ischaemic stroke with oral anticoagulation must be balanced against the risk of haemorrhage. The HAS-BLED score is recommended by European, Canadian and UK (NICE) guidelines. A high HAS-BLED score identifies patients with a high risk of bleeding (Box 30.16 and Fig. 30.47), and where risk factors exist, attempts may be made to modify them for instance by controlling hypertension and minimising alcohol intake.
When oral anticoagulation is required, either warfarin (dose adjusted to maintain an INR between 2.0 and 3.0) or one of the direct oral anticoagulants (the DOACs) can be used. These latter agents fall into two classes: direct thrombin inhibitors (e.g. dabigatran) and oral direct factor Xa inhibitors (e.g. rivaroxaban and apixaban). DOACs specifically block a single step in the coagulation cascade, in contrast to warfarin, which blocks several vitamin K-dependent factors (II, VII, IX and X). In comparison with warfarin, the DOACs have a rapid onset of action, shorter half-life and fewer food and drug interactions, and do not require INR testing. Trial data have shown them to be equally effective as, and maybe safer than, warfarin. Antiplatelet agents should not be used to reduce stroke risk. Percutaneous left atrial appendage occlusion (LAAO) may be offered where anticoagulation is contraindicated or not tolerated.

**Atrial flutter**

Atrial flutter is often associated with atrial fibrillation and frequently requires a similar initial therapeutic approach. Atrial flutter is usually an organized atrial rhythm with an atrial rate typically between 250 and 350 b.p.m. Typical, or isthmus-dependent, atrial flutter involves a macro re-entrant right atrial circuit around the tricuspid annulus. The wavefront circulates down the lateral wall of the right atrium, through the Eustachian ridge between the tricuspid annulus and the inferior vena cava, and up the interatrial septum, giving rise to the most frequent pattern, referred to as counter-clockwise flutter. Re-entry can also occur in the opposite direction (clockwise or reverse flutter).

The ECG shows regular sawtooth-like atrial flutter waves (F waves) between QRS complexes (see Fig. 30.46B). In typical counter-clockwise atrial flutter the F waves are negative in the inferior leads and positive in leads V1 and V2. In clockwise atrial flutter the deflection of the F waves is the opposite. If F waves are not clearly visible, it is worth trying to reveal them by slowing AV conduction by carotid sinus massage or by administering AV nodal blocking drugs such as adenosine or verapamil.

Symptoms are largely related to the degree of AV block. Most often, every second flutter beat conducts, giving a ventricular rate of 150 b.p.m. Occasionally, every beat conducts, producing a heart rate of 300 b.p.m. More often, especially when patients are receiving treatment, AV conduction block reduces the heart rate to approximately 75 b.p.m.

**Management**

Management of a symptomatic acute paroxysm is by electrical cardioversion. Patients who have been in atrial flutter for more than 1–2 days should be treated in a similar manner to those with atrial fibrillation and anticoagulated for 3 weeks prior to cardioversion. Acute pharmacological cardioversion can be achieved using class...
lc (lecainide, propafenone) or certain class III antiarrhythmic agents (dofetilide, ibutilide; these have better efficacy than in atrial fibrillation but are not available in many countries).

Recurrent paroxysms may be prevented by class III antiarrhythmic agents (sotalol, amiodarone). AV nodal blocking agents may be used to control the ventricular rate if the arrhythmia persists. However, the treatment of choice for patients with recurrent atrial flutter is catheter ablation (see p. 1059), which permanently interrupts re-entry by creating a line of conduction block within the isthmus between the inferior vena cava and the tricuspid valve ring. This technique offers patients whose only arrhythmia is typical atrial flutter an almost certain chance of a cure, although the later occurrence of atrial fibrillation is not uncommon.

Atrial tachycardia

This is an uncommon arrhythmia. Its prevalence is believed to be less than 1% in patients with arrhythmias. It is usually associated with structural heart disease but in many cases it is referred to as idiopathic. Macro re-entrant tachycardia often occurs after surgery for congenital heart disease. Atrial tachycardia with block is often a result of digitalis poisoning.

The mechanisms of atrial tachycardia are attributed to enhanced automaticity, triggered activity or intra-atrial re-entry. Atrial re-entrant tachycardia is usually relatively slow (125–150 b.p.m.) and can be initiated and terminated by atrial premature beats. The PP intervals are regular. The PR interval depends on the rate of tachycardia and is longer than in sinus rhythm at the same rate.

Automatic atrial tachycardia usually presents with higher rates (125–250 b.p.m.) and is often characterized by a progressive increase in the atrial rate with onset of the tachycardia (“warm-up”) and progressive decrease prior to termination (“cool-down”). Atrial tachycardia is typically caused by a focus that is frequently located along the crista terminalis in the right atrium, adjacent to a pulmonary vein in the left atrium, or around one of the atrial appendages. Automatic atrial tachycardia may also present as an incessant variety leading to tachycardia-induced cardiomyopathy. Short runs of atrial tachycardia may provoke more sustained episodes of atrial fibrillation.

Carotid sinus massage may increase AV block during tachycardia, thereby facilitating the diagnosis, but does not usually terminate the arrhythmia. Management options include cardioversion, antiarrhythmic drug therapy to maintain sinus rhythm, AV nodal slowing agents to control rate and, in selected cases, radiofrequency catheter ablation.

Atrial ectopic beats

These often cause no symptoms, although they may be sensed as an irregularity or heaviness of the heart beat. On the ECG, they appear as early and abnormal P waves and are usually, but not always, followed by normal QRS complexes. Treatment is not normally required unless the ectopic beats provoke more significant arrhythmias, when beta-blockers may be effective.

VENTRICULAR TACHYARRHYTHMIAS

Ventricular tachyarrhythmias can be discussed under the following headings:

- life-threatening ventricular tachyarrhythmias (sustained ventricular tachycardia, ventricular fibrillation, torsades de pointes)
- normal heart ventricular tachycardia
- non-sustained ventricular tachycardia

Ventricular tachycardia is more likely than supraventricular tachycardia with bundle branch block where there is:

- a very broad QRS (>0.14 sec)
- atrioventricular dissociation
- a bifid, upright QRS with a taller first peak in V1
- a deep S wave in V5
- a concordant (same polarity) QRS direction in all chest leads (V1–V6)
- ventricular premature beats (ectopics).

Some of these conditions are cardiac channelopathies, congenital disorders caused by mutations that affect the function of cardiac ion channels and hence the electrical activity of the heart. They include Brugada’s syndrome, congenital long QT syndrome, short QT syndrome, catecholaminergic polymorphic ventricular tachycardia (CPVT) and idiopathic ventricular fibrillation.

Sustained ventricular tachycardia

Sustained ventricular tachycardia (>30 sec) often results in pre-syncope (dizziness), syncope, hypotension and cardiac arrest, although it may be remarkably well tolerated in some patients. Examination reveals a pulse rate typically between 120 and 220 b.p.m. Usually, there are clinical signs of atrioventricular dissociation (i.e. intermittent cannon ‘a’ waves in the neck and variable intensity of the first heart sound).

The ECG shows a rapid ventricular rhythm with broad (often ≥0.14 sec), abnormal QRS complexes. AV dissociation may result in visible P waves, which appear to march through the tachycardia, capture beats (an intermittent narrow QRS complex owing to normal ventricular activation via the AV node and conducting system) and fusion beats (intermediate between ventricular tachycardia beat and capture beat).

SVT with bundle branch block may resemble ventricular tachycardia on the ECG. However, if a broad-complex tachycardia is due to SVT with either right or left bundle branch block, the QRS morphology should resemble a typical right bundle branch block or left bundle branch block pattern (see Figs 30.43A and 30.44). Other ECG criteria to differentiate ventricular tachycardia from SVT with aberrancy are indicated in Box 30.17. Some 80% of all broad-complex tachycardias are due to ventricular tachycardia and the proportion is even higher in patients with structural heart disease. Therefore, in all cases of doubt, ventricular tachycardia should be diagnosed.

Management

Treatment may be urgent, depending on the haemodynamic situation. If the patient is haemodynamically compromised (e.g. hypotensive or pulmonary oedema), emergency DC cardioversion may be required. On the other hand, if the blood pressure and cardiac output are well maintained, intravenous therapy with beta-blockers (esmolol), class I drugs or amiodarone is usually used. DC cardioversion is necessary if medical therapy is unsuccessful.

Ventricular fibrillation

This involves very rapid and irregular ventricular activation with no mechanical effect. The patient is pulseless and becomes rapidly unconscious; respiration ceases (cardiac arrest). The ECG shows shapeless, rapid oscillations and there is no hint of organized complexes (Fig. 30.48). It is usually provoked by a ventricular ectopic
ventricular fibrillation rarely reverses spontaneously. The only effective treatment is electrical defibrillation. Basic and advanced cardiac life support is needed (see p. 1045).

If the attack of ventricular fibrillation occurs during the first day or two of an acute myocardial infarction, it is probable that prophylactic therapy will be unnecessary. If the ventricular fibrillation was not related to an acute infarction, the long-term risk of recurrent cardiac arrest and sudden death is high.

Survivors of these ventricular tachyarrhythmias are, in the absence of an identifiable reversible cause (e.g. acute myocardial infarction, severe metabolic disturbance), at high risk of sudden death. Implantable cardioverter–defibrillators are first-line therapy in the management of these patients (see p. 1068).

**Brugada’s syndrome**

This inheritable condition accounts for part of a group of patients with idiopathic ventricular fibrillation who have no evidence of causative structural cardiac disease. It is more common in young male adults and in South-east Asia. The diagnosis is made by identifying the classic ECG changes that may be present spontaneously or may be provoked by the administration of a class I antiarrhythmic (flecainide or ajmaline – principally used as a diagnostic agent in suspected Brugada patients): right bundle branch block with coved ST elevation in leads V₁–V₃ (Fig. 30.49). Atrial fibrillation may occur.

In 20% of cases, this is a monogenic inheritable condition associated with loss of sodium-channel function due to a mutation in the SCN5A gene. Recently, other mutations in the SCN1B gene, glycerol-3-phosphate dehydrogenase-1-like gene (GPD1L-type) and genes related to calcium-channel subunits CACNA1C and CACNB2 have also been implicated in the genesis of this syndrome. It can present with sudden death during sleep, resuscitated cardiac arrest and syncope, or the patient may be asymptomatic and diagnosed incidentally or during familial assessment. There is a high risk of sudden death, particularly in the symptomatic patient or those with spontaneous ECG changes. The only successful treatment is an ICD. Beta-blockade is not helpful and may be harmful.

**Long QT syndrome**

This describes an ECG where the ventricular repolarization (QT interval) is greatly prolonged. The causes of long QT syndrome are listed in Box 30.18.

**Congenital long QT syndrome**

Two major syndromes have been described, one that is (Jervell–Lange-Nielsen syndrome) and one that is not (Romano–Ward syndrome) associated with congenital deafness.

The molecular biology of the congenital long QT syndromes has been shown to be heterogeneous. It is usually a monogenic disorder and has been associated with mutations in cardiac potassium and
sodium-channel genes. The different genes involved appear to correlate with different phenotypes (Fig. 30.50A) that can exhibit such variable penetrance that carriers may have completely normal ECGs. To date, thirteen long QT (LQT) subtypes have been identified but three major ones account for the majority of cases. These are:

- **LQT1** (KCNQ1 gene mutation affecting the *I*\(_{\text{ks}}\)\(_{\alpha}\) subunit), in which the arrhythmia is usually provoked by exercise, particularly swimming
- **LQT2** (KCNH2 gene mutation affecting the *I*\(_{\text{kr}}\)\(_{\alpha}\) subunit), in which arrhythmia provocation is associated with emotion and acoustic stimuli
- **LQT3** (SCN5A gene mutation affecting the *I*\(_{\text{Na}}\)\(_{\alpha}\) subunit), in which the arrhythmias occur during rest or when asleep.

It is likely that identification of the mutation involved will not only improve diagnostic accuracy, particularly with cascade screening in affected families, but also guide future therapy for the congenital long QT syndrome.

**Acquired long QT syndrome**

QT prolongation and torsades de pointes are usually provoked by bradycardia.

**Clinical features**

Patients with a long QT develop syncope and palpitations as a result of polymorphic ventricular tachycardia (torsades de pointes). They usually terminate spontaneously but may degenerate to ventricular fibrillation, resulting in sudden death.

**Torsades de pointes** is characterized on the ECG by rapid, irregular, sharp complexes that continuously change from an upright to an inverted position (Fig. 30.50B).

Between spells of tachycardia, or immediately preceding the onset of tachycardia, the ECG shows a prolonged QT interval; the corrected QT (see Box 30.9) is usually over 0.50 sec.

**Management**

Acute (acquired) long QT syndrome is treated as follows:

- Any electrolyte disturbance is corrected.
- Causative drugs are stopped.
- The heart rate is maintained with atrial or ventricular pacing.
- Magnesium sulphate 8 mmol (Mg\(^{2+}\)) is given over 10–15 min for acquired long QT.
- Intravenous isoprenaline may be effective when QT prolongation is acquired (isoprenaline is contraindicated for congenital long QT syndrome).

**Long-term**, congenital long QT syndrome is generally treated by beta-blockade, pacemaker therapy and, occasionally, left cardiac sympathetic denervation. LQT1 patients seem to respond well to beta-blockade while LQT3 patients are better treated with sodium-channel blockers. All long QT patients should avoid drugs known to prolong the QT interval. Patients who remain symptomatic despite conventional therapy, and those with marked QT prolongation or a strong family history of sudden death, usually need ICD therapy.
Short QT syndrome

Five types have been described; they are caused by genetic abnormalities that lead to faster repolarization. Ventricular arrhythmias and sudden death may occur and an ICD is the best treatment.

Normal heart ventricular tachycardia

Monomorphic ventricular tachycardia in patients with structurally normal hearts (idiopathic ventricular tachycardia) is usually a benign condition with an excellent long-term prognosis. Occasionally, it is incessant (so called Gallavardin’s tachycardia) and, if untreated, may lead to cardiomyopathy.

Normal heart ventricular tachycardia arises from a focus in either the right ventricular outflow tract or the left ventricular septum. Treatment of symptoms is usually with beta-blockers. There is a special form of verapamil-sensitive tachycardia that responds well to non-dihydropyridine calcium antagonists. In symptomatic patients, radiofrequency catheter ablation is highly effective, resulting in a cure in over 90% of cases. It is sometimes difficult to distinguish arrhythmogenic right ventricular hypertrophy (see p. 1121) from this seemingly benign disorder.

Non-sustained ventricular tachycardia

Non-sustained ventricular tachycardia (NSVT) is defined as ventricular tachycardia that is 5 consecutive beats or more but lasts for less than 30 seconds (Fig. 30.51A). NSVT can be found in 6% of patients with normal hearts and usually does not require treatment. It is documented in up to 60–80% of patients with heart disease. There is insufficient evidence on prognosis but an ICD has been shown to improve survival of patients with particularly poor left ventricular function (ejection fraction ≤30%) by preventing arrhythmic death. Antiarrhythmic suppression of NSVT is not usually advocated but beta-blockers may improve quality of life in symptomatic individuals.

Ventricular premature beats (ectopics)

These may be uncomfortable, especially when frequent. The patient complains of extra beats, missed beats or heavy beats because it may be the premature beat, the post-ectopic pause or the next sinus beat that is noticed. The pulse is irregular owing to the premature beats. Some early beats may not be felt at the wrist. When a premature beat occurs regularly after every normal beat, ‘pulsus bigeminus’ may occur. If premature ventricular beats are highly symptomatic, treatment with beta-blockade may be helpful. If the ectopics are very frequent, left ventricular dysfunction may develop; if the ectopics stem from a single focus, especially when in the right ventricle, catheter ablation can be very effective.

These premature beats (Fig. 30.51B–D) have a broad (>0.12 sec) and bizarre QRS complex because they arise from an abnormal (ectopic) site in the ventricular myocardium. Following a premature beat, there is usually a complete compensatory pause because the AV node or ventricle is refractory to the next sinus impulse. Early ‘R-on-T’ ventricular premature beats (occurring simultaneously with the upstroke or peak of the T wave of the previous beat) may induce ventricular fibrillation in patients with heart disease, particularly following myocardial infarction.

Ventricular premature beats are usually treated only if symptomatic. Simple measures, such as reassurance and beta-blocker therapy, are normally all that is required.

Long-term management of cardiac tachyarrhythmias

Options for the long-term management of cardiac tachyarrhythmias include:

- antiarrhythmic drug therapy
- ablation therapy
- device therapy.

Antiarrhythmic drugs

Drugs that modify the rhythm and conduction of the heart are used to treat cardiac arrhythmias. Antiarrhythmic drugs may aggravate
or produce arrhythmias (proarrhythmia) and they may also depress ventricular contractility and must therefore be used with caution. They are classified according to their effect on the action potential (Vaughan Williams classification; Box 30.19 and Fig. 30.52).

Class I drugs
These are membrane-depressant drugs that reduce the rate of entry of sodium into the cell (sodium-channel blockers). They may slow conduction, delay recovery or reduce the spontaneous discharge rate of myocardial cells. Class I agents have been found to increase mortality compared to placebo in post-myocardial infarction patients with ventricular ectopy (Cardiac Arrhythmia Suppression Trial (CAST) trials – class Ic agents) and in patients treated for atrial fibrillation (class la agent, quinidine). In view of this, class Ic agents, such as flecaïnide, and all other class I drugs should be reserved for patients who do not have significant coronary artery disease, left ventricular dysfunction or other forms of significant structural heart disease.

Class II drugs
These antisympathetic drugs prevent the effects of catecholamines on the action potential. Most are β-adrenoceptor antagonists. Cardioselective beta-blockers (β₁) include metoprolol, bisoprolol, atenolol and acebutolol. Beta-blockers suppress AV node conduction, which may be effective in preventing attacks of junctional tachycardia, and may help to control the ventricular rate during paroxysms of other forms of SVT (e.g. atrial fibrillation). In general, beta-blockers are anti-ischaemic and anti-adrenergic, and have proven beneficial effects in patients post myocardial infarction (by preventing ventricular fibrillation) and in those with congestive heart failure. It is therefore advisable to use beta-blocker therapy either alone or in combination with other antiarrhythmic drugs in patients with symptomatic tachyarrhythmias, particularly those with coronary artery disease.

Class III drugs
These prolong the action potential, usually by blocking the rapid component of the delayed rectifier potassium current (Iₖ₉), and do not affect sodium transport through the membrane. The drugs in this class are amiodarone and sotalol. Sotalol is also a beta-blocker.
Sotalol may result in acquired long QT syndrome and torsades de pointes. The risk of torsades is increased in the setting of hypokalaemia, and particular care should be taken in patients taking diuretic therapy. Amiodarone therapy, in contrast to most other antiarrhythmic drugs, carries a low risk of proarrhythmia in patients with significant structural heart disease, but its use may be limited due to toxic and potentially serious side-effects. Dronedarone is a multichannel-blocking drug that suppresses the recurrence of atrial fibrillation and reduces hospital admissions in patients with cardiovascular risk. However, it has proven harmful in patients with left ventricular dysfunction and is contraindicated in heart failure.
Vernakalant is a multichannel blocker that is approved for the rapid intravenous medical cardioversion of new-onset atrial fibrillation.

Class IV drugs
The non-dihydropyridine calcium-channel blockers are particularly effective at slowing conduction in nodal tissue. These drugs can prevent attacks of junctional tachycardia (AVNRT and AVRT) and may help to control ventricular rates during paroxysms of other forms of SVT (e.g. atrial fibrillation).

Clinical use of antiarrhythmic drugs
Antiarrhythmic drugs have not been shown to prolong life. Patient safety is the main factor in determining the choice of antiarrhythmic therapy, and proarrhythmic risks need to be carefully assessed prior to initiating therapy. As a generalization, class Ic agents are employed in patients with structurally normal hearts, and class III agents are used in those with structural heart disease, although exceptions exist.
Patients with structurally normal hearts and normal QT intervals, or those with implantable defibrillators, either are at very low risk of proarrhythmia or are protected from any life-threatening consequences; in these individuals, it is possible to persevere with drug therapy.

Catheter ablation
Catheter ablation (radiofrequency or cryoablation) is frequently employed in the management of symptomatic tachyarrhythmias.
Ablations are performed percutaneously by placing electrode catheters into the heart chambers, usually via femoral vessels. Successful ablation depends on accurate identification of either the site of origin of a focal tachycardia or a critical component of a macro re-entry tachycardia. Catheter ablation has been found to be highly effective in the following tachyarrhythmias:

- AVNRT
- AVRT with an accessory pathway, including WPW syndrome
- normal heart ventricular tachycardia
- atrial flutter
- atrial tachycardia
- paroxysmal atrial fibrillation (pulmonary vein isolation).

Symptomatic patients with a pre-excited ECG because of accessory pathway conduction (WPW syndrome) are advised to undergo catheter ablation as first-line therapy, owing to the risk of sudden death associated with this condition. This is especially the case in patients with pre-excited atrial fibrillation. Patients with accessory pathways that only conduct retrogradely from the ventricles to the atrium are not at increased risk of sudden death but experience symptoms due to AVRT. These individuals are commonly offered an ablation procedure if simple measures, such as AV nodal slowing agents, fail to suppress tachycardia. Asymptomatic patients with the WPW ECG pattern are now frequently offered an ablation procedure for prophylactic reasons. The main risk associated with accessory pathway ablation is thromboembolism in patients with left-sided accessory pathways. The success rate for catheter ablation of AVNRT and accessory pathways is more than 95%.

Patients with normal hearts and documented ventricular tachycardia should be referred for specialist evaluation. Unlike VT in patients with structural heart disease, normal heart VT is not associated with increased risk of sudden death and is easily cured by catheter ablation.

Catheter ablation is recommended in patients with atrial flutter that is not easily managed medically. Ablation of typical flutter is effective in 90–95% of cases. In the direct comparison of catheter ablation and antiarrhythmic therapy the rate of recurrence was significantly lower following ablation. Atrial tachycardia, especially in patients with structurally normal hearts, may also be cured by catheter ablation. In atrial fibrillation, adequate control of ventricular rates is sometimes not possible, despite optimal medical therapy. These patients experience a marked symptomatic improvement following AV node ablation (which leads to complete heart block) and pacemaker implantation.

In younger patients with structurally normal hearts, atrial ectopic beats, which commonly arise from a focus situated in the pulmonary veins, may trigger atrial fibrillation. Catheter ablation of this ectopic focus includes the application of radiofrequency energy around the pulmonary veins in order to abolish the connection between the sleeves of arrhythmogenic atrial myocardium surrounding or extending into the veins from the atrium (pulmonary vein isolation). The trigger is therefore eliminated and the arrhythmia does not recur. These techniques appear to be highly effective, especially in young patients with paroxysmal atrial fibrillation, normal atrial size and no underlying heart disease (70–80% long-term success), but are presently time-consuming procedures (4 h or more) and carry a risk of serious complications such as stroke, pericardial haemorrhage, pulmonary vein stenosis and atrio-oesophageal fistula in a small minority of patients (in experienced centres <2% altogether).

**Implantable cardioverter–defibrillator**

Life-threatening ventricular arrhythmias (ventricular fibrillation or rapid ventricular tachycardia with hypotension) result in death in up to 40% within 1 year of diagnosis. Large multicentre prospective trials, such as the Antiarrhythmics (amiodarone) Versus Implantable Defibrillator (AVID) trial, have proven that implantable defibrillators improve overall survival in patients who have experienced an episode of life-threatening ventricular tachyarrhythmia.

The implantable cardioverter–defibrillator (ICD) recognizes ventricular tachycardia or fibrillation and automatically delivers pacing or a shock to the heart to cause cardioversion to sinus rhythm. Modern ICDs are only a little larger than a pacemaker and the generator is implanted in a pectoral position (Fig. 30.53), although in younger patients a subcutaneous device may be appropriate. The device may have leads to sense and pace both the right atrium and ventricle, and the lithium batteries employed are able to provide energy for over 100 shocks, each of around 30 J. ICD discharges are painful if the patient is conscious. However, ventricular tachycardia may often be terminated by overdrive pacing the heart, which is painless. The ICD is superior to all other treatment options at preventing sudden cardiac death. The use of this device has cut the sudden death rate in patients with a history of serious ventricular arrhythmias to approximately 2% per year. However, the majority of these people have significant structural heart disease and overall cardiac mortality due to progressive heart failure remains high. As a result, the ICD is now first-line therapy in the secondary prevention of sudden death.

ICDs are also employed in the primary prevention of sudden cardiac death. The chances of surviving an out-of-hospital cardiac arrest are as low as 10%. Therefore, selected patients who have never experienced a spontaneous episode of life-threatening ventricular tachyarrhythmia but who are assessed to be at high risk of sudden death are advised to undergo ICD implantation. In two large primary prevention ICD trials, Multicenter Automated Defibrillator Implantation Trial (MADIT II) and Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT), therapy with an ICD reduced mortality by 23–31% on top of conventional treatment, which included revascularization, beta-blockers and ACE inhibitors. ICD combined with cardiac resynchronization therapy may improve both symptoms and life expectancy of patients with any degree of heart failure (the COMPANION, CARE-HF and MADIT-CRT trials).

The following groups of patients may merit prophylactic ICD placement for primary prevention:

- Patients with heart failure with a left ventricular ejection fraction of 35% or less and NYHA functional class below IV (see Box 30.23). In such patients who also have left bundle branch block (QRS >120 ms), there is additional benefit in combining ICD with cardiac resynchronization therapy (CRT-D; see p. 1075).
- Those with a familial condition and high risk of sudden death, such as dilated and hypertrophic cardiomyopathy, long QT syndrome, Brugada’s syndrome or other channelopathies, who have a strong family history of sudden cardiac death and arrhythmogenic right ventricular dysplasia.

**Further reading**

Heart failure is a complex syndrome that can result from any structural or functional cardiac disorder that impairs the ability of the heart to function as a pump to support a physiological circulation. Worldwide, the incidence of heart failure is variable but increases with advancing age, with approximately 26 million people affected. In the UK, overall incidence is about 2 in 1000. The prognosis of heart failure has improved over the past 10 years with evidence-based therapy, but the mortality rate remains high and approximately 50% of patients are dead at 5 years. Heart failure is the leading cause of medical hospital admissions in over 65-year-olds and accounts for 5% of admissions to hospital medical wards. The cost of managing heart failure in the UK exceeds £1 billion per year. Coronary artery disease is the most common cause of heart failure in Western countries.

The causes of heart failure are shown in Box 30.20.

**Pathophysiology**

There are a number of changes affecting the heart and peripheral vascular system in response to the haemodynamic changes associated with heart failure (Box 30.21). These physiological changes are compensatory and maintain cardiac output and peripheral perfusion. However, as heart failure progresses, these mechanisms are overwhelmed and become pathological. The development of pathological peripheral vasoconstriction and sodium retention in heart failure by activation of the renin-angiotensin–aldosterone system entails a loss of beneficial compensatory mechanisms and represents cardiac decompensation. Factors involved are venous...
return, outflow resistance, contractility of the myocardium, and salt and water retention.

**Venous return (preload)**

In the intact heart, myocardial failure leads to a reduction of the volume of blood ejected with each heart beat and an increase in the volume of blood remaining after systole. This increased diastolic volume stretches the myocardial fibres and, as Starling’s law of the heart (see p. 1025) would suggest, myocardial contraction is restored. However, the failing myocardium results in depression of the ventricular function curve (cardiac output plotted against the ventricular diastolic volume) (see Fig. 10.8).

Mild myocardial depression is not associated with a reduction in cardiac output because it is maintained by an increase in venous pressure (and hence diastolic volume). However, the proportion of blood ejected with each heart beat (ejection fraction) is reduced early in heart failure. Sinus tachycardia also ensures that any reduction of stroke volume is compensated for by the increase in heart rate; cardiac output (stroke volume × heart rate) is therefore maintained.

When there is more severe myocardial dysfunction, cardiac output can be maintained only by a large increase in venous pressure and/or marked sinus tachycardia. The increased venous pressure contributes to the development of dyspnoea, owing to the accumulation of interstitial and alveolar fluid, and ascites with hepatic enlargement and dependent oedema from increased systemic venous pressure. However, the cardiac output at rest may not be much depressed, but myocardial and haemodynamic reserve is so compromised that a normal increase in cardiac output cannot be produced by exercise. In very severe heart failure the cardiac output at rest is depressed, despite high venous pressures. The inadequate cardiac output is redistributed to maintain perfusion of vital organs, such as the heart, brain and kidneys, at the expense of the skin and muscle.

**Outflow resistance (afterload)**

Outflow resistance (afterload) (see Fig. 30.5) is the load or resistance against which the ventricle contracts. It is formed by:
- pulmonary and systemic resistance
- physical characteristics of the vessel walls
- the volume of blood that is ejected.

An increase in afterload decreases the cardiac output, resulting in a further increase of end-diastolic volume and dilation of the ventricle, which further exacerbates the problem of afterload. This is expressed by Laplace’s law: the tension of the myocardium (T) is proportional to the intraventricular pressure (P) multiplied by the radius of the ventricular chamber (R) – that is, T = PR.

**Myocardial contractility (inotropic state)**

The state of the myocardium also influences performance. The sympathetic nervous system is activated in heart failure via baroreceptors as an early compensatory mechanism, which provides inotropic support and maintains cardiac output. Chronic sympathetic activation, however, has deleterious effects by further increasing neurohormonal activation and myocyte apoptosis. This is compensated by a downregulation of β-receptors. Increased contractility (positive inotropism) can result from increased sympathetic drive and this is a normal part of the Frank–Starling relationship (see Fig. 30.5). Conversely, myocardial depressants (e.g. hypoxia) decrease myocardial contractility (negative inotropism).

**Neurohormonal and sympathetic system activation: salt and water retention**

The increase in venous pressure that occurs when the ventricles fail leads to retention of salt and water, and their accumulation in the interstitium, producing many of the physical signs of heart failure. Reduced cardiac output also leads to diminished renal perfusion, activating the renin–angiotensin system and enhancing salt and water retention (see Fig. 36.6), which further increases venous pressure (Fig. 30.54). The retention of sodium is, in part, compensated by the action of circulating atrial natriuretic peptides and antidiuretic hormone (see p. 176).

**Myocardial remodelling in heart failure**

Left ventricular remodelling is a process of progressive alteration of ventricular size, shape and function owing to the influence of mechanical, neurohormonal and possibly genetic factors in several clinical conditions, including myocardial infarction, cardiomyopathy, hypertension and valvular heart disease. Its hallmarks include hypertrophy, loss of myocytes and increased interstitial fibrosis. Remodelling continues for months after the initial insult, and the eventual change in the shape of the ventricle becomes responsible for the impairment of overall function of the heart (Fig. 30.55A). In cardiomyopathy, the process of progressive ventricular dilation or hypertrophy takes place without ischaemic myocardial injury or infarction (Fig. 30.55B).

**Abnormal calcium homeostasis**

Calcium ion flux within myocytes plays a pivotal role in the regulation of contractile function. Excitation of the myocyte cell membrane...
Heart failure causes the rapid entry of calcium into myocytes from the extracellular space via calcium channels. This triggers the release of intracellular calcium from the sarcoplasmic reticulum and initiates contraction (see Fig. 30.3). Relaxation results from the uptake and storage of calcium by the sarcoplasmic reticulum (see Fig. 30.9), controlled by changes in nitric oxide. In heart failure, there is a prolongation of the calcium current in association with prolongation of contraction and relaxation.

Natriuretic peptides (ANP, BNP and CNP)
- **Atrial natriuretic peptide (ANP)** is released from atrial myocytes in response to stretch. ANP induces diuresis, natriuresis, vasodilation and suppression of the renin–angiotensin system. Levels of circulating ANP are increased in congestive cardiac failure and correlate with functional class, prognosis and haemodynamic state.
- **B-type natriuretic peptide (BNP)** is predominantly secreted by the ventricles in response to increased myocardial wall stress. N-terminal (NT)-proBNP is an inactive protein that is cleaved from proBNP to release BNP. Both BNP and NT-proBNP are increased in patients with heart failure, and levels correlate with ventricular wall stress and the severity of heart failure. BNP and NT-proBNP are good predictors of cardiovascular events and mortality, although monitoring levels are not routinely used to guide heart failure management.
- **C-type natriuretic peptide (CNP)**, which is limited to vascular endothelium and the central nervous system, has similar effects to those of ANP and BNP.

Antidiuretic hormone (vasopressin)
Antidiuretic hormone (ADH) is raised in severe chronic heart failure, particularly in patients on diuretic treatment. A high ADH concentration precipitates hyponatraemia, which is an ominous prognostic indicator.

Endothelial function in heart failure
The endothelium has a central role in the regulation of vasomotor tone. In patients with heart failure, endothelium-dependent vasodilation in peripheral blood vessels is impaired and may be one mechanism of exercise limitation. The cause of abnormal endothelial responsiveness relates to abnormal release of both nitric oxide and vasoconstrictor substances, such as endothelin (ET).

The activity of nitric oxide, a potent vasodilator, is blunted in heart failure. ET secretion from a variety of tissues is stimulated by many factors, including hypoxia, catecholamines and angiotensin II. The plasma concentration of ET is elevated in patients with heart failure, and levels correlate with the severity of haemodynamic disturbance.

ET has many actions that potentially contribute to the pathophysiology of heart failure: vasoconstriction, sympathetic stimulation, renin–angiotensin system activation and left ventricular hypertrophy. Acute intravenous administration of ET antagonists improves haemodynamic abnormalities in patients with congestive cardiac failure, and oral ET antagonists are being developed.

Antidiuretic hormone (vasopressin)
Antidiuretic hormone (ADH) is raised in severe chronic heart failure, particularly in patients on diuretic treatment. A high ADH concentration precipitates hyponatraemia, which is an ominous prognostic indicator.

Clinical syndromes of heart failure
There are many causes of heart failure (see Box 30.20) that can present suddenly, with acute heart failure (AHF), or more insidiously, with chronic heart failure (CHF). One common classification of heart failure uses the left ventricular ejection fraction (LVEF):

- **Heart failure with reduced ejection fraction (HFREF)** (ejection fraction <40%) is commonly caused by ischaemic heart disease but can also occur with valvular heart disease and hypertension. It is only in this group of patients that heart failure therapies have been demonstrated to have benefit with reduced morbidity and mortality.

- **Heart failure with preserved left ventricular ejection fraction (HFPEF)** is a syndrome consisting of symptoms and signs of heart failure with an ejection fraction of >50%. There is increased stiffness in the ventricular wall and decreased left ventricular
compliance, leading to impairment of diastolic ventricular filling and hence decreased cardiac output. Echocardiography may demonstrate an increase in left ventricular wall thickness, increased left atrial size and abnormal left ventricular relaxation with normal or near-normal left ventricular volume. **Diastolic heart failure** is more common in elderly hypertensive patients but may occur with primary cardiomyopathies (hypertrophic, restrictive, infiltrative). Those patients in the grey zone with an LVEF of 40–50% have recently been classified as having heart failure with mid-range ejection fraction (HFmrEF).

- **Right ventricular systolic dysfunction (RVSD)** may be secondary to chronic left-sided heart disease but can occur with primary and secondary pulmonary hypertension, right ventricular infarction, arrhythmogenic right ventricular cardiomyopathy and adult congenital heart disease.

### Clinical features of heart failure

The symptoms and signs of heart failure are shown in **Box 30.22**.

The NYHA classification of heart failure (Box 30.23) can be used to describe the symptoms of heart failure and limitation of exercise capacity, and is useful for assessing response to therapy.

### Diagnosis of heart failure

The diagnosis of heart failure should be based on a detailed history, clinical findings, natriuretic peptide levels and objective evidence of cardiac dysfunction using measures of left ventricular structure and function (usually echocardiography). The underlying cause of heart failure should be established in all patients (Box 30.24 and Fig. 30.56).

### Investigations in heart failure

- **Blood tests.** Full blood count, serum creatinine and electrolytes, liver biochemistry, cardiac enzymes (eg troponin) in acute heart failure, BNP or NT-proBNP, and thyroid function should be measured.
- **Chest X-ray.** Look for cardiomegaly, pulmonary congestion with upper lobe diversion, fluid in fissures, Kerley B lines and pulmonary oedema.

- **ECG.** Identify ischaemia, ventricular hypertrophy or arrhythmia.
- **Echocardiography.** Assess cardiac chamber dimension, systolic and diastolic function, regional wall motion abnormalities, valvular disease and cardiomyopathies.
- **Stress echocardiography.** Assess viability in dysfunctional myocardium – dobutamine identifies contractile reserve in stunned or hibernating myocardium.
- **Nuclear cardiology.** Radionuclide angiography (RNA) can quantify ventricular ejection fraction; SPECT or PET can demonstrate myocardial ischaemia and viability in dysfunctional myocardium.
- **Cardiac MRI (CMR).** Assess cardiac structure and function and viability in dysfunctional myocardium with the use of dobutamine for contractile reserve or with gadolinium for delayed enhancement (‘infarct imaging’).
- **Cardiac catheterization.** This technique is employed for the diagnosis of ischaemic heart failure (and suitability for revascularization) and for measurement of pulmonary artery pressure, left atrial (wedge) pressure, left ventricular end-diastolic pressure.

### Box 30.24 Diagnosis of heart failure (European Society of Cardiology guidelines)

**Diagnosis of HF-REF requires three conditions to be satisfied**

1. Symptoms typical of heart failure
2. Signs typical of heart failure
3. Reduced LV ejection fraction

**Diagnosis of HF-PEF requires four conditions to be satisfied**

1. Symptoms typical of heart failure
2. Signs typical of heart failure
3. Normal or only mildly reduced LV ejection fraction and LV not dilated
4. Relevant structural heart disease (LV hypertrophy/left atrial enlargement) and/or diastolic dysfunction

**HF-REF = heart failure and a reduced ejection fraction; HF-PEF = heart failure with ‘preserved’ ejection fraction; LV = left ventricular.**

![Fig. 30.56 Algorithm for the diagnosis of heart failure.](Based on the European Society of Cardiology and NICE guidelines.)
The clinical condition of a person with heart failure fluctuates; lengthy and repeated hospital admissions are common, with an average inpatient stay of between 5 and 10 days. Monitoring of clinical status is necessary and this responsibility should be shared between primary and secondary healthcare professionals.

Essential monitoring includes assessment of:
- functional capacity (e.g. NYHA functional class, exercise tolerance test, echocardiography)
- fluid status (body weight, clinical assessment, and serum creatinine and electrolytes)
- cardiac rhythm (ECG, Holter monitoring).

Management of heart failure

Management is aimed at relief of symptoms, prevention and control of disease leading to cardiac dysfunction and heart failure, retarding of disease progression, and improvement in quality and length of life.

Measures to prevent heart failure include cessation of smoking, alcohol and illicit drugs, effective treatment of hypertension, diabetes and hypercholesterolaemia, and pharmacological therapy following myocardial infarction.

The management of heart failure requires any factor aggravating the failure to be identified and treated. Similarly, the cause of heart failure must be elucidated and, where possible, corrected. Community nursing programmes to help with drug compliance and detect early deterioration may prevent acute hospitalization.

General lifestyle advice

- **Education.** Effective counselling of patients and family, emphasizing weight monitoring and dose adjustment of diuretics, may prevent hospitalization. This is usually guided by primary care physicians and specialist community heart failure nurses.
- **Dietary modification.** Salt restriction is required, and foods rich in salt or salt added in cooking and at the table should be avoided. In severe heart failure, fluid restriction is necessary and patients may need to weigh themselves daily. Alcohol has a negative inotropic effect and heart failure patients should moderate consumption.
- **Smoking.** Smoking should be stopped with help from anti-smoking clinics if necessary (see p. 963).
- **Physical activity, exercise training and rehabilitation.** Low-level endurance exercise (e.g. 20–30 min walking 3–5 times per week or 20 min cycling at 70–80% of peak heart rate 5 times per week) is actively encouraged in patients with compensated heart failure in order to reverse ‘deconditioning’ of peripheral muscle metabolism. Strenuous isometric activity should be avoided. For hospitalized patients with exacerbations of congestive cardiac failure, limiting activity reduces the demands on the heart. Prolonged bed rest may, lead to the development of deep vein thrombosis (DVT); this can be avoided by daily leg exercises, low-dose subcutaneous heparin and elastic support stockings.
- **Vaccination.** It is recommended that patients with heart failure be vaccinated against pneumococcal disease and influenza (see p. 948).
- **Sexual activity.** Patients taking nitrate medication should not take concomitant phosphodiesterase type 5 inhibitors (e.g. sildenafil), as they may induce profound hypotension.
- **Driving.** Driving of cars and motorcycles may continue, provided that there are no symptoms that distract the driver’s attention. Symptomatic heart failure or an LVEF of less than 40% disqualifies patients from driving large lorries and buses in the UK.

Monitoring

The clinical condition of a person with heart failure fluctuates; lengthy and repeated hospital admissions are common, with an average inpatient stay of between 5 and 10 days. Monitoring of clinical status is necessary and this responsibility should be shared between primary and secondary healthcare professionals.

Essential monitoring includes assessment of:
- functional capacity (e.g. NYHA functional class, exercise tolerance test, echocardiography)
- fluid status (body weight, clinical assessment, and serum creatinine and electrolytes)
- cardiac rhythm (ECG, Holter monitoring).

Multidisciplinary team approach

Heart failure care should be delivered by a multidisciplinary team with an integrated approach across the healthcare community. The team should involve specialist healthcare professionals: cardiologist or physician with a specialist interest in heart failure, heart failure nurse, dietician, pharmacist, occupational therapist, physiotherapist and palliative care adviser. Understanding the information needs of patients and carers is vital. Good communication is essential for best clinical management, and should include advice on anxiety, depression and ‘end-of-life’ issues.

Drug management

Box 30.25 lists the drugs used in heart failure. Fig. 30.57 shows the stages of heart failure and the treatment options.

Diuretics

These act by promoting the renal excretion of salt and water by blocking tubular reabsorption of sodium and chloride (see p. 178). Loop diuretics (e.g. furosemide and bumetanide) and thiazide diuretics (e.g. bendroflumethiazide, hydrochlorothiazide) should be given in patients with fluid overload. Although diuretics provide symptomatic relief of dyspnoea and improve exercise tolerance, there is limited evidence that they affect survival. In severe heart failure patients, the combination of a loop and thiazide diuretic may be required, including the use of metolazone. Serum electrolytes and renal function must be monitored regularly (risk of hypokalaemia and hypomagnesaemia).

Angiotensin-converting enzyme inhibitors

The use of ACE inhibitors in patients with heart failure has been demonstrated in multiple large randomized controlled trials (CONSENSUS, SOLVD) to improve symptoms and reduce mortality significantly. ACE inhibitors also benefit patients with asymptomatic heart failure following myocardial infarction. Thus, ACE inhibitors improve survival in patients in all functional classes (NYHA I–IV) and are recommended in all patients at risk of developing heart failure. The main adverse effects of ACE inhibitors are cough, hypotension, hyperkalaemia and renal dysfunction. Contraindications to their use include renal artery stenosis, pregnancy and previous angioedema. In patients with heart failure, ACE inhibitors should be introduced at a low initial dose and gradually titrated, with regular monitoring of blood pressure and renal function.

Angiotensin II receptor antagonists

The angiotensin II receptor antagonists (ARAs; candesartan, losartan, valsartan) are indicated as second-line therapy in patients intolerant of ACE inhibitors. Unlike ACE inhibitors, they do not affect bradykinin metabolism and do not produce a cough. The CHARM Alternative Trial showed that candesartan reduced the risk of heart failure hospitalization compared to placebo in patients intolerant of ACE inhibitors. Other trials (Val-HeFT and ELITE II) have assessed other ARAs. Valsartan and a neprolysin inhibitor, sacubitril, in combination have demonstrated their promise in the treatment of heart failure.

</table>

ACE, angiotensin-converting enzyme; ARA, angiotensin II receptor antagonist; AV, atrioventricular.

**Beta-blockers**

Beta-blockers have been shown to improve functional status and reduce cardiovascular morbidity and mortality in patients with heart failure. Several trials (CIBIS, CIBIS II, MERIT-HF, COMET) have assessed the effects of beta-blockers in varying degrees of heart failure. Bisoprolol and carvedilol reduce mortality in any grade of heart failure. Nebivolol is used in the treatment of stable mild to moderate heart failure in patients over 70 years old. In patients with significant heart failure beta-blockers are started at a low dose and gradually increased, with monitoring of heart rate and blood pressure.

**Aldosterone antagonists**

The aldosterone antagonists spironolactone and eplerenone have been shown to improve survival in patients with heart failure. In the RALES study, spironolactone reduced total mortality by 30% in severe heart failure. However, gynaecomastia or breast pain occurred in 1 in 10 men taking spironolactone. In EPHESUS, eplerenone given to patients with an acute myocardial infarction and heart failure reduced total mortality by 15% and sudden cardiac death by 21%, with no gynaecomastia.

**Angiotensin receptor neprilysin inhibitor**

Angiotensin receptor neprilysin inhibitors (ARNIs) are a new class of drug that produce dual inhibition of the angiotensin (AT₁) receptor and the natriuretic system. The PARADIGM-HF trial studied sacubitril/valsartan in patients with established symptomatic heart failure and reduced ejection fraction, and demonstrated superiority over ACE inhibitor therapy in lowering morbidity and mortality.
Cardiac glycosides
Digoxin is a cardiac glycoside that is indicated in patients in atrial fibrillation with heart failure. It is infrequently used as add-on therapy in symptomatic heart failure patients already receiving ACE inhibitors and beta-blockers. Although the DIG study demonstrated that digoxin reduced hospital admissions in patients with heart failure, a subanalysis in the ROCKET AF trial suggested that mortality may, in fact, be increased.

Vasodilators and nitrates
The combination of hydralazine and nitrates reduces preload and afterload, and is used in patients intolerant of ACE inhibitors or ARAs. The Veterans Administration Cooperative Study demonstrated that it improved survival in patients with chronic heart failure. The A-HeFT trial showed that the same combination reduced mortality and hospitalization for heart failure in black patients with heart failure.

Inotropic and vasopressor agents
Intravenous inotropes and vasopressor agents (see Box 30.29) are used in patients with acute heart failure and severe haemodynamic compromise. Although they produce haemodynamic improvements, they have not been shown to improve long-term mortality when compared with placebo.

Other medications
In hospital, all patients require prophylactic anticoagulation. Heart failure is associated with a fourfold increase in the risk of stroke. Oral anticoagulants are recommended in patients with atrial fibrillation and in those with sinus rhythm and a history of thromboembolism, left ventricular aneurysm or thrombus. In people with known ischaemic heart disease, antiplatelet therapy (aspirin, clopidogrel) and statin therapy should be continued. Arrhythmias are common in heart failure and are implicated in sudden death. Although treatment of complex ventricular arrhythmias might be expected to improve survival, there is no evidence to support this and it may increase mortality. In SCD-HeFT, amiodarone showed no benefit compared to placebo in patients with impaired left ventricular function and mild to moderate heart failure (whereas an ICD reduced mortality by 23% compared to placebo). Patients with heart failure and symptomatic ventricular arrhythmias should be assessed for suitability for an ICD.

Ivabradine selectively decreases heart rate without affecting blood pressure by inhibiting the If channels in the sinoatrial node (see p. 1023). An elevated heart rate in patients with heart failure is associated with worse cardiovascular outcomes. The SHIFT study reported a reduction in cardiovascular death and heart failure hospitalization in patients in sinus rhythm with chronic heart failure and left ventricular dysfunction (LVEF ≤35%). Ivabradine can be used in patients in sinus rhythm with an elevated heart rate despite beta-blocker treatment or in those who are unable to tolerate beta-blockers.

Non-pharmacological treatment
Revascularization
While coronary artery disease is the most common cause of heart failure, the role of revascularization in patients with heart failure is unclear. Patients with angina and left ventricular dysfunction have a higher mortality from surgery (10–20%), but have the most to gain in terms of improved symptoms and prognosis. Factors that must be considered before recommending surgery include symptoms, age, co-morbidities and evidence of reversible myocardial ischaemia.

Hibernating myocardium and myocardial stunning
‘Hibernating’ myocardium can be defined as reversible left ventricular dysfunction due to chronic coronary artery disease that responds positively to inotropic stress and indicates the presence of viable heart muscle that may recover after revascularization. It is caused by reduced myocardial perfusion, which is just sufficient to maintain viability of the heart muscle. Myocardial hibernation results from repetitive episodes of cardiac stunning that occur, for example, with repeated exercise in a patient with coronary artery disease.

Myocardial stunning is reversible ventricular dysfunction that persists following an episode of ischaemia when the blood flow has returned to normal: that is, there is a mismatch between flow and function.
Some patients develop a ‘stiff heart’ syndrome, caused by rejection, results in a high resting heart rate, loss of diurnal blood pressure for the majority. The availability of heart transplantation is limited. 5 years. Irrespective of survival, quality of life is dramatically improved survival for patients following transplantation is over 90%, and 75% at less than 6 months. With careful recipient selection the expected 1-year patients with severe intractable heart failure, whose life expectancy is Cardiac transplantation has become the treatment of choice for younger (CRT-D). Patients with end-stage heart failure (NYHA IV) or other criteria for use of an ICD and should receive a combined device in more recent trials in patients with mild heart failure or no symptoms. Cardioverter–defibrillator (ICD). Heart allografts do not function normally, as cardiac denervation and ischaemic injury during organ harvest and implantation. Transplantation of an inappropriately small donor heart can also result in elevated right and left heart pressure. The complications of heart transplantation are summarized in Box 30.26. Many (infection, malignancy, hypertension and hyperlipidaemia) are related to immunosuppression. Allograft coronary atherosclerosis is the major cause of long-term graft failure and is present in 30–50% of patients at 5 years. It is due to a ‘vascular’ rejection process in conjunction with hypertension and hyperlipidaemia. There are specific contraindications to cardiac transplantation (Box 30.27); notably, high pulmonary vascular resistance and active malignancy are absolute contraindications. Acute heart failure Acute heart failure (AHF) occurs with the rapid onset of symptoms and signs of heart failure secondary to abnormal cardiac function, causing elevated cardiac filling pressures. This leads to severe dyspnoea, and fluid accumulates in the interstitium and alveolar spaces of the lung (pulmonary oedema). AHF is the leading cause of hospital admission in people above the age of 65 years; it has a poor prognosis, with a 60-day mortality rate of nearly 10% and a rate of death or rehospitalization of 35% within 60 days. In patients with acute pulmonary oedema, the in-hospital mortality rate is 12% and by 12 months this rises to 30%. Poor prognostic indicators include a high (>16 mmHg) pulmonary capillary wedge pressure, low serum sodium concentration, increased left ventricular end-diastolic dimension on echo and low oxygen consumption. The aetiology of AHF is similar to that of chronic heart failure: Ischaemic heart disease patients present with an acute coronary syndrome or develop a complication of myocardial infarction, such as papillary muscle rupture or ventricular septal defect requiring surgical intervention. Valvular heart disease patients also present with AHF due to valvular regurgitation in endocarditis or prosthetic valve thrombosis. A thoracic aortic dissection may produce severe aortic regurgitation. Hypertension patients present with episodes of ‘flash’ pulmonary oedema despite preserved left ventricular systolic function. Acute and chronic kidney disease both involve fluid overload and reduced renal excretion, which will produce pulmonary oedema. Atrial fibrillation is frequently associated with AHF and may require emergency cardioversion. Several clinical syndromes of AHF can be defined (Box 30.28). In a clinical environment, both the Killip score (based on a

**Cardiac resynchronization therapy or implantable cardioverter–defibrillator**

Cardiac resynchronization therapy (CRT) entails simultaneous pacing of both ventricles (biventricular pacing) using a lead placed in the right ventricle and another in the coronary sinus to pace the left ventricle (Fig. 30.58). It is an effective therapy in addition to optimal medical treatment in patients with significant left ventricular impairment and a prolonged QRS interval (left bundle branch block). Resynchronization may reverse the process of ventricular remodelling, reduce functional mitral regurgitation and improve left ventricular function. The CARE-HF and COMPANION trials reported symptomatic benefit and a reduction in heart failure events and mortality following CRT implantation in patients with heart failure in NYHA classes III and IV. Similar findings have been noted in more recent trials in patients with mild heart failure or no symptoms. Most patients with heart failure who receive CRT also meet the criteria for use of an ICD and should receive a combined device (CRT-D). Patients with end-stage heart failure (NYHA IV) or other co-morbidities that may significantly reduce lifespan are generally not candidates for an ICD.

**Cardiac transplantation**

Cardiac transplantation has become the treatment of choice for younger patients with severe intractable heart failure, whose life expectancy is less than 6 months. With careful recipient selection the expected 1-year survival for patients following transplantation is over 90%, and 75% at 5 years. Irrespective of survival, quality of life is dramatically improved for the majority. The availability of heart transplantation is limited. Heart allografts do not function normally, as cardiac denervation results in a high resting heart rate, loss of diurnal blood pressure variation and impaired renin–angiotensin–aldosterone regulation. Some patients develop a ‘stiff heart’ syndrome, caused by rejection,
cardiorespiratory clinical assessment, see p. 1090) and Forrester classification (based on right catheterization findings) provide therapeutic and prognostic information.

**Pathophysiology**

The pathophysiology of AHF is similar to that of chronic heart failure with activation of the renin–angiotensin–aldosterone axis and sympathetic nervous system. In addition, prolonged ischaemia (e.g. in acute coronary syndromes) results in myocardial stunning (see p. 1075), which exacerbates myocardial dysfunction but may respond to inotropic support. If myocardial ischaemia persists, the myocardium may exhibit hibernation (persistently impaired function due to reduced coronary blood flow), which may recover with successful revascularization.

**Diagnosis**

In a person presenting with symptoms and signs of heart failure, a structured assessment should result in the clinical diagnosis of AHF and direct initial treatment to stabilize the patient. Initial investigations performed in the accident and emergency department should include the following:

- **A 12-lead ECG** will identify acute coronary syndromes, left ventricular hypertrophy, atrial fibrillation, valvular heart disease and left bundle branch block.
- **A chest X-ray** may demonstrate cardiomegaly, pulmonary oedema, pleural effusions or non-cardiac disease.
- **Blood investigations** should include serum creatinine and electrolytes, full blood count, blood glucose, cardiac enzymes and troponin, C-reactive protein (CRP) and D-dimer.
- **Plasma BNP or NT-proBNP** (BNP >100 pg/mL or NT-proBNP >300 pg/mL) is suggestive of heart failure.
- **TTE** should be performed without delay to confirm the diagnosis of heart failure (see p. 1038) and possibly identify the cause.

If the baseline investigations confirm AHF, then treatment should be commenced.

**Management**

The goals of treatment in a patient with AHF include:

- immediate relief of symptoms and stabilization of haemodynamics (short-term benefits)
- reduction in length of hospital stay and hospital re-admissions
- reduction in mortality from heart failure.

Patients with AHF should be managed in a high-dependency area with regular measurement of temperature, heart rate, blood pressure and cardiac monitoring. All require prophylactic anticoagulation with low-molecular-weight heparin.

Individuals with haemodynamic compromise may need arterial lines for invasive blood pressure monitoring and arterial gas sampling, central venous cannulation (intravenous medication, inotropic support, monitoring of central venous pressure) and pulmonary artery catheterisation (calculation of cardiac output/index, peripheral vasoconstriction and pulmonary wedge pressure).

Initial therapy (Fig. 30.59 and Box 30.29) includes oxygen and diuretics (e.g. i.v. furosemide 50mg). If intravenous nitrates (e.g. glyceryl trinitrate infusion 10–200 μg/min) are required (e.g. concomitant myocardial ischaemia, severe hypertension), careful monitoring...
of the blood pressure is mandatory. Inotropic support (see p. 222) with dobutamine, phosphodiesterase inhibitors or levosimendan can be added in patients who do not respond to initial therapy.

Nesiritide (recombinant human B-type natriuretic peptide) can also be used in AHF as a bolus injection followed by an infusion. Patients with profound hypotension may require inotropes and vasopressors to improve haemodynamic status and alleviate symptoms but these have not been shown to improve mortality.

Non-invasive continuous positive airway pressure/positive pressure ventilation (CPAP/NIPPV; see p. 229) has been shown to provide earlier improvement in dyspnoea and respiratory distress than standard oxygen via mask; mortality is, however, unaffected.

**Mechanical assist devices**

Mechanical assist devices can be used in patients who fail to respond to standard medical therapy but in whom there is either
Coronary blood flow to a region of the myocardium may be reduced by a mechanical obstruction that is due to:
- atheroma
- thrombosis
- spasm
- embolus
- coronary ostial stenosis
- coronary arteritis (e.g. in systemic lupus erythematosus).

There can be a decrease in the flow of oxygenated blood to the myocardium that is due to:
- anaemia
- carboxyhaemoglobinaemia
- hypotension, causing decreased coronary perfusion pressure.

A higher demand for oxygen may occur owing to an increase in cardiac output (e.g. thyrotoxicosis) or myocardial hypertrophy (e.g. from aortic stenosis or hypertension).

Myocardial ischaemia most commonly arises as a result of obstructive coronary artery disease (CAD) in the form of coronary atherosclerosis. In addition to this fixed obstruction, variations in the tone of smooth muscle in the wall of a coronary artery may add another element of dynamic or variable obstruction.

CAD is the largest single cause of death in the UK and many parts of the world. In 2010, cardiovascular diseases were the UK’s biggest killer, accounting for nearly 180,000 deaths. CAD was responsible for 1 in 5 male deaths and 1 in 10 female deaths (approximately 80,000 deaths). Sudden cardiac death is a prominent feature of CAD, 1 in every 6 coronary attacks presenting with sudden death as the first, last and only symptom.

Pathophysiology of coronary atherosclerosis

Coronary atherosclerosis is a complex inflammatory process characterized by the accumulation of lipid, macrophages and smooth muscle cells in intimal plaques in the large and medium-sized epicardial coronary arteries. The vascular endothelium plays a critical role in maintaining vascular integrity and homeostasis. Mechanical shear stresses (e.g. from morbid hypertension), biochemical abnormalities (e.g. elevated low-density lipoprotein (LDL), diabetes mellitus), immunological factors (e.g., free radicals from smoking), inflammation and genetic alteration may contribute to the initial endothelial ‘injury’ or dysfunction, which is believed to trigger atherogenesis.

The development of atherosclerosis follows endothelial dysfunction, with increased permeability to and accumulation of oxidized lipoproteins, which are taken up by macrophages at focal sites within the endothelium to produce lipid-laden foam cells. Macroscopically, these lesions are seen as flat yellow dots or lines on the endothelium of the artery and are known as ‘fatty streaks’. The ‘fatty streak’ progresses with the appearance of extracellular lipid within the endothelium (transitional plaque). Release of cytokines, such as platelet-derived growth factor and transforming growth factor beta (TGF-β), by monocytes, macrophages or the damaged endothelium promotes further accumulation of macrophages, as well as smooth muscle cell migration and proliferation. The proliferation of smooth muscle with the formation of a layer of cells covering the extracellular lipid separates it from the adaptive smooth muscle thickening in the endothelium. Collagen is produced in larger and larger quantities by the smooth muscle and the whole sequence of events cumulates as an ‘advanced or raised fibrolipid plaque’. The ‘advanced plaque’ may grow slowly and encroach on the lumen, or become unstable, undergo thrombosis and produce an obstruction (complicated plaque).

Two different mechanisms are responsible for thrombosis on the plaques (Fig. 30.61):
The first process is superficial endothelial injury, which involves denudation of the endothelial covering over the plaque. Subendothelial connective tissue matrix is then exposed and platelet adhesion occurs because of reaction with collagen. The thrombus is adherent to the surface of the plaque.

The second process is deep endothelial fissuring, which involves an advanced plaque with a lipid core. The plaque cap tears (ulcerates, fissures or ruptures), allowing blood from the lumen to enter the inside of the plaque itself. The core with lamellar lipid surfaces, tissue factor (which triggers platelet adhesion and activation) produced by macrophages and exposed collagen is highly thrombogenic. Thrombus forms within the plaque, expanding its volume and distorting its shape. Thrombosis may then extend into the lumen.

A 50% reduction in luminal diameter (producing a reduction in luminal cross-sectional area of approximately 70%) causes a haemodynamically significant stenosis. At this point, the smaller distal intramyocardial arteries and arterioles are maximally dilated (coronary flow reserve is near zero), and any increase in myocardial oxygen demand provokes ischaemia.

CAD gives rise to a wide variety of clinical presentations, ranging from relatively stable angina through to the acute coronary syndromes of unstable angina and myocardial infarction (Fig. 30.62). Fig. 30.63 shows a plaque rupture.

Risk factors for coronary artery disease

CAD is an atherosclerotic disease that is multifactorial in origin, giving rise to the risk factor concept. Certain living habits promote atherogenic traits in genetically susceptible persons. A number of ‘risk’ factors are known to predispose to the condition (Box 30.30). Some of these, such as age, gender, race and family history, cannot be modified, whereas other major risk factors, such as serum cholesterol, smoking habits, diabetes and hypertension, can.

Atherosclerotic disease manifest in one vascular bed is often advanced in other territories. Patients with peripheral vascular disease (intermittent claudication) have a two- to fourfold increased risk of CAD, stroke or heart failure. Following initial myocardial infarction (MI), there is a three- to sixfold increase in the risk of heart failure and stroke. After stroke, the risk of heart failure and MI is increased twofold.

The disease can be asymptomatic in its most severe form, with 1 in 3 myocardial infarctions going unrecognized. Some 30–40% of individuals who present with an acute coronary syndrome have had no prior warning symptom to suggest the presence of underlying disease.

**Diagnosis**

Cardiovascular risk assessment for primary and secondary prevention of cardiovascular disease

*Primary prevention* can be defined as prevention of the atherosclerotic disease process and *secondary prevention* as treatment of the atherosclerotic disease process (i.e. treatment of the disease or its complications). The objective of prevention is to reduce the incidence of first or recurrent clinical events due to CAD, ischaemic stroke and peripheral artery disease.

In the UK, NICE guidelines recommend that primary care should use the QRISK®3 risk assessment tool (see Further reading) to identify people who are likely to be at high risk (10-year risk of cardiovascular disease ≥10%).

**Lipids**

A full lipid profile should be obtained, including total cholesterol, high-density lipoprotein (HDL) cholesterol, non-HDL cholesterol and triglyceride concentrations. Patients with a total cholesterol concentration of more than 7.5mmol/L and a family history of premature coronary heart disease may have *familial hypercholesterolaemia*. 
Lifestyle modifications
Patients should eat a diet with a reduced fat intake (≤30% of total energy intake, saturated fats ≤7% total energy intake) and a dietary cholesterol intake of less than 300 mg/day. Saturated fats should be replaced by monounsaturated and polyunsaturated fats (rapeseed and olive oils). People should aim to reduce their intake of sugar and food products that contain refined sugars (e.g. fructose), and to eat at least five portions of fruit and vegetables per day, two portions of fish per week, and four to five portions of unsalted nuts, seeds and legumes per week. The weekly exercise recommendations are 150 minutes or more of moderate-intensity aerobic activity or 75 minutes of vigorous-intensity aerobic activity. Weight/body mass index (BMI) should be <25 kg/m² (see p. 1247). In the UK the recommendation is not to drink more than 14 units per week (men and women), ideally spread evenly over 3 or more days, and smoking should be discontinued. Blood pressure and diabetes should be managed according to NICE guidelines in the UK.

Statin treatment
Atorvastatin 20 mg is recommended for the primary prevention of cardiovascular disease in people with a 10-year risk of cardiovascular disease of 10% or higher. In patients with established cardiovascular disease, NICE recommends atorvastatin 80 mg, unless there are potential drug interactions, a high risk of adverse effects or a different patient preference.

ANGINA
Myocardial ischaemia in patients with stable CAD occurs when there is a mismatch between blood supply and metabolic demand. This results in regional wall motion abnormalities, ST–T changes on the 12-lead ECG and cardiac ischaemic pain – angina. Ischaemic metabolites, including adenosine, stimulate nerve endings and produce pain.

Epidemiology
The prevalence of angina increases with age in both sexes: in women it is 5–7% at 45–64 years as opposed to 10–12% at 65–84 years, while in men it is 4–7% at 45–64 years as opposed to 12–14% at 65–84 years. The annual mortality rate ranges from 1.2% to 2.4% and there is an annual incidence of cardiac death of 0.6–1.4%. Risk factors include hypertension, hyperlipidaemia, diabetes mellitus, sedentary lifestyle, obesity, smoking and family history.

Diagnosis
The diagnosis of angina is largely based on the clinical history.
- **Classical angina** or typical angina is characterized by chest pain:
  - ‘Heavy’, ‘tight’ or ‘gripping’ central or retrosternal pain may radiate to the jaw and/or arms.
  - Pain occurs with exercise or emotional stress.
  - Pain eases rapidly with rest or with GTN.
- **Atypical angina** is described by NICE as chest pain with 2 out of 3 of the features above.
- **Non-angina chest pain** is described by NICE as chest pain with 1 out of 3 of the features above.
- **Stable angina** can be classified according to the Canadian Cardiovascular Society guidelines (Box 30.31).
- **Unstable angina** refers to angina of recent onset (<24 h) or deterioration in previous stable angina, with symptoms frequently occurring at rest: that is, acute coronary syndrome.
- **Refractory angina** refers to patients with severe coronary disease in whom revascularization is not possible and angina is not controlled by medical therapy.
- **Vasospastic** or variant (Prinzmetal’s) angina refers to angina that occurs without provocation, usually at rest, as a result of coronary artery spasm. It occurs more frequently in women. Characteristically, there is ST segment elevation on the ECG during the pain.
- **Microvascular angina** patients have exercise-induced angina but normal or unobstructed coronary arteries (on coronary angiography, CTCA). Intracoronary acetylcholine may cause coronary spasm. Whilst they have a good prognosis, they are often highly symptomatic and can be difficult to treat. In women with

patients with stable angina should have initial investigations (Box 30.32). The diagnosis of stable angina can be made on clinical assessment alone or by clinical assessment combined with anatomical (cardiac catheterization or CTCA) or functional imaging (SPECT, stress echocardiography, stress MRI).

Examination

There are usually no abnormal findings in angina. Signs to suggest anaemia, thyrotoxicosis or hyperlipidaemia (e.g. lipid arcus, xanthelasma, tendon xanthoma) should be sought. It is essential to exclude aortic stenosis (i.e. slow-rising carotid impulse and ejection systolic murmur radiating to the neck) as a possible cause of the angina. The blood pressure should be taken to identify coexistent hypertension. BMI or waist circumference should be measured.

Investigations

Patients with suspected angina should have initial investigations (Box 30.32). The diagnosis of stable angina can be made on clinical assessment alone or by clinical assessment combined with anatomical (cardiac catheterization or CTCA) or functional imaging (SPECT, stress echocardiography, stress MRI).

Patients without known CAD presenting with chest pain can be categorized as having typical angina, atypical angina or non-anginal chest pain.

- Patients with typical or atypical angina or patients with non-anginal chest pain but with ST changes or Q waves should be referred for 64-slice (or above) CTCA.
- If the results from CTCA are inconclusive, the patient should be referred for non-invasive functional tests (SPECT, stress echocardiography, stress MRI).
- If stable angina cannot be diagnosed in patients with known coronary artery disease, non-invasive functional tests would be appropriate.
- Patient with non-anginal chest pain (more likely if the pain is continuous, unrelated to exertion, exacerbated by respiration, or associated with dizziness, palpitations or difficulty in swallowing) and a normal ECG should be considered for alternative diagnoses and investigated appropriately.

Management of stable angina

Patients should be informed of the nature of their condition and reassured that the prognosis is good (annual mortality <2%). Lifestyle management should be instigated, as for prevention of CAD. The stable angina algorithm in Fig. 30.64 should be used to guide initial patient management, while Box 30.33 outlines pharmacological therapy.
early surgery). Dual antiplatelet therapy (aspirin and a P2Y12 inhibitor, e.g. clopidogrel) should continue for 6–12 months.

**Coronary artery bypass grafting**

With CABG, autologous veins or arteries are anastomosed to the ascending aorta and to the native coronary arteries distal to the area of stenosis (Fig. 30.67). Improved graft survival can be obtained with in situ internal mammary and gastroepiploic arteries grafted on to the stenosed coronary artery, compared to vein grafts. Operative mortality is well below 1% in patients with normal left ventricular function.

**PCI versus CABG**

The heart team (made up of interventional and non-interventional cardiologists, cardiac surgeons, cardiac anaesthetists and intensivists) should review whether patients should continue with medical therapy or be referred for PCI or CABG. The STS score and/or EuroSCORE II (see Further reading) can be utilized to determine in-hospital mortality and morbidity in patients referred for surgery. The SYNTAX score should be used for complex CAD to determine long-term mortality and morbidity in patients referred for PCI. In the current European Society of Cardiology (ESC) guidelines for revascularization (see Further reading), PCI is preferred to CAGB in patients with single- or double-vessel disease not involving the proximal left anterior descending (LAD) or left main stem (LMS) vessel. CABG and PCI are both appropriate in patients with proximal LAD stenosis, LMS or three-vessel disease (without diabetes mellitus) and a low SYNTAX score (0–22). CABG is preferred to PCI in patients with three-vessel disease and diabetes or elevated SYNTAX score (>22) and in patients with LMS and SYNTAX score of more than 22. Patient clinical characteristics (severe co-morbidities, reduced life expectancy, porcelain aorta (heavily calcified), need for additional surgery to the aorta or valves) may alter the modality of revascularization.

ACUTE CORONARY SYNDROMES

Acute coronary syndromes (ACSs) include:
- ST-elevation myocardial infarction (STEMI)
- non-ST-elevation myocardial infarction (NSTEMI)
- unstable angina (UA).

The difference between UA and NSTEMI is that, in the latter, there is occluding thrombus, which leads to myocardial necrosis and a rise in serum troponins or creatine kinase-MB (CK-MB). Myocardial infarction (MI) occurs when cardiac myocytes die due to myocardial ischaemia. It can be diagnosed on the basis of appropriate clinical history, 12-lead ECG and elevated biochemical markers: troponin I and T, and CK-MB.

There are five types of MI:
- type 1 – spontaneous MI with ischaemia due to a primary coronary event, e.g. plaque erosion/rupture, fissuring or dissection
- type 2 – MI secondary to ischaemia due to increased oxygen demand or decreased supply, such as in coronary spasm,
Acute coronary syndromes

**Pathophysiology**

The mechanism that is common to all ACSs is rupture or erosion of the fibrous cap of a coronary artery plaque. This leads to platelet aggregation and adhesion, localized thrombosis, vasoconstriction and distal thrombus embolization. The presence of a rich lipid pool within the plaque and a thin, fibrous cap is associated with an increased risk of rupture. Thrombus formation and the vasoconstriction produced by platelet release of serotonin and thromboxane A2 result in myocardial ischaemia due to reduction of coronary blood flow.

**Clinical features**

Patients with an ACS may complain of a new onset of chest pain, chest pain at rest or a deterioration of pre-existing angina. However, some present with atypical features, including indigestion, pleuritic chest pain or dyspnoea. Physical examination can detect alternative diagnoses, such as aortic dissection, pulmonary embolism or peptic ulceration. In addition, it can also identify adverse clinical signs, such as hypotension, basal crackles, fourth heart sounds and cardiac murmurs.

**Investigations**

**Electrocardiogram**

Although the 12-lead ECG may be normal, ST depression and T-wave inversion are highly suggestive of an ACS, particularly if associated with anginal chest pain. The ECG should be repeated when the patient is in pain and continuous ST-segment monitoring is recommended. With a STEMI, complete occlusion of a coronary vessel will result in a persistent ST elevation or left bundle branch block pattern, although transient ST elevation is seen with coronary vasospasm or Prinzmetal’s angina.

CAD, coronary artery disease; CK-MB, creatine kinase MB; MI, myocardial infarction; NSTEMI, non-ST-elevation myocardial infarction; TIMI, Thrombolysis in Myocardial Infarction; UA, unstable angina.

**Biochemical markers**

The cardiac troponin complex is made up of three distinct proteins (I, T and C), which are situated with tropomyosin on the thin actin filament that forms the skeleton of the cardiac myofilament. Tropomin T attaches the complex to tropomyosin, troponin C binds calcium during excitation–contraction coupling, and troponin I inhibits the myosin binding site on the actin. ‘Highly sensitive’ troponin assays can now detect troponins in normal people. There are many different assays and results should be interpreted in the context of the clinical picture and the ECG. A negative predictive value of 99.4% has been shown for a serum troponin below 5ng/L; this has been shown to be consistent across a wide group of patients. If the initial troponin assay is negative, it should be repeated 3 hours later. The troponin assay provides prognostic information: that is, a high serum troponin level carries an increased mortality risk in ACS (Box 30.34). It also defines which patients may benefit from aggressive medical therapy and early coronary revascularization.

**NSTEMI and unstable angina**

**Risk stratification**

Both the Thrombolysis in Myocardial Infarction (TIMI) score (Box 30.35) and the Global Registry of Acute Coronary Events (GRACE)
The platelet is a key part of the thrombosis cascade involved in ACS. Rupture of the atheromatous plaque exposes the circulating platelets to adenosine diphosphate (ADP), thromboxane A₂ (TXA₂), adrenaline (epinephrine), thrombin and collagen tissue factor. This causes platelet activation, with thrombin as an especially potent stimulant of such activity. Platelet activation stimulates the expression of glycoprotein (GP) IIb/IIIa receptors on the platelet surface.

These receptors bridge fibrinogen between adjacent platelets, causing platelet aggregates (see Fig. 16.32). ACS patients should be treated with dual antiplatelet agents:

- **aspirin 300mg** loading dose then 75-100mg daily and
- an ADP-receptor antagonist
  - **clopidogrel 300–600mg** loading then 75mg daily or
  - **prasugrel 60mg** loading then 10mg daily or
  - **ticagrelor 180mg** loading then 90mg twice daily.

**Antithrombin drugs**

An antithrombin should be added to dual antiplatelets in patients with ACS. **Unfractionated heparin (UFH)** requires frequent monitoring; the low-molecular-weight heparin **enoxaparin** appears to be superior and can be given subcutaneously twice daily. **Bivalirudin** is a direct thrombin inhibitor that reversibly binds to thrombin and inhibits clot-bound thrombin. In the ACUITY trial, bivalirudin appeared as effective as heparin plus GPIIb/IIIa inhibitors in reducing ischaemic events in patients pre-treated with a thienopyridine and undergoing diagnostic angiography or percutaneous intervention, but with less bleeding. **Fondaparinux** is a synthetic pentasaccharide that selectively binds to antithrombin; this inactivates factor Xa, resulting in strong inhibition of thrombin generation and clot formation. It does not inactivate thrombin and has no effect on platelets.

**Activated glycoprotein (GP) IIb/IIIa receptors** on platelets bind to fibrinogen, initiating platelet aggregation. Receptor antagonists (abciximab, eptifibatide, tirofiban) have been developed that are powerful inhibitors of platelet aggregation. However, their use in ACS patients should be restricted to patients with heavy thrombus burden identified during coronary angiography and for complications during PCI (e.g. distal embolization).

**Anti-ischaemia agents**

In patients with no contraindications (asthma, AV block, acute pulmonary oedema) beta-blockers are administered orally, to reduce myocardial ischaemia by blocking circulating catecholamines. This will lower the heart rate and blood pressure, reducing myocardial oxygen consumption. The dose can be titrated to produce a resting heart rate of 50–60b.p.m. In patients with on-going angina, nitrates should be given either sublingually or intravenously. They effectively reduce preload and produce coronary vasodilation. However, tolerance can become a problem and patients should be weaned off intravenous administration if symptoms resolve.
Acute coronary syndromes

Plaque stabilization/remodelling
HMG-CoA reductase inhibitor drugs (statins) and ACE inhibitors are routinely administered to patients with ACS. These agents may produce plaque stabilization, improve vascular and myocardial remodelling, and reduce future cardiovascular events. Starting the drugs while the patient is still in hospital increases the likelihood of these individuals receiving secondary drug therapy.

Coronary angiography and intervention
Very high-risk patients require urgent coronary angiography (<2h). This includes those individuals with persistent or recurrent chest pain not responding to medical therapy, clinical signs of heart failure or haemodynamic instability or cardiogenic shock, or life-threatening arrhythmias (ventricular fibrillation, ventricular tachycardia).

High-risk patients with rising or falling cardiac troponin levels, dynamic ST- or T-wave changes, or elevated GRACE scores (>140) require coronary angiography within 24h.

Intermediate-risk patients with diabetes mellitus, renal impairment (estimated glomerular filtration rate <60), LVEF below 40% or congestive cardiac failure, early post infarction angina, previous PCI or CABG, or a GRACE score of over 109 but less than 140 require coronary angiography within 72 h.

Clinical features

Any patient presenting with severe chest pain lasting more than 20 minutes may be suffering from MI. The pain does not usually respond to sublingual glyceryl trinitrate, and opiate analgesia is required. The pain may radiate to the left arm, neck or jaw. However, in some patients, particularly elderly or diabetic ones, the symptoms may be atypical and include dyspnoea, fatigue, pre-syncope or syncope. Autonomic symptoms are common and on examination the patient may be pale and clammy, with marked sweating. In addition, the pulse may be thready with significant hypotension, bradycardia or tachycardia.

Investigations

Electrocardiography

An ECG in patients with chest pain should be performed within 10 minutes of first contact with the emergency medical team (ambulance or emergency department). The baseline ECG is rarely normal, but if it is, it should be repeated every 15 minutes, while the patient remains in pain. Continuous cardiac monitoring is required because of the high likelihood of significant cardiac arrhythmias. ECG changes (Box 30.40) are usually confined to the ECG leads that “face” the infarction. The presence of new ST elevation (due to opening of the K+ channels) of 0.2 mV or more at the J-point in leads V1–V3 and 0.1 mV or more in other leads suggests anterior MI (Fig. 30.68). An inferior wall MI is diagnosed when ST elevation is seen in leads II, III and AVF (Fig. 30.69). Lateral MI produces changes in leads I, AVL and V5–V6. In patients with a posterior MI, there may be ST depression in leads V1–V3 with a dominant R wave, and ST elevation in lead V2/V6. New, or presumed new, left bundle branch block is compatible with coronary artery occlusion requiring urgent reperfusion therapy. It may not be possible to exclude MI in patients with a paced rhythm or right bundle branch block, and patients with symptoms compatible with MI should be triaged in the MI pathway. The evolution of the ECG during the course of STEMI is illustrated in Fig. 30.70.

Blood tests and other imaging

Blood samples should be taken for cardiac troponin I or T levels, although treatment should not be deferred until the results are available. Full blood count, serum electrolytes, glucose and lipid profile should be obtained. Transthoracic echocardiography (TTE) may be helpful to confirm an MI, as wall-motion abnormalities are detectable early in STEMI. TTE may detect alternative diagnoses, such as aortic dissection, pericarditis or pulmonary embolism.

Management

Early medical management

Initial assessment involves rapid triage for chest pain (note that time is muscle) and referral for reperfusion therapy (primary PCI or thrombolyis). Initial medical therapy includes oxygen (if saturations are <90%), intravenous opioids (morphine if in pain) and aspirin (300 mg) (see Box 30.38).

Primary percutaneous coronary intervention (PCI)

The preferred reperfusion therapy for STEMI in interventional cardiology centres is primary PCI with a target of 60 minutes for wire
Fig. 30.68 An acute anteroseptal myocardial infarction, shown by a 12-lead ECG. Note the ST segment elevation and pathological Q waves in leads V1-V3. Ischaemic changes with ST segment depression are also seen in the inferior leads (II, III and AVF).

Fig. 30.69 An acute inferior wall myocardial infarction, shown by a 12-lead ECG. Note the raised ST segment and Q waves in the inferior leads (II, III and AVF).

crossing of the culprit vessel. Recent updated ESC guidelines recommend performing complete revascularization during the index hospital admission. Data from the RIVAL and RIFLE STEACS studies demonstrate that radial access is the preferred route, as this reduces complications and may improve survival. Primary PCI performed with drug eluting stents is preferred to bare metal stents. Routine thrombus aspiration is not recommended. Dual antiplatelet therapy is with aspirin and an ADP-receptor blocker (prasugrel or ticagrelor). Anticoagulant options include unfractionated heparin, enoxaparin or bivalirudin. The routine use of GP IIb/IIIa inhibitors is no longer recommended.

**Thrombolysis**

Thrombolytic agents (see p. 370) enhance the breakdown of occlusive thromboses by the activation of plasminogen to form plasmin. Thrombolysis is appropriate if primary PCI is not deliverable within 120 minutes of STEMI diagnosis. A meta-analysis showed that thrombolysis within 6 hours of STEMI or left bundle branch block MI prevented 30 deaths in every 1000 patients treated. Between 7 and 12 hours, 20 in every 1000 deaths were prevented. After 12 hours the benefits are limited, and there is evidence to suggest less benefit for older patients, possibly because of the increased risk of strokes. The target for reperfusion therapy is less than 10 minutes delivery of bolus therapy. For patients who fail to reperfuse by 60–90 minutes, as demonstrated by 50% resolution of the ST-segment elevation, re-thrombolysis or referral for rescue coronary angioplasty is recommended. The contraindications to thrombolysis are provided in Box 30.41. Aspirin and clopidogrel are recommended in patients undergoing thrombolysis. Anticoagulant options include unfractionated heparin, enoxaparin or fondaparinux.

**Coronary artery bypass surgery**

Cardiac surgery is usually reserved for the complications of MI, such as ventricular septal defect or mitral regurgitation. Operative mortality is highest in the first 72 hours after STEMI.
Complications of myocardial infarction

Heart failure

Cardiac failure post STEMI is a poor prognostic feature that necessitates medical and invasive therapy to reduce the death rate. The Killip classification is used to assess patients with heart failure post MI:

- **Killip I** – no crackles and no third heart sound
- **Killip II** – crackles in <50% of the lung fields or a third heart sound
- **Killip III** – crackles in >50% of the lung fields
- **Killip IV** – cardiogenic shock.

Mild heart failure may respond to intravenous furosemide 40–80 mg i.v., with glyceryl trinitrate administration if the blood pressure is satisfactory. Oxygen is required, with regular oxygen monitoring.

ACE inhibitors can be given within 24–48 hours if the blood pressure is satisfactory. Patients with severe heart failure may require Swan–Ganz catheterization to determine the pulmonary wedge pressure. Intravenous inotropes, such as dopamine or dobutamine, are used in severe heart failure. If the patient is in cardiogenic shock, revascularization with or without mechanical circulatory support may be required.

Myocardial rupture and aneurysmal dilation

Rupture of the free wall of the left ventricle is usually an early, catastrophic and fatal event. The patient will have a haemodynamic collapse, then an electromechanical cardiac arrest. A subacute rupture may allow for pericardiocentesis, followed by surgical repair of the rupture. Aneurysmal dilation of the infarcted myocardium (Fig. 30.71) is a late complication that may require surgical repair.

Ventricular septal defect

A ventricular septal defect VSD (Fig. 30.72) may occur in 1–2.0% of patients with STEMI and may be associated with delayed or failed fibrinolysis. However, mortality is very high and there is a 12-month
non-operated mortality of 92%. An intra-aortic balloon pump and coronary angiography may allow patient optimization prior to surgery.

**Mitral regurgitation**

Severe mitral regurgitation can occur early in the course of STEMI. Three mechanisms may be responsible and a TOE may be necessary to confirm the aetiology:
- severe left ventricular dysfunction and dilation, causing annular dilation of the valve and subsequent regurgitation
- myocardial infarction of the inferior wall, producing dysfunction of the papillary muscle that may respond to coronary intervention
- myocardial infarction of the papillary muscles, producing sudden severe pulmonary oedema and cardiogenic shock (intra-aortic balloon pump, coronary angiography and early surgery may improve patient survival).

**Cardiac arrhythmias**

**Ventricular tachycardia** and ventricular fibrillation are common in STEMI, particularly with reperfusion. Cardiac arrest requires defibrillation. Ventricular tachycardia should be treated with intravenous beta-blockers (metoprolol 5 mg, esmolol 50–200 μg/kg per min), lidocaine 50–100 mg, or amiodarone 900–1200 mg/24 h. If the patient is hypotensive, synchronized cardioversion may be performed. Ensure that the serum potassium is over 4.5 mmol/l. Refractory ventricular tachycardia or fibrillation may respond to magnesium 8 mmol/L over 15 min i.v.

**Atrial fibrillation** occurs frequently, and treatment with beta-blockers and digoxin may be required. Cardioversion is possible but relapse is common.

**Bradyarrhythmias** can be treated initially with atropine 0.5 mg i.v. repeated up to six times in 4 h. Temporary transcutaneous or transvenous pacemaker insertion may be necessary in patients with symptomatic heart block.

**Conduction disturbances**

These are common following MI. AV block may occur during acute MI, especially of the inferior wall (the right coronary artery usually supplies the SA and AV nodes). When associated with haemodynamic compromise, heart block may need treatment with atropine or a temporary pacemaker. Such blocks may last for only a few minutes but frequently continue for several days. Permanent pacing may need to be considered if heart block persists for over 2 weeks.

**Post-MI pericarditis and Dressler’s syndrome**

See page 1126.

**Post-ACS lifestyle modification**

After recovery from an ACS, patients should be encouraged to participate in a cardiac rehabilitation programme that provides education and information appropriate to their requirements. An exercise programme forms part of the rehabilitation.

- Dietary recommendations include calorie control of obesity, increased fruit and vegetables, reduced trans and saturated fats, and reduced salt intake in patients with hypertension.
- Alcohol consumption should be maintained within safe limits (≤14 units per week for both men and women), avoiding binge drinking.
- Patients should be physically active (30 min of moderate aerobic exercise 5 times per week).
- Patients should stop smoking (nicotine patches and buprenorphine are safe).
- A healthy weight (BMI < 25 kg/m²) should be maintained.

- Blood pressure should be reduced to a systolic measurement < 140 mmHg.
- Patients with diabetes should be treated to maintain HbA1c < 7% (53 mmol/mol).

**Post-ACS drug therapy and assessment**

Extensive clinical trial evidence has been gathered in post-MI patients, demonstrating that a range of pharmaceuticals is advantageous in reducing mortality over the following years. Therefore, after MI, most patients should be taking most of the following medications:
- aspirin 75 mg daily
- ADP-receptor blocker
- oral beta-blocker to maintain heart rate < 60 b.p.m.
- proton pump inhibitor for patients at high risk of bleeding while on dual antiplatelet therapy
- ACE inhibitor or angiotensin receptor blocker, particularly if LVEF is < 40%
- high-intensity statin with target LDL cholesterol < 1.8 mmol/L
- aldosterone antagonist, if there is clinical evidence of heart failure and LVEF is < 40%; the serum creatinine is < 221 μmol/l (men) or < 177 μmol/l (women); and the serum potassium is < 5.0 mEq/L. Patients with permanent atrial fibrillation receiving medical therapy or CABG should be treated with dual therapy: aspirin or clopidogrel with anticoagulation warfarin or a DOAC.
- Patients with permanent atrial fibrillation receiving stenting should be assessed for their bleeding risk using the HAS-BLED score (see Box 30.16):
  - If this is 0–2, they can receive triple therapy for 6 months (aspirin and clopidogrel and warfarin) and then dual therapy (aspirin or clopidogrel with anticoagulation warfarin or a DOAC).
  - If it is over 2, they can receive triple therapy for 4 weeks (aspirin and clopidogrel and warfarin) and then dual therapy (aspirin or clopidogrel with anticoagulation warfarin or a DOAC) for a further 11 months.

**Further reading**

**VALVULAR HEART DISEASE**

**MITRAL VALVE**

The mitral valve consists of the fibrous annulus, anterior and posterior leaflets, chordae tendineae and the papillary muscles (Fig. 30.73).
Mitral stenosis

Mitral stenosis is commonly due to rheumatic heart disease following previous rheumatic fever due to infection with a group A β-haemolytic streptococcus; in low- to medium-income countries this affects nearly 20 million people. The condition is more common in women than men. Inflammation leads to commissural fusion and a reduction in mitral valve orifice area, causing the characteristic doming pattern seen on echocardiography. Over many years the condition progresses to valve thickening, cusp fusion, calcium deposition, a severely narrowed (stenotic) valve orifice and progressive immobility of the valve cusps.

Other causes of mitral stenosis include:
- congenital mitral stenosis
- Lutembacher’s syndrome (the combination of acquired mitral stenosis and an atrial septal defect)
- mitral annular calcification, rarely; this may lead to mitral stenosis if extensive, particularly in elderly patients and those with end-stage renal disease
- carcinoid tumours metastasizing to the lung, or primary bronchial carcinoid.

Pathophysiology

When the normal valve orifice area of 4–6 cm² is reduced to less than 1 cm², severe mitral stenosis is present. In order for sufficient cardiac output to be maintained, the left atrial pressure increases and left atrial hypertrophy and dilatation occur. Consequently, pulmonary venous, pulmonary arterial and right heart pressures also increase. The increase in pulmonary capillary pressure is followed by the development of pulmonary oedema, particularly when the rhythm deteriorates to atrial fibrillation with tachycardia and loss of coordinated atrial contraction. This is partially prevented by alveolar and capillary thickening and pulmonary arterial vasoconstriction (reactive pulmonary hypertension). Pulmonary hypertension leads to right ventricular hypertrophy, dilation and failure, with subsequent tricuspid regurgitation.

Clinical features

Symptoms

Usually, there are no symptoms until the valve orifice is moderately stenosed (area <2 cm²). In Europe, this does not usually occur until several decades after the first attack of rheumatic fever, but in low- to medium-income countries severe stenosis may occur at 10–20 years of age.

Progressively severe dyspnoea develops from the elevation in left atrial pressure, vascular congestion and interstitial pulmonary oedema. A cough productive of blood-tinged, frothy sputum or frank haemoptysis may occur. The development of pulmonary hypertension eventually leads to right heart failure and its symptoms of weakness, fatigue and abdominal or lower limb swelling.

The large left atrium predisposes to atrial fibrillation, giving rise to symptoms such as palpitations. Atrial fibrillation may result in systemic emboli, most commonly to the cerebral vessels, producing neurological sequelae, but mesenteric, renal and peripheral emboli are also seen.

Signs

See the ‘Clinical memo’ in Fig. 30.74.

Face

Severe mitral stenosis with pulmonary hypertension is associated with the so-called mitral facies or malar flush. This is a bilateral, cyanotic or dusky pink discoloration over the upper cheeks, which is due to arteriovenous anastomoses and vascular stasis.

Pulse

A small-volume pulse is typical in mitral stenosis. This may be regular early on in the disease process (patient in sinus rhythm), but as the disease progresses, an irregularly irregular pulse (atrial fibrillation) may occur and may cause symptomatic clinical deterioration.

Jugular veins

Right heart failure may develop, leading to jugular venous distension. When pulmonary hypertension or tricuspid stenosis is present, the ‘a’-wave will be prominent, provided that atrial fibrillation has not supervened.

Palpation

There is a tapping impulse felt parasternally on the left side. This is the result of a palpable first heart sound combined with left ventricular backward displacement produced by an enlarging right ventricle. A sustained parasternal impulse due to right ventricular hypertrophy may also be felt.

Auscultation

Auscultation (see Fig. 30.74) reveals a loud first heart sound if the mitral valve is pliable but this will not occur in calcific mitral stenosis. As the valve suddenly opens with the force of the increased left atrial pressure, an ‘opening snap’ will be heard. This is followed by a low-pitched, ‘rumbling’, mid-diastolic murmur, best heard with the bell of the stethoscope held lightly at the apex and the patient lying on the left side in expiration. If the patient is in sinus rhythm, the murmur becomes louder at the end of diastole as a result of atrial contraction (pre-systolic accentuation). Pulmonary hypertension may result in pulmonary valvular regurgitation, which causes an early diastolic murmur in the pulmonary area, known as a Graham Steell murmur.

Investigations

Chest X-ray

The chest X-ray may show left atrial enlargement with straightening of the left heart border and a ‘double shadow’ on the border of the right and left atria (see Fig. 30.14). Late in the course of the disease a calcified mitral valve may be seen on a penetrated or lateral view. Pulmonary vascular congestion and enlargement of the main pulmonary arteries may also be apparent in severe disease.
ECG

In sinus rhythm the ECG may show a bifid P wave owing to delayed left atrial activation (Fig. 30.75). However, atrial fibrillation is frequently present. As the disease progresses the ECG features of right ventricular hypertrophy (right axis deviation and, perhaps, tall R waves in lead V1) may develop (Fig. 30.76).

Echocardiogram

TTE is able to determine left atrial size and the degree of thickening, calcification and mobility of the mitral leaflets, as well as the degree of commissural fusion (Fig. 30.77). The severity of the mitral stenosis (Box 30.42) can be defined by mitral valve area on two-dimensional echocardiography, with continuous wave (CW) Doppler to measure the pressure half-time (the time taken for the pressure to halve from the peak value) and mean pressure drop across the valve. CW Doppler may also be used to estimate pulmonary artery pressure through measurement of the degree of tricuspid regurgitation.

Fig. 30.74 Features associated with mitral regurgitation and mitral stenosis. A2, aortic component of the second heart sound; MDM, mid-diastolic murmur; OS, opening snap; P2, pulmonary component of the second heart sound (loud with pulmonary hypertension); PSA, pre-systolic accentuation; PSM, pansystolic murmur; RV, right ventricle; S1, first heart sound; S2, second heart sound; S3, third heart sound.

Fig. 30.75 A bifid P wave, as seen on the ECG in mitral stenosis (P mitrale). Other P wave abnormalities are also shown for comparison.

Fig. 30.76 Severe mitral stenosis, shown by a 12-lead ECG. Note the right axis deviation (frontal plane axis = +120°), the left atrial conduction abnormality (large terminal negative component of the P wave in V1) and the right ventricular hypertrophy (R wave in V1 and right axis deviation).
TOE is performed to detect the presence of left atrial thrombus (see p. 1040) or to carry out a detailed assessment prior to consideration of surgical or percutaneous intervention. The Wilkins score is an echocardiographic assessment of the mitral valve (leaflet mobility, valve thickening, valve calcification and subvalvular apparatus) and is also used to determine suitability for percutaneous mitral valvoplasty.

**Cardiac catheterization**

Left and right heart catheterization may be required in patients with severe mitral stenosis referred for intervention.

**Management**

Early symptoms of mitral stenosis, such as mild dyspnoea, can usually be treated with low doses of diuretics. The onset of atrial fibrillation requires treatment with beta-blockers or DC cardioversion and anticoagulation to prevent atrial thrombus and systemic embolization. Patients with severe mitral stenosis who develop persistent symptoms or pulmonary hypertension are appropriate for intervention. There are four operative measures.

**Trans-septal balloon valvotomy**

A catheter is introduced into the right atrium via the femoral vein under local anaesthesia in the cardiac catheter laboratory. The inter-atrial septum is then punctured and the catheter advanced into the left atrium and across the mitral valve. A balloon is passed over the catheter to lie across the valve and then inflated briefly to split the valve commissures. As with other valvotomy techniques, significant regurgitation may result, necessitating valve replacement (see later). This procedure is ideal for patients with pliable valves in whom there is little involvement of the subvalvular apparatus and minimal mitral regurgitation. Contraindications include heavy calcification or more than mild mitral regurgitation and thrombus in the left atrium. TOE must be performed prior to this technique in order to exclude left atrial thrombus.

**Closed valvotomy**

This operation is advised for patients with mobile, non-calcified and non-regurgitant mitral valves. The fused cusps are forced apart by a dilator introduced through the apex of the left ventricle and guided into position by the surgeon’s finger inserted via the left atrial appendage. Cardiopulmonary bypass is not needed for this operation. Closed valvotomy may produce a good result for 10 years or more. The valve cusps often re-fuse and another operation may eventually be necessary.

**Open valvotomy**

This operation is often preferred to closed valvotomy. The cusps are carefully dissected apart under direct vision. Cardiopulmonary bypass is required. Open dissection reduces the likelihood of causing traumatic mitral regurgitation.

**Mitral valve replacement**

Replacement of the mitral valve is necessary if:

- mitral regurgitation is also present
- there is a badly diseased or calcified stenotic valve that cannot be re-opened without producing significant regurgitation

**Fig. 30.77 Echocardiograms in rheumatic mitral valve disease.**

-(A) A two-dimensional long-axis view, showing an enlarged left atrium and the ‘hooked’ appearance of the mitral valve leaflets, resulting from commissural fusion. (B) A magnified short-axis view, showing the mitral valve orifice as seen from the left atrium. The orifice area can be planimetered to assess the severity; in this case, it is 1.5 cm², indicating moderately severe disease. (C) A continuous-wave (CW) Doppler recording, showing the slow rate of decay of flow velocity from the left atrium to the left ventricle during diastole. It is also possible to derive the valve orifice area from the velocity decay rate. AMVL, anterior mitral valve leaflet; LA, left atrium; LV, left ventricle; PMVL, posterior mitral valve leaflet.
• there is severe mitral stenosis and thrombus in the left atrium despite anticoagulation. Artificial valves (see p. 1102) may work successfully for more than 20 years. Anticoagulants are generally necessary to prevent the formation of thrombus, which might obstruct the valve or embolize.

**Mitrail regurgitation**

Mitrail regurgitation occurs due to abnormalities of the valve leaflets, the annulus, the chordae tendineae or papillary muscles, or the left ventricle. The most frequent causes of mitral regurgitation are degenerative (myxomatous) disease, ischaemic heart disease, rheumatic heart disease and infectious endocarditis. Mitrail regurgitation is also seen in diseases of the myocardium (dilated and hypertrophic cardiomyopathy), rheumatic autoimmune diseases (e.g. systemic lupus erythematosus), collagen diseases (e.g. Marfan’s and Ehlers-Danlos syndromes) and disorders caused by drugs, including centrally acting appetite suppressants (fenfluramine) and dopamine agonists (cabergoline).

**Pathophysiology**

Regurgitation into the left atrium produces left atrial dilation but little increase in left atrial pressure if the regurgitation is longstanding, as the regurgitant flow is accommodated by the large left atrium. With acute mitral regurgitation the normal compliance of the left atrium does not allow much dilation and the left atrial pressure rises. Thus, in acute mitral regurgitation the left atrial v-wave is greatly increased and pulmonary venous pressure rises, leading to pulmonary oedema. Since a proportion of the stroke volume is regurgitated, the stroke volume increases to maintain the forward cardiac output and the left ventricle therefore enlarges.

The Carpentier classification (Fig. 30.78) uses mitral leaflet motion to divide patients into different classes according to the mechanism of regurgitation, which can be useful when considering surgical intervention.

**Clinical features**

**Symptoms**

Mitrail regurgitation can be present for many years and the cardiac dimensions greatly increase before any symptoms occur.

- **Dyspnoea** and **orthopnoea** develop because of pulmonary venous hypertension that arises as a direct result of the mitral regurgitation and secondarily as a consequence of left ventricular failure.
- **Fatigue** and **lethargy** develop because of the reduced cardiac output.

- In the late stages of the disease the symptoms of **right heart failure** also occur and eventually lead to congestive cardiac failure.
- **Cardiac cachexia** may develop.
- Thromboembolism is less common than in mitral stenosis but **subacute infective endocarditis** is much more common.

**Signs**

See Fig. 30.74.

The physical signs of uncomplicated mitral regurgitation are:

- **Laterally displaced (forceful) diffuse apex beat** and a **systolic thrill** (if severe).
- **Soft first heart sound**, owing to the incomplete apposition of the valve cusps and their partial closure by the time ventricular systole begins.
- **Pansystolic murmur**, due to the occurrence of regurgitation throughout the whole of systole, being loudest at the apex but radiating widely over the precordium and into the axilla.
- **Mid-systolic click**, which may be present with a floppy mitral valve (see later); it is produced by the sudden prolapse of the valve and the tensing of the chordae tendineae that occurs during systole. This may be followed by a late systolic murmur owing to some regurgitation.
- **Prominent third heart sound** (S3), owing to the sudden rush of blood back into the dilated left ventricle in early diastole (sometimes a short mid-diastolic flow murmur may follow the third heart sound).

The signs related to atrial fibrillation, pulmonary hypertension and left and right heart failure develop later in the disease. The onset of atrial fibrillation has a much less dramatic effect on symptoms than in mitral stenosis.

**Investigations**

**Chest X-ray**

The chest X-ray may show left atrial and left ventricular enlargement. There is an increase in the cardiothoracic ratio and valve calcification may be present.

**ECG**

The ECG shows the features of left atrial delay (bifid P waves) and left ventricular hypertrophy (Fig. 30.79), as manifested by tall R waves in the left lateral leads (e.g. leads I and V6) and deep S waves in the right-sided precordial leads (e.g. leads V1 and V3). (Note that S in V1 plus R in V5 or R in V6 >35mm indicates left ventricular hypertrophy.) Left ventricular hypertrophy occurs in about 50% of patients with mitral regurgitation. Atrial fibrillation may be present.

**Echocardiogram**

The echocardiogram (Fig. 30.80) shows a dilated left atrium and left ventricle. There may be specific features of chordal or papillary muscle rupture. The severity of regurgitation can be assessed with the use of colour Doppler, looking at the narrowest jet width (vena contracta) and area, and calculating the regurgitant fraction, volume or orifice area. Useful information regarding the severity of the condition can be obtained indirectly by observing the dynamics of ventricular function. **TOE** can be helpful to identify structural valve abnormalities before surgery (see Fig. 30.80) and intraoperative TOE can aid assessment of the efficacy of valve repair.

**Cardiac catheterization**

Left and right heart catheterization is appropriate for patients referred for surgical repair or replacement.
**Fig. 30.79** Left ventricular hypertrophy, shown in 12-lead ECGs. (A) Note the size of the S wave seen in V₁ (26 mm); S in V₁ + R in V₆ = >35 mm. (B) Left ventricular hypertrophy in a patient with hypertrophic cardiomyopathy, with additional repolarization changes of deep T-wave inversion in leads V₃–V₆ and leads I, II, III and AVF.

**Fig. 30.80** Mitral regurgitation. (A) Transoesophageal echocardiography with marked prolapse of part of the posterior mitral valve leaflet (PMVL). (B) Image A with colour Doppler demonstrating severe mitral regurgitation (MR) into the left atrium (LA). AMVL, aortic mitral valve leaflet; LV, left ventricle; PISA, proximal isovelocity surface area.
Management
Mild to moderate mitral regurgitation can be managed conservatively by following the patient with serial echocardiograms. Prophylaxis against endocarditis is discussed on page 1106.

Current ESC guidelines recommend surgical intervention in patients with symptomatic severe mitral regurgitation, LVEF of more than 30% and end-diastolic dimension of less than 55 mm, and in asymptomatic patients with left ventricular dysfunction (end-systolic dimension >45 mm and/or ejection fraction of <60%). Surgery should also be considered in patients with asymptomatic severe mitral regurgitation with preserved left ventricular function and atrial fibrillation and/or pulmonary hypertension. The advantages of surgical intervention are diminished in more advanced disease. (Sudden torrential mitral regurgitation, as seen with chordal or papillary muscle rupture or infective endocarditis, necessitates emergency mitral valve replacement.) When patients are not suited to surgical intervention or when surgery will be performed at a later date, management involves treatment with diuretics, ACE inhibitors and possibly anticoagulants. A percutaneous mitral valve repair (MitraClip) may be appropriate in selected patients unsuitable for cardiac surgery.

Prolapsing (billowing) mitral valve
This is also known as Barlow’s syndrome or floppy mitral valve. It is due to excessively large mitral valve leaflets, an enlarged mitral annulus, abnormally long chordae or disordered papillary muscle contraction. Histology may demonstrate myxomatous degeneration of the mitral valve leaflets. Prolapsing mitral valve is more commonly seen in young women than in men or older women, and has a familial incidence. Its cause is unknown but it is associated with connective tissue disorders (Marfan’s syndrome, Ehlers–Danlos syndrome and pseudoxanthoma elasticum).

AORTIC VALVE

Aortic stenosis
Aortic stenosis is a chronic progressive disease that limits left ventricular outflow, leading to symptoms of chest pain, breathlessness, syncope and pre-syncope, and fatigue.

Aortic valve stenosis includes calcific stenosis of a trileaflet aortic valve, stenosis of a congenitally bicuspid valve and rheumatic aortic stenosis.

Calcific aortic valvular disease (CAVD) is the most common cause of aortic stenosis and occurs mainly in the elderly. This is an inflammatory process involving macrophages and T lymphocytes, initially with thickening of the subendothelium and adjacent fibrosis. The lesions contain lipoproteins, which calcify, increasing leaflet stiffness and reducing systolic opening. This can occur in a tri- or bileaflet aortic valve. Risk factors for CAVD include old age, male sex, elevated lipoprotein(a) and LDL cholesterol, hypertension, diabetes and smoking.

Bicuspid aortic valve (BAV) (Fig. 30.81) is the most common form of congenital heart disease, occurring in 1–2% of live births; in about 9% of cases it is familial. Patients with familial bicuspid valve tend to present at an earlier age. BAV is associated with aortic coarctation, root dilation and, potentially, aortic dissection, and patients should have regular follow-up echocardiography.

Rheumatic fever can produce progressive fusion, thickening and calcification of the aortic valve. In rheumatic heart disease, the aortic valve is affected in about 30–40% of cases and there is usually associated mitral valve disease.

Other causes of valvular stenosis include chronic kidney disease, Paget’s disease of bone, previous radiation exposure and systemic lupus erythematosus. Valvular aortic stenosis should be distinguished from other causes of obstruction to left ventricular emptying (Fig. 30.82), which include:

- supravalvular obstruction – a congenital fibrous diaphragm above the aortic valve, often associated with learning difficulties and hypercalcaemia (Williams’ syndrome)
- subvalvular aortic stenosis – a congenital condition in which a fibrous ridge or diaphragm is situated immediately below the aortic valve
- hypertrophic cardiomyopathy – septal muscle hypertrophy obstructing left ventricular outflow.

Pathophysiology
Obstructed left ventricular emptying leads to increased left ventricular pressure and compensatory left ventricular hypertrophy. In turn, this results in relative ischaemia of the left ventricular myocardium and consequent angina, arrhythmias and left ventricular failure. The obstruction to left ventricular emptying is relatively more severe on
Exercise. Normally, exercise causes a many-fold increase in cardiac output, but when there is severe narrowing of the aortic valve orifice, the cardiac output can hardly increase. Thus, the blood pressure falls, coronary ischaemia worsens, the myocardium fails and cardiac arrhythmias develop. Left ventricular systolic function is typically preserved in patients with aortic stenosis.

**Clinical features**

**Symptoms**

There are usually no symptoms until aortic stenosis is moderately severe (when the aortic orifice is reduced to one-third of its normal size). At this stage, exercise-induced syncope, angina and dyspnoea develop. When symptoms occur, the prognosis is poor: on average, death occurs within 2–3 years if there has been no surgical intervention.

**Signs**

See Fig. 30.83.

**Pulse**

The carotid pulse is small-volume and slow-rising or plateau in nature (see p. 1030).

**Precordial palpation**

The apex beat is not usually displaced because hypertrophy (as opposed to dilation) does not produce noticeable cardiomegaly. However, the pulsation is sustained and obvious. A double impulse is sometimes felt because the fourth heart sound or atrial contraction (‘kick’) may be palpable. A systolic thrill may be felt in the aortic area.

**Auscultation**

The most obvious auscultatory finding in aortic stenosis is an ejection systolic murmur that is usually ‘diamond-shaped’ (crescendo–decrescendo). The murmur is usually longer when the disease is more severe, as a longer ejection time is needed. The murmur is usually rough in quality and best heard in the aortic area. It radiates into the carotid arteries and also the precordium. The intensity of the murmur is not a good guide to the severity of the condition because it is lessened by a reduced cardiac output. In severe cases the murmur may be inaudible.

Other findings include:

- **systolic ejection click**, unless the valve has become immobile and calcified
- **soft or inaudible aortic second heart sound** when the aortic valve becomes immobile
- **reversed splitting of the second heart sound** (splitting on expiration) (see p. 1032)
- **prominent fourth heart sound**, caused by atrial contraction and heard unless coexisting mitral stenosis prevents this.

**Investigations**

**Chest X-ray**

The chest X-ray usually reveals a relatively small heart with a prominent, dilated, ascending aorta. This occurs because turbulent blood flow above the stenosed aortic valve produces so-called ‘post-stenotic dilation’. The aortic valve may be calcified. The cardiothoracic ratio increases when heart failure occurs.

**ECG**

The ECG shows left ventricular hypertrophy and left atrial delay. A left ventricular ‘strain’ pattern due to ‘pressure overload’ (depressed ST segments and T-wave inversion in leads orientated towards the left ventricle, i.e. leads I, AVL, V5 and V6) is common when disease is severe. Usually, sinus rhythm is present but ventricular arrhythmias may be recorded.

**Echocardiogram**

Echocardiography readily demonstrates the thickened, calcified and immobile aortic valve cusps, and the presence of left ventricular hypertrophy; it can be used to determine the severity of aortic stenosis (Box 30.43 and Fig. 30.84). TOE is rarely indicated.

**Cardiac catheterization**

Cardiac catheterization is rarely necessary since all of this information can be gained non-invasively with echocardiography and CMR. Coronary angiography is required before surgery is recommended.
CMR and cardiac CT
These techniques are indicated for assessing the thoracic aorta for the presence of aneurysm, dissection or coarctation but are rarely needed.

Management
In patients with aortic stenosis, symptoms are a good index of severity and all symptomatic, appropriate patients should have aortic valve replacement. Patients with a BAV and ascending aorta of over 50 mm or expanding at more than 5 mm per year should be considered for surgical intervention. Asymptomatic patients should be under regular review for assessment of symptoms and echocardiography. Surgical intervention for asymptomatic people with severe aortic stenosis is recommended in those with:

- symptoms or hypotension during an exercise test
- an LVEF of less than 50%
- moderate to severe stenosis undergoing CABG, surgery of the ascending aorta or other cardiac valve.
  - peak velocity through the aortic valve >5.5 m/s
  - Systolic pulmonary artery pressure >60 mmHg
  - Rapid increase in velocity through the valve at >0.3 m/s/year

Antibiotic prophylaxis against infective endocarditis is discussed on page 1106. Provided that the valve is not severely deformed or heavily calcified, critical aortic stenosis in childhood or adolescence can be treated by valvotomy (performed under direct vision by the surgeon or by balloon dilation using X-ray visualization). This produces temporary relief from the obstruction. Aortic valve replacement will usually be needed a few years later. Balloon dilation (valvuloplasty) has been tried in adults, especially in the elderly, as an alternative to surgery. Generally, results are poor and such treatment is reserved for patients unfit for surgery or as a ‘bridge’ to surgery (as systolic function will often improve).

Percutaneous valve replacement
A novel treatment for patients unsuitable for surgical aortic valve replacement is transcatheter aortic valve implantation (TAVI), with a balloon expandable stent valve. Valve implantation has been shown to be successful (86%) with a procedural mortality of 2% and 30-day mortality of 12%. Good results have been reported in follow-up studies, and this technique may replace the need for surgery.

Aortic regurgitation
Aortic regurgitation can occur in diseases affecting the aortic valve, such as endocarditis, and diseases affecting the aortic root, such as Marfan’s syndrome (Box 30.44).

Pathophysiology
Aortic regurgitation is reflux of blood from the aorta through the aortic valve into the left ventricle during diastole. If net cardiac output is to be maintained, the total volume of blood pumped into the aorta must increase and, consequently, left ventricular size must enlarge. Because of the aortic runoff during diastole, diastolic blood pressure falls and coronary perfusion is decreased. In addition, the larger left ventricular size is mechanically less efficient, so that the demand for oxygen is greater and cardiac ischaemia develops.

Clinical features
Symptoms
In aortic regurgitation, significant symptoms occur late and do not develop until left ventricular failure develops. Angina pectoris may arise. Varying grades of dyspnoea occur, depending on the extent of left ventricular dilation and dysfunction. Arrhythmias are relatively uncommon.

Signs
See Fig. 30.83. The signs of aortic regurgitation are many and are due to the hyperdynamic circulation, reflux of blood into the left ventricle and increased left ventricular size.

The pulse is bounding or collapsing (see p. 1030). The following signs, which are rare, also indicate a hyperdynamic circulation:

- **Quincke’s sign** – capillary pulsation in the nail beds

**Fig. 30.84 Cardiac echograms.** (A) Two-dimensional echocardiogram (long-axis view) in a patient with calcific aortic stenosis. The calcium in the valve generates abnormally intense echoes. There is some evidence of associated left ventricular hypertrophy. (B) Continuous-wave (CW) Doppler signals obtained from the right upper parasternal edge, where the high-velocity jet from the stenotic valve is coming towards the transducer. AV, aortic valve; IVS, interventricular septum; LA, left atrium; LV, left ventricle; MV, mitral valve; PVW, posterior ventricular wall.
Acute aortic regurgitation
- Acute rheumatic fever
- Infective endocarditis
- Dissection of the aorta
- Ruptured sinus of Valsalva aneurysm
- Failure of prosthetic valve

Chronic aortic regurgitation
- Rheumatic heart disease
- Syphilis
- de Musset’s sign – head nodding with each heart beat
- Duroziez’s sign – a to-and-fro murmur heard when the femoral artery is auscultated with pressure applied distally (if found, it is a sign of severe aortic regurgitation)
- pistol shot femorals – a sharp bang heard on auscultation over the femoral arteries in time with each heart beat.

The apex beat is displaced laterally and downwards and is forceful in quality. On auscultation, there is a high-pitched early diastolic murmur best heard at the left sternal edge in the fourth intercostal space with the patient leaning forwards and the breath held in expiration. Because of the volume overload there is commonly an ejection systolic flow murmur. The regurgitant jet can impinge on the anterior mitral valve cusp, causing a mid-diastolic murmur (Austin Flint murmur).

Investigations
Chest X-ray
The chest X-ray features are those of left ventricular enlargement and, possibly, dilation of the ascending aorta. The ascending aortic wall may be calcified in syphilis, and the aortic valve calcified if valvular disease is responsible for the regurgitation.

ECG
The ECG appearances are those of left ventricular hypertrophy due to ‘volume overload’: tall R waves and deeply inverted T waves in the left-sided chest leads, and deep S waves in the right-sided leads. Normally, sinus rhythm is present.

Echocardiogram
The echocardiogram (Fig. 30.85) demonstrates vigorous cardiac contraction and a dilated left ventricle. The aortic root may also be enlarged. Diastolic fluttering of the mitral leaflets or septum occurs in severe aortic regurgitation (producing the Austin Flint rumble). The severity of aortic regurgitation is assessed with a combination of colour Doppler (extent of the regurgitant jet, width of the vena contracta; Fig. 30.85) and CW Doppler (diastolic flow reversal in the descending thoracic aorta, pressure half-time). TOE may provide additional information about the valves and aortic root.

Cardiac catheterization
Cardiac catheterization is appropriate for patients requiring valvular intervention, although CTCA or CT angiography may be an alternative in younger patients.

CMR and cardiac CT
These techniques may be indicated for assessing the thoracic aorta in cases of aortic dilation or dissection. CMR can be used to quantify regurgitant volume.

Management
The underlying cause of aortic regurgitation (e.g. syphilitic aortitis or infective endocarditis) may require specific treatment. Patients with acute aortic regurgitation may need treatment with vasodilators and inotropes. ACE inhibitors are useful in patients with left ventricular dysfunction and beta-blockers may slow aortic dilation in Marfan’s patients. Because symptoms do not develop until the myocardium fails and because the myocardium does not recover fully after surgery, operative valve replacement may be performed before significant symptoms occur.

Aortic surgery is indicated in:
- acute severe aortic regurgitation, e.g. endocarditis
- symptomatic patients (dyspnoea, NYHA class II–IV, angina) with chronic severe aortic regurgitation
- asymptomatic patients with an LVEF of ≤50%
- asymptomatic patients with an LVEF of >50% but with a dilated left ventricle (end-diastolic dimension >70 mm or systolic dimension >50 mm)
- those undergoing CABG or surgery of the ascending aorta or other cardiac valve.

Both mechanical prostheses and tissue valves are used. Tissue valves are preferred in the elderly and in cases where anticoagulants must be avoided, but are contraindicated in children and young adults because of the rapid calcification and degeneration of the valves.

Antibiotic prophylaxis against infective endocarditis (see p. 1106) is not recommended.

TRICUSPID VALVE

Tricuspid stenosis
This uncommon valve lesion, which is seen much more often in women than in men, is usually due to rheumatic heart disease and is frequently associated with mitral and/or aortic valve disease. Tricuspid stenosis is also seen in the carcinoid syndrome.

Pathophysiology
Tricuspid valve stenosis results in a reduced cardiac output, which is restored towards normal when the right atrial pressure increases. The resulting systemic venous congestion produces hepatomegaly, ascites and dependent oedema.
Clinical features
Symptoms
Patients with tricuspid stenosis are likely to have left side rheumatic valve disease that may be the main driver of symptoms. Symptoms of prominent tricuspid stenosis include abdominal pain (hepatomegaly), abdominal distension (ascites) and peripheral oedema.

Signs
See Fig. 30.86. The patient remains in sinus rhythm, which is unusual, and there is a prominent jugular venous a-wave. This pre-systolic pulsation may also be felt over the liver. There is usually a rumbling mid-diastolic murmur, which is heard best at the lower left sternal edge and is louder on inspiration. It may be missed because of the murmur of coexisting mitral stenosis. A tricuspid opening snap may occasionally be heard. Hepatomegaly, abdominal ascites and dependent oedema may be present.

Investigations
On the chest X-ray there may be a prominent right atrial bulge. On the ECG, the enlarged right atrium is shown by peaked, tall P waves (>3 mm) in lead II. The echocardiogram may show a thickened and immobile tricuspid valve but this is not so clearly seen as an abnormal mitral valve.

Management
Medical management consists of diuretic therapy and salt restriction. Tricuspid valvotomy is occasionally possible but tricuspid valve replacement is often necessary. Usually, other valves also need replacement because tricuspid valve stenosis is rarely an isolated lesion.

Tricuspid regurgitation
Functional tricuspid regurgitation (see Fig. 30.25) may occur whenever the right ventricle dilates: for example, in cor pulmonale, MI or pulmonary hypertension.

Organic tricuspid regurgitation may occur with rheumatic heart disease, infective endocarditis, carcinoid syndrome, Ebstein’s anomaly (a congenitally malpositioned tricuspid valve) and other congenital abnormalities of the AV valves.

Clinical features
The valvular regurgitation gives rise to high right atrial and systemic venous pressures. Patients may experience the symptoms of right heart failure (see p. 1092).

Signs (see Fig. 30.86) include a large jugular venous ‘cv’-wave and a palpable liver that pulsates in systole. Usually, a right ventricular impulse may be felt at the left sternal edge, and there is a blowing pansystolic murmur, best heard on inspiration at the lower left sternal edge. Atrial fibrillation is common.

Investigations
An echocardiogram shows dilation of the right ventricle with thickening of the valve.

Management
Functional tricuspid regurgitation usually disappears with medical management. Severe organic tricuspid regurgitation may require operative repair of the tricuspid valve (annuloplasty or annuloplication). Very occasionally, tricuspid valve replacement may be necessary. In intravenous drug users with infective endocarditis of the tricuspid valve, surgical removal of the valve is recommended to eradicate the infection. This is usually well tolerated in the short term. The insertion of a prosthetic valve for this condition is sometimes necessary.

PULMONARY VALVE
Pulmonary stenosis
This is usually a congenital lesion but may rarely result from rheumatic fever or from the carcinoid syndrome. Congenital pulmonary stenosis may be associated with Fallot’s tetralogy, Noonan’s syndrome or congenital rubella syndrome. Pulmonary stenosis may be valvular, subvalvular or supravalvular.

Clinical features
The obstruction to right ventricular emptying results in right ventricular hypertrophy, which, in turn, leads to right atrial hypertrophy. Severe pulmonary obstruction may be incompatible with life but lesser degrees of obstruction give rise to fatigue, syncope and the
symptoms of right heart failure. Mild pulmonary stenosis may be asymptomatic.

Physical signs (Fig. 30.87) are characterized by a harsh mid-systolic ejection murmur, best heard on inspiration, to the left of the sternum in the second intercostal space. This murmur is often associated with a thrill. The pulmonary closure sound is usually delayed and soft. There may be a pulmonary ejection sound if the obstruction is valvular. A right ventricular fourth sound and a prominent jugular venous a-wave are present when the stenosis is moderately severe. A right ventricular heave (sustained impulse) may be felt.

**Investigations**

The chest X-ray usually shows a prominent pulmonary artery owing to post-stenotic dilation. The ECG demonstrates both right atrial and right ventricular hypertrophy, although it may sometimes be normal, even in severe pulmonary stenosis. A Doppler echocardiogram is the investigation of choice.

**Management**

Management of severe pulmonary stenosis requires pulmonary valvotomy (balloon valvotomy or direct surgery).

**Pulmonary regurgitation**

This is the most common acquired lesion of the pulmonary valve. It results from dilation of the pulmonary valve ring, which occurs with pulmonary hypertension (Graham Steell murmur). It may also occur following tetralogy of Fallot repair. It is characterized by a decrescendo diastolic murmur, beginning with the pulmonary component of the second heart sound that is difficult to distinguish from the murmur of aortic regurgitation (‘Clinical memo’, Fig. 30.87). Pulmonary regurgitation usually causes no symptoms and treatment is rarely necessary.

**Pulmonary stenosis**

- Look: Young patient (congenital)
- Pulse: Sinus rhythm
- RV: Hyperdynamic palpable left parasternal heave
- Sounds: Ejection click, widely split second heart sounds, soft P2
- Murmurs: Ejection systolic murmur second LICS

**Pulmonary regurgitation**

- Look: Elevated JVP
- Pulse: Sinus rhythm
- RV: Hyperdynamic palpable left parasternal heave
- Sounds: Loud P2 (if pulmonary hypertension)
- Murmurs: Early diastolic murmur second to fourth LICS increased with inspiration (Graham Steell)

**PROSTHETIC VALVES**

There is no ideal replacement for our own normally functioning, native heart valves. There are two options for valve prostheses: mechanical (Fig. 30.88) or tissue (bioprosthetic).

The valves consist of two basic components: an opening to allow blood to flow through and an occluding mechanism to regulate the flow. Mechanical prostheses rely on artificial occluders: a ball and cage (Starr–Edwards), tilting disc (Björk–Shiley) or double tilting disc (St Jude). Tissue prostheses are derived from human (homograft) or porcine or bovine (xenograft) sources. A valve replacement from within the same patient (i.e. pulmonary to aortic valve position) is termed an autograft.

**Mechanical versus tissue valves**

Mechanical valves, being artificial structures, are more durable than their tissue counterparts, which tend to degenerate after 10 years. However, artificial structures are more thrombogenic. Mechanical valves require formal anticoagulation for the lifetime of the prosthesis. The target INR is determined by what type of valve is inserted,
where it is positioned, and whether the patient has additional risk factors for thromboembolism (mitral, tricuspid, pulmonary valve disease; previous thromboembolism; atrial fibrillation; left atrial diameter >50 mm; mitral stenosis; LVEF <35%; hypercoagulable state, see p. 1002):

- **low-thrombogenicity valve** (Carbomedics (aortic position), Medtronic, Hall, St Jude Medical (without silzone)): INR 2.5 without and 3.0 with additional risk factors
- **medium-thrombogenicity valve** (Björk–Shiley, other bileaflet valves): INR 3.0 without and 3.5 with additional risk factors
- **high-thrombogenicity valve** (Lillehei–Kaster, Omnicience, Starr–Edwards): INR 3.5 without and 4.0 with additional risk factors

Tissue valves require anticoagulation for a limited postoperative period only, while the suture lines endothelialize (the ESC recommends 3 months with a target INR of 2.5, although some centres use low-dose aspirin 75–100 mg daily); it can then be discontinued unless another risk factor for thromboembolism (e.g. atrial fibrillation) persists. There is currently no role for direct oral anticoagulants (DOACs).

On auscultation, tissue valve heart sounds are comparable to those of a native valve. Mechanical valve heart sounds are generally louder and both opening and closing sounds can be heard.

**Complications**

All prostheses carry a risk of infection. Prosthetic valve endocarditis is associated with significant morbidity and mortality; prevention is the cornerstone of management. Patient education about antibiotic prophylaxis is vital and should be reinforced at clinic visits. Details of antibiotic prophylaxis indicated in patients undergoing different types of interventional procedures are given on p. 161 and in Box 8.7. Additional prophylaxis indicated in patients at higher risk of endocarditis are discussed on p. 1106. This must be borne in mind when managing a patient with a prosthetic heart valve and steps should be taken to minimize the risk involved. The prosthetic valve oculding mechanism can be interrupted by vegetations but also by thrombosis and calcification, resulting in either stenosis or regurgitation. The prosthetic valve can become detached from the valve ring, resulting in a para-prosthetic leak. Evidence of structural failure can be detected by simple auscultation, with echocardiography as the initial investigation of choice. TTE is non-invasive but scattering of echoes by mechanical valves makes assessment difficult. TOE provides alternative views and higher image resolution, making it the investigation of choice when prosthetic valve endocarditis is suspected.

**Interruption of anticoagulant therapy**

For minor surgical procedures, including dental extraction and diagnostic endoscopy, anticoagulation should not be interrupted, although the target INR should be reduced to 2.0. Percutaneous arterial puncture is safe with an INR below 2.0, although radial catheterization may be possible at higher INR levels. For major surgical procedures, anticoagulation should be discontinued 5 days before the procedure and intravenous unfractionated heparin or subcutaneous low-molecular-weight heparin commenced when the INR is below 2.0.

**Pregnancy and prosthetic heart valves**

The types of valve prosthesis for use in women of childbearing age are as follows:

- **Bioprosthetic valves** are preferable during pregnancy, as they are less thrombogenic and do not require anticoagulation. How-

ever, valve degradation in women of childbearing age has been shown to be as high as 50% at 10 years and 90% at 15 years; women with a bioprosthetic valve may require redo valve surgery.

- **Mechanical heart valves** have excellent durability but are thrombogenic and require life-long anticoagulation with warfarin. Pregnancy is a hypercoagulable state due to increased levels of fibrinogen and factors VII, VIII and X, decreased levels of protein S activity, venous hypertension and stasis.

Pregnancy in women with a mechanical heart valve is associated with increased maternal mortality (1–4%) due to valve thrombosis because safe anticoagulation in these patients is complex. Warfarin crosses the placenta and is associated with a 5–12% risk of embryopathy during the first trimester. Warfarin also has an anticoagulant effect in the fetus, which may lead to spontaneous fetal intracranial haemorrhage. Many women will choose unfractionated heparin or low-molecular-weight heparin, as these drugs do not cross the placenta or cause fetal embryopathy. However, unfractionated heparin may not provide consistent therapeutic anticoagulation during pregnancy and there is a high incidence (25%) of valve thrombosis. Low-molecular-weight heparin provides a more consistent anticoagulant effect when given twice daily, with dose adjustment to maintain anti-Xa levels of 0.8–1.2 U/mL 4 hours after administration.

**Further reading**

**INFECTIVE ENDOCARDITIS**

Infective endocarditis is an endovascular infection of cardiovascular structures, including cardiac valves, atrial and ventricular endocardium, large intrathoracic vessels and intracardiac foreign bodies, such as prosthetic valves, pacemaker leads and surgical conduits. The annual incidence in the UK is 6–7/100 000 but higher in developing countries. Without treatment, mortality approaches 100%; even with treatment, there is significant morbidity and mortality.

**Aetiology**

Endocarditis is usually the consequence of two factors: the presence of organisms in the bloodstream, and abnormal cardiac endothelium that facilitates their adherence and growth.

Bacteraemia may arise for patient-specific reasons (poor dental hygiene, intravenous drug use, soft tissue infections) or may be associated with diagnostic or therapeutic procedures (dental treatment, intravascular cannulae, cardiac surgery or permanent pacemakers).

Damaged endocardium promotes platelet and fibrin deposition, which allows organisms to adhere and grow, leading to an infected vegetation. Valvular lesions may create non-laminar flow, and jet lesions from septal defects or a patent ductus arteriosus result in abnormal vascular endothelium. Aortic and mitral valves are most commonly involved in infective endocarditis; intravenous drug users are the exception, as right-sided lesions are more common in these patients.

**Organisms**

Common organisms and the sources of infection are shown in Fig. 30.89.
Rare causes

These include the HACEK group of organisms, which tend to run a more insidious course (Box 30.45).

Culture-negative endocarditis

This accounts for 5–10% of endocarditis cases. The usual cause is prior antibiotic therapy (good history-taking is vital) but some cases are due to a variety of fastidious organisms that fail to grow in normal blood cultures. These include **Coxiella burnetii** (the cause of Q fever), **Chlamydia species**, **Bartonella species** (organisms that cause trench fever and cat scratch disease) and **Legionella**.

Clinical features

The clinical presentation of infective endocarditis (Box 30.46) is dependent on the organism and the presence of predisposing cardiac conditions. Infective endocarditis may occur as an acute, fulminating infection but also as a chronic or subacute illness with low-grade fever and non-specific symptoms. A high index of clinical
Infective endocarditis

Infective endocarditis requires high clinical suspicion to identify patients with infective endocarditis and certain criteria should alert the physician.

High clinical suspicion
- New valve lesion (regurgitant) murmur.
- Embolic event(s) of unknown origin.
- Sepsis of unknown origin.
- ‘Fever’ plus:
  - Prosthetic material inside the heart
  - Other high predisposition for infective endocarditis, e.g. intravenous drug use
  - Newly developed ventricular arrhythmias or conduction disturbances
  - First manifestation of congestive cardiac failure
  - Positive blood cultures (with typical organism)
  - Cutaneous (Osler, Janeway) or ophthalmic (Roth) lesions (Fig. 30.90)
  - Peripheral abscesses (renal, splenic, spine) of unknown origin
  - Predisposition and recent diagnostic/therapeutic interventions known to result in significant bacteraemia.

Low clinical suspicion
- Fever plus none of the above.

Diagnosis
The criteria for the clinical diagnosis of endocarditis have been established – the modified Duke criteria (see Box 30.45).

Investigations
The mainstays of diagnosis of infective endocarditis are blood cultures and echocardiography, performed in order to identify the organism, ensure appropriate therapy and monitor the patient’s response to therapy (Box 30.47). Echocardiography is an extremely useful tool if used appropriately but is not an appropriate screening test for patients with just a fever or an isolated positive blood culture where there is a low pre-test probability of endocarditis. A negative echocardiogram does not exclude a diagnosis of endocarditis and TOE and CT-PET may be required, particularly in cases of suspected prosthetic valve infection.

Management
The location of the infection means that prolonged courses of antibiotics are usually required. The combination of antibiotics may be synergistic in eradicating microbial infection and minimizing resistance. Blood cultures should be taken prior to empirical antibiotic therapy (but this should not delay therapy in unstable patients). Antibiotic treatment should continue for 4–6 weeks. Typical therapeutic regimens are shown in Box 30.48 but advice on specific therapy should be sought from the local microbiology department, according to the organism identified and current sensitivities. Serum levels of gentamicin and vancomycin need to be monitored to ensure adequate therapy and prevent toxicity. In patients with penicillin allergy, one of the glycopeptide antibiotics, vancomycin or teicoplanin, can be used. Penicillins, however, are fundamental to the therapy of bacterial endocarditis; allergies therefore

**Antibiotics in endocarditis**

- **Clinical endocarditis, culture results awaited, no suspicion of staphylococci**
  - Penicillin 1.2 g 4-hourly, gentamicin 80 mg 12-hourly

- **Suspected staphylococcal endocarditis**
  - Intravenous drug user, recent intravascular devices or cardiac surgery, acute infection
  - Vancomycin 1 g 12-hourly, gentamicin 80–120 mg 8-hourly

- **Streptococcal endocarditis**
  - Penicillin 1.2 g 4-hourly, gentamicin 80 mg 12-hourly

- **Enterococcal endocarditis**
  - (No high-level gentamicin resistance)
  - Ampicillin/amoxicillin 2 g 4-hourly, gentamicin 80 mg 12-hourly

- **Staphylococcal endocarditis**
  - Vancomycin 1 g 12-hourly or
  - Flucloxacillin 2 g 4-hourly
  - Benzylpenicillin 1.2 g 4-hourly plus
  - Gentamicin 80–120 mg 8-hourly

**Persistent fever**

Most patients with infective endocarditis should respond within 48 hours of initiation of appropriate antibiotic therapy, as evidenced by a resolution of fever, reduction in serum markers of infection, and relief of systemic symptoms of infection. Failure of these factors to occur needs to be taken very seriously. The following should be considered:

- perivalvular extension of infection and possible abscess formation
- drug reaction (the fever should resolve promptly after drug withdrawal)
- hospital-acquired infection (i.e. venous access site, urinary tract infection)
- pulmonary embolism (secondary right-sided endocarditis or prolonged hospitalization).

In such cases, samples for culture should be taken from all possible sites and evidence sought of the above causes. A change of antibiotic dosage or regimen should be avoided unless there are positive cultures or a drug reaction is suspected. Emergence of bacterial resistance is uncommon. Close liaison with the microbiology department is recommended and a cardiothoracic surgical opinion should be sought.

**Surgery**

Decisions about surgical intervention in patients with infective endocarditis should be made after joint consultation between the cardiologist and cardiothoracic surgeon, taking into account patient-specific features (age, non-cardiac morbidities, presence of prosthetic material or cardiac failure) and infective endocarditis features (infective organism, vegetation size, presence of perivalvular infection, systemic embolization).

**Prevention**

In 2015 the ESC produced guidelines for the management of infective endocarditis. They identified three groups of patients who could be considered at highest risk of developing infective endocarditis and who suffered significant morbidity and mortality complications from it:

- those who have prosthetic valves (including transcatheter devices) or material used for valve repair
- those with a previous episode of IE
- those with uncorrected cyanotic congenital heart disease or who have received palliative shunts. Patients who have successful corrective surgery are at high risk for the first 6 months postoperatively.

The ESC recommends that these groups should receive antibiotic prophylaxis during high-risk procedures. This includes dental procedures that involve manipulation of the gingival or periapical part of the teeth or perforation of the oral mucosa. (The American Heart Association also considers that cardiac transplant patients with valvular heart disease should be included as highest-risk patients.)

The ESC also provided additional recommendations applicable to all patients with valvular heart disease (including the highest-risk patients). These include:

- regular dental check-ups (6 months for the highest-risk groups and 12 months for all others)
- disinfection of wounds and eradication of chronic bacterial carriage (skin, urine)
- curative antibiotics for any focus of bacterial infection
- no self-medication with antibiotics
- strict infection control during at-risk procedures
• avoidance of piercing or tattoos
• limitation of the usage of infusion catheters, preferring peripheral versus central catheters; peripheral catheters should be changed every 3–4 days.

CONGENITAL HEART DISEASE

Fetal circulation
Oxygenated blood and nutrients are supplied to the developing fetus via the placenta and the umbilical vein (Fig. 30.91). Half of that blood is directed to the fetal ductus venosus and carried to the inferior vena cava; the other half enters the liver. Blood moves from the inferior vena cava to the right atrium of the heart. In the fetus there is an opening between the right and left atrium (the foramen ovale) and most of the blood flows from the right into the left atrium, bypassing the pulmonary circulation. This blood goes into the left ventricle and is pumped through the aorta into the fetal body. Some of the blood flows from the aorta through the internal iliac arteries to the umbilical arteries and enters the placenta, where carbon dioxide and other waste products from the fetus are taken up and enter the woman’s circulation.

Some of the blood from the right atrium does not enter the left atrium, but rather enters the right ventricle and is pumped into the pulmonary artery. In the fetus there is a connection between the pulmonary artery and the aorta, the ductus arteriosus, which directs most of this blood away from the lungs. With the first breath after delivery, the lungs expand, vascular resistance in the pulmonary arteries falls, more blood moves from the right atrium to the right ventricle and pulmonary arteries, and oxygenated blood travels back to the left atrium through the pulmonary veins. The decrease in right atrial pressure and relative increase in left atrial pressure result in closure of the foramen ovale.

The ductus arteriosus usually closes off within 1 or 2 days of birth, completely separating the left and right systems. The umbilical vein and the ductus venosus close off within 2–5 days of birth, leaving behind the ligamentum teres and the ligamentum venosus of the liver, respectively.

Adult congenital heart disease
Heart defects are the most common birth defect and affect approximately 1% of babies born in the UK. As a result of improved medical and surgical management, the majority of those born with congenital cardiac disease are surviving into late adulthood, having families and leading active lifestyles. Patients with congenital heart disease require ongoing multidisciplinary specialist care and surveillance, as many need further intervention, surgery and electrophysiological input in adulthood. In the UK the majority of these patients will be reviewed in designated specialist centres at intervals, depending on clinical need; however, non-specialists often look after them in local hospitals and all physicians should therefore have a practical understanding of congenital heart disease.

Ventricular septal defect
Ventricular septal defect (VSD) is the most common congenital cardiac malformation. The haemodynamic consequences of the VSD are dependent on the defect and resultant shunt size. In
Cardiology

A small VSD produces no abnormal X-ray or ECG findings. This is often a clinical diagnosis and echocardiography is used to confirm the VSD and assess for left heart dilation. If there is none, these lesions are managed conservatively and the only risk is an increased risk of endarteritis or endocarditis.

In larger defects, echocardiography is used to assess the size and location of the VSD and its haemodynamic consequences. VSDs can occur just below the pulmonary and aortic valves, or in the perimembranous or muscular septum. Interventional options are either surgical repair or device closure. Closure (surgical or interventional) can occur just below the pulmonary and aortic valves, or in the peri-

Pathophysiology

• Left-to-right shunt
• When the left ventricle contracts, it ejects some blood into the aorta and some across the ventricular septal defect into the right ventricle and pulmonary artery
• Small VSDs (‘maladie de Roger’): loud and sometimes long systolic murmur
• Moderate VSDs: loud, ‘tearing’ pansystolic murmur
• Large VSDs: cause pulmonary hypertension and soft murmur

Eisenmenger’s complex may result

Harsh pansystolic murmur heard at the left sternal edge, accompanied by a systolic thrill ± left parasternal heave
Possible signs of pulmonary hypertension

**Clinical features**

• Restrictive VSDs (‘maladie de Roger’) are often found incidentally, as patients are asymptomatic. These defects are associated with a loud pansystolic murmur. The majority close spontaneously by the age of 10 years.

• Large (non-restrictive) VSDs usually present with heart failure symptoms in childhood and eventually lead to pulmonary hypertension and Eisenmenger’s syndrome. As pressures equalize, the murmur becomes softer. With established Eisenmenger’s syndrome, patients will be cyanosed and have evidence of clubbing.

**Investigations and treatment**

A small VSD produces no abnormal X-ray or ECG findings. This is often a clinical diagnosis and echocardiography is used to confirm the VSD and assess for left heart dilation. If there is none, these lesions are managed conservatively and the only risk is an increased risk of endarteritis or endocarditis.

In larger defects, echocardiography is used to assess the size and location of the VSD and its haemodynamic consequences. VSDs can occur just below the pulmonary and aortic valves, or in the perimembranous or muscular septum. Interventional options are either surgical repair or device closure. Closure (surgical or interventional) is offered for a significant shunt causing left atrial and ventricular enlargement with no evidence of irreversible pulmonary hypertension.

**Atrial septal defect**

The diagnosis of an atrial septal defect (ASD) is often made in adulthood, as patients remain asymptomatic through childhood and clinical signs can be subtle.

There are three main types of ASD (Fig. 30.93):

• Secundum defects (most common type): located in the mid-septum (fossa ovalis).

• Sinus venosus defects: located in the superior part of the septum near the superior vena cava (superior sinus venosus defect), or the inferior part of the septum near the inferior vena cava (inferior sinus venosus defect) entry point.

• Ostium primum (atrioventricular septal) defects (15%): located in the lower part of atrial septum at the level of, and often involving, the atrioventricular valves.

An ASD with a significant left-to-right shunt causes right heart volume overload and right atrial and ventricular dilation. This may lead to arrhythmia, which is often the presenting symptom, along with breathlessness and exercise intolerance. There is raised pulmonary pressure due to increased blood flow through the pulmonary vessels, but significant pulmonary vascular disease develops in less than 5% of patients.

**Clinical features**

The clinical findings in a patient with an ASD and significant shunt might be a flow murmur from increased blood flow across the pulmonary valve and a fixed, split second heart sound (see Fig. 30.93).

**Investigations and treatment**

• Chest X-ray may demonstrate prominent pulmonary arteries and cardiomegaly due to right heart dilation.

• ECG may show right bundle branch block and right axis deviation. Some patients with late diagnosis may have atrial arrhythmia.

• Echocardiography is used to confirm the diagnosis; it demonstrates the defect in the septum. The shunt direction is evaluated with colour Doppler. The right atrium and ventricle are assessed for dilation and the pulmonary pressure is measured. It is also
Congenital heart disease

It is important to assess the left heart, as if there is significant left ventricular or mitral pathology, this needs to be considered when considering whether and how to close the defect (Fig. 30.94). TOE may be helpful if the images are not clear, and guides device closure of the ASD.

- **CMR and CT** are helpful for assessing anomalous pulmonary venous drainage and confirming sinus venous defects.

Closure of an ASD is indicated if there is a significant left-to-right shunt, resulting in right atrial and ventricular enlargement with normal pulmonary vascular resistance and oxygen saturations.
Secundum defects can often be closed with a device by an interventionalist if the defect is not too large and there are adequate rims of atrial septal tissue (Fig. 30.95). All other ASDs are closed surgically, and if there is anomalous pulmonary venous drainage, it is redirected to the left atrium at the same time.

**Patent ductus arteriosus**

A patent ductus arteriosus (PDA) is a persistent communication between the proximal left pulmonary artery and the descending aorta, resulting in a continuous left-to-right shunt (Fig. 30.96). Normally, the ductus arteriosus closes within a few hours of birth in response to decreased pulmonary resistance; however, in some cases (particularly in premature babies and in cases with maternal rubella) the ductus persists. Indomethacin (a prostaglandin inhibitor) is given to stimulate duct closure. The shunt size is dependent on the size of the duct and the pressure difference between the pulmonary arteries and aorta. If the left-to-right shunt is significant, it will result in left heart volume overload. Those with large unrestrictive defects may present with congestive heart failure in infancy and, if untreated, may develop pulmonary vascular disease; with time, Eisenmenger’s syndrome will develop.

**Clinical features**

In adults, PDAs are graded as:
- **Silent**: tiny PDA, no murmur – incidental finding on echo.
- **Small**: no haemodynamic effect or significant shunt but audible systolic or continuous murmur.
- **Moderate**: bounding pulses (wide pulse pressure) and continuous murmur radiating to the back; displaced apex beat from left heart dilation and volume overload.
- **Large**: in adults these present with pulmonary hypertension; the murmur has often disappeared due to equalized pressures between the pulmonary artery and aorta. Patients with Eisenmenger’s PDA may have more pronounced clubbing and lower saturations in their toes than in their fingers.

**Investigations and treatment**

- **Chest X-ray** in an adult with a significant left-to-right shunt will show enlarged pulmonary arteries and an increased cardiothoracic ratio (left heart dilation).
- **ECG** may demonstrate left atrial abnormality (broad p waves) and high-voltage QRS complexes related to left heart overload. If there is right axis deviation and a tall R in V1, this may represent established Eisenmenger’s syndrome.
- **Echocardiography** colour and continuous wave Doppler imaging of the proximal pulmonary arteries may demonstrate the shunt. Echocardiography may show a dilated left atrium and left ventricle if there is a significant left-to-right shunt. Pulmonary pressure can be assessed. If there is pulmonary hypertension, the right ventricle will be hypertrophied.
- **A right heart catheter study** may be necessary in the adult who is diagnosed with a PDA and significantly raised pulmonary pressure to estimate the shunt and pulmonary vascular resistance.

![Fig. 30.95](image1)

**Heart sounds and murmurs**

Systole Diastole

- **Continuous ‘machinery’ murmur** best heard below the left clavicle in the first interspace or over the first rib
- A thrill can often be felt

**Pathophysiology**

- Left-to-right shunt
- Some of the blood from the aorta crosses the ductus arteriosus and flows into the pulmonary artery
- The murmur is produced by the turbulent aortic-to-pulmonary artery shunting in both systole and diastole
- Dilation of the pulmonary artery, left atrium and left ventricle
- As pulmonary hypertension (Eisenmenger’s reaction) develops, the murmur becomes quieter, may be confined to systole or may even disappear, causing central cyanosis

![Fig. 30.96](image2)
Coarctation of the aorta

A coarctation of the aorta is a narrowing of the aorta at, or just distal to, the insertion of the ductus arteriosus (distal to the origin of the left subclavian artery; Fig. 30.97). Rarely, it can occur proximal to the left subclavian. In 80% of cases the aortic valve is bicuspid. There is an association with circle of Willis aneurysms (affecting approximately 10%). Severe narrowing of the aorta encourages the formation of a collateral arterial circulation involving the intercostal arteries.

Coarctation of the aorta can be asymptomatic for many years. Adults with undetected coarctation may present with hypertension, headaches, nosebleeds and, in severe coarctation, claudication and cold legs may be present.

Clinical features

Physical examination of patients with significant coarctation reveals hypertension in the upper limbs and weak, delayed (radio-femoral delay) pulses in the legs. If coarctation is present in the aorta, proximal to the left subclavian artery; there will be asynchronous radial pulses in the right and left arms and often the arch itself is hypoplastic and the blood pressure in the right arm is higher than in the left. For heart sounds and murmurs in coarctation of aorta, see Fig. 30.97. Those who have had surgery to correct coarctation may have a thoracotomy scar.

Investigations and treatment

- **Chest X-ray** may reveal a dilated aorta indented at the site of the coarctation. This kink in the aortic contour in the upper left mediastinum is shaped like a number 3 and known as the ‘3 sign’. In adults, tortuous and dilated collateral intercostal arteries may cause rib notching.

- **ECG** may demonstrate left ventricular hypertrophy.

- **Echocardiography** of suprasternal aortic arch windows can be difficult in adults but may demonstrate turbulence in the descending aorta. Continuous Doppler of the descending aorta in significant coarctation will show high-velocity flow and slow diastolic runoff (diastolic tail) due to the obstruction.

- **CT and MRI** (Fig. 30.98) demonstrate the coarctation and the proximity to the aortic branch vessels, which needs to be considered in intervention. MRI is preferable for surveillance, as it does not use radiation. If the aortic valve is bicuspid, it is also important to obtain images of the ascending aorta for associated aortopathy.

Intervention/repair

Intervention is indicated if there is a peak–peak gradient across the coarctation of more than 20mmHg in the cardiac catheter laboratory or greater than 50% luminal narrowing with associated hypertension or left ventricular hypertrophy. If there is significant collateralization, there may be minimal gradient, even in the setting of significant coarctation. In neonates, coarctation is treated with surgical repair. In older children and adults, balloon dilation and stenting is the preferred option. Balloon dilation is preferred for re-coarctation.

Tetralogy of Fallot

Tetralogy of Fallot (Fig. 30.99) consists of:

- a large, malaligned VSD
- an overriding aorta
- right ventricular outflow tract obstruction
- right ventricular hypertrophy.

The term tetralogy of Fallot represents a spectrum of disease: some patients will have only mild pulmonary stenosis, whereas the more severe extreme is pulmonary atresia in which the pulmonary vasculature can also develop abnormally. Symptoms depend on the degree of pulmonary stenosis but the majority of patients with tetralogy present in childhood. In infancy, cyanosis usually develops due to increased right-sided pressures, resulting in a right-to-left shunt. Fallot’s spells are episodes of severe cyanosis noted in children due to spasm of the subpulmonary muscle; these can be relieved by increasing systemic
resistance using postural manoeuvres, such as squatting. In babies with severe pulmonary stenosis, systemic-to-pulmonary artery shunts (i.e. a Blalock–Taussig subclavian-to-pulmonary artery shunt) may have been used initially to increase pulmonary blood flow until the pulmonary arteries are large enough for repair. The majority of adults with tetralogy of Fallot will have undergone complete repair but repair in childhood will often leave them with significant pulmonary regurgitation, which is generally well tolerated into early adulthood; the majority, however, will need pulmonary valve replacement with time.

The overall survival of those who have had operative repair is excellent. Many patients with repaired tetralogy of Fallot lead unlimited active lives. They do require ongoing specialist follow-up as, in those with transannular patch repair (surgical or interventional), pulmonary valve replacements are needed during follow-up and late complications include ventricular and atrial arrhythmias, heart failure and sudden death.

Transposition of the great arteries

In transposition of the great arteries (TGA) the right atrium connects to the morphological right ventricle, which gives rise to the aorta, and the left atrium connects to the morphological left ventricle, which gives rise to the pulmonary artery (Fig. 30.100). This is incompatible with life, as blood circulates in two parallel circuits: that is, deoxygenated blood from the systemic venous return passes into the right heart and then, via the aorta, back to the systemic circulation. Babies with transposition are born cyanosed and rely on an ASD, VSD or PDA allowing oxygenated and deoxygenated blood to be mixed. In those without an adequate shunt an atrial septostomy is performed: a Rashkind’s balloon is deployed to dilate the foramen ovale and is used to maintain saturations at 50–80% until a definitive procedure can be performed.

The majority of adult patients with TGA who were born between the 1960s and mid-1980s will have had an ‘atrial switch’ operation. In this procedure, systemic venous blood was baffled across into the left atrium and then pumped via the left ventricle into the pulmonary artery; the pulmonary venous (oxygenated blood) returning to the left atrium was redirected via a baffle into the right atrium and right ventricle, and into the aorta. This palliation allowed patients a good quality of life into their fourth decade, but the right ventricle remains the systemic ventricle and with time starts to fail. Atrial arrhythmia is also common in this group.

The first arterial switch procedure was performed in 1975 and it is now routinely performed in babies with TGA in the first 2 weeks of life. The aorta is reconnected to the left ventricle and the pulmonary artery is connected to the right ventricle. The coronary arteries are re-implanted. Late complications include coronary complications, narrowing of the pulmonary arteries, which are stretched around the aorta, and neovalvular regurgitation.

Congenitally corrected transposition of the great arteries

In congenitally corrected transposition of the great arteries (ccTGA), systemic venous return to the right atrium enters a
Marfan’s syndrome (MFS) is a connective tissue disorder with autosomal dominant inheritance pattern and a prevalence estimated at 1:5000. One-quarter of cases are not inherited and are due to de novo mutations. In 1991 it was established that MFS is caused by a mutation in the FBN1 gene on chromosome 15q21. The FBN1 gene encodes for a protein known as fibrillin-1. Fibrillin-1 is a component of structures called microfibrils, which are part of the extracellular matrix.

**Diagnosis**

Despite the finding of a causative gene, there is no specific definitive test for MFS. Diagnosis requires a complete medical and family history, examination, relevant investigations and, in equivocal cases, genetic analysis. This syndrome can affect the eyes, lungs, skeletal system and cardiovascular system (Figs 30.101 and 30.102). The diagnosis is currently made using the Modified Ghent Criteria (Box 30.49). The findings of aortic root aneurysm (ectopia lentis) lens dislocation or a family history of MFS are major criteria in the diagnosis of MFS in these guidelines.

**Management**

The management of patients with MFS requires multidisciplinary input from geneticists, cardiologists, cardiothoracic, vascular and orthopaedic surgeons, ophthalmologists and physiotherapists, among others.

**Cardiovascular surveillance and management**

The primary cause of death in MFS is cardiovascular. In the 1970s the mean age of death was reported to be 32 years, but survival has significantly improved with better means of assessing for this condition and with prophylactic aortic root replacement for those with...
dilated ascending aortas. Patients with MFS are followed up with serial cardiovascular imaging, tailored to the specific cardiovascular findings of the individual. Yearly follow-up of aortic dimensions is recommended; however, patients with a cross-sectional diameter of more than 4.5 cm on the initial scan or a growth rate of 0.5 cm or more per year require more frequent (6-monthly) measurements. Echocardiography is readily available and useful for assessing the aortic sinuses, sinotubular junction and part of the ascending aorta, as well as valvular and left ventricular function, which may be impaired in MFS. Cross-sectional imaging (CT or MRI) is necessary to assess the arch and descending aorta, which can also be involved. These modalities give more readily reproducible images to monitor interval change and may be preferred for this purpose in patients approaching the need for surgical intervention.

The current indication (European and American guidelines) for prophylactic root replacement in patients with MFS is an aortic root measuring 5 cm (or 4.5 cm in those with a family history of dissection). An aneurysm of 6 cm or more in the descending aorta qualifies the patient for an open surgical repair, with surgery preferred over endovascular stenting due to fragility of the vasculature.

**Medical therapy**

- **Beta-blockers.** These are considered standard therapy for patients with aortic dilation and MFS; however, the evidence base for their use is conflicted, and composed of small series and only one randomized control led trial of 70 patients.

- **Angiotensin receptor blockers (ARBs).** Deficiency of fibrillin-1 leads to excessive activation of the TGF cytokine. Mouse model studies have shown that dysregulation of TGF-β leads to aortic aneurysms and mitral valve prolapse, and that TGF-β antagonism rescued this phenotype. ARBs specifically inhibit TGF-β. In one randomized controlled trial, there was no difference between ARB therapy and beta-blockers over a three year period in terms of aortic dilation progression or cardiovascular events. Further research with randomized controlled trials is still required, to help establish the relative effectiveness of the various medications used in MFS.

**Lifestyle**

Contact sports and strenuous and isometric exertion should be avoided but moderate cardiovascular exercise is encouraged. Patients with Marfan’s are excluded from joining the military.

**Pregnancy**

All women with MFS should have preconceptual assessment and counselling. There is a 50% chance of their child being affected and they need to be made aware of the options for pre-implantation genetic diagnosis (in vitro fertilization pregnancy where embryos can be assessed for the FBN mutation prior to implantation) and prenatal diagnosis (amniocentesis and chorionic villus sampling). Women having MFS with or without aortic dilation are at increased risk of aortic dissection. This is estimated at 1% if the aortic root measures
Pulmonary heart disease

Pulmonary hypertension

Pulmonary hypertension (PH) is defined as an mPAP of more than 25 mmHg at rest, as measured on right heart catheterization. The clinical classification of PH is provided in Box 30.50.

Pathophysiology

The different groups are characterized by variable amounts of hypertrophy, proliferation and fibrotic changes in distal pulmonary arteries (pulmonary arterial hypertension, PAH; pulmonary veno-occlusive disease, PVOD; pulmonary hypertension, PH, due to left heart disease; PH due to lung disease and/or hypoxia). Pulmonary venous changes are seen in PVOD and PH groups due to left heart disease, and the vascular bed may be destroyed in emphysematous or fibrotic areas seen in lung disease. In chronic thromboembolic pulmonary hypertension (CTEPH), organized thrombi are seen in the elastic pulmonary arteries. Patients with PH with unclear and/or multifactorial mechanisms have variable pathological findings.

Patients with progressive PH develop right ventricular hypertrophy, dilation, heart failure and death.

Pulmonary artery hypertension

Epidemiology

A French registry of 674 patients with PAH identified 39.2% with idiopathic pulmonary artery hypertension (IPAH), 3.9% with familial (or heritable) disease, 9.5% with drug and toxin (anorexigens) causes, 15.3% with autoimmune rheumatic disease, 11.3% with congenital heart disease, 10.4% with portal hypertension and 6.2% with HIV-associated disease. In familial or heritable PAH, mutations in the bone morphogenetic protein receptor type 2 (BMPR2) gene are detected in over 70% of cases; other mutations are seen in patients with hereditary haemorrhagic telangiectasia (Osler–Weber–Rendu syndrome).

Drugs and toxins known to cause PAH include fenfluramine, dexfenfluramine, toxic rapeseed oil and the anorectic agents aminorex and benfluorex.

Clinical features

Patients with PAH may present with symptoms of dyspnoea, fatigue, weakness, angina, syncope or abdominal distension. Clinical signs of PAH and right heart hypertrophy include a left parasternal heave,

less than 4 cm and 10% if it is over 4 cm. Pregnancy should be discouraged in women with aortic dimensions of more than 4.5 cm and they should be offered prophylactic root replacement prior to pregnancy. Current recommendations are that echocardiography should be performed every 6–8 weeks throughout pregnancy and the postpartum period. Blood pressure should be regularly monitored and hypertension treated aggressively. ARBs are teratogenic and women planning pregnancy should be converted to beta-blockers.

Maximum total 20 points; score ≥7 indicates systemic involvement.

The normal mean pulmonary artery pressure (mPAP) at rest is 14 ± 3 mmHg with an upper limit of normal of 20 mmHg. The normal values for mPAP, mean capillary wedge pressure (mPCWP) and cardiac output (CO) are 12 ± 2 mmHg, 6 ± 2 mmHg and 5 L/min, respectively. The fall in pressure across the lung circulation is known as the transpulmonary gradient and reflects the difference between mPAP and mPCWP. The normal transpulmonary gradient is 6 ± 2 mmHg.

The pulmonary vascular resistance (PVR) is calculated by the formula:

\[
\text{mPAP} - \text{mPCWP} \quad \frac{\text{CO}}{
\]

It is normally about 1.5 mmHg/L per min (1.5 Wood units). Approximately 60% of the body’s endothelial surface is in the lungs and the lungs normally offer a low resistance to blood flow. This is because the media of the pre-capillary pulmonary arterioles is thin, as compared with their more muscular systemic counterparts that have to respond constantly to postural changes under the influence of gravity. The fact that the lung circulation normally offers a low resistance to flow explains the preferential passage of blood through the lungs in specific forms of congenital heart disease, which may eventually lead to remodelling of the lung circulation and pulmonary hypertension.
a loud P2 heart sound, a soft pansystolic murmur with tricuspid regurgitation or early diastolic murmur with pulmonary regurgitation. Right heart failure leads to jugular venous distension, ascites, peripheral oedema and hepatomegaly. Clinical signs of associated diseases, such as systemic sclerosis or chronic liver disease, should be sought.

**Investigations**

- **Routine blood tests** include full blood count, renal and liver biochemistry, thyroid function tests, and serological assays for underlying autoimmune rheumatic diseases, HIV and hepatitis.
- **Chest X-ray** shows enlargement of the pulmonary arteries and the major branches, with marked tapering (pruning) of peripheral arteries. The lung fields are usually lucent and there may be right atrial and right ventricular enlargement. The chest X-ray may facilitate the diagnosis of PH due to left heart or chronic lung disease.
- **ECG** shows right ventricular hypertrophy and right atrial enlargement (P pulmonale).
- **Echocardiography** (Fig. 30.103) with tricuspid regurgitation can be used for determination of PAP using the simplified Bernoulli equation (PAP = 4 × (tricuspid regurgitation velocity)² + estimated right atrial pressure). Right atrial pressure can be assumed at 5–10 mmHg unless there is significant dilation of the inferior vena cava with reduced respiratory variation. mPAP = 0.61 × PA systolic pressure + 2 mmHg (although the Bernoulli equation may not be accurate in cases of severe tricuspid regurgitation).

- **CMR** may be useful in adult congenital heart disease and in assessing right ventricular function on serial assessment.
- **Abdominal liver ultrasound** is useful to exclude liver cirrhosis and portal hypertension.
- **Right heart catheterization** may be indicated as part of the clinical assessment to confirm the diagnosis (elevated PAP), determine the pulmonary wedge pressure (PWP), calculate the cardiac output, and assess for pulmonary vascular resistance and reactivity. In PAH, a vasodilator challenge (inhaled nitric oxide, intravenous adenosine or epoprostenol) should be performed to identify patients who might benefit from vasodilator therapies. A responder is defined as a reduction in mean PAP of 10 mmHg or more to reach an absolute mPAP of 40 mmHg or less with increased or unchanged cardiac output. These vasodilator challenges are not recommended in patients with other types of PH (types 2–5).

Management

- **Physical activity.** Patients should be encouraged to remain physically active but avoid exertion that precipitates severe dyspnoea, chest pain or pre-syncpe.
- **Pregnancy.** Patients with PAH have a very high mortality rate during pregnancy (30–50%) and should be counselled against conception. Contraception may include barrier methods, progestosterone-only pill or Mirena coil.
- **Travel.** During plane travel, supplementary oxygen at 2 L/min may be appropriate for patients with reduced functional class and with resting hypoxia of less than 8kPa.
- **Vaccination.** Vaccination should be given for influenza and pneumococcal pneumonia.
- **Elective surgery.** Epidural anaesthesia may be preferable to a general anaesthetic.
- **Oral anticoagulation.** There is evidence to support the use of oral anticoagulation in patients with IPAH, heritable PAH and PAH due to anorexigen. The European target INR is 2.0–3.0.
- **Diuretics.** These are used in patients with right heart failure and fluid overload.
- **Digoxin.** This may be helpful in patients with tachyarrhythmias.
- **Calcium-channel blockers.** These can be effective in high doses in selected patients with IPAH who demonstrate a response to a vasodilator challenge. Right heart catheterization should be repeated in 3–4 months to assess response to therapy.
- **Prostanoids.** Prostacyclin is a potent vasodilator that also inhibits platelet aggregation and cell proliferation. Synthetic prostacyclins are generally short-acting compounds requiring continuous intravenous or subcutaneous infusion or regular aerosol inhalation. They provide symptomatic relief and can improve exercise capacity; epoprostenol can improve survival in patients with both IPAH and associated pulmonary arterial hypertension. Oral selexipag has been approved by the US Food and Drug Administration for PAH treatment.
- **Endothelin receptor antagonists.** Endothelin-1 is a potent vasoconstrictor and mitogen that binds to endothelin A and B receptors in the pulmonary vasculature. Both dual antagonists (bosentan) and selective A receptor antagonists (sitaxentan, ambrisentan) can improve symptoms, exercise capacity and haemodynamics in patients with IPAH.
- **Phosphodiesterase type 5 inhibitors.** These produce vaso-dilation in the pulmonary vasculature and reduce cellular proliferation. Sildenafil and tadalafil have been demonstrated to provide symptomatic relief and improve exercise capacity in patients with IPAH.
- **Balloon atrial septostomy.** This technique may be considered as palliative therapy in severe cases of PH.
- **Lung transplantation.** This is used in patients with an adverse prognosis, although the 5-year survival following transplantation may be only 40–50%.

Other pulmonary hypertension groups

Left-sided heart disease (systolic and diastolic heart failure) and valvular heart disease are frequently associated with PH, as is advanced chronic obstructive pulmonary disease (see p. 956), pulmonary fibrosis and emphysema. Following acute pulmonary embolism, 0.5–2.0% of patients will develop chronic thromboembolic pulmonary hypertension (CTEPH).

MYOCARDIAL AND ENDOCARDIAL DISEASE

CARDIAC TUMOURS

Primary cardiac tumours are rare and three-quarters of these are benign.

Atrial myxomas are the most common. Most are sporadic but some are familial or part of a multi-system syndrome (Carney complex – hyperpigmented skin lesions with extracardiac tumours). Histologically, they are benign, polypoid, gelatinous structures. Most are solitary and occur in the left atrium (75%), attached by a pedicle to the atrial septum. The tumour may obstruct the mitral valve or may be a site of thrombi, which can embolize. The mean age of presentation is 50 years and there is a female predominance. Patients may be asymptomatic or present with dyspnoea, syncope or a mild fever. Physical signs include a loud first heart sound, a tumour ‘plop’ (a loud third heart sound produced as the pedunculated tumour comes to an abrupt halt), a mid-diastolic murmur and/or signs of embolization. Echocardiography, CT and CMR are appropriate to
confirm the diagnosis (Fig. 30.104) prior to cardiac surgery. Because of local recurrence, long-term surveillance is recommended.

Other benign cardiac tumours include lipoma, papillary fibroelastoma, fibroma, haemangioma and rhabdomyoma.

Malignant primary cardiac tumours include angiosarcoma, undifferentiated sarcoma, rhabdomyosarcoma (children), osteosarcoma and leiomyosarcoma. Primary cardiac lymphoma typically occurs in the right heart.

Metastatic spread (secondary cardiac tumours) is 20–40 times more common. Direct invasion can occur with bronchogenic, breast and oesophageal carcinoma. There may be haematogenous or lymphatic spread with lymphoma, leukaemia, transvenous renal cell carcinoma, hepatoma and adrenal tumours. Pericardial effusions are common and pericardiocentesis may be required for diagnosis or for cases with cardiac tamponade.

### MYOCARDIAL DISEASE

Myocardial disease that is not due to ischaemic, valvular or hypertensive heart disease, or a known infiltrative, metabolic/toxic or neuromuscular disorder, may be caused by:

- an acute or chronic inflammatory pathology (myocarditis)
- idiopathic myocardial disease (cardiomyopathy).

### Acute inflammation of the myocardium

Acute inflammation of the myocardium has many causes (Box 30.51). In North America and Europe the most common causes of inflammation are viruses (enteroviruses, adenoviruses, human herpes virus-6, Epstein–Barr virus, cytomegalovirus, hepatitis C and parvovirus B19). Chagas’ disease, due to Trypanosoma cruzi, which is endemic in South America, is one of the most common causes of myocarditis worldwide. Additionally, toxins (including prescribed drugs), physical agents, hypersensitivity reactions and autoimmune conditions may also cause myocardial inflammation.

### Pathology

In the acute phase, myocarditic hearts are flabby with focal haemorrhages; in chronic cases, they are enlarged and hypertrophied.

### Causes of myocarditis

- Idiopathic
- Infective:
  - Viral: coxsackievirus, adenovirus, cytomegalovirus, echovirus, influenza, polio, hepatitis, HIV
  - Parasitic: Trypanosoma cruzi, Toxoplasma gondii (a cause of myocarditis in the newborn or immunocompromised)
  - Bacterial: streptococcus (most commonly, rheumatic carditis), diphtheria (toxin-mediated heart block common)
  - Spirochaetal: Lyme disease (heart block common), leptospirosis
  - Fungal
  - Rickettsial
- Toxic: Drugs: those causing hypersensitivity reactions, e.g. methyldopa, penicillin, sulphonamides, antituberculous, modafinil
- Autoimmune: An autoimmune form with autoactivated T cells and organ-specific antibodies may occur
  - Giant cell myocarditis
  - Alcohol
  - Hydrocarbons

### Causes of sudden cardiac death

**Coronary artery disease**

- Acute myocardial infarction – STEMI
- Chronic ischaemic heart disease
- Following coronary artery bypass surgery
- Following successful resuscitation for cardiac arrest
- Congenital anomaly of coronary arteries
- Coronary artery embolism
- Coronary atheritis

**Non-coronary artery disease**

- Hypertrophic cardiomyopathy
- Dilated cardiomyopathy (ischaemic or idiopathic)
- Arrhythmogenic right ventricular cardiomyopathy
- Congenital long QT syndrome
- Brugada’s syndrome
- Valvular heart disease (aortic stenosis, mitral valve prolapse) ± infective endocarditis
- Cyanoic heart disease (tetralogy of Fallot, transposition)
- Acyanotic heart disease (ventricular septal defect, patent ductus arteriosus)

STEMI, ST elevation myocardial infarction.

Histologically (Fig. 30.105), an inflammatory infiltrate is present – lymphocytes predominating with viral causes, polymorphonuclear cells with bacterial causes, and eosinophils with allergic and hypersensitivity causes.

### Clinical features

Myocarditis typically presents in young adult patients. Presentation may vary from mild fatigue, palpitations, chest pain and dyspnoea through to fulminant congestive cardiac failure. Physical examination reveals soft heart sounds, a prominent third sound and often a tachycardia. A pericardial friction rub may be heard.

### Investigations

- ECG may demonstrate diffuse ST- and T-wave abnormalities (concave ST elevation) and arrhythmias. AV block may be seen with Lyme disease, sarcoid, giant-cell myocarditis and Chagas’ disease (see later).
Echocardiography is required and may reveal normal or reduced bi-ventricular function with resting regional wall motion abnormalities.

Blood tests include ESR and CRP, which are frequently elevated in the acute presentation. Cardiac troponin and creatine kinase levels will also be elevated. Viral serology is not usually helpful.

CMR is recommended to confirm the diagnosis. Patients with acute myocarditis may demonstrate myocardial oedema on T2-weighted images and patchy myocardial enhancement with gadolinium (Fig. 30.106).

Endomyocardial biopsy is considered the gold standard for the diagnosis of myocarditis although its use is reserved for selected patients (fulminant presentation or clinical deterioration) as this is an invasive test performed in specialised units.

Coronary angiography is frequently performed to exclude acute ischaemia as the cause of the patient’s presentation.

Management

Myocarditis resolves within a few weeks in the majority of patients, although a small percentage of patients deteriorate and may require urgent transfer to a cardiac centre with access to extracorporeal membrane oxygenation and/or cardiac transplantation. Bed rest is recommended in the acute phase of the illness and athletic activities should be avoided for 6 months. Heart failure should be treated in the usual way (see p. 1073).

Giant cell myocarditis

This severe form of myocarditis is characterized by the presence of multinucleated giant cells within the myocardium. The cause is unknown but it may be associated with sarcoidosis, thymomas and autoimmune disease. The disease has a rapidly progressive course and a poor prognosis. Immunosuppression is recommended.

Chagas’ disease

Chagas’ disease (see p. 568) is caused by the protozoon Trypanosoma cruzi and is endemic in South America, where upwards of 20 million people are infected. Acutely, features of myocarditis are present with fever and congestive heart failure. Chronically, there is progression to a dilated cardiomyopathy with a propensity towards heart block and ventricular arrhythmias. Treatment is discussed on page 569. Amiodarone is helpful for the control of ventricular arrhythmias; heart failure is treated in the usual way.

Cardiomyopathy

Cardiomyopathies are a group of diseases of the myocardium that affect the mechanical or electrical function of the heart. The ESC provides a classification system according to morphological and functional differences:

- Hypertrophic cardiomyopathy (HCM)
- Arrhythmogenic cardiomyopathy (ACM)
- Dilated cardiomyopathy (DCM)
- Restrictive cardiomyopathies (RCM)
- Unclassified.

Patients can be further divided into familial (genetic) and non-familial subtypes.

Hypertrophic cardiomyopathy

HCMs include a group of inherited conditions that produce hypertrophy of the myocardium in the absence of an alternative cause (e.g. aortic stenosis or hypertension). It is the most common cause of sudden cardiac death in young people and affects 1 in 500 of the population. The majority of cases are familial autosomal dominant and are due to mutations in the genes encoding sarcomeric proteins (Fig. 30.107). The most common causes of HCM are mutations of the β-myosin heavy chain MYH7 and myosin-binding protein C MYBPC3.

There are non-sarcomeric protein mutations in genes that control cardiac metabolism that result in glycogen storage diseases (Danon’s, Pompe’s and Fabry’s diseases) and cause cardiac hypertrophy that may be indistinguishable from inherited HCM on echocardiography.

Clinical features

HCM is characterized by myocardial hypertrophy that frequently involves the interventricular septum, and by disorganization (‘dis-array’) of cardiac myocytes and myofibrils. Some 25% of patients have dynamic left ventricular outflow tract obstruction due to the
combined effects of hypertrophy, systolic anterior motion of the anterior mitral valve leaflet and rapid ventricular ejection. The salient clinical and morphological features of the disease vary according to the underlying genetic mutation. For example, marked hypertrophy is common with β-myosin heavy chain mutations, whereas mutations in troponin T may be associated with mild hypertrophy but a high risk of sudden death. The hypertrophy may not manifest before completion of the adolescent growth spurt, making the diagnosis difficult in children. HCM due to myosin-binding protein may not manifest until the sixth decade of life or later.

**Symptoms**
- Many cases are asymptomatic and are detected by family screening of an affected individual or by a routine ECG examination.
- Chest pain, dyspnoea, syncope or pre-syncope (typically with exertion), cardiac arrhythmias and sudden death are seen.
- Sudden death occurs at any age but the highest rates (up to 6% per annum) occur in adolescents or young adults. Risk factors for sudden death are discussed later.
- Dyspnoea occurs due to impaired relaxation of the heart muscle or the left ventricular outflow tract obstruction that occurs in some patients. The systolic cavity remains small until the late stages of disease, when progressive dilation may occur. If a patient develops atrial fibrillation, there is often a rapid deterioration in clinical status due to the loss of atrial contraction and the tachycardia, resulting in elevated left atrial pressure and acute pulmonary oedema.

**Signs**
- Double apical pulsation (forceful atrial contraction producing a fourth heart sound).

**Fig. 30.107** Cardiomyopathy: clinical categories and genetic basis. Hypertrophic and dilated cardiomyopathies share the same genes, as do the less common restrictive cardiomyopathy and left ventricular non-compaction. Arrhythmogenic cardiomyopathy (ACM) is genetically different. AMPK, adenosine monophosphate-activated kinase; GLA, galactosidase A; LAMP2, lysosomal assisted membrane protein 2; TMEM43, transmembrane protein 43. (From Watkins H, Ashrafian H, Redwood C. Inherited cardiomyopathies. N Engl J Med 2011; 364:1643–1656, with permission.)

**Fig. 30.108** Hypertrophic cardiomyopathy. A two-dimensional echocardiogram (short-axis view). The grossly thickened interventricular septum is shown, resulting in a small left ventricular cavity. This condition is associated with an abnormal anterior motion of the mitral valve during systole (arrowed). LA, left atrium; LV, left ventricle.

- Jerky carotid pulse because of rapid ejection and sudden obstruction to left ventricular outflow during systole.
- Ejection systolic murmur due to left ventricular outflow obstruction late in systole; it can be increased by manoeuvres that decrease afterload, such as standing or Valsalva, and decreased by manoeuvres that increase afterload and venous return, such as squatting.
- Pansystolic murmur due to mitral regurgitation (secondary to systolic anterior motion).
- Fourth heart sound (if not in atrial fibrillation).

**Investigations**
- **ECG** abnormalities in HCM include left ventricular hypertrophy (see Fig. 30.79), ST- and T-wave changes, and abnormal Q waves, especially in the inferolateral leads.
- **Echocardiography** is usually diagnostic. In classical HCM, there is asymmetric left ventricular hypertrophy (involving the septum more than the posterior wall), systolic anterior motion of the mitral valve, and a vigorously contracting ventricle (Fig. 30.108). However, any pattern of hypertrophy may be seen, including concentric and apical hypertrophy.
- **CMR** can detect both the hypertrophy and abnormal myocardial fibrosis (Fig. 30.109) and can differentiate between HCM and infiltrative cardiomyopathies.
- **Genetic analysis**, where available, may confirm the diagnosis and provide prognostic information for the patient and relatives.

**Management**
The management of HCM includes treatment of symptoms and prevention of sudden cardiac death in the patient and relatives. Risk factors for sudden death are:
- massive left ventricular hypertrophy (>30mm on echocardiography)
- family history of sudden cardiac death (<50 years old)
- non-sustained ventricular tachycardia on 24-hour Holter monitoring
- prior unexplained syncope
- abnormal blood pressure response on exercise (flat or hypotensive response).
The presence of these cardiac risk factors is associated with an increased risk of sudden death (Box 20.52), and patients with two
or more should be assessed for ICD insertion. When the risk is less, amiodarone is an appropriate alternative.

Chest pain and dyspnoea are treated with beta-blockers and verapamil, either alone or in combination. An alternative agent is disopyramide if patients have left ventricular outflow tract obstruction. In some individuals with significant left outflow obstruction and symptoms, dual-chamber pacing is necessary. Alcohol (non-surgical) ablation of the septum has been investigated and appears to give good results in reduction of outflow tract obstruction and subsequent improvement in exercise capacity. This procedure carries risks, including the development of complete heart block and MI. Occasionally, surgical resection of septal myocardium may be indicated. Vasodilators should be avoided because they may aggravate left ventricular outflow obstruction or cause refractory hypotension.

Arrhythmogenic cardiomyopathy/arrhythmogenic right ventricular cardiomyopathy

Arrhythmogenic cardiomyopathy (ACM) is an uncommon (1 in 1000–5000 population) inherited condition that predominantly affects the right ventricle with fatty or fibro-fatty replacement of myocytes, leading to segmental or global dilation (Fig. 30.110). Left ventricular involvement has been reported in up to 75% of cases. The fibro-fatty replacement leads to ventricular arrhythmia and risk of sudden death in its early stages, and right ventricular or biventricular failure in its later stages.

Autosomal dominant ACM has been mapped to mutations in genes coding for desmosomal proteins. These are the cardiac ryanodine receptor RyR2 (see p. 1024; also responsible for familial catecholaminergic polymorphic ventricular tachycardia, CPVT), desmoplakin, plakophilin-2 and mutations altering the regulatory sequences of the TGF-β gene.

There are two recessive forms: Naxos disease (associated with palmoplantar keratoderma and woolly hair), which is due to a mutation in junctional plakoglobin, and Carvajal's syndrome, due to a mutation in desmoplakin.

Clinical features

Most patients are asymptomatic. Symptomatic ventricular arrhythmia, syncope or sudden death occurs. Occasionally, presentation is with symptoms and signs of right heart failure, although this is more common in the later stages of the disease. Some patients may be detected through family screening, although frequently the morphological appearance of the right ventricle is normal, despite significant cardiac arrhythmias.

Investigations and diagnosis

- ECG is usually normal but may demonstrate T-wave inversion in the precordial leads related to the right ventricle (V1–V3). Small-amplitude potentials occurring at the end of the QRS complex (epsilon waves) may be present (Fig. 30.111) and incomplete or complete right bundle branch block is sometimes seen. Signal-averaged ECG may indicate the presence of late potentials and the delayed depolarization of individual muscle cells; 24-hour Holter monitoring may demonstrate frequent extrasystoles of right ventricular origin or runs of non-sustained ventricular tachycardia.
Echocardiography is frequently normal but with more advanced cases may demonstrate right ventricular dilation and aneurysm formation; there may be left ventricular dilation.

CMR can assess the right ventricle more accurately and in some cases can demonstrate fibro-fatty infiltration (Fig. 30.112).

Genetic testing may soon be the diagnostic ‘gold standard’. Clinical diagnosis is made using Task Force Criteria, which include:

- structural abnormalities of the right ventricle and right ventricular outflow tract (dilation and abnormal wall motion on echocardiography or MRI)
- fibro-fatty replacement of myocytes on tissue biopsy
- repolarization and conduction abnormalities on ECG or signal-averaged ECG
- ventricular tachycardia or frequent ventricular extrasystoles on Holter monitoring
- family history of ACM in a first- or second-degree relative
- premature sudden death (<35 years) due to ACM.

Management

Beta-blockers are first-line treatment for patients with non-life-threatening arrhythmias. Amiodarone or sotalol is used for symptomatic arrhythmias but for refractory or life-threatening arrhythmias an ICD is required. Occasionally, cardiac transplantation is indicated for either intractable arrhythmia or cardiac failure.

Dilated cardiomyopathy

Dilated cardiomyopathy (DCM) has a prevalence of 7–12 in 100000 and is characterized by dilation of the ventricular chambers and systolic dysfunction with preserved wall thickness.

Familial DCM is predominantly autosomal dominant and can be associated with over 20 abnormal loci and genes (Fig. 30.113). Many of these are genes encoding cytoskeletal or associated myocyte proteins (dystrophin in X-linked cardiomyopathy; actin, desmin, troponin T, β-myosin heavy chain, sarcoglycans, vinculin and lamin α/c in autosomal dominant DCM; Fig. 30.114). Many of these have prominent associated features, such as skeletal myopathy or conduction system disease, and therefore differ from the majority of cases of DCM.

Sporadic DCM can be caused by multiple conditions:

- myocarditis: Coxsackievirus, adenoviruses, erythroviruses, HIV, bacteria, fungi, mycobacteria, parasitic (Chagas' disease)
- toxins: alcohol, chemotherapy, metals (cobalt, lead, mercury, arsenic)
- autoimmune disorders
- endocrine disorders
- neuromuscular disorders.

Clinical features

DCM can present with heart failure, cardiac arrhythmias, conduction defects, thromboembolism or sudden death. Increasingly, evaluation of relatives of DCM patients is allowing identification of early asymptomatic disease, prior to the onset of these complications. Clinical evaluation should include a family history and construction of a pedigree where appropriate.
Myocardial disease

Investigations

- **ECG** may demonstrate diffuse non-specific ST-segment and T-wave changes. Sinus tachycardia, conduction abnormalities and arrhythmias (i.e. atrial fibrillation, ventricular premature contractions or ventricular tachycardia) are also seen.

- **Echocardiogram** reveals dilation of the left and/or right ventricle with poor global contraction function (Fig. 30.115).

- **CMR** may demonstrate other aetiologies of left ventricular dysfunction (e.g. previous MI) or show abnormal myocardial fibrosis (Fig. 30.116).

- **Coronary angiography** or CTCA should be performed to exclude coronary artery disease in all individuals at risk (generally, patients >40 years, or younger if symptoms or risk factors are present).

- **Biopsy** is not normally indicated outside specialist care.

Management

Treatment consists of the conventional management of heart failure with the option of cardiac resynchronization therapy and ICDs in patients with NYHA III/IV grading. Cardiac transplantation is appropriate for certain patients.

Left ventricular non-compaction

Left ventricular non-compaction (LVNC) is associated with a sponge-like appearance of the left ventricle. The condition predominantly affects the apical portion of the left ventricle and may be associated with congenital heart abnormalities. LVNC is diagnosed by echocardiography, CMR or left ventricular angiography. The natural history is unresolved but includes congestive cardiac failure, thromboembolism, cardiac arrhythmias and sudden death. Familial and spontaneous cases have been described.

Primary restrictive non-hypertrophic cardiomyopathy

In this rare condition there is normal or decreased volume of both ventricles with bi-atrial enlargement, normal wall thickness, normal cardiac valves and impaired ventricular filling with restrictive physiology but near-normal systolic function. The restrictive physiology produces symptoms and signs of heart failure. Conditions associated with this form of cardiomyopathy include amyloidosis (most common, see p. 1358), sarcoidosis, Loeffler’s endocarditis and endomyocardial fibrosis; in the latter two conditions there is myocardial and endocardial fibrosis, associated with eosinophilia. The idiopathic form of restrictive cardiomyopathy may be familial.

Clinical features

Patients with restrictive cardiomyopathy may present with dyspnoea, fatigue and embolic symptoms. On clinical examination there will be elevated JVP with diastolic collapse (Friedreich’s sign) and elevation of venous pressure with inspiration (Kussmaul’s sign), hepatic enlargement, ascites and dependent oedema. Third and fourth heart sounds may be present.

Investigations

- **ECG** may demonstrate low-voltage QRS and ST-segment and T-wave abnormalities.

- **Echocardiography** shows symmetrical myocardial thickening and often a normal systolic ejection fraction, but impaired ventricular filling. In amyloid patients the myocardium typically appears speckled with absent radial thickening, as demonstrated by ‘tramlines’ on M-mode echocardiography (Fig. 30.117).

- **CMR** may show abnormal myocardial fibrosis in amyloidosis or sarcoidosis.
• Cardiac catheterization and haemodynamic studies may help distinguish between restrictive cardiomyopathy and constrictive pericarditis, although volume loading may be required.

• Endomyocardial biopsy is often useful in this condition, in contrast to other cardiomyopathies, and may permit a specific diagnosis, such as amyloidosis, to be made.

Management

There is no specific treatment. Cardiac failure and embolic manifestations should be treated. Cardiac transplantation is necessary in some severe cases, especially the idiopathic variety. Management of primary amyloidosis is discussed elsewhere (p. 1358). However, patients with cardiac amyloidosis have a worse prognosis than those with other forms of the disease, and the disease often recurs after transplantation. Liver transplantation may be effective in familial amyloidosis (due to production of mutant pre-albumin) and may lead to reversal of the cardiac abnormalities.

Acquired cardiomyopathies

Stress (Tako-tsubo/octopus pot/apical ballooning syndrome) cardiomyopathy

Patients with this condition present acutely with chest pain and breathlessness associated with ECG changes and elevated cardiac biomarkers consistent with acute MI. Diagnostic coronary angiography typically demonstrates unobstructed coronary arteries, with characteristic akinesia of the mid-apical segments of the left ventricle on ventriculography or echocardiography, and preserved basal function (Fig. 30.118). The pathophysiology is uncertain but disease may be due to transient catecholamine excess, coronary vasospasm, abnormalities of the coronary microcirculation and hypertrophy of the basal septum. The syndrome is more common in middle-aged to elderly women. Severe cases may have cardiogenic shock and pulmonary oedema. Patients with a significant left ventricular gradient may respond to cautious beta-blockade. Complete recovery of function is usual within 4–6 weeks but there are recurrences.

Peripartum cardiomyopathy

This rare condition affects women in the last trimester of pregnancy or within 5 months of delivery. It presents as a dilated cardiomyopathy, is more common in obese, multiparous women over 30 years old, and is associated with pre-eclampsia. Nearly half of patients will recover to normal function within 6 months but in some it can cause progressive heart failure and sudden death.

Tachycardia cardiomyopathy

Prolonged periods of supraventricular or ventricular tachycardia will lead to dilated cardiomyopathy. Cardioversion and ablation may be necessary to restore sinus rhythm and allow for recovery of cardiac function.

PERICARDIAL DISEASE

The pericardium acts as a protective covering for the heart. It consists of an outer fibrous pericardial sac and an inner serous pericardium; the latter is made up of the inner visceral epicardium that lines the heart and great vessels, and its reflection, the outer parietal pericardium that lines the fibrous sac. The normal amount of pericardial fluid is 20–49 mL and this fluid lubricates the surface of the heart. Presentations of pericardial disease include:

- acute, incessant and chronic pericarditis
- pericardial effusion and cardiac tamponade
- constrictive pericarditis
- pericardial masses.

Acute pericarditis

This term refers to inflammation of the pericardium, which may account for 5% of accident and emergency presentations with chest pain. The condition is more common in men, particularly young adults. Acute pericarditis has numerous aetiologies (Box 30.53), although, in most cases, a cause is not identified (idiopathic).

Clinical features and investigations

There are four common clinical features of acute pericarditis:

- **chest pain** that may be pleuritic, exacerbated by movement and relieved by sitting forwards
- **pericardial friction rub**
- **ECG abnormalities** with widespread concave-upwards (saddle-shaped) ST elevation (**Fig. 30.119**), reciprocal ST depression in leads AVR and V1, and PR segment depression
- **pericardial effusion** (**Fig. 30.120**).

A clinical diagnosis of acute pericarditis can be made with two out of four of these features.

Inflammatory blood tests will be elevated (**CRP, ESR, white cell count**) and can be used to monitor disease resolution. Cardiac troponin and creatine kinase may be elevated in cases with myocardial pericarditis. Chest X-ray may demonstrate cardiomegaly in patients with a large pericardial effusion.

Management and treatment

In 70–90% of cases acute pericarditis is self-limiting. Most patients can be treated with aspirin 750–1000 mg 3 times daily or ibuprofen 600–800 mg 3 times daily for 1–2 weeks, together with colchicine (0.5 mg twice daily for 3 months). Corticosteroids should be reserved for patients with a known immune cause, as their use is associated with an increased rate of recurrence. High-risk patients (fever >38°C, subacute onset, large effusion, tamponade, lack of response to therapy) should be admitted for treatment. Activity should be restricted until the inflammatory markers are normalized. Competitive athletes are advised to avoid exercise for at least 3 months.

Incessant or chronic pericarditis

About 20% of cases of acute pericarditis go on to develop idiopathic relapsing pericarditis, which may be incessant (recurring within 6 weeks) or chronic (lasting >3 months). The first-line treatment is non-steroidal anti-inflammatory drugs (NSAIDS) or aspirin.
with colchicine for up to 6 months. In resistant cases oral corticosteroids may be effective, and in some patients pericardectomy may be appropriate. CT or CMR may be helpful in demonstrating thickened (>4 mm) or inflamed pericardium.

**Tuberculous pericarditis**

This is uncommon (<5%) in the developed world but may account for over 50% of cases in developing countries and over 90% in patients with HIV. Tuberculous pericarditis usually presents with chronic low-grade fever, particularly in the evening, associated with features of acute pericarditis, dyspnoea, malaise, night sweats and weight loss. Pericardial aspiration is often required to make the diagnosis. Constrictive pericarditis is a frequent outcome. Treatment is as for pulmonary tuberculosis (see p. 969) with added prednisolone 60 mg daily for 2–6 weeks.

**Post-cardiac injury syndromes**

This includes pericarditis following MI (Dressler’s syndrome), cardiac surgery or trauma. An autoimmune reaction is triggered by myocardial or pericardial damage, leading to pericarditis. Recurrences are common.

**Malignant pericarditis**

Carcinoma of the bronchus, carcinoma of the breast and Hodgkin’s lymphoma are the most common causes of malignant pericarditis. Leukaemia and malignant melanoma are also associated with pericarditis. A substantial pericardial effusion is very typical and is due to obstruction of lymphatic drainage from the heart. The effusion is often haemorrhagic. Radiation and therapy for thoracic tumours may cause radiation injury to the pericardium, resulting in serous or haemorrhagic pericardial effusion and pericardial fibrosis.

**Pericardial effusion and cardiac tamponade**

A pericardial effusion is a collection of fluid within the potential space of the serous pericardial sac (Fig. 30.121); it commonly accompanies an episode of acute pericarditis. When a large volume collects in this space, ventricular filling is compromised,

"Fig. 30.120 Pericardial effusion. (A) Note the globular appearance to the cardiac silhouette on chest X-ray. (B) CT scan confirms the circumferential pericardial effusion (arrowed). Note the absence of pericardial calcification that is a feature of chronic pericardial disease.

**Fig. 30.121 Two-dimensional echocardiogram (short-axis view) from a patient with a large pericardial effusion associated with pulmonary tuberculosis.** The exudate is seen between the visceral and parietal layers of the pericardium and would give a false impression of cardiomegaly on a chest X-ray. Note the multiple fibrous strands within the effusion, showing that it is consolidating and will probably lead to constriction of cardiac function. LA, left atrium; LV, left ventricle; PE, pericardial effusion; RA, right atrium; RV, right ventricle.

leading to embarrassment of the circulation. This is known as cardiac tamponade.

**Clinical features**

Symptoms of a pericardial effusion commonly reflect the underlying pericarditis. On examination:

- Heart sounds are soft and distant.
- Apex beat is commonly obscured.
- A friction rub may be evident due to pericarditis in the early stages, but this becomes quieter as fluid accumulates and pushes the layers of the pericardium apart.
• Rarely, the effusion may compress the base of the left lung, producing an area of dullness to percussion below the angle of the left scapula (Ewart’s sign).
• As the effusion worsens, signs of cardiac tamponade may become evident:
  • raised JVP with sharp x descent
  • Kussmaul’s sign (rise in JVP/increased neck vein distension during inspiration)
  • pulsus paradoxus (an exaggeration in the normal variation in pulse pressure seen with inspiration, such that there is a drop in systolic blood pressure of ≥10 mmHg)
  • reduced cardiac output.

Investigations
• ECG reveals low-voltage QRS complexes (<0.5 mV in limb leads) with sinus tachycardia and there may be electric alternans (alteration of QRS amplitude or axis between beats).
• Chest X-ray (see Fig. 30.120A) shows a large, globular or pear-shaped heart with sharp outlines. Typically, the pulmonary veins are not distended.
• Echocardiography (see Fig. 30.121) is the most useful technique for demonstrating the effusion and looking for evidence of tamponade: late diastolic collapse of the right atrium, early diastolic collapse of the right ventricle, ventricular septum displacement into the left ventricle during inspiration, diastolic flow reversal in the hepatic veins during expiration, and dilated inferior vena cava with ≥50% reduction during inspiration.
• Cardiac CT or MRI is helpful if loculated pericardial effusions are suspected (post cardiac surgery).
• Pericardiocentesis is the removal of pericardial fluid with an aseptic technique under echocardiographic guidance (see Fig. 30.36). It is indicated when a tuberculous, malignant or purulent effusion is suspected.
• Pericardial biopsy may be needed if tuberculosis is suspected and pericardiocentesis is not diagnostic.

Other tests may be needed to identify underlying causes: for example, blood cultures or autoantibody screen.

Management
An underlying cause should be sought and treated if possible. Most pericardial effusions resolve spontaneously. However, when the effusion collects rapidly, tamponade may result. Pericardiocentesis is then indicated to relieve the pressure; a drain may be left in place temporarily to allow sufficient release of fluid. Pericardial effusions may re-accumulate, most commonly due to malignancy (in the UK). This may require pericardial fenestration: that is, creation of a window in the pericardium to allow the slow release of fluid into the surrounding tissues. This procedure may be performed either transcutaneously under local anaesthetic or using a conventional surgical approach.

Constrictive pericarditis
Certain causes of pericarditis, such as tuberculosis, haemopericardium, bacterial infection and rheumatic heart disease, result in the pericardium becoming thick, fibrous and calcified. This may also develop late after open heart surgery, and fibrosis also occurs with the use of dopamine agonists, such as cabergoline and pergolide. In many cases these pericardial changes do not cause any symptoms. If, however, the pericardium becomes so inelastic as to interfere with diastolic filling of the heart, constrictive pericarditis is said to have developed. As these changes are chronic, allowing the body time to compensate, this condition is not as immediately life-threatening as cardiac tamponade, in which the circulation is more acutely embarrassed.

Constrictive pericarditis should be distinguished from restrictive cardiomyopathy (see p. 1123). The two conditions are very similar in their presentation but the former is fully treatable, whereas most cases of the latter are not. In the later stages of constrictive pericarditis, the subepicardial layers of myocardium may undergo fibrosis, atrophy and calcification.

Clinical features
The symptoms and signs of constrictive pericarditis occur due to:
• reduced ventricular filling (similar to cardiac: Kussmaul’s sign, sharp, pulsus paradoxus; different to tamponade: raised JVP with deep y descent or Friedrich’s sign)
• systemic venous congestion (ascites, dependent oedema, hepatomegaly and raised JVP)
• pulmonary venous congestion (dyspnoea, cough, orthopnoea, paroxysmal nocturnal dyspnoea)

Less commonly, the cause may be:
• reduced cardiac output (fatigue, hypotension, reflex tachycardia)
• rapid ventricular filling (a ‘pericardial knock’ is heard in early diastole at the lower left sternal border)
• atrial dilation (30% of cases have atrial fibrillation).

Investigations
• Chest X-ray shows a relatively small heart in view of the symptoms of heart failure. Pericardial calcification may be present in up to 50%. A lateral chest film may be useful for detecting calcification that is missed on a postero-anterior film. However, a calcified pericardium is not necessarily a constricted one.
• ECG reveals low-voltage QRS complexes with generalized T-wave flattening or inversion.
• Echocardiography shows thickened, calcified pericardium and small ventricular cavities with normal wall thickness. Doppler studies may be useful.
• CT and CMR are used to assess pericardial anatomy and thickness (≥4 mm) (see Fig. 30.28).
• Endomyocardial biopsy may be helpful in distinguishing constrictive pericarditis from restrictive cardiomyopathy in difficult cases.
• Cardiac catheterization will usually reveal equal end-diastolic pressures in the left and right ventricles, owing to pericardial constriction.

Restrictive cardiomyopathy is a close mimic of constrictive pericarditis and all the above tests may help to distinguish the two conditions.

Management
The treatment for chronic constrictive pericarditis is complete resection of the pericardium. This is a risky procedure with a high complication rate due to the presence of myocardial atrophy in many cases at the time of surgery. Thus, early pericardiectomy is suggested in non-tuberculous cases, before severe constriction and myocardial atrophy have developed.

In cases of tuberculous constriction, the presence of pericardial calcification implies chronic disease. Early pericardiectomy with antituberculous drug cover is used in these cases. If there is no calcification, a course of antituberculous therapy should be attempted first. If the patient’s haemodynamic state remains static or deteriorates after 4–6 weeks of therapy, pericardiectomy is recommended.

PERIPHERAL VASCULAR DISEASE

PERIPHERAL ARTERIAL DISEASE

Peripheral vascular disease (PVD) is commonly caused by atherosclerosis and usually affects the aorto-iliac or infra-inguinal arteries. It is present in 7% of middle-aged men and 4.5% of middle-aged women, but the mortality associated with coexisting cardiovascular and cerebrovascular disease means that only a proportion of patients with PVD progress to losing their leg.

Limb ischaemia

Limb ischaemia may be classified as chronic or acute.

Chronic lower limb ischaemia

Common risk factors are:
- smoking
- diabetes
- hypercholesterolaemia
- hypertension.

Premature atherosclerosis in patients aged below 45 years may be associated with thrombophilia and hyperhomocysteinaemia.

Clinical features

Symptoms

Peripheral arterial disease can be described using the Fontaine classification:
- Stage I: asymptomatic
- Stage II: intermittent claudication
- Stage III: rest pain/nocturnal pain
- Stage IV: necrosis/gangrene.

Patients with intermittent claudication complain of exertional discomfort, most commonly in the calf, which is relieved by rest. Patients with aorto-iliac disease may experience pain in the buttock, hip or thigh and may notice erectile dysfunction. The ‘claudication distance’ may be reproducible.

Patients with rest pain experience severe, unrelenting pain in the foot, which stops a patient from sleeping. It is partially relieved by dangling the foot over the edge of the bed or standing on a cold floor.

Patients with severe PVD or critical lower limb ischaemia may have ulceration or necrosis of the tissue (gangrene).

Signs

The lower limbs are cold with dry skin and lack of hair. Pulses may be diminished or absent. Ulceration may occur in association with dark discolouration of the toes or gangrene. The abdomen should be examined for a possible aortic aneurysm.

Differential diagnosis

Symptoms may be confused with those of:
- spinal canal claudication (when all pulses are present)
- osteoarthritis of the hip/knee (knee pain often at rest)
- peripheral neuropathy (associated with numbness and tingling)
- popliteal artery entrapment (young patients who may have normal pulses)
- venous claudication (bursting pain on walking with a previous history of a DVT)
- fibromuscular dysplasia
- Buerger’s disease (young males, heavy smokers).

Investigations

An estimation of the anatomical level of disease may be possible with the examination of pulses. The severity of disease is indicated by the ankle/brachial pressure index (ABPI). This is a measurement of the cuff pressure at which blood flow is detectable by Doppler in the posterior tibial or anterior tibial artery compared to the pressure in the brachial artery (ankle/brachial pressure). Intermittent claudication is associated with an ABPI of 0.5–0.9, while values less than 0.5 are associated with critical limb ischaemia. The sensitivity of the test may be improved by a fall in ABPI after exercise. If the arteries are heavily calcified and incompressible, commonly where there is coexisting renal or diabetic disease, the ABPI will be falsely elevated. In these patients toe pressure values are more sensitive. Diagnostic imaging includes the following options:
- Duplex ultrasound using B-mode ultrasound and colour Doppler is usually the first-line investigation and can provide an accurate anatomical map of the lower limbs with sensitivity of 87% and specificity of 94% compared to formal angiography.
- Contrast-enhanced MR angiography provides excellent imaging of both legs with a single contrast injection without exposure to ionizing radiation, and is commonly used to assess the extent of disease prior to planned intervention.
- CT angiography is an effective alternative to MR angiography where MR is contraindicated, although extensive calcification may obscure stenoses. CT angiography requires ionizing radiation and iodinated contrast media.
- Digital subtraction angiography (DSA) provides an arterial map (Fig. 30.122) but requires peripheral arterial cannulation and exposes the individual to iodinated contrast; it should be reserved for use in patients immediately prior to intervention.

Management

Medical

All patients need aggressive risk factor management, as PVD also puts them at significant risk of ischaemic heart disease and cerebrovascular disease. Those with diabetes require careful glycaemic control and regular review by a chiropodist.

A supervised exercise programme should be offered to all patients with intermittent claudication, where they are encouraged to undergo aerobic exercise for at least 2 hours per week, up to the point of maximal pain.

Naftidrofuryl oxalate is a vasodilator agent that inhibits vascular and platelet 5-hydroxytryptamine_2 (5-HT_2) receptors and can reduce lactic acid levels. At a dose of 1–200 mg three times a day, it may increase walking distance and improve quality of life. It should be considered for a trial period of 3–6 months when patients are reluctant to undergo interventional treatment and supervised exercise has proved insufficient to control symptoms.

Surgical and radiological

Vascular intervention for stable claudication is not generally recommended, except when symptoms are severe or disabling. Percutaneous transluminal angioplasty is the first option and is carried out via a catheter inserted into the femoral artery. The long-term
Peripheral vascular disease

Aneurysmal disease

Aneurysms are defined as a permanent dilation of the artery to twice the normal diameter and may be classified as true or false. In true aneurysms, the arterial wall forms the wall of the aneurysm. The arteries most frequently involved are the abdominal aorta, the iliac, popliteal and femoral arteries, and the thoracic aorta (in decreasing frequency). In false aneurysms (pseudoaneurysms) the surrounding tissues form the wall of the aneurysm. False aneurysms can occur following femoral artery puncture. A haematoma is formed because of inadequate compression of the entry site and continued bleeding into the surrounding compressed soft tissue forms the wall of this aneurysm.

Abdominal aortic aneurysm

Abdominal aortic aneurysms (AAAs) occur most commonly below the renal arteries (infra-renal). The incidence increases with age, AAAs being present in 5% of the population over 60 years of age. They arise five times more frequently in men, and in 1 in 4 male children of an affected individual. Aneurysms may occur secondarily to atherosclerosis, infection (syphilis, *Escherichia coli*, *Salmonella*) and trauma, or may be genetic (Marfan’s or Ehlers-Danlos syndrome).
Screening
In England and Wales the prevalence of AAA is 3–4% of men aged 65 years or more, and approximately 6000 deaths occur each year from a ruptured aortic aneurysm. The mortality rate for elective surgery is 3.5% or lower, compared to 50% for an emergency repair. There are fixed risk factors – age, male gender, strong family history – and modifiable risk factors – smoking, hypertension, hypercholesterolaemia.

The UK recommendation is that screening should be offered to men aged 65–74 years, who receive an abdominal ultrasound.

- Normal or <3cm aortas do not require treatment or further scans.
- Small (3–4.4 cm) aortas require annual ultrasound surveillance and GP review to optimize lifestyle.
- Medium (4.5–5.4 cm) aortas require quarterly ultrasound surveillance and cardiovascular secondary prevention therapy.
- Large (≥5.5 cm) aortas are referred for assessment and possible elective repair.

Screening of female patients is not recommended, as the prevalence is much lower.

Clinical features
Symptoms
Most aneurysms are asymptomatic and are found on routine abdominal examination or plain X-ray, or during urological investigations. Rapid expansion or rupture of an AAA may cause severe pain (epigastric pain radiating to the back). A ruptured AAA causes hypotension, tachycardia, profound anaemia and sudden death. The symptoms of rupture may mimic renal colic, diverticulitis and severe lower abdominal or testicular pain. Gradual erosion of the vertebral bodies may cause non-specific back pain. The aneurysm may embolize distally causing acute limb ischaemia. Inflammatory aneurysms can obstruct adjacent structures, such as the ureter, duodenum and vena cava. Rarely, aneurysms can present with severe haematemesis secondary to an aortoduodenal fistula.

Signs
The aorta is retroperitoneal and in overweight patients there may be no overt signs. An aneurysm is suspected if a pulsatile, expansile abdominal mass is felt. The presence of an AAA should alert a clinician to the possibility of popliteal aneurysms. Patients may present with ‘trash feet’, dusky discoloration of the digits secondary to emboli from the aortic thrombus.

Management
As with any operation, treatment of an asymptomatic aneurysm depends on the balance of operative risk and conservative management. The UK Small Aneurysm Trial showed that patients with infra-renal AAAs did best with an operation if the aneurysm was:

- ≥5.5 cm in diameter
- expanding at a rate of >1 cm/year
- symptomatic.

Medical
Aneurysmal disease needs careful control of hypertension, smoking cessation and lipid-lowering medication. Patients with AAAs of less than 5.5 cm are followed up by regular ultrasound surveillance.

Surgical and endovascular intervention
Intervention to treat AAA can be performed by open aneurysm repair, hand-assisted or total laparoscopic repair, or endovascular stent insertion (via the femoral or iliac arteries). The Endovascular Aneurysm Repair (EVAR) studies (stent versus open surgical repair) and EVAR 2 (stent versus medical therapy in patients unsuitable for open repair) investigated the role of endovascular stents in patients with an AAA of 5.5 cm or more on CT. In EVAR, the 30-day mortality rate was 1.7% with stenting versus 4.7% with surgery (p = 0.009) but the long-term mortality rate was similar in both groups at 4 years. In EVAR 2, the 30-day mortality rate with stenting was 9%. Long-term mortality rate was similar in both stent and medical therapy groups. Current UK guidance recommends surgical repair rather than EVAR for unruptured aneurysms, although this is presently being reviewed. EVAR has a more prominent role in treating ruptured aneurysms, especially in older and frailer patients.

Prognosis
After repair, patients with an AAA should return to normal activity within a few months.

Thoraco-abdominal aneurysm
The ascending, arch or descending thoracic aorta may become aneurysmal. Ascending thoraco-abdominal aneurysms (TAAs) occur most commonly in patients with Marfan’s syndrome or hypertension. Descending or arch TAAs occur secondary to atherosclerosis and are now rarely due to syphilis.

Clinical features
Most aneurysms are asymptomatic and are found on routine chest X-ray or cardiological investigation. Rapid expansion may cause severe pain (chest pain radiating to the upper back) and rupture is associated with hypotension, tachycardia and death. Chest symptoms from expansion may include stridor (compressed bronchial tree), haemoptysis (aortobronchial fistula) and hoarseness (compression of the recurrent laryngeal nerve). Aorto-oesophageal fistula is an uncommon cause of haematemesis.

Investigations
- CT or MRI scan is used for assessment of a TAA.
- Aortography may be helpful for assessing the position of the key branches in relation to the aneurysm.
- TOE can be useful for identifying an aortic dissection.

Management
If the aneurysm is bigger than 6 cm, then operative repair or stenting may be appropriate, but these procedures can be technically difficult and carry a high risk of mortality and paraplegia. EVAR is, at present, the procedure of choice for isolated descending thoracic aneurysms.

Acute aortic syndromes
Acute aortic syndromes include aortic dissection, intramural haematoma (IMH) and penetrating aortic ulcers. Aortic dissection usually begins with a tear in the intima. Blood penetrates the diseased medial layer and then cleaves the intimal laminal plain, leading to dissection. IMH is considered a precursor of dissection, in which there is rupture of the vasa vasorum in the aortic media with aortic wall infarction. IMH is typically in the descending thoracic aorta. Deep penetrating aortic plaques may lead to IMH, dissection or ulceration/perforation. There is a predisposition to aortic dissection in patients with autoimmune rheumatic disorders and Marfan’s and Ehlers–Danlos syndromes.

Aortic dissection can be classified according to the timing of diagnosis from the origin of symptoms: acute, less than 2 weeks; subacute, 2–8 weeks; and chronic, more than 8 weeks, with
mortality and extension decreasing with time. It can also be classified anatomically:

- **Type A** involves the aortic arch and aortic valve proximal to the left subclavian artery origin. This category includes De Bakey type I (extends to the abdominal aorta) and De Bakey type II (localized to the ascending aorta).

- **Type B** involves the descending thoracic aorta distal to the left subclavian artery origin. This category includes De Bakey type III (Fig. 30.123).

**Clinical features**

**Symptoms**
Most patients present with a sudden onset of severe and central chest pain that often radiates to the back and down the arms, mimicking MI. The pain is often described as tearing in nature and may be migratory.

**Signs**
Patients may be shocked and may have neurological symptoms secondary to loss of blood supply to the spinal cord. They may develop aortic regurgitation, coronary ischaemia and cardiac tamponade. Distal extension may produce acute kidney failure, acute lower limb ischaemia or visceral ischaemia. Peripheral pulses may be absent.

**Investigations**
The mediastinum may be widened on chest X-ray; urgent CT scan, TOE or MRI will confirm the diagnosis (see Fig. 30.102).

---

**Management**
At least 50% of patients are hypertensive and may require urgent antihypertensive medication to reduce blood pressure to below 120mmHg; intravenous beta-blockers (labetalol, metoprolol) and vasodilators (GTN) are used. Type A dissections should undergo surgery (arch replacement) if the patient is fit enough, as medical management carries a high mortality (50% within 2 weeks). Type B dissections carry a better prognosis and have a survival rate of 89% at 1 month; initially, these patients should be managed medically unless they develop complications. Endovascular intervention with stents may be indicated in individuals with rapidly expanding dissections (>1 cm/year), critical diameter (>5.5 cm), refractory pain or malperfusion syndrome, blunt chest trauma, penetrating aortic ulcers or IMH. Patients will require long-term follow-up with CT or MRI.

**Other types of peripheral arterial disease**

**Raynaud’s phenomenon or Raynaud’s disease**
Raynaud’s phenomenon consists of spasm of the digital arteries, usually precipitated by cold and relieved by heat. If there is no underlying cause, it is known as Raynaud’s disease. This affects 5% of the population, mostly women. The disorder is usually bilateral and fingers are affected more commonly than toes.
Clinical features
Vasoconstriction causes skin *pallor* followed by *cyanosis* due to sluggish blood flow, then redness secondary to hyperaemia. The duration of the attacks is variable but they can sometimes last for hours. Numbness, a burning sensation and severe pain occur as the fingers warm up. In chronic, severe disease tissue, *infarction* and *digital loss* can occur.

Diagnosis
Primary Raynaud’s disease needs to be differentiated from secondary treatable causes leading to Raynaud’s phenomenon. These are the rheumatic autoimmune disorders, such as systemic sclerosis. It can be associated with atherosclerosis or occupations that involve the use of vibrating tools. Ergot-containing drugs and beta-blockers, as well as smoking, can aggravate symptoms.

Management
Patients should avoid cold provocation by wearing gloves and warm clothes, and stop smoking. Vasodilators can be prescribed but are often unacceptable, as cerebral vasodilation causes severe headaches. Sympathectomy or prostacyclin infusion can be helpful in severe disease.

Takayasu’s disease
This is rare, except in Japan. It is known as the pulseless disease or aortic arch syndrome. It is of unknown aetiology and occurs in females. There is a vasculitis involving the aortic arch, as well as other major arteries. A systemic illness is also present, with pain and tenderness over the affected arteries. Absent peripheral pulses and hypertension are common. Corticosteroids help the constitutional symptoms. Eventually, heart failure and strokes may occur but most patients survive for at least 5 years. Treatment may involve a surgical bypass to improve perfusion of the affected areas.

Thromboangiitis obliterans (Buerger’s disease)
This disease, involving the small vessels of the lower limbs, occurs in young men who smoke. Although sometimes clinically indistinguishable from atheromatous disease, pathologically there is inflammation of the arteries and sometimes veins, which may indicate a separate disease entity. Clinically, it presents with severe claudication and rest pain, leading to gangrene. A thrombophlebitis is sometimes present. Treatment is as for all peripheral vascular disease but patients must stop smoking.

Cardiovascular syphilis
This gives rise to:
- uncomplicated aortitis
- aortic aneurysms, usually in the ascending part
- aortic valvulitis with regurgitation
- stenosis of the coronary ostia.

The diagnosis is confirmed by serology. Treatment is with penicillin. Aneurysms and valvular disease are treated as necessary by the usual methods.

PERIPHERAL VENOUS DISEASE
Venous thromboembolic disease is covered in Chapter 29.

Varicose veins
Varicose veins are a common problem and sometimes give rise to pain. They may be treated by surgery, injection with ultrasound-guided foam sclerotherapy, or thermal ablation with endovenous lasers.

Superficial thrombophlebitis
This commonly affects the saphenous vein and is often associated with varicosities. Occasionally, the axillary vein is involved, usually as a result of trauma. There is local superficial inflammation in the vein wall, with secondary thrombosis.

The clinical picture is of a painful, tender, cord-like structure with associated redness and swelling.

The condition usually responds to symptomatic treatment with rest, elevation of the limb and analgesics (e.g. NSAIDs). The Comparison of Arixtra in Lower Limb Superficial Vein Thrombosis with Placebo (CALISTO) trial demonstrated that a 45-day course of subcutaneous fondaparinux (2.5 mg daily), compared with placebo, significantly decreased the rate of thromboembolic events (pulmonary embolism and DVT) from 1.3% to 0.2%, and limited the extension of superficial vein thrombosis to the saphenofemoral junction from 3.4% to 0.3% with no increased risk of bleeding.

Hypertension is a major cardiovascular risk factor affecting one-third of the adult population. It should be managed as part of a comprehensive cardiovascular risk reduction strategy, while also assessing for hypertensive end-organ damage and ruling out secondary causes. Treatment involves modifying lifestyle to improve diet and body weight, and making use of a range of antihypertensive medications.

Most hypertension is managed in primary care. However, young patients with hypertension, or patients who have uncontrolled hypertension despite taking three or more antihypertensives, should be referred for expert evaluation. Doctors may subspecialize in the management of hypertension after completing training in clinical pharmacology, cardiology, renal medicine or another medical specialty.

Hypertension is a disease of ageing. It is rare in children and adolescents, and a diagnosis in those under 30 years of age requires careful evaluation of possible underlying secondary causes (see p. 1136). Due to age-related stiffening in large arterial structure...
Hypertension is largely asymptomatic, though it is associated with increased prevalence of headaches, epistaxis and, less commonly, other neurological symptoms such as visual disturbance and dizziness. Furthermore, in the absence of a hypertensive emergency syndrome (see p. 1144), symptoms related to raised BP are not an indication for treatment. Indeed, antihypertensive therapy is more likely to be the cause of adverse symptoms, such as postural intolerance. History and examination should seek out identifiable causes of raised BP and asymptomatic organ damage.

There are four key considerations in the clinical assessment of patients with hypertension (Fig. 31.2) that can be determined through history, examination and investigations:

- What is the true BP level?
- Is there an identifiable reason for high BP?
- Does the BP level require lowering?
- Are there compelling reasons to use certain therapeutic approaches above others?

**Examination and investigations**

These should include:

- ‘out-of-office’ BP level
- asymptomatic organ damage: eyes, kidneys, heart (Fig. 31.2)
- exclusion of secondary causes where relevant
- estimation of total cardiovascular risk.

**MEASUREMENT OF BLOOD PRESSURE**

Due to the non-continuous, pulsatile blood flow maintained by the cardiac cycle, BP is represented by two numbers: systolic (peak arterial pressure during cardiac contraction) and diastolic (lowest arterial pressure during cardiac relaxation). It is presented as systolic pressure/diastolic pressure in mmHg (millimetres of mercury). BP is dynamic and has patterns of variability over seconds (related to breathing, sympathetic activation), minutes (exertion), hours (wake–sleep, circadian hormonal patterns) and the longer term (seasonal). Therefore, the measurement of BP and its use to determine the treatment of hypertension are inherently imprecise and a single measure may not reliably represent the usual (real) BP and its contribution to overall cardiovascular risk. As with any biological variable, the true usual BP is better approximated with multiple measurements at each assessment, and sometimes over several different assessment episodes, before decisions are made regarding changes in treatment.

BP can be measured in several different locations on the body, though readings are traditionally taken in the non-dominant arm. Initially, the BP may be checked in both arms; if there is a significant difference (usually considered to be >10mmHg), then the arm with the higher BP is used for subsequent measurements.

It is important to measure BP in the correct manner. Methodological variation can falsely and hugely over- or underestimate BP.
Measurement of blood pressure

For static measurements (office/surgery, home), BP should be measured in the seated position after 5 minutes’ uninterrupted rest, with the back supported and the legs uncrossed. The BP bladder should encircle at least 80% of the upper arm circumference and should be placed at the level of the heart; the arm should be supported (Fig. 31.3).

Although the unit of BP is still ‘millimetres of mercury’ (mmHg), mercuric sphygmomanometers are obsolete. Modern monitors are usually electronic, oscillometric devices that are automated and have been validated against mercuric devices or intra-arterial BP catheters.

One situation where auscultatory (i.e. using a cuff and stethoscope to listen over the brachial artery) methods are still preferred is in atrial fibrillation (see p. 1059), where variations in pulse volume and rapid variation in BP due to variable left ventricular filling time lead to inaccuracies when oscillometric BP machines are used, especially when ventricular rates are uncontrolled. In particular, diastolic BP tends to be poorly estimated in this situation.

Office/surgery measurement

This refers to measurement of the BP by a healthcare professional in a healthcare setting, such as a primary care surgery or hospital outpatient department. This is the most established method of measurement and all clinical trials of antihypertensive drugs have used it to assess for inclusion and for titration towards target.

It is established practice to take more than two sequential BP readings and to use either the mean or the lowest of these to represent office BP.

Ambulatory measurement

Ambulatory BP monitors are portable, oscillometric devices that measure BP discontinuously throughout a 24-hour period, most commonly every 20–30 minutes during waking hours and every 30–60 minutes during sleep.

The large number of readings that this provides gives an accurate estimate of true BP. The 24-hour mean of the sequence of daytime and nocturnal BP measurements is more predictive of cardiovascular events than both home and office BP measurements. Ambulatory BP monitoring is now recommended in the UK instead of office BP for diagnosis, and is recommended as a complementary strategy to office BP in most other high-income health economies.

Similar to home BP, ambulatory BP allows in a single measurement:

- improved diagnostic accuracy over office BP
- identification of different BP phenotypes.

Daytime ambulatory BP is 5–10/5 mmHg lower than office BP in the same patient. Issues with this approach include dislike of repeated BP measurement, especially at night.

PHENOTYPES OF HYPERTENSION

The measurement techniques described can describe different phenotypes of hypertension (Box 31.1). Although both white coat hypertension and masked hypertension represent intermediate cardiovascular risk phenotypes, masked hypertension is treated using out-of-office values to guide treatment, while antihypertensives are not recommended for use in white coat hypertension, despite elevated cardiovascular risk, due to a current lack of evidence.

There are other common phenotypes of hypertension:

Isolated systolic hypertension

Due to age-related arterial stiffening, systolic BP continues to rise in patients above 50 years of age, with a corresponding reduction in diastolic BP. This widening pulse pressure (the difference between systolic and diastolic BP, usually <50 mmHg) is associated with increased vascular damage. Drug treatment in isolated systolic hypertension is the same as for combined hypertension (where both systolic and diastolic BP are elevated), though care is needed not to reduce diastolic BP below 60 mmHg, which could cause problems with coronary blood flow (largely due to diastolic flow/pressure). Aortic valve incompetence can also cause an isolated systolic phenotype, though this is normally apparent on cardiac auscultation and/or echocardiography.
Orthostatic hypotension
This refers to a sustained fall in BP within 3 minutes of assuming an upright position of either more than 20 mmHg systolic or more than 10 mmHg diastolic BP. It is more common in older age, and in conditions associated with autonomic neuropathies, such as diabetes mellitus and Parkinson’s disease. It is typically asymptomatic, although it can cause postural intolerance or instability, dizziness and falls. It should be actively screened for in those with typical symptoms or risk factors. Most guidelines recommend using the standing BP as the true BP value for guiding treatment.

Variable blood pressure
Although BP is a highly dynamic variable, the degree of variability is exaggerated in some patients. This is often due to disorders of the autonomic nervous or endocrine system. Reliable assessment is achieved only through a combination of repeated short-term (ambulatory) and long-term (home) methodologies. Management of BP levels in such patients is often complex and best performed in specialist clinics.

CAUSES OF RAISED BLOOD PRESSURE

Up to 90% of patients have no singular identifiable cause of their elevated BP: this is called primary hypertension (preferred to the historical term, ‘essential hypertension’, see later). Advances in genomic research have increased our understanding of polygenic effects on BP (see p. 30). We now know that several hundred genes are individually associated with prevalent BP levels but that each one contributes only small amounts (perhaps 0.5–1 mmHg). Combined, however, they may account for 60% of the BP level in any one person. As such, a family history of hypertension is common, though a family history of hypertension or strokes at unusually young ages should instigate careful evaluation for secondary causes. While there are a large number of distinct genetic influences on BP regulation, for the purposes of clinical assessment and management the main mechanisms affecting BP are vascular volume, contractility, and cardiac output (Fig. 31.4). The remaining effects on BP (up to 40%) are mediated by environmental (e.g. temperature, noise) and lifestyle stressors (e.g. diet).

Sudden development of severe hypertension or worsening of previously good control should alert healthcare professionals to the need for careful evaluation of adherence, and for consideration of lifestyle and secondary causes of hypertension if adherence is confirmed. Adherence issues and causes of secondary hypertension should also be borne in mind in patients with resistant hypertension (usually defined as uncontrolled BP despite three separate, guideline-recommended antihypertensives).

Lifestyle-related issues

Diet
Relevant dietary information provided by patients is often inaccurate. Nevertheless, some clear dietary patterns are associated with raised BP:

- high salt intake
- low vegetable and fruit intake
- high saturated fat intake
- high simple carbohydrate intake
- excessive liquorice (inhibits an enzyme that normally prevents cortisol from activating the mineralocorticoid receptor).

Lack of exercise
Both cardiovascular and strength training forms of exercise are associated with lower BP values, along with other health benefits.

Population interventions
In view of the potential effects of these lifestyle issues, together with those associated with obesity (see later), population approaches are increasingly being taken to reduce BP, including:

- public health education drives to:
  - reduce salt and body weight
  - increase exercise
• regulatory approaches to reducing salt in processed foods
• consideration of sugar taxes and minimum alcohol unit pricing.

Drugs
Many patients with hypertension will have other co-morbidities that require additional pharmacological treatment, and consideration should therefore be given to the possible interference of these other drugs with BP control. Both over-the-counter medicines, such as non-steroidal anti-inflammatory drugs (NSAIDs), and recreational drugs, such as alcohol and sympathomimetic stimulants, should be taken into account, as patients may not mention them when a history is being taken unless specific enquiry is made.

Commonly implicated drugs that raise BP include:
• alcohol
• stimulant, recreational drugs
• oral contraceptive pill
• NSAIDs
• corticosteroids
• calcineurin inhibitors
• vascular endothelial growth factor inhibitors
• some antidepressants (e.g. venlafaxine).

Secondary hypertension
Hypertension can have an identifiable singular cause, removal or reversal of which leads to normalization of BP. These are secondary causes of hypertension, and are broadly categorised into renal, vascular, endocrine and neural problems (Box 31.2). Together, these are present in only 10% of all hypertensive patients (though this proportion is higher in those under 30 years of age). The most common causes of secondary hypertension are largely thought to be primary hyperaldosteronism (increased salt/water retention), obstructive sleep apnoea and obesity (the last two causing sympathetic overdrive), though the precise proportions ascribed to these and other causes vary in different studies due to advances in evaluation and diagnostics.

Although it is not usually considered a secondary cause, pregnancy can be associated with raised BP. The normal physiological response to pregnancy is an increase in circulating volume that is offset by significant vasodilation, leading to lower BP, particularly in the second trimester. However, in some pregnant women, defects in placental formation or vascularity lead to pregnancy-induced hypertension and/or pre-eclampsia (see p. 1454). Hypertension associated with pregnancy often improves within a few months of the infant’s delivery but women with hypertensive disorders of pregnancy are more likely to develop hypertension earlier in life than age-matched controls. The history should establish whether women of child-bearing age are actively trying to become pregnant, as many of the first-line drugs are not recommended in this situation (see Box 31.6).

Thresholds and targets in hypertension
Primary hypertension used to be termed ‘essential’ as, in the 19th century, raised BP was largely thought to be an appropriate physiological adaptation. However, with the advent of randomized clinical trials and modern therapeutics, evidence has grown that lowering BP is beneficial, reducing both cardiorenal events and overall mortality.

The first Veterans Administration Cooperation study randomized patients with a diastolic BP of 115–129 mmHg to active or placebo treatments. By modern standards, this would be considered to be severe hypertension, yet we know of the benefit of lowering BP only from these and subsequent trials.

Since around 1990, the threshold for diagnosis of hypertension has mostly been an office BP of more than 140 mmHg systolic or more than 90 mmHg diastolic (whichever is worse). Treatment has largely been reserved for those with grade 2 hypertension (Box 31.3), as there is a large evidence base for lowering BP with medications in these patients. For grade 1 hypertension, it has been usual practice to persevere with lifestyle changes to lower BP and to recommend immediate treatment for those with an overall elevated cardiovascular risk (>1% per year, using validated cardiovascular risk equations), or evidence of organ injury due to hypertension (hypertensive target organ damage). Drug therapy is advocated, however, if BP fails to normalize after a 3–12-month period of best-tolerated lifestyle changes.

For the most part, then, the target has been an office BP of less than 140/90 mmHg, with stricter targets for patients with diabetes and proteinuric chronic renal disease (<130/80 mmHg). However, recent trials such as SPRINT and meta-analysis of other trials have suggested that there is incremental benefit in targeting all patients to a BP below 130/80 mmHg; this is reflected in most international guidelines, though not currently in those produced by the National Institute for Health and Care Excellence (NICE) in the UK.

In older people (over 80 years), there is less evidence for treating mild hypertension, and most guidelines recommend treating only moderate (i.e. grade 2) hypertension. Some guidelines (e.g. NICE) suggest a lax target office BP of below 150/90 mmHg in patients diagnosed over 80 years of age. However, age is often used incorrectly as a surrogate for frailty, and although there is good reason to lower BP cautiously and judiciously in the frail elderly or in those at increased risk of falls or postural hypotension, there is a similar trend in some up-to-date international guidelines, such as those of the European Society of Cardiology (ESC) and the European Society of Hypertension (ESH), to reduce office BP to below 130/80 mm Hg in biologically fit elderly patients, if tolerated.

There are additional considerations relating to these values. As mentioned, there has been a consistent shift to using out-of-office methods, preferably ambulatory, for diagnosis. Because these methods avoid any white coat effect, the thresholds for diagnosis are based on different numerical values, usually considered to be 5–10/5 mmHg lower than in the office.

Further reading

Hypertensive target organ damage
Hypertension can cause structural or functional changes in the heart, kidney and central nervous system that may be regarded as intermediate end-points with respect to reducing absolute clinical end-points of myocardial infarction, heart failure, end-stage renal disease and strokes.

Eyes
Direct ophthalmoscopy (fundoscopy) of the dilated eye is recommended in most guidelines for evaluation of hypertensive vascular changes. The most commonly used grading classification is the

Keith–Wagener–Barker system, comprising four distinct ophthalmic hypertensive phenotypes (retinopathy). More recent evaluation, however, has suggested combining the two milder phenotypes, leaving three grades to consider (Fig. 31.5):

- **Mild**: Generalized arteriolar narrowing, focal arteriolar narrowing, arteriovenous nicking (modest association with cardiovascular and cerebral events).
- **Moderate**: Haemorrhage (blot, dot or flame-shaped), microaneurysm, cotton-wool spot, hard exudate, or a combination of these signs (strong association with cardiovascular and cerebral events).
- **Severe**: Signs of moderate retinopathy plus papilloedema (swelling of optic head) (strong association with cardiovascular events, stroke and death).

**Heart**

The heart is a muscle and hypertrophy may occur in response to increased workload. Left ventricular remodelling is initially a compensatory phenomenon to reduce wall stress but eventually leads to a pathogenic increase in left ventricular mass.

Hypertensive left ventricular hypertrophy is usually asymptomatic but can be detected as a thrusting apex beat on precordial palpation. It is also sometimes detected on standard 12-lead electrocardiography (ECG), demonstrating various patterns of increased voltages in the chest leads and T-wave abnormalities (see Fig. 30.79). There are many different scoring systems for ECG criteria for diagnosing left ventricular hypertrophy; all are quite insensitive (20–50%) but specificity is better (>90%), which means that if criteria are positive, true left ventricular hypertrophy is likely to be present.

ECGs are recommended in all hypertensive patients, as they are widely available and cheap, and do not require much in the way of additional training to interpret, especially as modern ECG machines have in-built reporting algorithms. However, cardiac imaging, using transthoracic echocardiography and cardiac MRI, is more sensitive and specific than ECG (when compared to autopsy data), though access, cost and need for additional trained staff to conduct and report these tests limit their wide utility and acceptance in all hypertensive patients. These cardiac imaging modalities can estimate the actual mass of the left ventricle; this is indexed to height and weight, and has sex-specific normal values.

**Kidney**

Kidney disease is both a cause and a consequence of hypertension. Early hypertensive kidney damage is most easily detectable through an increase in microalbuminuria on urine test strips or as an increased laboratory albumin:creatinine ratio. Estimates of glomerular filtration rate (GFR), based on serum creatinine and demographic criteria, are also obtained, especially as several antihypertensive medications are potentially nephrotoxic. However, there is usually an initial reduction in GFR associated with chronic BP-lowering from any cause, and this usually reflects intra-renal haemodynamic changes rather than intrinsic renal damage; it is therefore common practice to allow GFR to reduce by up to 10% on initiation of antihypertensive therapy. More regular follow-up is mandated to ensure that this does not indicate progressive renal decline.

**TREATMENT**

Meta-analyses of large-scale RCTs have shown that a 10/5 mmHg reduction in BP is associated with a 15% reduction in all-cause mortality, 35% reduction in stroke, 40% reduction in heart failure and 20% reduction in myocardial infarction. Hypertension is treated to reduce these major cardiovascular and renal events. For this reason, treatment of hypertension without managing other modifiable cardiovascular risk factors (raised cholesterol, diabetes mellitus, tobacco smoking, obesity) is suboptimal. Cardiovascular risk scores, such as QRISK2®, are useful for integrating all of these risk factors, to judge when there is benefit in treating hypertensive patients. Ten-year risk estimates are less useful than lifetime risk estimates in young patients, given the powerful role of age in all cardiovascular risk scores.

**Lifestyle changes**

These are recommended for all hypertensive patients, irrespective of grade or duration of disease. The BP reductions accompanying such lifestyle changes are complementary and similar in magnitude (compared to half-standard monotherapy) to those achieved by antihypertensive medications (Box 31.4).

**Bariatric surgery** is indicated for those with hypertension and a body mass index (BMI) of more than 35 kg/m², but it is not commonly performed without the additional co-morbidity of type 2 diabetes. Recent data confirm the profound BP-lowering effect of such surgery, which may be due to additional gut hormonal changes postoperatively, in addition to expected weight loss.

**Drug treatment**

A single antihypertensive medication at standard dose reduces BP by about 9/5 mmHg in mild hypertension. Although patients with mild hypertension may achieve control with monotherapy, those with moderate or worse hypertension invariably require several drugs in combination. Greater effects are obtained by combining medications from different classes, targeting different mechanisms. Three antihypertensives at half-standard dose reduce BP by 20/11 mmHg. Most adverse effects with antihypertensives, in keeping with most pharmaceuticals, are type A adverse reactions (see p. 258) and are thus dose-dependent. Keeping doses to a minimum but combining different classes minimizes the chances of adverse effects and maximizes the likelihood of effectively lowering BP to target levels.

As mentioned, **adherence** is increasingly recognized as a key barrier to achieving BP control. Although there are different validated measures to assess this, such as the Morisky-8 Medication
Fig. 31.5 Hypertensive retinopathy. (A–B) Examples of mild hypertensive retinopathy. (A) Arteriovenous nicking (black arrows) and focal narrowing (white arrow). (B) Opacification (silver or copper wiring) of arteriolar wall (white arrows). (C–D) Examples of moderate hypertensive retinopathy. (C) A flame-shaped retinal haemorrhage (white arrow). (D) A cotton-wool spot (white arrow), retinal haemorrhages and microaneurysms (black arrows). (E–F) Severe hypertensive retinopathy. (E) Exudates and flame haemorrhages in grade 3 retinopathy. (F) Signs of malignant hypertension in grade 4 disease, with a swollen optic disc and macular exudate. (A–D From Schachat AP, Sadda SVR, Hinton DR et al. Ryan’s Retina, 6th edn. Elsevier Inc., 2018, Figs 52.1 and 52.2; E–F from Innes JA, Dover AR, Fairhurst K. Macleod’s Clinical Examination, 14th edn. Elsevier Ltd, 2018, Fig. 8.19CD.)
Adherence Scale (Box 31.5), along with prescription refill rate
whether patients receive a resupply at the right time to have
therapy every day), modern drug analytical techniques on plasma or
urine have demonstrated that question-/refill-based assessment
correlates poorly to objective evidence of measurable drug in
biological matrices. From these newer techniques, it appears that up
to two-thirds of patients in specialist care do not take some or any
of their antihypertensive medications. There are no easy solutions to
such covert non-adherence but keeping an open, non-judgemental
approach can facilitate the volunteering of this information and then
shared-decision making can determine how best to proceed and what
patients want for their own health.

In view of this, and with evidence that suggests there is an
elevated cardiovascular risk when control is achieved over pro-
tracted (≥6 months) timeframes, guidelines have recently tended
to abandon monotherapy and suggest starting with a combination
of medicines to achieve BP control effectively and rapidly. Cur-
rent ESH/ESC guidelines have taken this further and have used
evidence that single-pill combinations of two or more antihy-
tensive medications improve adherence to suggest that most
patients should be started on single-pill combination therapy.

There are numerous classes of antihypertensive medication
available and their key features are described in Box 31.6.

Most guidelines recommend choosing one (or two) of the fol-
lowing three classes of drugs, as initial therapy:

- angiotensin-converting enzyme (ACE) inhibitors/angiotensin II
  receptor blockers (ARBs),
- calcium channel blockers
- thiazide-like diuretics.

Current UK NICE guidelines use age and ethnicity as surro-
gates for plasma renin activity. Older and black African ances-
tries are associated with low renin status and so have reduced
responsiveness to drugs ACEIs and ARBs as monotherapy; hence
calcium-channel blockers are recommended in these groups.
Younger white patients are recommended to start on an ACEI or
ARB. These are largely thought to be interchangeable, except that
ARBs are better tolerated, with less cough and angio-oedema.

There is clear evidence from the PATHWAY-2 study that
spironolactone is the best fourth-line drug, in preference to beta-
or alpha-blockers, though it is unlicensed for this indication in
most countries and patients should be appropriately counselled.
Once a patient is on three or four drugs and remains uncontrolled
(resistant hypertension), they should be referred for specialist
assessment.

In keeping with the view that reduction in total cardiovascular
risk is paramount, cholesterol-lowering therapy, most commonly
with small doses of potent statins, is recommended in all patients
with a total cardiovascular risk of more than 1% per year. This
threshold may not be reached in younger patients due to the power
of age in the risk calculators, and so a more long-term view of risk
reduction should be taken in these patients. Although low-dose
aspirin has been used in primary cardiovascular prevention
for many decades, contemporary large-scale trials have not demon-
strated a net benefit on mortality, even in patients with diabetes,
with any gains from reduction in cardiovascular events offset by
increases in bleeding events. Given these data, aspirin is no longer
recommended in any patient group for primary prevention.

Future approaches
Poor hypertension control rates are apparent with available pre-
scribed medicines, largely due to adherence issues rather than
ineffectiveness of the drugs. Nevertheless, patients are keen to explore medicine-free mechanisms to lower BP.

Neural sympathetic signalling has a key role in vascular homeostasis, with effects mediated via afferent renal and aortic/carotid baroreceptor functions. Novel interventional approaches to alter this signalling are currently under evaluation to improve BP in both medicine-naive and treated hypertensive patients. The most advanced, in terms of regulatory pathways and evidence base, is renal sympathetic denervation. This group of procedures uses modern endovascular catheter-based approaches to the renal sympathetic nerves, which lie on the outside of the renal artery. Catheters can then deliver energy (radio-frequency, ultrasound) or neurotoxins (such as alcohol) across the renal artery wall to reach the sympathetic nerves and abrogateafferent signalling to the vasomotor centres, thus reducing total sympathetic drive and BP. Although the technological advancements are impressive and there is evidence of robust BP-lowering using modern out-of-office measurements, the magnitude of these effects is similar to that of antihypertensive monotherapy and thus most patients will still require drug therapy to control BP in the long term. Furthermore, these are new technologies: the long-term safety of the procedures is not clear, as regards

the renal artery or otherwise, and there are no outcome studies investigating cardiac, renal, stroke or death end-points using any technology apart from drugs.

Managing blood pressure in hospital 1143

31
Hypertension

reducing BP acutely in the preoperative period to controlled levels is beneficial. Patients with uncontrolled BP (evidence of chronic poor control of >160/100 mmHg in treated patients, or opportunistic measurements in pre-assessment in previously normotensive patients of >180/110 mmHg) are commonly referred back to their primary care doctor for adequate management of hypertension prior to elective procedures, though this is not a reason to delay necessary emergency surgical intervention. Although ACEIs and ARBs are often withheld arbitrarily for 24 hours preoperatively, it is usual to continue antihypertensive medications throughout the perioperative period unless there is documented hypotension or other related issues, such as withholding nephrotoxic antihypertensives if there is acute kidney injury.

Intraoperative

Sympathetic activation during induction of anaesthesia can cause elevation of BP by 30 mmHg, with far larger responses in patients with untreated hypertension. Subsequently, with maintenance of anaesthesia, BP tends to fall due to the direct sympatholytic and vasodilating actions of anaesthetic drugs and loss of baroreflex regulation of BP. Patients with pre-existing uncontrolled hypertension are more likely to experience intraoperative BP lability (i.e. hypotension or hypertension), which is a risk factor for myocardial ischaemia and injury. Intraoperative hypertension is most commonly associated with inadequate analgesia or depth of anaesthesia, though it is prudent and recommended to exclude serious problems with airway, oxygen delivery and breathing first.

Postoperative

Pain and (inadvertent) omission of antihypertensive medications are the most common reasons for postoperative hypertension. Once these factors have been corrected, there are no data to support the further active lowering of BP in the postoperative period without evidence of acute end-organ damage, though it is usual practice to try to keep BP below 180/110 mmHg, in part to reduce the risk of problems with postoperative haemostasis.

Blood pressure on the wards

Patients with hypertension are often admitted to hospital for other medical reasons. Various factors can contribute to acute elevations of BP, such as antihypertensive medication omission, drug-induced hypertension (see earlier), anxiety, pain, bladder distension, recreational drug withdrawal and neurological injury. In the absence of a hypertensive emergency or other co-morbidity that requires acute BP management (e.g. to facilitate thrombolysis in acute stroke), uncontrolled BP does not require immediate management. However, as with most phenotypes, there is a threshold value that makes most healthcare professionals anxious about increased cerebral and cardiovascular risk, even in inpatients, and it is therefore common for BPs consistently above 180/110 mmHg to be treated, where there is no other clear precipitant. There is no role for short-acting drugs, such as sublingual glyceryl trinitrate (GTN) or nifedipine, and titration of standard chronic therapies with on-going monitoring is preferred.

Hypertensive emergencies

Only a small subset of patients with significantly elevated BP (usually >180/120 mmHg) have signs or symptoms of acute target-organ damage, termed hypertensive emergencies. The rate and magnitude of any increase in BP may be more important than the absolute level of BP in determining the severity of organ injury; this is key in obstetric medicine, where the usual BP in younger women may be verging on hypotensive (90–110/60–70 mmHg), and pre-eclampsia may develop with a BP over 140/90 mmHg.

In all hypertensive emergencies, intravenous antihypertensive medication therapy is indicated to cause rapid reduction of BP, as this is thought to minimize on-going organ damage and prevent or reduce the risk of morbidity and mortality. The timing, magnitude and other considerations related to the management of these conditions are considered in Box 31.7.

Referral to specialist care

The majority of hypertensive patients are managed in primary care. Apart from the clear indications related to hypertensive emergencies described earlier, there are other reasons to mandate referral to specialist secondary care:

- Patients taking ≥3 drugs with uncontrolled hypertension (resistant hypertension).
- Suspected secondary causes:
  - Young age (<30–40 years)
  - Historical features (i.e. obstructive sleep apnoea, phaeochromocytoma)
  - Examination findings (i.e. abdominal bruit suggesting renal artery stenosis)
  - Sudden change in BP.
- Target organ damage detected with normal BP values.
- Symptomatic hypertension or hypotension.
- Labile or highly variable BP.
- Mild hypertension when it is not clear whether a patient would benefit from BP-lowering.

Gastroenterology
Noor Jawad and Charlotte Skinner

CORE SKILLS AND KNOWLEDGE

Gastrointestinal disease is common throughout the world. The WHO estimates that diarrhoeal illnesses alone caused 1.4 million deaths in 2016. Gastrointestinal disease accounts for approximately 10% of primary care appointments, and colorectal cancer is the third commonest cancer globally.

Gastroenterologists care for patients in inpatient settings (e.g., for those with acute flares of inflammatory bowel disease or gastrointestinal bleeding), outpatient clinics (for long-term management of chronic gastrointestinal conditions, or diagnosis of newly presenting patients), and they provide diagnostic, therapeutic and screening endoscopy services. Gastroenterology research is a fertile area with many exciting new therapies and technologies appearing in recent years, and gastroenterologists may also be active in medical education or hospital management.

Key skills in gastroenterology include:

- managing and investigating acute and chronic gastrointestinal bleeding
- understanding different treatment strategies for inflammatory bowel disease, including the role for biological agents and surgical treatment
- developing an understanding of functional gastrointestinal disease and how to help patients suffering with problems such as irritable bowel syndrome.

There are many opportunities to gain the knowledge and skills to successfully manage patients with gastrointestinal diseases, including reviewing patients on general gastroenterology wards, attending general and specialist outpatient clinics, observing endoscopic procedures and attending multidisciplinary team (MDT) meetings. MDTs commonly exist for upper and lower gastrointestinal cancers and inflammatory bowel disease, and allow the discussion of patients by gastroenterologists, radiologists, histopathologists, surgeons, oncologists and nurse specialists.
**History and examination**

Gastrointestinal disease can present with a variety of different symptoms and signs and an experienced clinician needs to be able to elicit these in a focused manner, and also ask about relevant risk factors (Box 32.1). The figure opposite illustrates signs of common gastrointestinal diseases to be found on examination.

**Visualizing the bowel**

The different types of endoscopy are discussed fully on page 1158. Box 32.3 illustrates the ability of different techniques of endoscopy (including contrast techniques in ERCP) to visualize different parts of the gastrointestinal and biliary tract. Most are readily available in the majority of units, although capsule endoscopy and balloon enteroscopy remain more specialist procedures. All except capsule endoscopy allow biopsies to be taken and a range of therapeutic procedures to be performed.

---

**History-taking in gastroenterology**

**Symptoms of upper gastrointestinal disease**
- **Dysphagia** – distinguish between a likely *neurological cause* (often high in mouth or pharynx, worse with swallowing liquids, often speech involvement), and a likely *anatomical cause* (lower down in chest or upper abdomen, worse with larger and more solid food boluses).
- **Dyspepsia** – often a non-specific symptom, but establish the relationship with food ingestion posture – symptoms of reflux disease are worsened by both.
- **Early satiety** – may be a symptom of stomach cancer
- **Nausea and vomiting** – these may be mediated by central causes, but a close relationship with food (e.g. projectile vomiting after eating) suggests a pyloric stricture.
- **Haematemesis** – vomiting of fresh red blood should be treated as a medical emergency. Vomiting of altered blood (sometimes described as ‘coffee grounds’) is more difficult to evaluate, but should still be taken seriously. Haematemesis after a prolonged bout of vomiting may suggest a Mallory–Weiss tear.
- **Melana** – this describes the passage of thick, black, 'tarry' altered blood from the rectum and indicates upper gastrointestinal bleeding – a medical emergency.

**Symptoms of lower gastrointestinal disease**
- **Change in bowel habit** – while constipation is often a symptom of inadequate diet or physical exercise, unexplained loosening of stool, particularly if persistent, may be a symptom of colonic diseases, including cancer and colitis.
- **Rectal bleeding** – fresh blood dripping after passing stool, or present on wiping, suggests anorectal disease including haemorrhoids. Blood mixed with stool may indicate colitis or colonic malignancy.
- **Tenesmus** – a feeling of incomplete rectal emptying after defecation suggests anorectal pathology such as a tumour.

‘**Red flag’ symptoms suggestive of malignancy**
- Progressive weight loss.
- Anorexia.
- Symptoms of anaemia from chronic blood loss.

**Past medical history**
- Gastrointestinal disease.
- Autoimmune disease.
- Abdominal surgery.

**Drug history**
- All prescription drugs.
- Non-steroidal anti-inflammatories, over-the-counter drugs and herbal remedies.
- Recent courses of antibiotics.

**Social history**
- Smoking.
- Alcohol consumption.

INTRODUCTION

The gastrointestinal tract has many functions, such as digestion, absorption and excretion, as well as the synthesis of hormones, growth factors and cytokines. In addition, a complex enteric nervous system controls its function and communicates with the central and peripheral nervous systems. Finally, as the gastrointestinal tract is the part of the body containing the largest source of foreign antigens, it has very well-developed arms of both the innate and the acquired immune systems. The intestinal microbiota exerts a range of beneficial functions aiding nutrition, absorption and the development of a mature immune system. Disruption of the composition and diversity of the microbiota is associated with the development of gastrointestinal and systemic disease.

ANATOMY AND PHYSIOLOGY OF THE GASTROINTESTINAL TRACT

Mouth, oropharynx and oesophagus

The oral cavity extends from the lips to the pharynx and contains the tongue, teeth and gums. Its primary functions are mastication, swallowing and speech. The pharynx consists of the nasal, oral and laryngeal sections. The latter is the part of the throat that connects to the oesophagus.

The oesophagus is a muscular tube approximately 20 cm long that connects the pharynx to the stomach just below the diaphragm. Its only function is to transport food from the mouth to the stomach. In the upper portion of the oesophagus, both the outer longitudinal layer and inner circular muscle layers are striated. In the lower two-thirds of the oesophagus, including the thoracic and abdominal parts containing the lower oesophageal sphincter, both layers are composed of smooth muscle.

The oesophagus is lined by stratified squamous epithelium, which extends distally to the squamocolumnar junction where the oesophagus joins the stomach, recognized endoscopically by a zig-zag (‘Z’) line, just above the most proximal gastric folds.

The oesophagus is separated from the pharynx by the upper oesophageal sphincter (UOS), which is normally closed due to tonic activity of the nerves supplying the cricopharyngeus. The lower oesophageal sphincter (LOS) consists of a 2–4-cm zone in the distal end of the oesophagus that has a high resting tone and, assisted by the diaphragmatic sphincter, is largely responsible for the prevention of gastric reflux.

Swallowing

During swallowing, the bolus of food is voluntarily moved from the mouth to the pharynx. This process is mediated by a complex reflex involving a swallowing centre in the dorsal motor nucleus of the vagus in the brainstem. Once activated, the swallowing centre neurones send pre-programmed discharges of inhibition followed by excitation to the motor nuclei of the cranial nerves. This results in initial relaxation, followed by distally progressive activation of neurones to the oesophageal smooth muscle and LOS. Pharyngeal and oesophageal peristalsis mediated by this swallowing reflex causes primary peristalsis. Secondary peristalsis arises as a result of stimulation by a food bolus in the lumen, mediated by a local intra-oesophageal reflex. Tertiary contractions indicate pathological non-propulsive contractions resulting from aberrant activation of local reflexes within the myenteric plexus.

Stomach and duodenum

The stomach occupies a small area immediately distal to the oesophagus (the cardia), the upper region (the fundus, under the left diaphragm), the mid-region or body and the antrum, which extends to the pylorus (see Fig. 32.10). It serves as a reservoir where food can be retained and broken up before being actively expelled into the proximal small intestine.

The smooth muscle of the wall of the stomach has three layers: outer longitudinal, inner circular and innermost oblique layers. There are two sphincters: the gastro-oesophageal sphincter and the
pyloric sphincter. The latter is largely made up of a thickening of the circular muscle layer and controls the exit of gastric contents into the duodenum.

The duodenum has outer longitudinal and inner circular smooth muscle layers. It is C-shaped and the pancreas sits in the concavity. It terminates at the duodenojejunal flexure, where it joins the jejunum.

• The **mucosal lining** of the stomach can stretch in size with feeding. The greater curvature of the undistended stomach has thick folds or rugae. The mucosa of the upper two-thirds of the stomach contains **parietal cells**, which secrete hydrochloric acid, and **chief cells**, which secrete pepsinogen (which initiates proteolysis). There is often a colour change at the junction between the body and the antrum of the stomach, which can be seen macroscopically and confirmed by measuring surface pH.

• The **antral mucosa** secretes bicarbonate and contains mucus-secreting cells and **G cells**, which secrete gastrin, stimulating acid production. There are two major forms of gastrin, G17 and G34, depending on the number of amino-acid residues. G17 is the major form found in the antrum. Somatostatin, a suppressant of acid secretion, is also produced by specialized antral cells (D cells).

• **Mucus-secreting cells** are present throughout the stomach and secrete mucus and bicarbonate. The mucus is made of glycoproteins called mucins.

• The **mucosal barrier**, made up of the plasma membranes of mucosal cells and the mucus layer, protects the gastric epithelium from damage by acid and, for example, alcohol, aspirin, non-steroidal anti-inflammatory drugs (NSAIDs) and bile salts. Prostaglandins stimulate secretion of mucus, and their synthesis is inhibited by aspirin and NSAIDs, which inhibit cyclo-oxygenase (see p. 1176).

• The **duodenal mucosa** has villi like the rest of the small bowel, and also contains Brunner's glands, which secrete alkaline mucus. This, along with the pancreatic and biliary secretions, helps to neutralize the acid secretion from the stomach when it reaches the duodenum.

## Physiology

**Acid secretion** is central to the functionality of the stomach; factors controlling acid secretion are shown in Fig. 32.2. Acid is not essential for digestion but does prevent some food-borne infections. It is under neural and hormonal control, and both stimulate acid secretion through the direct action of histamine on the parietal cell. Acetylcholine and gastrin also release histamine via the enterochromaffin cells. Somatostatin inhibits both histamine and gastrin release, and therefore acid secretion.

Other major gastric functions are:

- reservoir for food
- emulsification of fat and mixing of gastric contents
- secretion of intrinsic factor
- absorption (of only minimal importance).

**Gastricemptying** depends on many factors. There are osmo-receptors in the duodenal mucosa, which control gastric emptying by local reflexes and the release of gut hormones. In particular, intraduodenal fat delays gastric emptying by negative feedback through duodenal receptors.

---

**Small intestine anatomy**

The small intestine extends from the duodenum to the ileo-caecal valve. It is 3–6 m in length, and 300 m² in surface area. The upper...
40% is the duodenum and jejunum; the remainder is the ileum. Its surface area is enormously increased by circumferential mucosal folds that bear multiple finger-like projections called villi. On the villi, the surface area is further increased by microvilli on the luminal side of the epithelial cells (enterocytes) (Fig. 32.3).

Each villus consists of a core that contains blood vessels, lacteals (lymphatics) and cells (e.g. plasma cells and lymphocytes). The lamina propria contains plasma cells, lymphocytes, macrophages, eosinophils and mast cells. The crypts of Lieberkühn are the spaces between the bases of the villi.

Enterocytes are formed at the bottom of the crypts and migrate toward the tops of the villi, where they are shed. This process takes 3–4 days. On its luminal side, the enterocyte is covered by microvilli and a gelatinous layer called the glycocalyx. Scattered between the epithelial cells are mucin-secreting goblet cells and occasional intraepithelial lymphocytes and Paneth cells. Most of the blood supply to the small intestine is via branches of the superior mesenteric artery. The terminal branches are end arteries; there are no local anastomotic connections.

Enteric nervous system

The enteric nervous system (ENS) controls the functioning of the small bowel; it is an independent system that coordinates absorption, secretion, blood flow and motility. It is estimated to contain 10⁸ neurones (as many as the spinal cord), organized in two major ganglionated plexuses: the myenteric plexus between the muscular layers of the intestinal wall, and the submucosal plexuses associated with the mucosa. The ENS communicates with the central nervous system (CNS) via autonomic afferent and efferent pathways but can operate autonomously.

Coordination of small intestinal function involves a complex and partly understood interplay between many neuroactive mediators and their receptors, ion channels, gastrointestinal hormones, nitric oxide and other transmitters. Acetylcholine, adrenaline (epinephrine), adenosine triphosphate (ATP), vasoactive intestinal peptide (VIP), and other hormones and opioids have been shown to have actions in the small bowel but the exact role of each is not yet clear.

Gut motility

The contractile patterns of the small intestinal muscular layers are primarily determined by the ENS. The CNS and gut hormones also have a modulatory role in motility. The interstitial cells of Cajal, which lie within the smooth muscle, appear to govern rhythmic contractions.

**During fasting,** a distally migrating sequence of motor events, termed the migrating motor complex (MMC), occurs in a cyclical fashion. The MMC consists of:

- a period of motor quiescence (phase I)
- a period of irregular contractile activity (phase II)
- a short (5–10-min) burst of regular phasic contractions (phase III).

Each MMC cycle lasts for approximately 90 minutes. In the duodenum, phase III is associated with increased gastric, pancreatic and biliary secretions. The role of the MMC is unclear, but the strong phase III contractions propel secretions, residual food and desquamated cells towards the colon. It is named the ‘intestinal housekeeper’.

**After a meal,** the MMC pattern is disrupted and replaced by irregular contractions. This seemingly chaotic pattern lasts typically for 2–5 hours after feeding, depending on the size and nutrient content of the meal. The irregular contractions of the fed pattern have a mixing function, moving intraluminal contents to and fro and aiding the digestive process.

**Gut hormones**

Gut hormones play a part in the regulation and integration of the functions of the small bowel and other metabolic activities, including appetite. Their actions are complex and interactive, both with each other and with the ENS (Box 32.4).

**Small intestine physiology**

In the small bowel, digestion and absorption of nutrients and ions takes place, as does the regulation of fluid absorption and secretion. The epithelial cells of the small bowel form a physical barrier that is selectively permeable to ions, small molecules and macromolecules. Digestive enzymes, such as proteases and disaccharidases, are produced by intestinal cells and expressed on the surface of microvilli; others, such as lipases produced by the pancreas, are associated with the glycocalyx. Some nutrients are absorbed most actively in specific parts of the small intestine: iron and folate in the duodenum and jejunum, and vitamin B₁₂ and bile salts in the terminal ileum, where they have specific receptors.

**General principles of absorption**

**Simple diffusion**

This process is non-specific, requires no carrier molecule or energy, and takes place if there is a concentration gradient from the intestinal lumen (high concentration) to the bloodstream (low concentration). Vitamin B₁₂ can be absorbed from the jejunum by this means.

**Facilitated diffusion**

Absorption takes place down a concentration gradient but a membrane carrier protein is involved, conferring specificity on the process. Fructose transport is an example.
Anatomy and physiology of the gastrointestinal tract

Active transport

Absorption occurs via a specific carrier protein, powered by cellular energy, allowing a substance to be transported against a concentration gradient. Many carrier proteins are powered by ion gradients across the enterocyte wall. For example, glucose crosses the enterocyte microvillous membrane from the lumen into the cell against a concentration gradient by using a co-transporter carrier molecule. This is the sodium/glucose co-transporter, SGLT1 (Fig. 32.4). The process is powered by the energy derived from the flow of Na⁺ ions from a high concentration outside the cell to a low concentration inside. The sodium gradient across the cell wall is maintained by a separate ATP-consuming Na⁺/K⁺ exchanger in the basolateral membrane. Glucose leaves the cell on the serosal side by facilitated diffusion via a sodium-independent carrier (GLUT-2) in the basolateral membrane.

Another active transport mechanism operates for Na⁺ absorption in the ileum using an Na⁺/H⁺ exchange mechanism, powered by the outwardly directed gradient of H⁺ across the cell membrane.

Absorption of nutrients in the small intestine

Carbohydrate

Dietary carbohydrate consists mainly of starch, with some sucrose and a small amount of lactose. Starch is a polysaccharide made up of numerous glucose units. In order to have a nutrient value, starch must be digested into smaller oligo-, di- and finally monosaccharides, which may then be absorbed.
Poly saccharide hydrolysis begins in the mouth and is catalyzed by salivary amylase, though the majority takes place under the action of pancreatic amylase in the upper intestine. The breakdown products of starch digestion are maltose and maltotriose, together with sucrose and lactose. These are further hydrolysed on the microvillous membrane by specific oligo- and disaccharidases to form glucose, galactose and fructose. These monosaccharides are then able to be transported across the enterocytes into the blood (see Fig. 32.4).

**Protein**

Dietary protein is digested by pancreatic proteolytic enzymes to amino acids and peptides prior to absorption. These enzymes are secreted by the pancreas as pro-enzymes and transformed to active forms in the lumen. Protein in the duodenal lumen stimulates the enzymatic conversion of trypsinogen to trypsin, and this, in turn, activates the other pro-enzymes, chymotrypsin and elastase.

These enzymes break down protein into oligopeptides. Some di- and tripeptides are absorbed intact by carrier-mediated processes, while the remainder are broken down into free amino acids by peptidases on the microvillous membranes of the enterocytes, prior to absorption into the cell by a variety of amino acid and peptide carrier systems.

**Fat**

Dietary fat consists mainly of triglycerides with some cholesterol and fat-soluble vitamins. Fat is emulsified by mechanical action in the stomach. Bile containing the amphipathic detergents, bile acids and phospholipids enters the duodenum following gall bladder contraction. These substances act to solubilize fat and promote hydrolysis of triglycerides in the duodenum by pancreatic lipase to yield fatty acids and monoglycerides. Bile acids, phospholipids and the products of fat digestion cluster together with their hydrophilic ends on the outside to form aggregations called mixed micelles. Trapped in the centre of the micelles are the hydrophobic monoglycerides, fatty acids and cholesterol. At the cell membrane, the lipid contents of the micelles are absorbed, while the bile salts remain in the lumen. Inside the cell, the monoglycerides and fatty acids are re-esterified to triglycerides. The triglycerides and other fat-soluble molecules (e.g. cholesterol, phospholipids) are then incorporated into chylomicrons to be transported into the lymph.

Any unabsorbed lipids that reach the ileum delay gastric emptying via peptide YY, which is secreted by the ileum (called the ‘ileal brake’). This delay allows more time for absorption of lipids in the small intestine.

Medium-chain triglycerides (MCTs, fatty acids of chain length 6–12) are transported via the portal vein with a small amount of long-chain fatty acid. Patients with pancreatic exocrine or bile salt insufficiency can therefore supplement their fat absorption with MCTs.

Bile salts are not absorbed in the jejunum, so the intraluminal concentration in the upper gut is high. They pass down the intestine to be absorbed in the terminal ileum and are transported back to the liver. This enterohepatic circulation prevents excess loss of bile salts (see p. 1266).

The pathophysiology of fat absorption is shown in Fig. 32.5. Interference with absorption can occur at all stages, as indicated, giving rise to steatorrhoea (<17 mmol or 6 g of faecal fat per day).

**Water and electrolytes**

Large amounts of water and electrolytes, partly dietary but mainly from intestinal secretions, are absorbed, coupled with absorption of monosaccharides, amino acids and bicarbonate in the upper jejunum. Water and electrolytes are also absorbed paracellularly (between the enterocytes) down electrochemical and osmotic gradients. Additional water and electrolytes are absorbed in the ileum and colon, where active sodium transport is not coupled to solute absorption. Secretion of fluid and electrolytes occurs together to maintain the normal functioning of the gut. Secretory diarrhoea (see p. 1185) can occur because of defects in intestinal secretory mechanisms.

**Water-soluble vitamins, essential metals and trace elements**

These are all absorbed in the small intestine. Vitamin B₁₂ (see p. 335) and bile salts are absorbed by specific transport mechanisms in the terminal ileum; malabsorption of both these substances often occurs following ileal resection.

**Calcium**

Calcium absorption is discussed on page 474.

**Iron**

Iron absorption is discussed on page 329.

**Response of the small bowel to antigens and pathogens**

The small bowel has a number of mechanisms to prevent colonization and invasion by pathogens while simultaneously preventing...
inappropriate responses to foreign antigens or the indigenous bacterial population. At the same time, commensal bacteria maintain the integrity of the small bowel and play a major role in host physiology.

**Mechanisms**

**Physical defence**
- The mucus layer.
- Continuous shedding of surface epithelial cells.
- The physical movement of the luminal contents.
- Colonization resistance – the ability of the indigenous microbiota to outcompete pathogens for a survival niche in the gut.

**Innate chemical defence**
- **Enzymes** such as lysozyme and phospholipase A₂, secreted by Paneth cells at the base of the crypts, help ensure an infection-free environment in the gut, even in the presence of commensal bacteria.
- **Antimicrobial peptides** are secreted from enterocytes and Paneth cells in response to pathogenic bacteria. These include **defensins**, which are 15–20 amino-acid peptides with potent activity against a broad range of pathogens, including Gram-positive and Gram-negative bacteria, fungi and viruses.
- **Trefoil peptides** are a family of small proteins secreted by goblet cells. They consist of a three-loop structure with intra-chain disulphide bonds, which makes the molecules highly resistant to digestion. Their actions include stabilization of mucus, promotion of cell migration to injured areas, and promotion of repair. Three trefoil factors (TFFs) are found in humans (TFF1, TFF2 and TFF3), all of which have been implicated in the response to gastrointestinal injury in experimental models. Their molecular mode of action is not yet known.

**Innate immunological defence**
- **Humoral defence**. IgA is the principal mucosal antibody. It mediates mucosal immunity by agglutinating and neutralizing pathogens in the lumen and preventing colonization of the epithelial surface (Fig. 32.6). IgA is secreted from immunocytes in the lamina propria as dimers joined by a protein called the ‘joining chain’ (J-chain); in this form, it is known as polymeric IgA (pIgA). This pIgA is internalized by endocytosis at the basolateral membrane of enterocytes. It crosses the cell as a complex of pIgA/pIgAR and is secreted on to the mucosal surface.
**B-cell sensitization.** Antigens from the lumen of the bowel are transported by M cells and dendritic cells in the follicle-associated epithelium (FAE). This covers Peyer’s patches in the ‘dome’ region that contain abundant virgin B cells, helper T cells and antigen-presenting cells. Activated B cells then produce IgA locally and are programmed to home back to the lamina propria. They travel through mesenteric lymph nodes and then via the thoracic duct to the blood and back to the small bowel and other mucosal surfaces (such as the airways), where they undergo terminal differentiation into plasma cells. Homing back to the gut is facilitated by the α4β7-integrin on gut-derived lymphocytes binding to MAdCAM-1, uniquely expressed on blood vessels in the gut.

- **Cellular defence.** T lymphocytes also provide host defence and initiate, activate and regulate adaptive immune responses. **Intestinal T lymphocytes** occur principally in three major compartments:
  - **Organized gut-associated lymphoid tissue (GALT),** such as Peyer’s patches, where mucosal T cell responses are generated, and after which cells leave the organized lymphoid tissue and home back to the mucosa.
• The lamina propria, containing mostly CD4 cells.
• The surface epithelium, where these lymphocytes are known as intraepithelial lymphocytes (IELs) and are mostly CD8 cells. T cells are sensitized to antigen in the Peyer’s patch lymphoid tissue in a similar fashion to B cells, and pass through mesenteric lymph nodes into the thoracic duct and into the circulation, homing back to the small bowel to end up in the lamina propria or the epithelium. It is probable that IELs are cytotoxic cells, capable of killing virally or bacterially infected epithelial cells. CD4 cells in the lamina propria of healthy individuals are highly activated cells, probably protecting against low-grade infections, since loss of these cells, as in HIV infection, leads to colonization of the gut by protozoa such as cryptosporidia.

The gut microbiome
The relationship between the hundred thousand billion microbes in the human gut and the host is only beginning to be appreciated. New molecular sequencing techniques have allowed the identification and classification of the gut microbiota. The use of metabolomics has aided the assessment of its functional output. There is increasing evidence that a reduction in the diversity of the gut microbiota is associated with a range of conditions, including inflammatory bowel disease and metabolic syndrome. Germ-free mice have essentially no mucosal immune system, showing that the abundant and activated immune system seen in healthy individuals is driven by the flora, without adverse effects. Bacteria also release chemical signals, such as lipopolysaccharide (LPS) and lipoteichoic acid, which are recognized by Toll-like receptors (TLRs) (see p. 47) present on a variety of intestinal cells, priming repair processes and enhancing the ability of the epithelium to respond to injury.

Oral tolerance
The immune system must guard against pathogens and toxins while avoiding an excessive response to the multiplicity of food antigens and commensal bacteria. The mechanisms by which tolerance occurs are multiple, including maintenance of barrier function to prevent excess antigen uptake, active inhibition via regulatory T cells, and promotion of tolerogenic rather than immunogenic T-cell responses by dendritic cells. All of these are likely to play a role in diseases such as coeliac disease, caused by an excessive T-cell response to gluten, or Crohn’s disease, where tolerance to the indigenous bacterial population is defective.

Colon and rectal anatomy
The large intestine starts at the caecum, on the posterior medial wall of which is the appendix.

The colon is made up of ascending, transverse, descending and sigmoid parts, which join the rectum at the rectosigmoid junction (Fig. 32.7). The muscle wall consists of an inner circular layer and an outer longitudinal layer. The outer layer is incomplete, coming together to form the taeniae coli, which produce the haustral pattern seen in the normal colon.

The mucosa of the colon is lined with epithelial cells and goblet cells. There are crypts but no villi, so that the surface is flat. A variety of cells, mainly lymphocytes and macrophages, are found in the lamina propria.

The blood supply to the colon is from the superior and inferior mesenteric vessels. The colon is innervated mainly by the enteric nervous system with input from the parasympathetic and sympathetic pathways. Spinal afferent neurones from the dorsal root ganglia innervate the entire colon.

The rectum is about 12 cm long. Its interior is divided by three crescentic circular muscles that produce shelf-like folds. These are the rectal valves, which can be seen at sigmoidoscopy. The anal canal has an internal and an external sphincter.

Physiology of the colon
The main roles of the colon are the absorption of water and electrolytes (Box 32.5) and the propulsion of contents from the caecum to the anorectal region. Approximately 1.5–2 L of fluid pass the ileocaecal valve each day. Absorption is stimulated by short-chain fatty acids, which are produced predominantly in the right colon by the anaerobic metabolism of dietary fibre by bacterial polysaccharidase enzyme systems. Colonic contents are mixed, aiding absorption by non-propagative segmenting muscular contractions. High-amplitude propagative colonic contractions cause propulsion. Peristalsis is induced by the release of serotonin (5-HT) from neuroendocrine cells in response to luminal distension. Serotonin activates the HT₃ receptors, which, in turn, results in the activation of sensory (calcitonin gene-related peptide, CGRP) neurones. Normal colonic transit time is 24–48 hours with normal stool weights of up to 250 g/day.

Physiology of defecation
The role of the rectum and anus in defecation is complex. The rectum is normally empty. Stool is propelled into the rectum by
propagated colonic contractions. A sensation of fullness, a desire to defecate and urgency to defecate are experienced with increasing volumes of rectal content (threshold 100 mL). The sensations are associated with rectal contraction and a relaxation of the internal anal sphincter, both of which serve to push the stool down into the proximal anal canal. This increases the defecatory urge, which can only be suppressed by vigorous contraction of the external sphincter and puborectalis. If conditions are appropriate for defecation, the subject sits or squats, contracts the diaphragm and abdominal muscles, and relaxes the pelvic floor muscles, including puborectalis, and the anal sphincter muscles, with the result that stool is expelled.

**INVESTIGATION OF GASTROINTESTINAL DISEASE**

Routine haematology and biochemistry, followed by endoscopy and radiology, are the principal investigations.

**Blood tests**

All patients undergoing investigation for gastrointestinal disease should have routine blood tests. These include a full blood count, serum creatinine and electrolytes, liver function tests and clotting. This basic screen checks for anaemia, elevated/depleted white cell or platelet counts, electrolyte disturbances and clotting abnormalities which can be present in several gastrointestinal diseases.

**Stool tests**

Stool tests are vital investigation for GI disease. Stool should always be sent for microscopy, culture and sensitivities (MCS) in order to exclude infection in patients presenting with diarrhoea. For patients who have travelled abroad recently it can be useful to also look for stool ova, cysts and parasites to check for infections such as giardiasis, amoebiasis or tapeworm. Faecal calprotectin is a protein found in stool during intestinal inflammation (e.g. IBD or infection). It is commonly used in outpatients both diagnostically (it is 93% sensitive and 96% specific for inflammatory bowel disease in adults) and for monitoring disease activity. Below 100 μg/g is within normal limits and a level higher than 200 μg/g is suggestive of inflammatory bowel disease or an infective colitis. It should not be used in older patients where malignancy is suspected.

**Endoscopy**

Video endoscopes relay colour images to a high-definition television monitor. The tip of the endoscope can be angled in all directions, and channels in the instrument are used for air insufflation, water injection, suction, and the passage of accessories such as biopsy forceps or brushes for obtaining tissue, snares for polypectomy and needles for injection therapies.

- **Oesophagogastroduodenoscopy (OGD, ’gastroscopy’)** is the investigation of choice for upper gastrointestinal disorders with the possibility of therapy and mucosal biopsy. Findings include reflux oesophagitis, gastritis, ulcers and cancer. Therapeutic OGD is used to treat upper gastrointestinal haemorrhage and both benign and malignant obstruction. The mortality for diagnostic endoscopy is 0.001% with significant complications in 1:10000, usually when performed as an emergency (e.g. gastrointestinal haemorrhage).

**Box 32.6 Gastroscopy and colonoscopy**

- Explain the procedure to the patient, including benefits and risks.
- Discuss the need for sedation.
- Obtain written informed consent.

**Gastroscopy**

- The patient should be fasted for at least 4 h.
- Give oxygen and monitor oxygen saturation with an oximeter.
- Give lidocaine throat spray or sedation (midazolam ± opiate if required).
- Pass the gastroscope to the duodenum under direct vision.
- Examine during insertion and withdrawal.
- Gastroscopy takes 5–15 min, depending on the indication and findings.
- Withhold fluid and food until local anaesthetic/sedation wears off.
- Complications are rare but beware of over-sedation, perforation and aspiration.
- The patient must be accompanied home if sedation has been given.

**Colonoscopy**

- Stop oral iron a week before the procedure.
- Restrict the diet to low-residue foods for 48 h; clear fluids only for 24 h.
- Use a local bowel-cleansing regime, usually starting 24 h beforehand (e.g. two sachets of sodium picosulfate with magnesium citrate and 2–4 bisacodyl tablets, or macrogol 2–4 L, or local alternative; more if constipated).
- Give oxygen and monitor O₂ levels.
- Give sedation (midazolam ± opiate) if required by the patient.
- Pass the colonoscope to the caecum or ileum under direct vision.
- Examine in detail during withdrawal.
- Colonoscopy takes 15–30 min, depending on the colon anatomy, indication and findings.
- Withhold fluid and food until sedation wears off.
- Observe the patient for at least an hour after sedation has been given.
- Complications are rare but beware of over-sedation, perforation and aspiration.
- The patient must be accompanied home if sedation has been given.

**Box 32.7 Proctoscopy**

- The proctoscope is passed into the anus and the obturator is removed.
- The patient strains down as the proctoscope is removed.
- Haemorrhoids are seen as purple veins in the left lateral, right posterior or right anterior position.
- Fissures may also be seen, but pain often prevents the procedure from being performed.

- **Colonoscopy** allows good visualization of the whole colon and terminal ileum. Biopsies can be obtained and polyps removed. Benign strictures can be dilated and malignant strictures stented. Cancer, polyps and diverticular disease are the most common significant findings. Perforation occurs in 1:1000 examinations but this is higher (up to 2%) after polypectomy and endoscopic mucosal resection (Box 32.6).

- **Proctoscopy** (Box 32.7) is performed in all patients with a history of bright red rectal bleeding to look for anorectal pathology such as haemorrhoids; a rigid sigmoidoscope is too narrow and long to enable adequate examination of the anal canal.

- **Sigmoidoscopy**, either flexible or rigid, is part of the routine hospital examination in cases of diarrhoea and in patients with lower
abdominal symptoms such as a change in bowel habit or rectal bleeding. *Rigid sigmoidoscopy* can visualize the distal 20–25 cm of large bowel, whereas *flexible sigmoidoscopy* (FS) can reach up to the splenic flexure (60 cm), and is typically performed in the endoscopy unit after evacuation of the distal colon using an enema or suppository.

- **Balloon enteroscopy**, either double- or single-balloon, can examine the small bowel from the duodenum to the ileum, adopting both cranial and caudal approaches, and using specialized enteroscopes in expert centres.
- **Capsule endoscopy** is used for the evaluation of obscure gastrointestinal bleeding (after negative gastroscopy and colonoscopy) and for the detection of small bowel tumours and occult inflammatory bowel disease. It should be avoided if strictures are suspected.
- **pH studies, impedance monitoring and manometry** are all discussed in more detail in the upper gastrointestinal disease section.

**Imaging**

**Plain X-rays**

Plain X-rays of the chest and abdomen are chiefly used in the investigation of an acute abdomen. Interpretation depends on analysis of gas shadows inside and outside the bowel. Plain films are particularly useful where obstruction or perforation is suspected, to exclude toxic megacolon in colitis, and to assess faecal loading in constipation. Calcification may be seen with gall-bladder stones and in chronic pancreatitis, though computed tomography is more sensitive for both.

**Ultrasound**

Ultrasoundography involves no radiation and is the first-line investigation for abdominal distension: for example, in ascites, a mass or suspected inflammatory conditions. It can show dilated, fluid-filled loops of bowel in obstruction, and thickening of the bowel wall. It can be used to guide biopsies or percutaneous drainage. In an acute abdomen, ultrasound can diagnose cholecystitis, appendicitis, enlarged mesenteric glands and other inflammatory conditions.

**Computed tomography**

Computed tomography (CT) involves a significant dose of radiation (approximately 10 millisieverts). Modern multislice fast scanners and techniques, involving intraluminal and intravenous contrast, enhance diagnostic capability. Intraluminal contrast may be positive (Gastrografin or Omnipaque) or negative (usually water). The bowel wall and mesentery are well seen after intravenous contrast, especially with negative intraluminal contrast. Clinically unsuspected diseases of other abdominal organs are quite often also revealed (Fig. 32.8A).

CT is widely used as a first-line investigation for the acute abdomen. It is sensitive for small volumes of gas from a perforated viscus, as well as leakage of contrast from the gut lumen. Inflammatory conditions, such as abscesses, appendicitis, diverticulitis, Crohn’s disease and its complications, are well demonstrated. In high-grade bowel obstruction, CT is usually diagnostic of both the presence and the cause of the obstruction.

CT is widely used in cancer staging and as guidance for biopsy of tumour or lymph nodes.

**CT pneumocolon/CT colonography** (virtual colonoscopy) after CO₂ insufflation into a previously cleansed colon provides an alternative to colonoscopy for diagnosis of colonic mass lesions (see Fig. 32.8B). It is being evaluated as a screening test for colon pathology with sensitivities of over 90% for polyps larger than 10 mm.

**Magnetic resonance imaging**

Magnetic resonance imaging (MRI) uses no radiation and is particularly useful in the evaluation of rectal cancers and of abscesses and fistulae in the perianal region. It is also useful in small bowel disease (MR enteroclysis) and in hepatobiliary and pancreatic disease.

**Positron emission tomography**

Positron emission tomography (PET) relies on detection of the metabolism of fluorodeoxyglucose. It is used for staging oesophageal, gastric and colorectal cancer and in detecting metastatic and recurrent disease. PET/CT adds additional anatomical information.

**Contrast studies**

These include barium swallow examination, double-contrast barium meal and small-bowel follow through or meal. *Absorbable water-soluble (Gastrografin or Omnipaque) contrast agents* should be used in preference to barium when perforation is suspected anywhere in the gut. These are useful examinations for the upper GI tract and small bowel but do rely on good technique. They are gradually being superseded by other modalities of imaging, particularly MRI.

**Radioisotopes**

Radionuclides are used to a varying degree, depending on availability and expertise. Some of the more common indications are measuring the rate of gastric emptying, demonstration of a Meckel’s diverticulum, evaluation of neuroendocrine tumours, assessment of bile salt malabsorption (SeHCAT scan) or detection of bacterial overgrowth. These will be explored in more detail in the relevant sections.

**FUNCTIONAL GASTROINTESTINAL DISORDERS**

There is a large group of gastrointestinal disorders that are termed ‘functional’ because symptoms occur in the absence of any demonstrable abnormalities in the digestion and absorption of nutrients, fluid and electrolytes, and no structural abnormality can be identified in the gastrointestinal tract, although there may be discernible abnormalities in neuromuscular function, such as dysmotility and visceral hypersensitivity, which are not routinely investigated.

**Pathophysiology and brain–gut interactions**

People with functional gastrointestinal disorders (FGIDs) are characterized by having a greater gastrointestinal motility response to life events than normal subjects. There is, however, a poor association between measured gastrointestinal motility changes and symptoms in many of the FGIDs. Patients with FGID have been shown to have abnormalities in visceral sensation and to have a lower pain threshold when tested with balloon distension (visceral hyperalgesia). Visceral hypersensitivity possibly relates to:

- altered receptor sensitivity at the viscus itself
increased excitability of the spinal cord dorsal horn neurones
altered central modulation of sensations.

A systematic review of published studies suggests that 10% of patients who experience an acute infective gastroenteritis develop a degree of FGID. It is not clear whether this is caused by post-infectious bile salt malabsorption, alterations in the mucosal immune system or the use of antibiotics to treat the index infection.

The brain–gut axis describes a combination of intestinal motor, sensory and activities (Fig. 32.9). Thus, extrinsic (e.g. vision, smell) and intrinsic (e.g. emotion, thought) information can affect gastrointestinal sensation because of the neural connections from higher centres. Conversely, viscerotrophic events can affect central pain perception, mood and behaviour.

Psychological stress can exacerbate gastrointestinal symptoms, and psychological disturbances are more common in patients with FGIDs. These disturbances alter attitude to illness, promote healthcare seeking, and often lead to a poor clinical outcome. They have psychosocial consequences with poor quality of life at home and work. Early in life, genetic and environmental influences (e.g. family attitudes towards bowel training, verbal or sexual abuse, exposure to an infection) may affect psychosocial development (susceptibility to life stress, psychological state, coping skills, development of social support) or the development of gut dysfunction (abnormal motility or visceral hypersensitivity). Therefore, FGID should be regarded as a dysregulation of brain–gut function.
Recurrent aphthous ulceration

Idiopathic aphthous ulceration is common and affects up to 25% of the population. Recurrent painful round or ovoid mouth ulcers are seen with inflammatory halos. They are more common in females and non-smokers, usually appear first in childhood, and tend to reduce in number and frequency before the age of 40. Other family members may be affected. There is no sign of systemic disease.

- **Minor aphthous ulcers** are the most common; they are less than 10 mm diameter, have a grey/white centre with a thin erythematous halo, and heal within 14 days without scarring. They rarely affect the dorsum of the tongue or hard palate.
- **Major aphthous ulcers** (>10 mm diameter) often persist for weeks or months and heal with scarring.

The cause is not known. Deficiencies of iron, folic acid or vitamin B12 (with or without gastrointestinal disorders) are sometimes found but are not causally linked. Secondary causes, such as Crohn's disease, should be excluded (Box 32.8).

There are no specific effective therapies. Sufferers should avoid oral trauma, and acidic foods or drinks that cause pain. Topical (1% triamcinolone) or systemic corticosteroids may lessen the duration and severity of the attacks. Chlorhexidine gluconate or tetracycline mouthwash, dapsone, colchicine, thalidomide and azathioprine have all been used with variable effect.

Neoplasia (squamous cell carcinoma)

Malignant tumours of the mouth account for 1% of all malignant tumours in the UK. The majority develop on the floor of the mouth or lateral borders of the tongue. Early lesions may be painless, but advanced tumours are easily recognizable as hard, indurated ulcers with raised and rolled edges. Aetiological agents include tobacco, heavy alcohol consumption and the areca nut. Human papillomavirus 16 causes some oral cancers. Pre-malignant lesions include leucoplakia (single adherent white patch), lichen planus, submucous fibrosis and erythroplakia (a red patch).

Management

Treatment is by surgical excision, which may require extensive neck dissection to remove involved lymph nodes and/or radiotherapy. Ablative treatment with photodynamic therapy is being pioneered for early lesions.

Pigmented neoplastic lesions

These include melanotic naevi on the hard palate and buccal mucosa. These are rarer in the mouth than on the skin. Malignant melanomas are rare, but more common in males, and occur mainly on the upper jaw. The 5-year survival is only 5%.

Non-neoplastic lesions

Oral white patches

Transient white patches either are due to Candida infection or are very occasionally found in systemic lupus erythematosus. Local causes include mechanical, irritative or chemical trauma from drugs (e.g. ill-fitting dentures or aspirin). Oral candidiasis in adults is seen following therapy with broad-spectrum antibiotics or inhaled steroids, and in people with diabetes, patients who are seriously ill or those who are immunocompromised.

Persistent white patches can be due to leucoplakia, which is associated with alcohol and (particularly) smoking; it is pre-malignant. A biopsy should always be taken; histology shows alteration in the keratinization and dysplasia of the epithelium. Treatment is unsatisfactory. Isotretinoin possibly reduces disease progression. **Oral lichen planus** presents as white striae, which can rarely extend into the oesophagus.

Oral pigmented lesions

Racial pigmentation is scattered and symmetrically distributed. Amalgam tattoo is the most common form of localized oral
pigmentation and consists of blue–black macules involving the gingivae; it results from dental amalgam sequestering into the tissues. Diseases causing pigmentation include Peutz–Jeghers syndrome and Addison’s disease. Heavy metals (e.g., lead, bismuth and mercury) and drugs (e.g., phenothiazines and antimalarials) all cause pigmentation of the gums.

**Tongue**

The tongue may be affected by inflammatory or malignant processes, with similar lesions to those described above.

**Glossitis**

Glossitis is a red, smooth, sore tongue associated with vitamin $B_{12}$, folate, iron, riboflavin and nicotinic acid deficiency. It is also seen in infections due to *Candida*.

**Geographic tongue**

A geographic tongue is an idiopathic condition occurring in 1–2% of the population and may be familial. There are erythematous areas surrounded by well-defined, slightly raised irregular margins. The lesions are usually painless and the patient should be reassured.

**Gums**

The gums (gingivae) are the mucous membranes covering the alveolar processes of the mandible and the maxilla. Diseases of the gum are shown in **Box 32.9**.

**Teeth**

Dental caries occur as a result of bacterial damage to tooth structures leading to tooth decay and ‘cavities’. The main cause in humans is *Streptococcus mutans*, which is cariogenic only in the presence of dietary sugar. Dental caries can progress to pulpitis and pulp necrosis, and spreading infection can cause dentoalveolar abscesses. If there is soft tissue swelling, antibiotics (e.g., amoxicillin or metronidazole) should be prescribed prior to dental intervention.

Erosion of the teeth can result from exposure to acid (e.g., in bulimia nervosa) or, very occasionally, from severe gastro-oesophageal reflux disease.

**SALIVARY GLANDS**

Diseases of the salivary glands are shown in **Box 32.10**.

**PHARYNX AND OESOPHAGUS**

**Gastro-oesophageal reflux disease**

**Epidemiology and pathophysiology**

Gastro-oesophageal reflux disease (GORD) is common with a prevalence of 10–20% in the developed world. It is more common in the Western world than in Asia. There are a number of lifestyle risk factors as well as possible genetic factors, and the cardinal clinical feature is heartburn. Psychosocial factors are often determinants of symptom severity, with heartburn increased during times of stress. Factors associated with GORD are shown in **Box 32.11**.

The underlying cause of GORD is reflux of gastric acid, pepsin, bile and duodenal contents back into the oesophagus. This can be influenced by many factors that overcome the innate defence mechanisms, primarily the lower oesophageal sphincter (LOS). Between swallows, the muscles of the oesophagus are relaxed, except for those of the two sphincters. The LOS in the distal oesophagus remains closed because of the unique property of the muscle, and relaxes when swallowing is initiated (see p. 1150). **Transient lower (o)esophageal sphincter relaxations** (TLESRs) are part of normal physiology, but occur more frequently in patients with GORD, allowing gastric acid to flow back into the oesophagus (**Fig. 32.10**). Increased abdominal pressure (pregnancy) and low LOS pressure also predispose to GORD.

**Other anti-reflux mechanisms** involve the intra-abdominal segment of the oesophagus, which acts as a flap valve. In addition, the mucosal rosette, formed by folds of the gastric mucosa, and the crural diaphragm at the LOS, which contracts and acts like a pinchcock, prevent acid reflux. A hiatus hernia can impair this mechanism.
Pharynx and oesophagus

**Box 32.11 Factors associated with gastro-oesophageal reflux**
- Pregnancy or obesity
- Fat, chocolate, coffee or alcohol ingestion
- Large meals
- Cigarette smoking
- Drugs – antimuscarinic, calcium-channel blockers, nitrates
- Systemic sclerosis
- Treatment for achalasia
- Hiatus hernia

**Box 32.12 Hiatus hernia**

**Sliding hiatus hernia**
The oesophageal–gastric junction and part of the stomach ‘slide’ through the hiatus so that it lies above the diaphragm.
- Present in 30% of people over 50 years
- Produces no symptoms – any symptoms are due to reflux

**Rolling or para-oesophageal hernia**
Part of the fundus of the stomach prolapses through the hiatus alongside the oesophagus.
- The lower oesophageal sphincter remains below the diaphragm and remains competent
- Occasionally, severe pain occurs due to volvulus or strangulation

*Fig. 32.10 The main anti-reflux mechanisms. These are shown on the right.*

**Box 32.13 Classic features of the pain of gastro-oesophageal reflux and cardiac ischaemia**

**Reflux pain: burning, worse on bending, stooping or lying down**
- Seldom radiates to the arms
- Worse with spicy food, hot drinks or alcohol
- Relieved by antacids

**Cardiac ischaemic pain**
- Gripping or crushing
- Radiates to neck or left arm
- Worse with exercise
- Accompanied by dyspnoea

Promote acid exposure. The patient typically complains of pain on eating spicy food or drinking hot liquids or alcohol.

The correlation between heartburn and oesophagitis is poor. Some patients have mild oesophagitis but severe heartburn, while others have severe oesophagitis in the absence of symptoms, and can present with haematemesis or iron deficiency anaemia from chronic blood loss.

Differentiation of cardiac and oesophageal pain can be difficult; 20% of cases seen in emergency departments have GORD (Box 32.13). A trial of antacid therapy is often useful, resolving reflux-induced pain, before progressing to 24-hour pH studies only if symptoms persist.

**Regurgitation** of food and acid into the mouth occurs, particularly on bending or lying flat. This can lead to excess salivation in the mouth, commonly known as water-brash. Aspiration pneumonia is unusual without an accompanying obstruction, but cough and asthma can occur and respond slowly (1–4 months) to a proton pump inhibitor (PPI).

**Laryngopharyngeal reflux disease (LPRD)** is the transport of gastric contents into the larynx and pharynx, usually, although not exclusively, in the context of GORD. Heartburn may be one of the associated symptoms but cough, hoarse voice, postnasal drip and asthma are more frequently seen, but are not common.

**Diagnosis and investigations**
The clinical diagnosis can usually be made without investigation. Unless there are alarm signs, especially dysphagia (see p. 901), patients under the age of 45 years can safely be treated initially without investigations. If investigation is required, there are two aims:
- **Assess oesophagitis and hiatal hernia by endoscopy.** If there is oesophagitis (Fig. 32.11) or Barrett’s oesophagus (see p. 1165), reflux is confirmed.
- **Intraluminal monitoring** (Fig. 32.12). Intraluminal pH monitoring or impedance combined with manometry is helpful if there is no response to PPIs and should always be performed to confirm reflux before surgery. Ambulatory 24-hour pH monitoring consists of passing a nasogastric tube with a pH probe at its tip which is placed at the level of the LOS. This allows measurements of acid exposure and is worn for 24 hours. Some centres now offer a wireless probe (known as a Bravo capsule) which is clipped to the lower oesophagus without the need for an NG tube. This then gradually detaches and is passed in the stool. A composite score of the various parameters measured is then calculated, with a score higher than 14.72 indicating reflux. This is known as a DeMeester score. There should also be a good correlation between reflux (pH <4.0) and symptoms. Impedance testing is when a catheter is used to measure the resistance to flow of ‘alternating current’ in the contents of the oesophagus. It can also be helpful to assess oesophageal dysmotility as a potential cause of the symptoms, leading to impaired oesophageal clearance.

*Fig. 32.11 Acid pocket soars over the LOS. The distal oesophagus is supradiaphragmatic, especially on lying flat. This can be specifically targeted with an antacid–alginate combination.*

*Fig. 32.12* Intraluminal pH monitor. The probe includes a pH sensor, a thermistor for temperature measurement and two impedance sensors. Standard intraluminal impedance is measured in parallel with the pH sensor. A wireless ambulatory pH monitoring catheter is shown (Baron et al., 2004).
Management

Approximately half of patients with reflux symptoms in primary care can be treated successfully with simple antacids, loss of weight and raising the head of the bed at night. Precipitating factors should be avoided, with dietary measures, reduction in alcohol and caffeine consumption, and cessation of smoking. These measures are simple to say but difficult to carry out, though they are useful in mild disease in compliant patients.

Drugs

Alginate-containing antacids
Alginate-containing antacids (10 mL three times daily) are the most frequently used ‘over-the-counter’ agents for GORD. They form a gel or ‘foam raft’ with gastric contents to reduce reflux. Magnesium-containing antacids tend to cause diarrhoea while aluminium-containing compounds may cause constipation.

Proton pump inhibitors
Proton pump inhibitors (PPIs; omeprazole, rabeprazole, lansoprazole, pantoprazole, esomeprazole) inhibit gastric hydrogen/potassium-adenosine triphosphatase. PPIs reduce gastric acid secretion by up to 90% and are the drugs of choice for all but mild cases. Most patients with GORD will respond well, with approximately 60% symptom-free after 4 weeks of a once-daily PPI. Patients with severe symptoms may need twice-daily PPIs and prolonged treatment, often for years. Once oesophageal sensitivity has normalized, a lower dose, e.g. omeprazole 20 mg, may be sufficient for maintenance. Long-term PPI prescription is not uncommon, and although some recent data have suggested side-effects such as osteoporosis, and an increase in gastrointestinal infections such as *Clostridium difficile*, these are uncommon and tend to occur in at-risk patients.

Patients who do not respond to a PPI and have continuing symptoms with a normal endoscopy are described as having non-erosive reflux disease (NERD) (Fig. 32.13). These patients are usually female and often the symptoms are functional, although a small group have a ‘hypersensitive’ oesophagus, giving discomfort with only slight changes in pH. Isomers of some of the original PPIs (e.g. dexlansoprazole) have the benefit of more effective gastric acid inhibition over a longer time period, as their metabolism of the active metabolite is slower.

*H₂*-receptor antagonists
*H₂*-receptor antagonists (e.g. cimetidine, ranitidine, famotidine and nizatidine) are frequently used for acid suppression if antacids fail, as they can easily be obtained. They can be used in conjunction with PPIs for patients with more severe GORD.

Dopamine antagonist prokinetic agents
The dopamine antagonist prokinetic agents metoclopramide and domperidone are occasionally helpful, as they enhance peristalsis and speed gastric emptying, but there are few data to substantiate this. The role of domperidone has been limited still further following reports of serious cardiac side-effects.

Endoluminal gastroplication
In this endoscopic procedure, multiple plications or pleats are made below the gastro-oesophageal junction. Randomized controlled trials have shown benefit with reduction in heartburn, acid reflux
episodes and PPI usage, but not sustained improvements in the oesophageal pH measurements.

Surgery

Surgery should never be performed for a hiatus hernia alone. The best predictors of a good surgical result are typical reflux symptoms with documented acid reflux, which correlates with symptoms and response to a PPI. With such highly selected cases in experienced hands, the laparoscopic Nissen fundoplication has a satisfaction rate of over 90% at 5 years, and available 10-year data show satisfaction rates remain high at 88%. Current surgical techniques return the oesophagogastric junction to the abdominal cavity, mobilize the gastric fundus, close the diaphragmatic crura snugly and involve a short, tension-free fundoplication.

The Linx reflux management system consists of a row of magnets that increase LOS closure pressure, allowing food passage during swallowing; it is inserted laparoscopically. Improvement in quality of life with no PPI therapy has been shown but further studies are necessary. Patients cannot have an MRI study with the device in situ.

Indications for operation are not clear-cut but include intolerance to medication, the desire for freedom from medication, the expense of therapy and concern about long-term side-effects.

The most common cause of mechanical fundoplication failure is recurrent hiatus hernia.

Complications of gastro-oesophageal reflux disease

Peptic stricture

Since the advent of PPIs, peptic strictures have become far less common. They usually occur in patients over the age of 60 and present with intermittent dysphagia for solids, which worsens gradually over a long period. Mild cases may respond to PPIs alone. More severe cases need endoscopic dilation and long-term PPI therapy. Surgery is required if medical treatment fails.

Barrett’s oesophagus

Barrett’s oesophagus (Fig. 32.14) is a condition in which part of the normal oesophageal squamous epithelium is replaced by metaplastic columnar mucosa to form a segment of ‘columnar-lined oesophagus’ (CLO). It is a complication of GORD and there is almost always a hiatus hernia present.

Diagnosis and classification

The diagnosis is made if endoscopy shows proximal displacement of the squamocolumnar mucosal junction and biopsy demonstrates columnar lining above the proximal gastric folds (>1 cm); intestinal metaplasia is no longer a requirement of the British Society of Gastroenterology definition but is central to the American College of Gastroenterology guidelines. Barrett’s oesophagus may be seen as a continual circumferential sheet, as finger-like projections extending upwards from the squamocolumnar junction or as islands of columnar mucosa interspersed with areas of squamous mucosa. The Prague classification (Fig. 32.15) is used for recording the endoscopic distribution, stating both the length of circumferential CLO (C measurement) and the maximum length (M measurement), the distance from the top of the gastric folds to the most proximal tongue of the columnar mucosa.
Central obesity increases the risk of Barrett’s by 4.3 times. Long-segment (>3 cm) and short-segment (<3 cm) Barrett’s is found, respectively, in 5% and 15% of patients undergoing endoscopy for reflux symptoms. Barrett’s is also often found incidentally in endoscoped patients without reflux symptoms. It is most common in middle-aged obese men. The major concern is that approximately 0.12–0.5% of Barrett’s patients develop oesophageal adenocarcinoma per year; the majority, probably, through a gradual transformation from intestinal metaplasia to low-grade then high-grade dysplasia, before invasive adenocarcinoma. Barrett’s increases the chance of developing oesophageal adenocarcinoma 30- to 50-fold in early studies but recent studies have shown the risk to be much lower and closer to a 1% lifetime risk in the typical patient.

Because of the poor correlation between Barrett’s oesophagus and symptoms, screening is not recommended; however, in the absence of high-quality trial evidence, endoscopic surveillance is recommended by some. This involves inspection of the oesophageal mucosa with a high-definition gastroscope, and the taking of targeted biopsies of any focally abnormal tissue in addition to random biopsies from all four quadrants (every 1–2 cm) of the CLO. The interval between endoscopies is determined by the length of the CLO and the degree of cellular disturbance within it (Fig. 32.16). High-grade dysplasia (HGD) is usually associated with endoscopically visible nodules or ulceration, optimally visualized with a high-definition endoscope. Chromo-endoscopy (the topical application of stains or pigments via the endoscope), narrow band and autofluorescence imaging may aid the diagnosis of dysplasia and carcinoma. Endoscopic technology has improved the detection of pre-malignant lesions, enabling their removal by either endoscopic mucosal resection (EMR) or endoscopic submucosal dissection, therefore preventing surgical oesophagectomy.

If low-grade dysplasia is found on endoscopic surveillance, a repeat endoscopy with quadrantic biopsies every 1 cm is usually performed within 6 months, while on high-dose proton pump inhibition. Recent guidelines now suggest that if low-grade dysplasia persists then these patients should be offered endoscopic ablation therapy or 6-monthly surveillance.

If high-grade dysplasia is found, it is usually in the context of an endoscopically visible lesion, which, if nodular, is removed by endoscopic mucosal resection for more accurate histological staging. If high-grade dysplasia is detected in the absence of any endoscopically visible lesion, high-dose proton pump inhibition is started and repeat biopsies taken within 3 months. Endoscopic ultrasound is frequently used to stage this patient group more accurately, in order to exclude cancer and associated significant lymphadenopathy.

**Fig. 32.15** The Prague criteria for endoscopically suspected oesophageal columnar metaplasia/Barrett’s oesophagus.
**Radiofrequency ablation (RFA)** has superseded photodynamic therapy as the technique of choice for endoscopic treatment of dysplasia within Barrett’s segments following removal of any nodular lesions, returning the oesophagus to squamous lining. The benefit of RFA in low-grade dysplasia is currently under evaluation.

**Motility disorders**

**Achalasia**

Achalasia is characterized by oesophageal aperistalsis and impaired relaxation of the lower oesophageal sphincter. The lower oesophageal pressure is elevated in more than half of patients.

**Clinical features**

The incidence of achalasia is 1:100,000 and is equal in males and females. It occurs at all ages but is rare in childhood. Patients usually have a long history of intermittent dysphagia, characteristically for both liquids and solids from the onset. Regurgitation of food from the dilated oesophagus occurs, particularly at night, and aspiration pneumonia is a complication. Spontaneous chest pain occurs and is said to be due to oesophageal ‘spasm’; it may be misdiagnosed as cardiac pain. Dysphagia may be mild and accepted by the patient as normal; weight loss is usually minimal.

**Pathogenesis**

The aetiology of achalasia is unknown, with autoimmune, viral and neurodegenerative aetiologies all being postulated. A similar clinical picture is seen in chronic Chagas’ disease (American trypanosomiasis; see p. 568), where there is damage to the neural plexus of the gut. Histopathology shows inflammation of the myenteric plexus of the oesophagus with reduction of ganglion cell numbers. Cholinergic innervation appears to be preserved. Reduction in nitric oxide synthase-containing neurones has been shown by immunohistochemical staining. Pharmacological studies in patients with achalasia support the selective loss of inhibitory, nitrergic neurones.

**Differential diagnosis**

The differential diagnosis of achalasia worldwide includes genetic syndromes, infectious diseases, neoplasms and chronic inflammatory conditions.

**Investigations**

- **Chest X-ray** shows a dilated oesophagus, sometimes with a fluid level seen behind the heart. The fundal gas shadow is absent.
- **Barium swallow** shows lack of peristalsis and often synchronous contractions in the body of the oesophagus, sometimes with dilation. The lower end shows a ‘bird’s beak’ due to failure of the sphincter to relax (Fig. 32.17).
• **Oesophagastroduodenoscopy** is performed to exclude a carcinoma at the lower end of the oesophagus, as this can produce a similar X-ray appearance. When there is marked dilation, a 24-h liquid-only diet and a washout, prior to endoscopy, are useful to remove food debris. In true achalasia, the endoscope passes through the LOS with little resistance.
• **CT scan** excludes distal oesophageal cancer.
• **Manometry** shows aperistalsis of the oesophagus and failure of relaxation of the LOS (Fig. 32.18).

**Management**

All current forms of treatment for achalasia are **palliative**. Drug therapy rarely produces satisfactory or durable relief; nitrates or sildenafil can be tried initially.

Endoscopic and surgical therapies are equally effective. Endoscopic dilation of the LOS, using a pneumatic balloon under X-ray control, weakens the sphincter and is initially successful in 80% of cases. About 50% of patients require a second or third dilation in the first 5 years. There is a low but significant risk of perforation. Intraspincteric injection of botulinum toxin A produces satisfactory initial results but the effects wear off within months. Further injections can be given. It is safer and simpler than dilation, so may be valuable in patients at risk of death if a perforation occurs. Neither pneumatic dilation nor botulinum toxin works as well in younger patients.

Surgical division of the LOS, Heller’s operation, usually performed laparoscopically, is the surgical treatment of choice. Per oral endoscopic myotomy (POEM) is a novel technique, which is a division of the LOS using a gastroscope. The early results show great promise.

Reflex oesophagitis complicates all procedures and aperistalsis of the oesophagus remains.

**Complications**

There is a slight increase in the incidence of squamous carcinoma of the oesophagus in both treated and untreated cases (7% after 25 years).

**Systemic sclerosis**

The oesophagus is involved in almost all patients with this disease. Diminished peristalsis and oesophageal clearance, detected manometrically (see Fig. 32.18) or by barium swallow, is due to replacement of the smooth muscle by fibrous tissue. LOS pressure is decreased, allowing reflux with consequent mucosal damage. Strictures may develop. Initially, there are no symptoms, but dysphagia and heartburn occur as the oesophagus becomes more severely involved. Similar motility abnormalities may be found in other autoimmune rheumatic disorders, particularly if Raynaud’s phenomenon is present. Treatment is as for reflux disease (see p. 1162) and benign stricture.

**Diffuse oesophageal spasm**

This is a severe form of oesophageal dysmotility that can sometimes produce retrosternal chest pain and dysphagia. It can accompany GORD. Swallowing is accompanied by bizarre and marked contractions of the oesophagus without normal peristalsis (see Fig. 32.18). On barium swallow, the appearance may be that of a ‘corkscrew’ oesophagus. However, asymptomatic oesophageal ‘dysmotility’ is not infrequent, particularly in patients over the age of 60 years.
A variant of diffuse oesophageal spasm is the ‘nutcracker’ oesophagus, which is characterized by very high-amplitude peristalsis (pressures >200 mmHg) within the oesophagus. Chest pain is more common than dysphagia.

**Management**

True oesophageal spasm producing severe symptoms is uncommon and treatment is often difficult. PPIs may be successful if reflux is a factor. Antispasmodics, nitrates, calcium-channel blockers and γ-aminobutyric acid (GABA) receptor agonists (e.g. baclofen) are used. Occasionally, balloon dilation or even longitudinal oesophageal myotomy is necessary.

**Miscellaneous motility disorders**

Abnormalities of motility that occasionally produce dysphagia are found in the elderly, and in diabetes mellitus, myotonic dystrophy, oculopharyngeal muscular dystrophy and myasthenia gravis, as well as neurological disorders involving the brainstem.

**Oesophageal diverticulum**

Diverticula occur:
- immediately above the upper oesophageal sphincter (pharyngeal pouch – Zenker’s diverticulum; see p. 912)
- near the middle of the oesophagus (traction diverticulum due to inflammation, or associated with diffuse oesophageal spasm or mediastinal fibrosis)
- just above the lower oesophageal sphincter (epiphrenic diverticulum – associated with achalasia).

Usually detected incidentally on a barium swallow performed for other reasons, these are often asymptomatic. Dysphagia and regurgitation can occur with a pharyngeal pouch, becoming more problematic as the diverticula increase in size (see p. 901). These can be treated surgically and endoscopically.

**Rings and webs**

An oesophageal web is a thin, membranous tissue flap covered with squamous epithelium. Most acquired webs are located anteriorly in the postcricoid region of the cervical oesophagus and are well seen on barium swallow. They may produce dysphagia. In the Plummer-Vinson syndrome (or Paterson-Brown-Kelly syndrome), a web is associated with chronic iron deficiency anaemia, glossitis and angular stomatitis. This rare syndrome affects mainly women and its aetiology is not understood. The web may be difficult to see at endoscopy and is often ruptured unintentionally by the passage of the endoscope. Dilation of the web is rarely necessary. Iron is given for the iron deficiency.

**Lower oesophageal rings**

Lower oesophageal rings are of two types:
- **Mucosal** (Schatzki’s ring, also called B ring) is located at the squamocolumnar mucosal junction and is common (Fig. 32.19). It is associated with a characteristic history of intermittent bolus obstruction.
- **Muscular** (A ring) is located proximal to the mucosal ring and is uncommon. It is covered by squamous epithelium and may cause dysphagia.

**Management** for these rings is usually with reassurance and dietary advice, but dilation is occasionally necessary. After a single dilation, 68% of patients with Schatzki’s rings are symptom-free at 1 year and 35% remain symptom-free after 2 years, but only 11% are symptom-free at 3 years. Many also respond to oral PPI, either alone or with dilation.

**Benign oesophageal stricture**

Peptic stricture (Fig. 32.20) secondary to reflux is the most common cause of benign strictures (for treatment, see p. 1165). They also occur after the ingestion of corrosives, radiotherapy, sclerotherapy of varices and prolonged nasogastric intubation. Dysphagia is usually treated by endoscopic dilation. Surgery is sometimes required.

**Oesophageal infections**

Infection is a cause of painful swallowing and is seen particularly in immunosuppressed (e.g. on chemotherapy) and debilitated patients, and in those with acquired immunodeficiency syndrome (AIDS). Infection can occur with:
- *Candida*
- herpes simplex
- cytomegalovirus
- *Mycobacterium tuberculosis*.

It is occasionally difficult to distinguish between these disorders on oesophagoscopy, as only widespread ulceration is seen. In candidiasis, the characteristic white plaques are frequently found; oral candidiasis is not always present. The diagnosis of *Candida* infection can be confirmed by examining a direct smear taken at endoscopy, but often infections are mixed and cultures and biopsies must be performed. Tuberculosis causes deep ulceration with associated mediastinal lymphadenopathy.

**Management**

Most patients on large doses of immunosuppressive agents are treated prophylactically for candidiasis with nystatin, fluconazole or
amphotericin. Antifungal or antiviral treatment is prescribed appropriately for other infections.

**Mallory–Weiss syndrome**
This is described on page 1184.

**Eosinophilic oesophagitis**

Eosinophils can be seen in the oesophageal mucosa (which is usually devoid of eosinophils microscopically) due to a variety of causes, such as eosinophilic (or allergic) oesophagitis and GORD.

Eosinophilic oesophagitis (**Fig. 32.21**) is increasingly recognized but its pathogenesis is unknown. There may be a personal or family history of allergic disorders, such as food allergy, eczema or asthma.

Patients present with a long history of dysphagia, food impaction, ‘heartburn’ and oesophageal pain caused by the eosinophil-induced oesophageal inflammation. Usually, the patient is male and white, and has an average age at diagnosis of 35, but eosinophilic oesophagitis is becoming more common in children.

Typical endoscopic abnormalities include mucosal furrowing, loss of vascular pattern due to a thickened mucosa, plaques of eosinophilic surface exudate and prominent circular folds, but the oesophagus may appear macroscopically normal. Reflux oesophagitis and Schatzki’s rings may coexist. Endoscopic forceps biopsies should be taken throughout the oesophagus for histology and eosinophil numbers calculated.

The eosinophilic infiltration of the oesophagus due to reflux disease tends to have a different microscopic appearance and fewer eosinophils.

**Management**

First-line treatment is with topical steroids, such as swallowing fluticasone spray or budesonide syrup. If this is not effective, systemic steroids or empirical elimination diets may also be used (dietary treatment is more beneficial in children). A cohort of patients respond to PPIs in the absence of GORD. Dilation is sometimes necessary, with a risk of perforation of 2%.

**Oesophageal perforation**

Oesophageal perforation most commonly occurs at the time of endoscopic dilation and, rarely, following insertion of a nasogastric tube, gastroscope or transoesophageal echoprobe. Patients with malignant, corrosive or post-radiotherapy strictures are more likely to perforate than those with a benign peptic stricture.

**Management**

This normally involves placement of an expanding covered oesophageal stent, which usually seals the hole. A water-soluble contrast X-ray is performed after 2–3 days to check the perforation has sealed.

**Oesophageal rupture**

‘Spontaneous’ oesophageal rupture occurs with violent vomiting (Boerhaave’s syndrome), producing severe chest pain and collapse in typical cases. Diagnosis can be difficult because classic symptoms are absent in about one-third of cases, and delays in presentation for medical care are common. Rupture may follow alcohol ingestion. A chest X-ray shows a hydro pneumothorax. The diagnosis is made with a water-soluble contrast swallow or on CT. The mortality rate is approximately 35%, making it the most lethal perforation of the gastrointestinal tract. The best outcomes are associated with early diagnosis and definitive surgical management within 12 hours of rupture. If intervention is delayed longer than 24 hours, the mortality rate (even after surgery) rises to above 50%, and to nearly 90% after 48 hours.

**Oesophageal tumours**

**Cancer of the oesophagus**

This is the sixth most common cancer worldwide. Squamous cancers occurring in the middle third account for 40% of tumours, and for 15% in the upper third. Adenocarcinomas occur in the lower third of the oesophagus and at the cardia, and represent approximately 45% of tumours. Primary small cell cancer of the oesophagus is extremely rare.

**Epidemiology and aetiology**

**Squamous cell carcinoma**

The geographic variation in incidence is greater than for any other carcinoma – often in regions very close to one another. Squamous cell carcinoma (SCC) is common in Ethiopia, China, South and East Africa, and the Caspian regions of Iran. By contrast, North, Central and West Africa have low rates.

In the UK, the incidence is 5–10 per 100 000 and SCC represents 2.2% of all malignant disease. The incidence is decreasing, in contrast to that of adenocarcinoma. SCC of the oesophagus is more common in men (2:1). Risk factors are shown in **Box 32.14**.

High levels of alcohol consumption increase the risk of squamous cell cancer of the oesophagus, while tobacco use is associated with an increased incidence of both squamous cell and adenocarcinomas of the oesophagus. Smoking, obesity and low

fruit and vegetable consumption are implicated in approximately 9 in 10 squamous cell cancers of the oesophagus.

Diets rich in fibre, carotenoids, folate, vitamin C and non-starchy vegetables probably decrease the risk of oesophageal cancer, whereas diets high in saturated fat, cholesterol and refined cereals have been associated with an increased risk. Red and processed meat intake has been associated with an increased risk of both oesophageal SCC and adenocarcinoma. Conversely, fish and white meat consumption have been inversely associated with risk of oesophageal SCC in case-control studies from Italy, Switzerland and Uruguay.

**Adenocarcinoma**

These tumours primarily arise in columnar-lined epithelium in the lower oesophagus (see p. 1165). The incidence of this tumour is increasing in Western industrialized countries. It currently accounts for more than 70% of all new oesophageal cancer diagnoses. Extension of an adenocarcinoma of the gastric cardia into the oesophagus can present with the same symptoms. Previous reflux symptoms increase the risk up to eightfold and the risk is proportional to their severity.

**Clinical features**

Carcinoma of the oesophagus occurs mainly in those aged 60–70 years. Dysphagia is progressive and unrelenting. Initially, there is difficulty in swallowing solids but, typically, dysphagia for liquids follows within weeks. Impaction of food causes pain but more persistent pain implies infiltration of adjacent structures.

The lesion may be ulcerative, proliferative or scirrhous, extending variably around the wall of the oesophagus to produce a stricture. Direct invasion of the surrounding structures and metastases to lymph nodes are more common than disseminated metastases. Weight loss, due to the dysphagia as well as to anorexia, is frequent. Oesophageal obstruction eventually causes difficulty in swallowing saliva, coughing and aspiration into the lungs.

Weight loss, anorexia and lymphadenopathy are the most common physical signs.

**Investigations**

**Diagnosis**

- **Endoscopy** provides histological proof of the carcinoma (Fig. 32.22A).
- **Barium swallow** can be useful where the differential diagnosis of dysphagia includes a motility disorder such as achalasia (see Fig. 32.22B).

**Staging**

The TNM staging system is used (see p. 1179); it is similar to the one used for gastric cancer. Tumour invasion of the wall of the oesophagus (T), presence of tumour in lymph nodes (N) and metastases (M)

---

**Fig. 32.22 Carcinoma of the oesophagus.** (A) Endoscopic image. (B) Barium swallow demonstrating a tight stricture in the mid-oesophagus (arrow) due to oesophageal cancer. (C) Endoscopic ultrasound. The central concentric circles are the probe. The arrow points to a break in the muscle layer and the soft tissue mass of the carcinoma.
are combined into stage categories. Tumours arising in the cervical, thoracic or abdominal oesophagus, including those that arise from within 5 cm from the gastro-oesophageal junction, share the same TNM staging criteria, but recent reclassification has differentiated between squamous and adenocarcinoma cancers.

- **CT scan** of the thorax and upper abdomen shows the volume of the tumour, local invasion, peritumoral and coeliac lymph node involvement, and metastases in the lung and elsewhere.
- **MRI** is equivalent to CT in local staging but not as good for pulmonary metastases.
- **Endoscopic ultrasound** has an accuracy rate of nearly 90% for assessing depth of invasion and infiltration, and of 80% for staging lymph node involvement. It is useful if CT has not already demonstrated that a cancer is too advanced for surgery. A fine-needle aspiration (FNA) of lymph nodes improves staging accuracy. Accurate T staging is necessary, as cancers confined to the superficial mucosa can be removed endoscopically (see Fig. 32.22C).
- **Laparoscopy** is useful if the tumour is at the cardia, to look for peritoneal and node metastases.
- **PET** after fluorodeoxyglucose is used principally to confirm distant metastases suspected on CT.

Management

Although oesophageal SCC and adenocarcinoma are undoubtedly two different disease processes with independent tumour biology, the majority of trial data do not discriminate between the two. The influence of histology on treatment is therefore unclear and varies around the globe.

Treatment is dependent on the age and performance status of the patient and the stage of the disease, with approximately 40% of all patients still alive 1 year after diagnosis. Five-year survival with stage 1 disease is 80% \((T_1/T_2, N_0, M_0)\), stage 2 is 30%, stage 3 is 18% and stage 4 is 4%. Some 70% of patients present with stage 3 or greater disease, so that overall survival is 40% at 1 year and around 15% at 5 years. Management should be undertaken by multidisciplinary teams, including gastroenterologists, upper gastrointestinal surgeons, oncologists, palliative care physicians and dieticians.

- **Surgery** provides the best chance of a cure but should only be used when imaging (see above) has shown that the tumour has not infiltrated outside the oesophageal wall. Less than 40% of patients will have potentially resectable disease at the time of presentation. Patients must be evaluated preoperatively, particularly with regard to performance status (see p. 1179), and surgery should be undertaken in designated units. Poor outcome data from surgery alone have challenged its role as monotherapy and it is more often used in conjunction with neo-adjuvant (preoperative) and adjuvant (postoperative) treatment. The role of surgery in early oesophageal SCC is less clear. As mentioned previously, endoscopic mucosal resection may be appropriate for early mucosal disease.

- **Preoperative (neo-adjuvant) chemoradiation therapy** may benefit patients with stage 2b and 3 disease. Prolongation of survival has been shown in some studies. In the USA, neo-adjuvant chemoradiotherapy is preferred to the neo-adjuvant chemotherapy alone that is typically used in the UK.

- **Palliative therapy** is often the only realistic possibility. Dilation is only of short-term benefit and the perforation risk is higher than for benign strictures. Combination of endoscopic dilation with laser or brachytherapy (see p. 115) prolongs luminal patency and gives as, if not better, functional results than stenting.

Insertion of an expanding metal stent allows liquids and soft foods to be eaten.

- **Chemoradiation alone** is sometimes given but evidence of benefit is poor, except in early-stage SCC.
- **Nutritional support**, as well as support for the patient and their family, is vital in this distressing condition.

Other oesophageal tumours

Most other tumours are rare. **Gastrointestinal stromal tumours** (see p. 124) and **leiomyomas** (both submucosal tumours) are found usually by chance; 10% cause dysphagia or bleeding. Surgical removal is performed for symptomatic lesions or those over 3 cm, which are more likely to harbour malignancy. Small, benign tumours are relatively common and often do not require treatment.

**Kaposi’s sarcoma** is found in the oesophagus as well as the mouth (see p. 1448) and hypopharynx in patients with AIDS.

**Functional oesophageal disorders**

The criteria for diagnosis rest mainly on compatible symptoms. However, pathological gastro-oesophageal reflux and eosinophilic oesophagitis may need to be excluded (see p. 1170).

**Globus**

This presents as:

- persistent or intermittent sensation of a lump or foreign body in the throat
- occurrence of the sensation between meals
- absence of dysphagia and pain on swallowing (odynophagia).

Management is with explanation and reassurance, and a trial of anti-reflux therapy. Antidepressants may be tried.

**Functional chest pain of presumed oesophageal origin**

This is characterized by episodes of mainly midline chest pain, not burning in nature, that are potentially of oesophageal origin and occur in the absence of a cardiological cause, gastro-oesophageal reflux and achalasia.

More than half of patients will respond to high-dose acid-suppression therapy in the first week; some will respond to nitrates and calcium-channel blockers.

Antidepressant therapy, e.g. amitriptyline or the selective serotonin reuptake inhibitor (SSRI) citalopram, have been shown to be effective.

**Further reading**

Gastritis and gastropathy

‘Gastritis’ indicates inflammation associated with mucosal injury (although the term is often used loosely by endoscopists to describe ‘redness’), and ‘gastropathy’ indicates epithelial cell damage and regeneration without inflammation.

Gastritis

Several classifications of gastritis (e.g. Sydney classification) have been proposed but are controversial due to lack of correlation between endoscopic and histological findings. *H. pylori* infection is the most common cause of gastritis, with autoimmune gastritis being seen in 5% of cases; the remaining causes include viruses (e.g. cytomegalovirus and herpes simplex), duodenogastric reflux and specific causes, e.g. Crohn’s, more common in children than adults. Chronic inflammation, particularly if induced by *H. pylori*, can lead to gastric intestinal metaplasia, a precursor to gastric cancer. The role of surveillance in these patients is unclear.

Autoimmune gastritis

This affects the fundus and body of the stomach (pan gastritis), leading to atrophic gastritis and loss of parietal cells, with achlorhydria and intrinsic factor deficiency causing the clinical syndrome of ‘pernicious anaemia’ (see p. 334). Metaplasia, usually of the intestinal type, is almost always in the context of atrophic gastritis. Serum autoantibodies to gastric parietal cells are common and non-specific; antibodies to intrinsic factor are rarer and more significant (see p. 334).

Gastropathy

Gastropathy is usually caused by irritants (drugs, NSAIDs and alcohol), bile reflux and chronic congestion. Acute erosive/haemorrhagic gastropathy can also be seen after severe stress (stress ulcers); secondary to burns (Curling ulcers), trauma, shock or renal failure; and in portal hypertension (called portal gastropathy). The underlying mechanism for these ulcers is unknown but may be related to an alteration in mucosal blood flow.

Helicobacter pylori infection

*Helicobacter pylori* is a slow-growing, spiral, Gram-negative, flagellate, urease-producing bacterium (Fig. 32.23), which plays a major role in gastritis and peptic ulcer disease. It colonizes the mucous layer in the gastric antrum, but is also found in the duodenum in areas of gastric metaplasia. *H. pylori* is found in greatest numbers under the mucous layer in gastric pits, where it adheres specifically to gastric epithelial cells. It is protected from gastric acid by the juxtamucosal mucous layer, which traps bicarbonate secreted by antral cells, and ammonia produced by bacterial urease.

Epidemiology

The prevalence of *H. pylori* is high in developing countries (80–90% of the population) and much lower (20–50%) in developed countries. Infection rates are highest in lower-income groups. Infection is usually acquired in childhood; although the exact route is uncertain, it may be faecal–oral or oral–oral. The incidence increases with age, probably due to acquisition in childhood when hygiene was poorer (cohort effect) rather than infection in adult life, which is most likely far less than 1% per year in developed countries.

Pathogenesis

The pathogenetic mechanisms are not fully understood, with the majority of the colonized population remaining asymptomatic throughout their life. *H. pylori* is highly adapted to the stomach environment, exclusively colonizing gastric epithelium and inhabiting the mucous layer, or just beneath. It adheres by a number of adhesion molecules including BabA, which binds to the Lewis antigen expressed on the surface of gastric mucosal cells and causes gastritis in all infected subjects. Damage to the gastric epithelial cell is caused by the release of enzymes and the induction of apoptosis through binding to class II major histocompatibility complex (MHC) molecules. The production of urease enables the conversion of urea to ammonium and chloride, which are directly cytotoxic. Ulcers are most common when the infecting strain expresses CagA (cytotoxic-associated protein) and VacA (vacuolating toxin) genes secondary to a more pronounced inflammatory and immune response. Expression of CagA and VacA is associated with greater induction of interleukin 8 (IL-8), a potent mediator of gastric inflammation. Genetic variations in the host are also thought to be involved; for example, polymorphisms leading to increased levels of IL-1β are associated with atrophic gastritis and cancer.

Results of *H. pylori* infection

- Inflammation (antral gastritis and gastric intestinal metaplasia).
- Peptic ulcers (duodenal and gastric).
- Gastric cancer (see p. 1178).

Antral gastritis

Antral gastritis is the usual effect of *H. pylori* infection. It is normally asymptomatic, although patients without ulcers do sometimes experience relief of dyspeptic symptoms after *Helicobacter* eradication. Chronic antral gastritis causes hypergastrinaemia due to gastrin release from antral G cells. The subsequent increase in acid output is usually asymptomatic but can lead to duodenal ulceration.

Duodenal ulcer

The prevalence of *H. pylori* infection in patients with duodenal ulcers (DUs; Fig. 32.24A) is falling and in the developed world is now between 50% and 75%, whereas duodenal ulceration was once rare in the absence of *H. pylori* infection. This has been attributed to a decrease in prevalence of the bacterium and an increase in NSAID use. Eradication of the infection improves ulcer healing and decreases the incidence of recurrence.

The precise mechanism of duodenal ulceration is unclear, as only 15% of patients infected with *H. pylori* (50–60% of the adult population worldwide) develop duodenal ulcers. Factors that have been implicated include increased gastrin secretion, smoking, bacterial virulence and genetic susceptibility.

---

*Fig. 32.23 Helicobacter pylori.* (A) Organisms (arrowed) are shown on the gastric mucosa (cresyl fast violet (modified Giemsa) stain). (B) Scanning electron microscopy, showing the spiral-shaped bacterium (arrowed). (A, Courtesy of Dr Alan Phillips, Department of Paediatric Gastroenterology, Royal Free Hospital.)
Gastric ulcer

Gastric ulcers (GUs; see Fig. 32.24B) are associated with gastritis affecting the body as well as the antrum of the stomach (pangastritis), causing parietal cell loss and reduced acid production. The ulcers are thought to occur because of a reduction of gastric mucosal resistance due to cytokine production caused by the infection, or perhaps because of alterations in gastric mucus.

Peptic ulcer disease

A peptic ulcer consists of a break in the superficial epithelial cells penetrating down to the muscularis mucosa of either the stomach or the duodenum; there is a fibrous base and an increase in inflammatory cells. Erosions, by contrast, are superficial breaks in the mucosa alone. DUs are most commonly found in the duodenal cap; the surrounding mucosa appears inflamed, haemorrhagic or friable (duodenitis). GUs are most commonly seen on the lesser curve near the incisura, but can be found in any part of the stomach.

Epidemiology of peptic ulcer disease

DUs affect approximately 10% of the adult population and are 2–3 times more common than GUs.

Ulcer rates are declining rapidly for younger men and increasing for older individuals, particularly women. Both DUs and GUs are common in the elderly. There is considerable geographical variation, with peptic ulcer disease being more prevalent in developing countries related to the high H. pylori infection. In the developed world, the percentage of NSAID-induced peptic ulcers is increasing as the prevalence of H. pylori declines.

Clinical features of peptic ulcer disease

The characteristic feature of peptic ulcer is recurrent, burning epigastric pain. It has been shown that if a patient points with a single finger to the epigastrium as the site of the pain, this is strongly suggestive of peptic ulcer disease. The relationship of the pain to food is variable and, on the whole, not helpful in diagnosis. The pain of a DU classically occurs at night (as well as during the day) and is worse when the patient is hungry, but this is not reliable. The pain of both GUs and DUs may be relieved by antacids.

Nausea may accompany the pain; vomiting is infrequent but can relieve the pain. Anorexia and weight loss may occur, particularly with GUs. Persistent and severe pain suggests complications, such as penetration into other organs. Back pain suggests a penetrating posterior ulcer. Severe ulceration can occasionally be symptomless, as many who present with acute ulcer bleeding or perforation have no preceding ulcer symptoms.

Untreated, the symptoms of a DU relapse and remit spontaneously. The natural history is for the disease to remit over many years due to the onset of atrophic gastritis and a decrease in acid secretion.

Fig. 32.24 Endoscopic views in Helicobacter pylori infection. (A) Duodenal ulcer with inflamed duodenal folds. (B) Benign gastric ulcer.

Fig. 32.25 Metabolism of urea by Helicobacter pylori (Hp). The different tests available for the detection of H. pylori are shown.

Epigastric tenderness is common in both ulcer and non-ulcer dyspepsia.

Diagnosis of Helicobacter pylori infection

Diagnosis of H. pylori is necessary if the clinician plans to treat a positive result. This is usually in the context of active peptic ulcer disease, previous peptic ulcer disease or mucosa-associated lymphoid tissue (MALT) lymphoma, or to "test and treat" patients with dyspepsia under the age of 55 with no alarm symptoms (i.e. weight loss, anaemia, dysphagia, vomiting or family history of gastrointestinal cancer). Examination is usually unhelpful.

Non-invasive methods

- **Serological tests** detect immunoglobulin G (IgG) antibodies and are reasonably sensitive (90%) and specific (83%). They have been used in diagnosis and in epidemiological studies. IgG titres may take up to 1 year to fall by 50% after eradication therapy and therefore are not useful for confirming eradication or the presence of a current infection. Antibodies can also be found in the saliva but tests are not as sensitive or specific as serology.

- **13C-Urea breath test** (Fig. 32.25) is a reliable test for H. pylori and can be used as a screening test. The measurement of 13CO2 in the breath after ingestion of 13C-urea requires a mass spectrometer. The test is sensitive (90%) and specific (96%), but the sensitivity can be improved by ensuring the patient has not taken antibiotics in the 4 weeks before the test and PPIs in the previous 2 weeks.

- **Stool antigen test** has superseded breath testing as the method used to determine H. pylori status. A specific immunooassay, using monoclonal antibodies for the qualitative detection of H. pylori antigen, is now widely available. The overall sensitivity is 97.6% and specificity is 96%. The test is useful in the diagnosis of H. pylori infection and for monitoring efficacy of eradication therapy. Patients should be off PPIs for 2 weeks but can continue with H2-blockers. Newer stool antigen tests are being developed that can be performed in the clinic setting, although at present the sensitivity and specificity are not as good as for those performed in the laboratory.
Invasive methods (endoscopy)

- **Biopsy urease test** (Campylobacter-like organism – CLO test). Gastric biopsies, usually antral unless additional material is needed to exclude proximal migration, are added to a substrate containing urea and phenol red. If *H. pylori* is present, the urease enzyme that the bacteria produce splits the urea to release ammonia, which raises the pH of the solution and causes a rapid colour change (yellow to red). This enables patients’ *H. pylori* status to be determined before they leave the endoscopy suite. The test may be falsely negative if patients are taking PPIs or antibiotics at the time.

- **Histology.** *H. pylori* can be detected histologically on routine (Giemsa) stained sections of gastric mucosa obtained at endoscopy. The sensitivity is reduced if a patient is on PPIs, but less so than with the urease test. Sensitivity can be improved with immunohistochemical staining using an anti-*H. pylori* antibody.

- **Culture.** Biopsies obtained can be cultured on a special medium, and *in vitro* sensitivities to antibiotics can be tested. This technique is typically used for patients with refractory *H. pylori* infection to identify the appropriate antibiotic regimen; routine culture is rare.

**Investigation of suspected peptic ulcer disease**

- **Patients under 55 years of age,** with typical symptoms of peptic ulcer disease who test positive for *H. pylori*, can start eradication therapy without further investigation.

- **Older patients** require endoscopic diagnosis (see Fig. 13.24) and exclusion of cancer. All gastric ulcers must be biopsied to exclude an underlying malignancy and should be followed up endoscopically until healing has taken place.

- **All patients with ‘alarm symptoms’** should undergo endoscopy:
  - iron deficiency anaemia
  - weight loss
  - anorexia
  - haematemesis/melaena
  - persistent vomiting
  - epigastric mass.

**Management**

**Eradication therapy**

Current recommendations are that all patients with duodenal and gastric ulcers should have *H. pylori* eradication therapy if the bacteria are present. Many patients have incidental *H. pylori* infection with no GU or DU. On balance, whether all such patients should have eradication therapy is controversial.

The increase in the prevalence of GORD and adenocarcinoma of the lower oesophagus in the last few years is currently unexplained, but has been postulated to be linked to eradication of *H. pylori*; this seems unlikely but is not disproven.

Depending on local antibacterial resistance patterns, standard eradication therapies in the developed world are successful in approximately 90% of patients. Re-infection is very uncommon (1%) in developed countries. In developing countries, re-infection is more common, compliance with treatment may be poor and metronidazole resistance is high (>50%, as it is frequently used for parasitic infections), so failure of eradication is common.

There are many regimens for eradication, but all must take into account that:

- Good compliance is essential.
- There is a high incidence of resistance to metronidazole and clarithromycin, particularly in some populations. Clarithromycin resistance has doubled in Europe in the last decade.

- **Oral metronidazole has frequent side-effects.**
- **Bismuth chelate is unpleasant to take, even as tablets.**

Metronidazole, clarithromycin, amoxicillin, tetracycline and bismuth are the most widely used agents. Resistance to amoxicillin (1–2%) and tetracycline (<1%) is low, except in countries where they are available without prescription, where resistance may exceed 50%. Quinolones (such as ciprofloxacin), furazolidone and rifabutin are also used when standard regimens have failed (‘rescue therapy’). None of these drugs is effective alone; eradication regimens therefore usually comprise two antibiotics, given with powerful acid suppression in the form of a PPI. Bismuth-containing quadruple therapy is advocated as first-line treatment because of increasing clarithromycin resistance: the standard clarithromycin-based triple therapy has been replaced as the treatment of choice in areas where resistance is high.

**Example regimens**

- Omeprazole 20 mg + clarithromycin 500 mg and amoxicillin 1 g – all twice daily.
- Omeprazole 20 mg + metronidazole 400 mg and clarithromycin 500 mg – all twice daily.

These should be given for 7 or 14 days. Two-week treatments increase the eradication rates but increased side-effects may reduce compliance.

In **eradication failures** and in areas of clarithromycin resistance, bismuth chelate (120 mg 4 times daily), metronidazole (400 mg 3 times daily), tetracycline (500 mg 4 times daily) and a PPI (20–40 mg twice daily) for 14 days is used. Sequential courses of therapy are also used in such cases (5 days of PPI and amoxicillin, followed by a 5-day period of PPI with clarithromycin and tinidazole). With the increase in clarithromycin resistance, many are using this quadruple therapy for initial treatment.

Prolonged therapy with a PPI after a course of PPI-based 7-day triple therapy is not necessary for ulcer healing in most *H. pylori*-infected patients. The effectiveness of treatment for uncomplicated duodenal ulcer should be assessed symptomatically. If symptoms persist, breath or stool testing should be performed to check eradication (off PPI therapy).

Patients with a risk of bleeding or those with complications, such as haemorrhage or perforation, should always have a 13C-urea breath test or stool test for *H. pylori* 6 weeks after the end of treatment to be sure that eradication has been successful. Long-term PPIs may be necessary if a rebleed would be likely to be fatal.

**General measures**

Stopping smoking should be strongly encouraged, as smoking slows mucosal healing.

Patients with gastric ulcers should be routinely re-endoscoped at 6 weeks to confirm mucosal healing and exclude an underlying gastric cancer. Repeat biopsies may be necessary.

**Complications of peptic ulcer disease**

**Haemorrhage**

See page 1181.

**Perforation**

The frequency of perforation of peptic ulceration is decreasing, partly because of medical therapy. DUs perforate more commonly than GUs, usually into the peritoneal cavity; perforation into the lesser sac also occurs. Detailed management of perforation is described on page 1222. Laparoscopic surgery is usually performed to close the perforation and drain the abdomen. Conservative management
using nasogastric suction, intravenous fluids and antibiotics is occasionally used in elderly and very sick patients.

**Gastric outlet obstruction**

The obstruction may be pre-pyloric, pyloric or duodenal. The obstruction occurs either because there is an active ulcer with surrounding oedema or because the healing of an ulcer has been followed by scarring. However, obstruction due to peptic ulcer disease and gastric malignancy are now uncommon; Crohn’s disease or external compression from a pancreatic carcinoma is a more common cause. Adult hypertrophic pyloric stenosis is a very rare cause.

After gastric outlet obstruction, the stomach becomes full of gastric juice and ingested fluid and food, giving rise to the main symptom of vomiting, usually without pain, as the characteristic ulcer pain has abated owing to healing.

Vomiting is infrequent, projectile and large in volume; the vomitus contains particles of previous meals. On examination of the abdomen, there may be a mass or distension. The diagnosis is made by endoscopy but can be suspected from the nature of the vomiting; by contrast, psychogenic vomiting is frequent, small-volume and usually noisy.

Severe or persistent vomiting causes loss of acid from the stomach and a hypokalaemic metabolic alkalosis (see p. 201). Vomiting will often settle with intravenous fluid and electrolyte replacement, gastric drainage via a nasogastric tube, and potent acid suppression therapy. Endoscopic dilation of the pyloric region is useful, as is luminal stenting, and overall, 70% of patients can be managed without surgery.

**Surgical treatment and its long-term consequences**

Once the mainstay of treatment, surgery is now used in peptic ulcer disease only for complications including:

- recurrent uncontrolled haemorrhage
- perforation, which is oversewn.

No other procedure, such as gastrectomy or vagotomy, is required.

In the past, two types of operation were performed: a partial gastrectomy or a vagotomy. In the latter, either a truncal vagotomy with a pyloroplasty or gastro-jejunostomy was performed, or highly selective vagotomy or proximal gastric vagotomy, which did not require a bypass procedure.

**Long-term complications** of surgery, which are still seen occasionally, include:

- **Recurrent ulcer.** If this occurs, check for *H. pylori;* rule out Zollinger–Ellison syndrome (see p. 1336). Malignancy needs to be excluded in all cases.
- **Dumping.** This term describes a number of upper abdominal symptoms (e.g. nausea and distension associated with sweating, faintness and palpitations) that occur in patients following gastrectomy or gastroenterostomy. It is due to ‘dumping’ of food into the jejunum, causing rapid fluid shifts from plasma to dilute the high osmotic load with reduction of blood volume. The symptoms are usually mild and patients adapt to them. It is rare for it to be a long-term problem, and if so, the symptoms usually have a functional element. Hypoglycaemia can also occur.
- **Diarrhoea.** This was chiefly seen after vagotomy. Recurrent severe episodes occurred in about 1% of patients. Antidiarrhoeals are the usual treatment.
- **Nutritional complications.** In the long term, almost any gastric surgery, but particularly gastrectomy, may be followed by:
  - iron deficiency, due to poor absorption
  - folate deficiency, usually due to poor intake
  - vitamin B<sub>12</sub> deficiency, due to intrinsic factor deficiency
  - weight loss, usually due to reduced intake.

**Other *H. pylori*-associated diseases**

- **Gastric adenocarcinoma.** The incidence of distal (but not proximal) gastric cancer parallels that of *H. pylori* infection in countries with a high incidence of gastric cancer. Serological studies show that people infected with *H. pylori* have a higher incidence of distal gastric carcinoma (see p. 1178).
- **Gastric B-cell lymphoma.** Over 70% of patients with gastric B-cell lymphomas (MALT) have *H. pylori*. *H. pylori* gastritis has been shown to contain the clonal B cell that eventually gives rise to the MALT lymphoma (see p. 1180).

**NSAIDs, Helicobacter and ulcers**

Aspirin and other NSAIDs deplete mucosal prostaglandins by inhibiting the cyclo-oxygenase (COX) pathway, which leads to mucosal damage. Cyclo-oxygenase occurs in two main forms: COX-1, the constitutive enzyme; and COX-2, inducible by cytokine stimulation in areas of inflammation. COX-2-specific inhibitors have less effect on the COX-1 enzyme in the gastric mucosa; they still produce gastric mucosal damage but less than with other conventional NSAIDs. Their use is limited by concern regarding cardiovascular side-effects.

Some 50% of patients taking regular NSAIDs will develop gastric mucosal damage and approximately 30% will have ulcers on endoscopy. Only a small proportion of patients have symptoms (about 5%) and only 1–2% have a major problem: that is, gastrointestinal bleed or perforation. Because of the large number of patients on NSAIDs, including low-dose aspirin for vascular prophylaxis, this is a significant problem, particularly in the elderly.

*H. pylori* and NSAIDs are independent and synergistic risk factors for the development of ulcers. In a meta-analysis, the odds ratio (OR) for the incidence of peptic ulcer was 61.1 in patients infected with *H. pylori* and also taking NSAIDs, compared with uninfected controls not taking NSAIDs.

**Management**

- Stop the ingestion of NSAIDs.
- Give a PPI.
- Start *H. pylori* eradication therapy if the patient is *H. pylori*-positive.

In many people with severe arthritis, stopping NSAIDs may not be possible. Therefore use:

- **An NSAID** with low GI side-effects at the lowest dose possible.
  - If there is no cardiovascular risk, a COX-2 NSAID can be used (see p. 431).
- **Prophylactic cytoprotective therapy,** e.g. PPI or misoprostol (a synthetic analogue of prostaglandin E<sub>1</sub> 800 μg/day) for all high-risk patients, i.e. over 65 years, those with a peptic ulcer history, particularly with complications, and those on corticosteroid or anticoagulant therapy. PPIs reduce the risk of endoscopic duodenal and gastric ulcers and are better tolerated than misoprostol, which causes diarrhoea.

**Gastroparesis**

Gastroparesis results when there is delayed gastric emptying. There are a number of known causes such as:

- diabetes
- amyloidosis
- scleroderma
- parkinsonism
- multiple sclerosis
- stress
Dyspepsia

‘Indigestion’ is common: 80% of the population will suffer from this symptom at some time. Dyspepsia is an inexact term used to describe a number of upper abdominal symptoms such as heartburn, acidity, pain or discomfort, nausea, wind, fullness or belching. Patients who use the term ‘indigestion’ may also be describing lower gastrointestinal symptoms such as constipation or the presence of undigested vegetable material in the stool, so obtaining a precise history is necessary.

Features of dyspepsia that are suggestive of serious diseases such as cancer are known as ‘alarm symptoms’. They include:

- dysphagia
- weight loss
- vomiting
- anorexia
- haematemesis or melaena.

Nausea and vomiting can be caused by a huge number of varied conditions, infections, medications and toxins. The choice of antiemetic depends on the cause of the vomiting and the side-effect profile of the antiemetic (Box 32.15).

Patients aged 55 years or over who demonstrate these features have a higher possibility of significant gastrointestinal pathology and should be investigated on an urgent basis. However, most patients with dyspepsia can be managed in primary care without need for referral to a gastroenterologist. See the current NICE guideline algorithm for managing a patient with dyspepsia (https://www.nice.org.uk/guidance/cg184).

Cyclical vomiting syndrome

This syndrome is characterized by typical bouts of intense vomiting lasting for hours to days, separated by periods with no symptoms. It can occur in children or adults. There is a link to migraine headaches but the cause is not known. In some cases, provocative triggers can be identified; for example, there is a specific syndrome associated with frequent cannabis use – cannabinoid hyperemesis syndrome.

Diagnosis of cyclical vomiting syndrome is by recognition of the pattern of symptoms and ruling out of other causes.

Management

Treatment is with antiemetics and intravenous rehydration and electrolyte replacement during bouts, with avoidance of triggers where these are known. Prophylactic treatment of migraine, when it coexists, may help.

Nausea and vomiting

Nausea is the sensation of being about to vomit, which can occur with or without vomiting. It can be more unpleasant and disabling for patients than vomiting alone. There are two central areas that are responsible for triggering nausea and vomiting. The nucleus tractus solitarius in the medulla, which acts as a central pattern generator for vomiting, and the area postrema in the floor of the fourth ventricle. This contains the ‘chemoreceptor trigger zone’, which has five different receptors:

- 5-HT receptors
- histamine H1 receptors
- muscarinic receptors
- dopamine D2 receptors
- substance P (neurokinin-1-neuropeptide).

Substances such as opioids, hormones, ketoacids and urea can all stimulate the CTZ directly as they are carried in the bloodstream. Nausea and vomiting can be caused by a huge number of varied conditions, infections, medications and toxins. The choice of antiemetic depends on the cause of the vomiting and the side-effect profile of the antiemetic.
Gastric tumours

Adenocarcinoma

Gastric cancer is currently the fourth most common cancer found worldwide and the second leading cause of cancer-related mortality. The incidence increases with age (peak incidence 50–70 years), and it is rare under the age of 30 years. The highest incidence of the disease is found in Eastern Asia, Eastern Europe and South America. The incidence in men is twice that in women and varies throughout the world, being high in Japan (M: 53/100000, F: 21.3/100000) and Chile, and relatively low in the USA (M: 7/100000, F: 2.9/100000). In the UK, carcinoma of the stomach (Fig. 32.26) is the eighth most common cancer (M: 16/100 000, F 9/100 000). The overall worldwide incidence of gastric carcinoma is falling, even in Japan, probably due to reductions in the incidence of Helicobacter and, before this, improvements in food storage. However, the incidence of proximal gastric cancers is increasing in the West and they have very similar demographic and pathological features to Barrett’s-associated oesophageal adenocarcinoma.

Epidemiology and pathogenesis

- **H. pylori infection** and distal gastric cancer are strongly linked. H. pylori is recognized by the International Agency for Research in Cancer (IARC) as a group 1 (definite) gastric carcinogen. H. pylori infection causes chronic gastritis, which eventually leads to atrophic gastritis and pre-malignant intestinal metaplasia (Fig. 32.27). Much of the earlier epidemiological data (i.e. the increase of cancer in lower socioeconomic groups) can be explained by the intrafamilial spread of H. pylori. Epstein–Barr virus is detected in 2–16% of gastric cancers worldwide, but its role in aetiology is not well understood.
- **Dietary factors** may also be involved (as both initiators and promoters) and have separate roles in carcinogenesis. Diets high in salt probably increase the risk. Dietary nitrates can be converted into nitrosamines by bacteria at neutral pH; nitrosamines are known to be carcinogenic in animals but the evidence in human carcinogenesis is limited. Nitrosamines are also present in the stomach of patients with achlorhydria, who have an increased cancer risk.
- **Tobacco smoking** is associated with an increased incidence of stomach cancer.
- **Genetic abnormality** is also a factor. The most common abnormality is a loss of heterozygosity (LOH) of tumour suppressor genes such as p53 (in 50% of cancers, as well as in pre-cancerous states) and the gene encoding adenomatous polyposis coli (APC) (in over one-third of gastric cancers). These abnormalities are similar to those found in colorectal cancers. Some rare families with diffuse gastric cancer have been shown to have mutations in the E-cadherin gene (CDH-1). There is a higher incidence of gastric cancer in blood group A patients.
- **First-degree relatives** of patients with gastric cancer have 2–3-fold increased relative risk of developing the disease, but this may be environmental rather than inherited.
- **Pernicious anaemia** carries a small increased risk of gastric carcinoma due to the accompanying atrophic gastritis.
- **Partial gastrectomy** (postoperative stomach) carries an increased risk of gastric cancer, whether performed for a GU or DU; this is probably due to untreated H. pylori infection.

Screening

Earlier diagnosis has been advocated in an attempt to improve the poor prognosis of gastric cancer. (Screening is discussed on p. 102.) Although the incidence of gastric cancer is falling in Japan, where aggressive screening by barium studies is followed by endoscopy if there is doubt, there is no evidence that screening has had an effect on overall mortality. Similarly, early investigation of dyspepsia has had little effect on mortality, possibly because of the relatively low prevalence of cancer.

Early gastric cancer

Early gastric cancer is defined as a carcinoma that is confined to the mucosa or submucosa, regardless of the presence of lymph node
Pathology

There are two major types of gastric cancer:

- **Intestinal (type 1)** with well-formed glandular structures (differentiated). The tumours are polypoid or ulcerating lesions with heaped-up, rolled edges. Intestinal metaplasia is seen in the surrounding mucosa, often with *H. pylori*. This type is more likely to involve the distal stomach and occur in patients with atrophic gastritis. It has a strong environmental association.

- **Diffuse (type 2)** with poorly cohesive cells (undifferentiated) that tend to infiltrate the gastric wall. It may involve any part of the stomach, especially the cardia, and has a worse prognosis than the intestinal type. Loss of expression of the cell adhesion molecule E-cadherin is the key event in the carcinogenesis of diffuse gastric cancers. Unlike type 1 gastric cancers, type 2 cancers have similar frequencies in all geographic areas and occur in a younger population.

Some 50% of gastric cancers in Western countries occur in the proximal stomach.

Clinical features

Symptoms

Around 50% of patients with EGC discovered at screening have no symptoms. Most patients with carcinoma of the stomach have advanced disease at the time of presentation. The most common symptom of advanced disease is epigastric pain, indistinguishable from the pain of peptic ulcer disease; it may be relieved by food and antacids. The pain can vary in intensity but may be constant and severe, and there may also be nausea, anorexia and weight loss. Vomiting is frequent and can be severe if the tumour encroaches on the pylorus. Dysphagia can occur with tumours involving the fundus. Gross haematemesis is unusual but anaemia from occult blood loss is frequent. No pattern of symptoms is suggestive of EGC.

Widely spreading submucosal gastric cancer causes diffuse thickening and rigidity of the stomach wall and is called ‘limitis plastica’.

Patients can present at a late stage with malignant ascites or jaundice due to liver involvement. Metastases also occur in bone, brain and lung, producing appropriate symptoms.

Signs

Weight loss is often the dominant feature. Nearly 50% of patients have a palpable epigastric mass with abdominal tenderness. A palpable lymph node is sometimes found in the supravacular fossa (Virchow’s node, usually on the left side), and metastases are present in up to one-third of patients at presentation. This cancer is the most frequently associated with dermatomyositis (see p. 462) and acanthosis nigricans.

Diagnosis

Gastroscopy (Fig. 32.28) allows biopsies to be taken for histological assessment. Positive biopsies can be obtained in almost all cases of obvious carcinoma, but a negative biopsy does not necessarily rule out the diagnosis. For this reason, 8–10 biopsies should be taken from suspicious lesions. Diffuse type gastric cancer infiltrates the submucosa and muscularis propria and can be undetected on endoscopy; multiple deep biopsies help.

Staging

- **CT scan of the chest and abdomen** with a gastric water load can demonstrate gastric wall thickening, lymphadenopathy and lung and liver secondaries, but has limited ability to determine the depth of local tumour invasion.

- **Endoscopic ultrasound** is useful for local staging to demonstrate the depth of penetration of the cancer through the gastric wall and extension into local lymph nodes. It complements CT and ultrasound but is most relevant to confirm that a cancer is confined to the superficial mucosa, before endoscopic resection.

- **Laparoscopy** is useful in patients being considered for surgery to exclude serosal disease.

- **PET and CT/PET** can be helpful in further delineation of the cancer.

The TNM classification is used. The tumour grade (T) indicates depth of tumour invasion, N denotes the presence or absence of lymph nodes, and M indicates presence or absence of metastases. TNM classification is then combined into stage categories 0–4. At presentation, two-thirds of patients are at stage 3 or 4: that is, advanced disease (Box 32.16). The histological grade of the tumour also determines survival.
Management

As with all cancers, treatment is discussed with a multidisciplinary team. Early non-ulcerated mucosal lesions can be removed endoscopically by either endoscopic mucosal resection or endoscopic submucosal dissection.

Surgery remains the most effective form of treatment if the patient is an operative candidate. Careful selection has reduced the numbers undergoing surgery and has improved the overall survival 5-year survival rates to around 30%. Five-year survival rates in ‘curative’ operations are as high as 50%. Surgery, combined chemoradiotherapy and treatment of advanced disease are described on page 124. The multinational MAGIC trial demonstrated the benefits of perioperative chemotherapy with epirubicin, cisplatin and infusional 5-fluorouracil (ECF) (see p. 124), where 5-year survival in operable gastric and lower oesophageal adenocarcinomas increased from 23% to 36%. An alternative regimen is oral epirubicin, oxaliplatin and capecitabine. Despite the improved results, the overall survival rate for a patient with gastric carcinoma has not dramatically improved, with a maximum 5-year survival rate of 10% overall. Palliative care, with relief of pain and counselling, is usually required.

Gastrointestinal stromal tumours

Gastrointestinal stromal tumours (GISTs) are a subset of gastrointestinal mesenchymal tumours of varying differentiation. They are usually asymptomatic and found by chance but occasionally they can ulcerate and bleed. There are 200–900 new cases each year in the UK. GISTs mostly affect people between 55 and 65 years of age.

These tumours were previously classified as gastrointestinal leiomyomas, leiomyosarcomas, leiomyoblastomas or schwannomas. Truly benign leiomyomas do occur, mainly in the oesophagus, but GISTs are now recognized as a distinct group of mesenchymal tumours and comprise about 80% of gastrointestinal mesenchymal tumours. They are of stromal origin and are thought to share a common ancestry with the interstitial cells of Cajal. They have varying differentiation, with mutations occurring in the cellular proto-oncogene KIT (which leads to activation and cell-surface expression of the tyrosine kinase KIT (CD 117)) in 80%, and also in platelet-derived growth factor receptor-α (PDGFRα) in up to 10% of patients.

Management

Treatment is surgical as far as possible. These tumours generally grow slowly but may be malignant. Imatinib, a tyrosine kinase inhibitor (see p. 113), is chosen for unresectable or metastatic disease, and is now used as adjunctive therapy after surgical removal of the primary in the absence of metastatic disease. Some patients are resistant to this; sunitinib can be used as an alternative agent over a short time period.

Primary gastric lymphoma

Mucosa-associated lymphatic tissue (MALT) lymphomas are indolent B-cell marginal zone lymphomas that primarily involve sites other than lymph nodes (gastrointestinal tract, thyroid, breast or skin). They constitute about 10% of all types of non-Hodgkin’s lymphoma (NHL).

Aetiology

About 90% of cases are due to Helicobacter pylori infection. Chromosome abnormalities t(1;14)(p22; q32) and t(11;18)(q21; q21) have also been noted in this form of NHL.

Clinical features

Most patients are diagnosed in their 60s with stage I or stage II disease outside the lymph nodes. Patients have stomach pain, ulcers or other localized symptoms, but rarely have systemic complaints such as fatigue or fever.

Management

Eradication of Helicobacter pylori infection may resolve cases of local gastric involvement. After standard eradication regimens, 50% of patients show resolution at 3 months. Other patients may resolve after 12–18 months of observation. Stage III or IV disease is treated with surgery or chemotherapy with or without radiation. The prognosis is good, with an estimated 90% 5-year survival.

Gastric polyps

Gastric polyps are found in about 1% of endoscopies, usually by chance. They rarely produce symptoms, but larger lesions can result in anaemia or haematemesis. Endoscopic biopsy is the usual approach to diagnosis and treatment is possible polypectomy based on histological finding. Occasional large or multiple polyps may require surgery.

- **Hyperplastic polyps** are by far the most common type. Most are smaller than 2 cm. The polyps are rarely pre-malignant, but may be accompanied by pre-malignant atrophic gastritis.
- **Adenomatous polyps** are usually solitary lesions in the antrum. Approximately 3% progress to gastric cancer, especially if greater than 2 cm in diameter, but they are not a common cause of gastric cancer (compare this with colorectal cancer).
- **Cystic gland polyps** contain microcysts that are lined by fundic-type parietal and chief cells. They are located in the fundus and body of the stomach. They are found in otherwise normal subjects, but are especially common in familial polyposis syndromes and patients on PPIs. Their malignant potential is negligible, although low-grade dysplasia is seen in the absence of familial adenomatous polyposis coli (FAP), and high-grade dysplasia exclusively in its presence.
- **Inflammatory fibroid polyps** are benign spindle cell tumours infiltrated by eosinophils. Excision of these polyps is indicated because of their propensity to enlarge and cause obstruction.

Acute upper gastrointestinal bleeding

GI bleeds are one of the most common medical emergencies (>4 unit transfused). Incidence is 1.33/1000 population, or 85,000 cases/year. In the 2015 NCEPOD report on the management of GI haemorrhage, 40% of patients in the study population, who received treatment for acute upper GI bleeding, were inpatients being treated for another condition when they had an acute upper GI bleed.

The cardinal features are haematemesis (the vomiting of blood) and melaena (the passage of black tarry stools, the black colour being due to blood altered by passage through the gut). Melaena can occur with bleeding from any lesion proximal to the right colon. Rarely, melaena can also result from bleeding from the right colon.

Following a bleed from the upper gastrointestinal tract, unaltered blood can appear per rectum, but the bleeding must be massive and is almost always accompanied by shock. The passage of dark blood and clots without shock is most often due to lower gastrointestinal bleeding. Of note, stool may be frankly bloody or maroon with massive or brisk upper GI bleeding.

Aetiology

Peptic ulceration is the most common cause of serious and life-threatening gastrointestinal bleeding (Fig. 32.29 and Box 32.17). The relative incidence of causes depends on the patient population; overall, incidence has fallen. In the developing world, haemorrhagic viral infections (see Box 20.37) can cause significant gastrointestinal bleeding.

Drugs

Aspirin (even 75 mg/day) and other NSAIDs can produce ulcers and erosions. These agents are also responsible for gastrointestinal haemorrhage from both duodenal and gastric ulcers, particularly in the elderly. They are available over the counter in the UK and patients may not be aware that they are taking aspirin or an NSAID. Corticosteroids in the usual therapeutic doses have no influence on gastrointestinal haemorrhage. The estimated relative risks of glucocorticoids alone for gastrointestinal adverse effects, including GI bleeding, vary from 1.1 (not significant) to 1.5 (marginally significant). However, the combination of glucocorticoids and NSAIDs results in a synergistic increase in the incidence of gastrointestinal haemorrhage. Anticoagulants and antiplatelet agents do not cause acute gastrointestinal haemorrhage per se, but bleeding from any cause is greater if the patient is anticoagulated.

Clinical approach to the patient with acute upper GI bleeding

All cases with a recent (i.e. within 48 hours) significant gastrointestinal bleed should be seen in hospital. In many, no immediate

---

**Box 32.17 Overview of emergency assessment of severe upper gastrointestinal bleeding in adults**

**Major causes**
- Peptic ulcer, oesophagogastric varices, arteriovenous malformation, tumour, oesophageal (Mallory–Weiss) tear

**Clinical features**

**History**
- Use of: non-steroidal anti-inflammatory drugs (NSAIDs), aspirin, anticoagulants, antiplatelet agents
- Alcohol misuse; previous gastrointestinal (GI) bleed; liver disease; coagulopathy

**Symptoms and signs**
Abdominal pain; haematemesis or ‘coffee ground’ emesis; passing melaena/tarry stool (stool may be frankly bloody or maroon with massive or brisk upper GI bleeding)

**Examination**
- Tachycardia, orthostatic blood pressure changes suggest moderate to severe blood loss; hypotension suggests life-threatening blood loss (hypotension may be late finding in healthy younger adult)
- Rectal examination is performed to assess stool colour (melaena versus haematochezia versus brown)
- Significant abdominal tenderness accompanied by signs of peritoneal irritation (e.g. involuntary guarding) suggests perforation

**Management**
- Obtain type and crossmatch for haemodynamic instability, severe bleeding, or high-risk patient
- Obtain Hb (may be inaccurate with acute severe haemorrhage), PLT count, PT with INR, AST, ALT, albumin and creatinine
- Closely monitor airway, clinical status, observations, cardiac rhythm, urine output
- Do NOT give patient anything by mouth
- Establish two large bore i.v. lines (16-gauge or larger)
- Provide supplemental oxygen
- Treat hypotension initially with rapid, bolus infusions of isotonic crystalloid
- Monitored bed or ITU depending on the severity of bleeding

ALT, alanine aminotransferase; AST, aspartate aminotransferase; INR, international normalized ratio; PLT, platelet count; PT, prothrombin time.
treatment is required, as there has been only a small amount of blood loss. Approximately 85% of patients stop bleeding spontaneously within 48 hours.

Scoring systems have been developed to assess the risk of rebleeding or death. Boxes 13.18 and 13.19 show the Rockall score, which is based on clinical and endoscopy findings. The Blatchford score uses the level of plasma urea, haemoglobin and clinical markers, but not endoscopic findings, to determine the need for intervention such as blood transfusion or endoscopy in gastrointestinal bleeding. Incorporation of a validated risk score for upper gastrointestinal bleeding into routine clinical practice facilitates optimal triage decisions.

The following factors affect the risk of rebleeding and death:

- age
- evidence of co-morbidity, e.g. cardiac failure, ischaemic heart disease, chronic kidney disease and malignant disease
- presence of the classical clinical features of shock (pallor, cold peripheries, tachycardia and low blood pressure)
- endoscopic diagnosis, e.g. Mallory-Weiss tear, peptic ulceration, gastric antral vascular ectasia (GAVE; Fig. 32.30)
- endoscopic stigmata of recent bleeding, e.g. adherent blood clot, spurting vessel
- clinical signs of chronic liver disease.

Bleeding associated with liver disease is often severe and recurrent if it is from varices. Liver failure can develop.

Management

Immediate management

This is shown in Box 32.20. In addition, stop NSAIDs, aspirin, clopidogrel and warfarin if patients are taking them (Boxes 32.21 and 32.22). Stopping antiplatelets can be dangerous and may produce thrombosis; discuss this urgently with a cardiologist.

Many hospitals have multidisciplinary specialist teams with agreed protocols and the latter should be followed. Patients should be managed in monitored beds or ITU depending on the severity of bleeding. Oxygen should be given and the patient should be kept nil by mouth until an endoscopy has been performed.

Patients with large bleeds and clinical signs of shock require urgent resuscitation. Details of the management of shock are given in Fig. 10.24.

Blood volume

See Box 32.23. The major principle is to restore the blood volume rapidly to normal via two or more large-bore intravenous cannulae; plasma expanders or 0.9% saline are given until the blood becomes available (see p. 221). Transfusion of red cell concentrates is used with a proposed transfusion threshold of 70 g/L. This has yet to be universally adopted.

Transfusion must be monitored to avoid overload leading to heart failure, particularly in the elderly. The pulse rate and venous pressure are guides to adequacy of transfusion. A central venous pressure line is inserted for patients with organ failure who require blood transfusion, and in those most at risk of developing heart failure.

Haemoglobin levels are generally a poor indicator of the need to transfuse because anaemia does not develop immediately as...
Management of acute gastrointestinal bleeding

- Take history and perform examination. Note co-morbidity
- Monitor pulse and BP half-hourly
- Take blood for haemoglobin, urea, electrolytes, liver biochemistry, coagulation screen, group and crossmatching (2 units initially)
- Establish intravenous access — two large-bore i.v. cannulae
- Give blood transfusion/collodid if necessary. Indications for blood transfusion are:
  a. Shock (pallor, cold nose, systolic BP below 100 mmHg, pulse >100 beats/min)
  b. Haemoglobin <100 g/L in patients with recent or active bleeding
- Give oxygen therapy
- Perform urgent endoscopy in shocked patients/active bleeding
- Continue to monitor pulse and BP
- Re-endoscope for continued bleeding/hypovolaemia
- Arrange surgery if bleeding persists

Management of upper GI bleed in patients on direct oral anticoagulants

- Resuscitation based on clinical evaluation
- Stop DOAC
- Half-lives of DOAC agents (normal renal function):
  - rivaroxaban 5–9 h
  - apixaban 8–15 h
  - dabigatran 12–14 h
  - edoxaban 10–14 h
- There is a reversal agent for dabigatran available, idarucizumab, but as the half-life of these drugs is short, most GI bleeds will settle with resuscitation, blood products and cessation of the drug.

Management of major upper GI bleed in patients with coagulopathy

- Initial resuscitation
- Blood transfusion with care
- Platelets if platelets <50 and actively bleeding/haemodynamically unstable and/or platelet dysfunction (e.g. chronic aspirin therapy)
- Fresh frozen plasma if fibrinogen <1 g/L or PT/INR or APTT >1.5 times normal
- Prothrombin complex concentrate if taking warfarin and actively bleeding
- Tranexamic acid
- N.B. In patients on dual antiplatelets with coronary artery stents in situ aim to restart both antiplatelets within 5–7 days.

A PT/INR, prothrombin time/international normalized ratio.

Endoscopy will usually diagnose, stratify risk and enable therapy to be performed if needed. Endoscopy should be carried out as soon as possible after the patient has been resuscitated. Patients with Rockall scores of 0 or 1 pre-endoscopy may be candidates for immediate discharge (see below) and outpatient endoscopy the following day, depending on local policy.

Endoscopy can detect the cause of the haemorrhage in 80% or more of cases. In patients with a peptic ulcer, if the stigmata of a recent bleed are seen (i.e. a spurring vessel, active ooze, fresh or organized blood clot or black spots), the patient is more likely to rebleed. Calculation of the post-endoscopy Rockall score gives an indication of the risk of rebleeding and death (see Box 32.19). Box 32.24 shows medical treatment prior to endoscopy.

At first endoscopy:
- Varices should be treated, usually with banding.
- Stenting is also used for bleeding varices but is not yet widely available (see p. 1294). It is an alternative to a Sengstaken tube.
- Bleeding ulcers and those with stigmata of recent bleeding should be treated using two or three haemostatic methods: injection with adrenaline (epinephrine) and thermal coagulation (with heater probe, bipolar probe, or laser or argon plasma coagulation) or endoscopic clipping; dual and triple therapy is more effective than monotherapy in reducing rebleeding. Haemostatic powders have recently been developed that can be sprayed through a catheter during gastroscopy. These are useful in the more difficult bleeds, such as cancer-related bleeding and challenging ulcers.
- Antral biopsies should be taken to look for H. pylori. A positive biopsy urease test is valid but a negative test is not reliable. If the urease test is negative, gastric histology should always be performed.

Balloon tamponade may be performed as a temporizing measure for patients with uncontrollable haemorrhage likely due to varices using any of several devices (e.g. Sengstaken–Blakemore tube). Tracheal intubation is necessary if such a device is to be placed; ensure proper device placement prior to inflation to avoid oesophageal rupture.

Drug therapy
After diagnosis at endoscopy, an intravenous PPI (e.g. omeprazole 80 mg followed by infusion 8 mg/h for 72 h) should be given to all patients with actively bleeding ulcers or ulcers with a visible vessel, as it reduces rebleeding rates and the need for surgery. Tranexamic acid is an antifibrinolytic agent that has been studied in patients with upper GI bleeding. A meta-analysis that included eight randomized trials of tranexamic acid in patients with upper GI bleeding found a benefit with regard to mortality but not with regard to bleeding, surgery, or transfusion requirements.

Uncontrolled or repeat bleeding
Endoscopy should be repeated to assess the bleeding site and to treat, if possible. Embolization by an interventional radiologist may
be necessary if the bleeding persists. If this is not available locally or is unsuccessful, surgery is used to control the haemorrhage primarily.

**Discharge policy**
The patient’s age, diagnosis on endoscopy, co-morbidity, the presence or absence of shock and the availability of support in the community should be taken into consideration. In general, all patients who are haemodynamically stable and have no stigmata of recent haemorrhage on endoscopy (Rockall score pre-endoscopy 0, post-endoscopy <1) can be discharged from hospital within 24 hours. All shocked patients and patients with co-morbidity need longer inpatient observation.

**Specific conditions**

**Oesophageal varices**
These are discussed on page 1294.

**Mallory–Weiss tear**
This is a linear mucosal tear occurring at the oesophagogastric junction and produced by a sudden increase in intra-abdominal pressure. It often follows a bout of coughing or retching, and is classically seen after alcoholic ‘dry heaves’. There may, however, be no antecedent history of retching. Most bleeds are minor and discharge is usual within 24 hours. The haemorrhage may be large but most patients stop spontaneously. Early endoscopy confirms diagnosis and allows therapy such as clipping if necessary. Surgery with oversewing of the tear is rarely needed.

**Chronic peptic ulcer**
Eradication of *H. pylori* is started as soon as possible (see p. 1175). A PPI is continued for 4 weeks to ensure ulcer healing. Eradication of *H. pylori* should always be checked in a patient who has bled, and long-term acid suppression is given if *H. pylori* eradication cannot be achieved. If bleeding is not controlled, the patient should either undergo angiography and embolization or be referred directly for surgery.

**Gastric carcinoma**
Most of these patients do not have large bleeds but surgery is occasionally necessary for uncontrolled or repeat bleeding. Usually, surgery can be delayed until the patient has been fully evaluated (see p. 1178). Oozing from gastric cancer is very difficult to control endoscopically. Radiotherapy can occasionally be successful but its effects are not immediate.

**Bleeding after percutaneous coronary intervention**
In the era of ever more aggressive percutaneous coronary intervention (PCI), the list of antithrombotic medication grows longer: glycoprotein IIb/IIIa inhibitors, unfractionated heparin, low-molecular-weight heparin, fondaparinux and platelet inhibitors (e.g., clopidogrel, prasugrel and ticagrelor). Taken in addition to the oral anticoagulants that this group of patients are often taking, these give rise to a gastrointestinal bleeding rate of approximately 2% of patients undergoing PCI (who are on antiplatelet therapy, e.g., clopidogrel), and there is a high mortality of 5–10%. It has become increasingly evident in this patient group that gastroscopy should be performed on an urgent basis and not deferred for days or weeks. A bolus of intravenous PPI is administered, followed by an infusion; platelet infusion is given to counter the effect of clopidogrel. Management is difficult, as cessation of antiplatelet therapy has a high risk of acute stent thrombosis and also an associated high mortality. Using a risk assessment score (e.g. Blatchford), a reasonable approach is to stop all antiplatelet therapy in high-risk patients but continue it in low-risk ones. Co-prescribed proton pump inhibition does not decrease the antiplatelet effect of clopidogrel, as was first thought. These patients should be under the combined care of a cardiologist and a gastroenterologist.

See Box 32.25 for take-home messages for the management of upper GI bleeding.

**Prognosis**
The mortality from gastrointestinal haemorrhage has not changed from 5–12% over the years, despite many changes in management, mainly because of a demographic shift to more elderly patients with co-morbidity. The lowest mortality rates are achieved in dedicated medical/surgical gastrointestinal units.

**Acute lower gastrointestinal bleeding**
Massive bleeding from the lower gastrointestinal tract is rare and is usually due to diverticular disease or ischaemic colitis. Common causes of small bleeds are haemorrhoids and anal fissures (Fig. 32.31).

**Management**
Most acute lower gastrointestinal bleeds start and stop spontaneously. The few patients who continue bleeding and are haemodynamically unstable need resuscitation using the same principles as for upper gastrointestinal bleeding (see p. 1181). Surgery is rarely required.

![Fig. 32.31 Causes of lower gastrointestinal bleeding.](image-url)
A diagnosis is made using the history and examination, including rectal examination and the following investigations as appropriate:

- **Proctoscopy** (e.g. anorectal disease, particularly haemorrhoids)
- **Flexible sigmoidoscopy or colonoscopy** (e.g. inflammatory bowel disease, cancer, ischaemic colitis, diverticular disease, angiodysplasia)
- **Video capsule endoscopy** (Fig. 32.32)
- **Angiography** to seek vascular abnormality (e.g. angiodysplasia). The yield of angiography is low, so it is a test of last resort.

Isolated episodes of rectal bleeding in the young (<45 years) usually only require rectal examination and flexible sigmoidoscopy because the probability of a significant proximal lesion is very low, unless there is a strong family history of colorectal cancer at a young age. Individual lesions are treated as appropriate.

**Chronic gastrointestinal bleeding**

Patients with chronic bleeding usually present with iron deficiency anaemia (see p. 330).

Chronic blood loss producing iron deficiency anaemia in men, and in women after the menopause, is always due to bleeding from the gastrointestinal tract. The primary concern is to exclude cancer, particularly of the stomach or right colon, and coeliac disease. Occult stool tests are unhelpful.

**Diagnosis**

Chronic blood loss can occur with any lesion of the gastrointestinal tract that produces acute bleeding (see Figs 32.29 and 32.31). However, oesophageal varices usually bleed overtly and rarely present as chronic blood loss. Although uncommon in developed countries, hookworm is the most common worldwide cause of chronic gastrointestinal blood loss.

History and examination may indicate the most likely site of the bleeding, but if no clue is available, it is usual to investigate both the upper and lower gastrointestinal tract endoscopically at the same session (‘top and tail’), especially in males and postmenopausal females:

- **Upper gastrointestinal endoscopy** is usually performed first. Duodenal biopsies should always be taken to diagnose coeliac disease, even if coeliac serology has been performed.
- **Colonoscopy** follows and any lesion should be biopsied or removed, though it is unsafe to assume that colonic polyps are the cause of chronic blood loss.
- **Unprepared CT** scanning is a reasonable test to look for colon cancer in frail patients.
- **CT colonography** can be used as an alternative to colonoscopy.

If gastroscopy, colonoscopy and duodenal biopsy have not revealed the cause, investigation of the small bowel is necessary. **Capsule endoscopy** is the diagnostic investigation of choice but currently has no therapeutic ability. Positive diagnostic yield varies from 60% to 85%, depending on series. Bleeding lesions can be identified and later treated with balloon-assisted enteroscopy.

Occasionally, intravenous technetium-labelled colloid may be used to demonstrate a potential bleeding site in a Meckel’s diverticulum.

**Management**

The cause of the bleeding should be dealt with, if found. Oral iron is given to treat anaemia (see p. 332), although intravenous infusions are occasionally required. Some patients will require maintenance with regular transfusion as a last resort.

---

**SMALL INTESTINE**

**Diarrhoea**

The word ‘diarrhoea’ comes from the Greek meaning ‘to flow through’. It is a very common manifestation of GI disease with many causes. There are many definitions but commonly it is accepted as being more than three loose stools in 24 hours.

**Pathophysiology**

**Osmotic diarrhoea**

The gut mucosa acts as a semipermeable membrane and fluid enters the bowel if there are large quantities of non-absorbed hypertonic substances in the lumen. This occurs because the patient:

- has ingested a non-absorbable substance (e.g. a purgative, such as magnesium sulphate or magnesium-containing antacid)
- has generalized malabsorption, so that high concentrations of solute (e.g. glucose) remain in the lumen
- has a specific absorptive defect (e.g. disaccharidase deficiency or glucose-galactose malabsorption).

The volume of diarrhoea produced by these mechanisms is reduced by the absorption of fluid by the ileum and colon. The diarrhoea stops when the patient stops eating or the malabsorptive substance is discontinued.

**Secretory diarrhoea**

In this disorder, there is both active intestinal secretion of fluid and electrolytes, and decreased absorption. The mechanism of intestinal secretion is shown in Fig. 32.33A.
Common causes of secretory diarrhoea are:

- enterotoxins (e.g. cholera, *E. coli* thermolabile or thermostable toxin, *C. difficile* toxin)
- hormones (e.g. vasoactive intestinal peptide in Verner–Morrison syndrome; see p. 1336)
- bile salts (in the colon) following ileal resection
- fatty acids (in the colon) following ileal resection
- some laxatives (e.g. docusate sodium).

**Inflammatory diarrhoea (mucosal destruction)**

Diarrhoea occurs because of damage to the intestinal mucosal cell so that there is a loss of fluid and electrolytes. Causes are usually infective (e.g. dysentery due to *Shigella*) or inflammatory (IBD).

**Abnormal motility**

Diabetic, post-vagotomy and hyperthyroid diarrhoea are all due to abnormal motility of the upper gut. Symptoms may be exacerbated by small bowel bacterial overgrowth.

**Acute diarrhoea**

Acute diarrhoea is defined as lasting less than 14 days. The cause is usually infectious, most commonly viral in children but sometimes bacterial (usually more severe cases). Common infectious causes include:

- Viral infection, e.g. norovirus or rotavirus
- *E. coli* food poisoning (causes a secretory diarrhoea)
- Food poisoning from *Salmonella*, *Campylobacter* or *Staphylococcus* bacteria
- *Clostridium difficile* infection (usually due to recent course of antibiotics)
- Contaminated food or water (‘traveller’s diarrhoea’), often *Giardia* or *Entamoeba histolytica*. Clinical features associated with acute diarrhoea include fever, abdominal pain and vomiting. Stools are usually loose and watery but can also be bloody. If the diarrhoea is severe then dehydration can occur, especially in very young or elderly patients.

The key investigation is to send a stool sample to try to isolate an organism. **Stool microscopy culture sensitivities (MCS)** should be sent in all patients. Samples for *C. difficile* toxin should be sent in at risk patients (elderly, nursing home residents, recent antibiotic...

</table>

use). Stool for ova, cysts and parasites should be sent in the following cases:
- persistent diarrhoea (>14 days <30 days)
- men who have sex with men
- immunocompromised patients
- recent travel abroad
- if suspecting giardiasis/amoebiasis/cryptosporidium.

Management of acute diarrhoea usually focuses on volume repletion, usually with oral rehydration solutions that contain water, salt and sugar. In severe cases of dehydration, patients may need to be admitted to hospital for intravenous fluid resuscitation. Antibiotics are not usually empirically given unless it is a particularly severe case or complications develop (Box 32.26 lists common antibiotic regimens). Antimotility agents (e.g. codeine phosphate or loperamide) should be avoided if possible.

Indications for antibiotic treatment include:
- severe/prolonged symptoms (>5 days)
- systemic signs of infection
- extremes of age
- immunocompromise
- presence of complications
- bloody or mucoid stools.

Chronic diarrhoea
This is defined as diarrhoea present for longer than 30 days. Causes are listed in Box 32.27.

A thorough history is important including the onset, timeframe and severity of symptoms. Important points to address are any associated features such as bloody stools, abdominal pain, weight loss, steatorrhoea, recent changes in medication, food/other triggers and a full past medical history. A full examination is needed. Initial investigations should include:
- full blood count, serum creatinine and electrolytes, thyroid function
- coeliac screen (tissue transglutaminase (TTG) or endomysial antibodies (EMA) antibodies)
- faecal calprotectin (see p. 1158 for more information)
- stool MCS, C. difficile toxin.

If the above do not reveal a cause then patients should undergo a flexible sigmoidoscopy. In the following circumstances, however, patients should undergo a full colonoscopy:
- iron deficiency anaemia
- abnormal faecal calprotectin with a suspicion of IBD
- older patients where screening for polyps and colorectal cancer would be advantageous.

Further investigations include bowel imaging (CT abdomen, MRI small bowel, pancreatic CT), video capsule endoscopy, SeHCAT scan and lactose hydrogen breath tests; the choice will depend on the individual patient’s symptoms. Management of chronic diarrhoea involves treating the underlying cause and this will be discussed in more detail later. See Box 32.28 for a summary of take-home messages for the patient.

Irritable bowel syndrome
Irritable bowel syndrome (IBS) is the most common functional gastrointestinal disorder. In Western populations, up to 1 in 5 people report symptoms consistent with IBS. Approximately 50% will consult their doctors and, of these, up to 30% will be referred by their doctor to a hospital specialist. Up to 40% of all patients seen in specialist gastroenterology clinics will have IBS. Estimates in the UK put the annual cost of IBS to healthcare resources as £45.6 million; in the USA, the cost is higher at $8 billion. In the UK, approximately one-quarter of IBS patients take time off work for periods ranging from 7 to 13 days each year.

The factors that determine whether an IBS sufferer in the community seeks medical advice include higher illness attitude scores and higher anxiety and depression scores than non-consulters. Consulters perceive that their symptoms are more severe than those of non-consulters, and consulting behaviour may be determined by the number of presenting symptoms. Female consultants outnumber male consultants by a factor of 2–3 to 1.

IBS – a multisystem disorder

IBS patients suffer from a number of non-intestinal symptoms (Box 32.29), which may be more intrusive than the classical features. IBS coexists with chronic fatigue syndrome (see p. 770), fibromyalgia (see p. 430) and temporomandibular joint dysfunction.

The biopsychosocial conceptualization of the pathogenesis and clinical expression of FGIDs is particularly relevant to IBS (see Fig. 32.9), and Box 32.30 lists some common factors that have been shown to trigger IBS symptoms. Infectious diarrhoea precedes the onset of IBS symptoms in 7–30% of patients. Whether this is a factor for all patients or just a small subgroup remains controversial. Risk factors in these patients have been shown to include female sex, severity and duration of diarrhoea, pre-existing adverse life events and high hypochondriacal anxiety and neurotic scores at the time of the initial illness. Symptoms of anxiety and depression are more common in IBS patients, and stress or adverse life events often precede the onset of chronic bowel symptoms.

Diagnosis

Diagnostic criteria (Rome IV 2016) state that, in the preceding 3 months, there should be at least 1 day per week in the last 3 months of recurrent abdominal pain associated with two or more of the following:

1. Related to defecation.
2. Onset associated with a change in frequency of stool.
3. Onset associated with a change in form (appearance) of stool.

These are useful for comparative studies. Subgroups of IBS patients can be identified according to the criteria listed in Box 32.31.

The decision as to whether to investigate and the choice of investigations should be based on clinical judgement. Pointers to the need for thorough investigation are the presence of the above symptoms in association with rectal bleeding, nocturnal pain, fever and weight loss, and a clinical suspicion of organic diarrhoea. A raised stool calprotectin would suggest inflammation needing further investigation.

Management

Current strategies for the treatment of IBS include therapies target central and end-organ pathways (Box 32.32); these are not mutually exclusive.

Box 32.29 Non-gastrointestinal features of irritable bowel syndrome

- Affective disorders, e.g. depression, anxiety
- Psychological stress and trauma
- Gastrointestinal infection
- Antibiotic therapy
- Sexual, physical or verbal abuse
- Pelvic surgery
- Eating disorders

Patients with IBS are often worried that their symptoms are due to a serious disease such as cancer. Alarm symptoms much be investigated when present. However, a positive diagnosis of IBS with an explanation of the symptoms and reassurance is often helpful and may require no further investigation or treatment. It is helpful to establish and maintain a good clinician–patient relationship from the beginning. Box 32.32 shows the overall management strategies used in IBS for those with severe and longstanding

problems. Lifestyle and dietary modifications should be the mainstay of management for patients with mild–moderate symptoms with pharmacologic therapy used adjunctively for those who fail to respond or who have more severe symptoms.

Pain/gas/bloat syndrome/midgut dysmotility
Disordered motility and visceral sensation that predominantly affects the small intestine or midgut results in symptoms of pain and bloating without altered defecation. Other symptoms include postprandial fullness, nausea and, on occasions, anorexia and weight loss.

Management of patients with pain/gas/bloat syndrome is not easy, and in some, pain can be chronic and severe. The main approaches are summarized below:

- Narcotics should always be avoided.
- Central and end-organ-targeted treatment approaches should be combined: for example, the SSRI paroxetine combined with a prokinetic agent, such as domperidone, or a smooth muscle relaxant, such as mebeverine.
- Small bowel bacterial overgrowth can be a contributory feature that can be treated with non-absorbed antibiotics such as rifaximin, however this is expensive and cheaper antibiotics such as doxycycline can also offer symptomatic benefit.
- Research has highlighted the benefit of altering the fermentable components of the diet. A diet with reduced fermentable oligo-, di- and monosaccharides and polyols (low FODMAP) will exclude a range of food types, including garlic, onions, specific beans, fructose-containing fruit, wheat-containing products, and certain natural and synthetic sweeteners. Small sham-diet-controlled clinical trials have shown significant benefit in patients with functional symptoms but long-term randomized controlled studies are necessary.
- The role of probiotics for management of IBS patients is not yet clear. A recent meta-analysis found some evidence for the efficacy of various probiotics in helping with symptoms such as pain, bloating and flatulence but with varying methodological limitations in most of the studies. Two studies found that Bifidobacterium infantis versus placebo led to symptomatic improvement in patients with IBS. It is likely that future work will focus on subgroups of patients, particularly those with diarrhoea-predominant IBS, and aim to correct the microbiome on an individual level according to the particular alterations of the compositional flora rather than give a generic probiotic.

Some patients with pain/gas/bloat syndrome have particularly severe and chronic symptoms, which may be nocturnal. A small subgroup of these has been shown to have manometric features consistent with a diagnosis of chronic idiopathic intestinal pseudo-obstruction (CIIP), and specifically of an enteric neuropathy. Full-thickness small intestinal biopsies confirm this diagnosis by showing a deficiency of α actin staining in the inner circular layer of smooth muscle. More appropriately, these patients should be considered as having a gastrointestinal neuromuscular disorder of the gut. About 10% of these individuals are subsequently found to have an underlying autoimmune overlap disorder (see p. 463).

Management of patients with neuromuscular disorders of the gut requires a multidisciplinary approach, with an emphasis on the management of pain, psychological state and nutrition. Patients with underlying autoimmune rheumatic disorders may benefit from primary treatment of these. Patients with intestinal failure as a result of CIIP need long-term parenteral nutrition.

Functiona intervene rhoea
In this form of functional bowel disease, symptoms occur in the absence of abdominal pain. They commonly include:

- the passage of several stools in rapid succession, usually first thing in the morning; no further bowel action may occur that day, or defecation takes place only after meals
- a first stool of the day that is usually formed, the later ones being mushy, looser or watery
- urgency of defecation
- anxiety, and uncertainty about bowel function with restriction of movement (e.g. travelling)
- exhaustion after defecation.

Chronic diarrhoea without pain is caused by many diseases that are indistinguishable by history from functional diarrhoea. Features that are atypical of a functional disorder (e.g. large-volume stools, rectal bleeding, nutritional deficiency and weight loss) call for more extensive investigations.

Treatment of functional diarrhoea is with loperamide, often combined with a tricyclic antidepressant prescribed at night (e.g. clomipramine 10–30mg).

Purgative abuse
This is most commonly seen in females who surreptitiously take high-dose purgatives and are often extensively investigated for chronic diarrhoea. The diarrhoea is usually of high volume (>1L daily) and patients may have a low serum potassium. Biochemical analysis of the stool may help diagnose laxative abuse. Management is difficult, as most patients deny purgative ingestion. Purgative abuse often occurs in association with eating disorders and patients may need psychiatric help.

Malabsorption
In many small bowel diseases, malabsorption of specific substances occurs, but these deficiencies do not usually dominate the clinical picture. An example is Crohn’s disease, in which malabsorption of vitamin B12 can be demonstrated, but this is not usually the major problem; diarrhoea and general ill-health are the major features.

The major disorders of the small intestine that cause malabsorption are shown in Box 32.33.

Coeliac disease (gluten-sensitive enteropathy)
Coeliac disease is an autoimmune condition in which there is inflammation of the mucosa of the upper small bowel that improves when gluten is withdrawn from the diet and relapses when gluten is reintroduced. Gluten is the entire protein content of the cereals wheat, barley and rye. Up to 1% of many populations are affected, though most have clinically silent disease.
Aetiology

The aetiology of coeliac disease is multifactorial with both genetic and environmental factors needed for the disease to manifest. Prolamins (gliadin from wheat, hordeins from barley, secalins from rye) are the damaging factors in these patients. These proteins are resistant to digestion by pepsin and chymotrypsin because of their high glutamine and proline content, and remain in the intestinal lumen, triggering the immune responses that result in coeliac disease. Gliadin peptides pass through the epithelium (para- and/or intracellularly) and are deaminated by tissue transglutaminase, which increases their immunogenicity. Gliadin peptides then bind to antigen-presenting cells, which interact with CD4+ T cells in the lamina propria via HLA class II molecules DQ2 or DQ8. These T cells produce pro-inflammatory cytokines, particularly interferon-γ. CD4+ T cells also interact with B cells to produce endomyosial and tissue transglutaminase antibodies. Gliadin peptides also cause release of IL-15 from enterocytes, activating intraepithelial lymphocytes with a natural killer cell marker. This inflammatory cascade releases metalloproteinases and other mediators, which contribute to the villous atrophy and crypt hyperplasia that are typical of the disease.

The mucosa of the proximal small bowel is predominantly affected, the mucosal damage decreasing in severity towards the ileum as gluten is digested into smaller ‘non-toxic’ fragments.

Genetic factors

There is an increased incidence of coeliac disease within families but the exact mode of inheritance is unknown; 10–15% of first-degree relatives will have the condition, although it may be asymptomatic. The concordance rate in identical twins is about 70%.

HLA-DQ2 (DQA1*0501, DQB1*0201) and HLA-DQ8 (DQA1*0301, DQB1*0302) are associated with coeliac disease. Over 90% of patients will have HLA-DQ2, compared with 20–30% of the general population. Studies in twins and siblings indicate that HLA genes are responsible for less than 50% of the genetic cause of the disease. Many unaffected people also carry these genes, so other factors must also be involved. Non-HLA genes may also contribute to coeliac disease; for example, chromosome regions 19p13.1, 11q, 5q31–33 and 6q21–22. The CD28/CTLA4 gene cluster has also shown linkage with coeliac disease.

Environmental factors

Breast-feeding and the age of introduction of gluten into the diet are significant. Rotavirus infection in infancy also increases the risk; adenovirus-12, which has sequence homology with α-gliadin, was suspected as a causative agent but this is now thought to be unlikely.

Clinical features

Coeliac disease can present at any age. In infancy, it sometimes appears after weaning on to gluten-containing foods. The peak period for diagnosis in adults is in the fifth decade, with a female preponderance. Many patients are asymptomatic (silent) and come to attention because of routine blood tests: for example, a raised MCV, or iron deficiency in pregnancy. The symptoms are very variable and often non-specific; they include tiredness and malaise, often associated with anaemia.

Gastrointestinal symptoms may be absent or mild. Coeliac disease should be tested for in all patients with symptoms suggestive of irritable bowel syndrome. Diarrhoea or steatorrhoea, abdominal pain and weight loss suggest more severe disease. Mouth ulcers and angular stomatitis are frequent and can be intermittent. Infertility and neuropsychiatric symptoms of anxiety and depression can occur.

Rare complications include tetany, osteomalacia or gross malnutrition with peripheral oedema. Long-term problems include osteoporosis, which occurs even in patients on long-term gluten-free diets. Neurological symptoms, such as paraesthesia, ataxia (due to cerebellar calcification), muscle weakness or a polynuropathy occur; the prognosis for these symptoms is variable. There is an increased incidence of atopy and autoimmune disease, including thyroid disease, type 1 diabetes and Sjögren’s syndrome. Other associated diseases include:

- inflammatory bowel disease
- primary biliary cholangitis
- chronic liver disease
- interstitial lung disease
- epilepsy
- IgA deficiency is more common than in the general population.

Physical signs are usually few and non-specific, and are related to anaemia and malnutrition.

Diagnosis

Small bowel biopsy is still considered to be the ‘gold standard’ for positive diagnosis and is therefore desirable in all but the most clear-cut cases, because treatment involves a life-long diet that is both expensive and socially limiting. However, with the increasing accuracy of serological tests, it is no longer necessary to take duodenal biopsies for suspected coeliac disease in patients without antibodies. For example, in patients undergoing endoscopy for iron deficiency anaemia with negative coeliac serology, the pretest value of small bowel histology is less than 0.03%.

If biopsies are to be taken, 4–6 forceps biopsies should be taken from the second part of the duodenum and the bulb because the disease is sometimes patchy and it can be difficult to orientate endoscopic biopsies for histological section. Endoscopic signs, including absence of mucosal folds, mosaic pattern of the surface and scalloping of mucosal folds, are often present; however, their absence is not conclusive because they are markers of relatively severe disease. Patients must be consuming gluten at the time of the endoscopy for the test to be diagnostic.

Histology

Histological changes are of variable severity and are graded using the Marsh–Oberhuber classification (Box 32.34) with types 2 and 3 being diagnostically supportive of coeliac disease. Villous atrophy can be caused by other conditions (e.g. tropical sprue, common variable immunodeficiency, non-coeliac enteropathy), but coeliac disease is the most common cause of subtotal villous atrophy.

Serology

Indications for testing include fatigue, persistent diarrhoea, folate or iron deficiency, unexplained abnormal liver biochemistry, a family history of coeliac disease and associated autoimmune disease.

The most sensitive tests are for endomysial (EMA) and tissue transglutaminase (tTG) antibodies (95% sensitivity). Titres of either of these correlate with the severity of mucosal damage and so they can be used for dietary monitoring. Standard tests use IgA class antibodies. Selective IgA deficiency occurs in 2.5% of coeliac disease patients but only 0.25% of normals. In a few cases, this may render these tests falsely negative. In situations in which CD is strongly suspected in a patient negative for EMA antibodies, IgA levels should be measured; if low, IgG-based tests should then be used (e.g. deaminated gliadin peptide (DGP) antibody).

**HLA typing**

HLA-DQ2 is present in 90–95% of coeliac disease patients and HLA-DQ8 in about 8% – most of the rest. The absence of both alleles has a high negative predictive value for coeliac disease. HLA typing can be useful for risk assessment: for example, in patients already on a gluten-free diet, in whom serology would be negative.

**Other investigations**

- **Haematology.** Mild or moderate anaemia is present in 50% of cases. Folate deficiency is common, often causing macrocytosis. Vitamin B12 deficiency is rare. Iron deficiency, due to malabsorption of iron and increased loss of desquamated cells, is common. A blood film may therefore show microcytes and macrocytes (i.e. a dimorphic picture), as well as hypersegmented polymorphonuclear leucocytes and Howell–Jolly bodies (see p. 356) due to splenic atrophy.

- **Biochemistry.** In severe cases, biochemical evidence of osteomalacia may be seen (low calcium and high phosphate) and there is hypoalbuminaemia.

- **Imaging.** A small bowel barium follow-through or MRI enteroclysis may show dilation of the small bowel with slow transit. Folds become thicker, and in severe disease, total effacement is seen. Imaging is mainly used when a complication, such as lymphoma, is suspected.

- **Bone densitometry.** Dual energy X-ray absorptiometry (DXA) should be performed on all patients because of the risk of osteoporosis.

- **Capsule endoscopy** (see p. 1158). This is used to look for gut abnormalities when a complication is suspected.

**Management**

**Replacement minerals and vitamins,** such as iron, folic acid, calcium and vitamin D, may be needed initially to replace body stores. Management is with a gluten-free diet for life. Dietary elimination of wheat, barley and rye usually produces a clinical improvement within days or weeks. Morphological improvement often takes months, especially in adults. Oats are tolerated by most people with CD but must not be contaminated with flour during their production. Meat, dairy products, fruits and vegetables are naturally gluten-free and are all safe.

**Gluten-free products** can be expensive, unless subsidized by national health services; however, this is slowly improving as gluten-free diets are becoming more popular amongst the general population in the industrialized world. Patient support organizations, such as the Coeliac Society (UK), are valuable as information sources and for advice about diet, recipes and gluten-free processed foods. Referral to a dietician for help with what to eat can be very beneficial for some patients. Despite advice, many patients do not keep to a strict diet but maintain good health. The long-term effects of this low gluten intake are uncertain but osteoporosis can occur, even in treated cases.

The usual cause of failure to respond to the diet is poor compliance. Dietary adherence can be monitored by serial tests for EMA and tTG. If clinical progress is suboptimal, then a repeat intestinal biopsy should be taken. If the diagnosis is equivocal on the diagnostic mucosal biopsy, or if the patient has already started on a gluten-free diet, then a gluten challenge, i.e. re-introduction of oral gluten, with evidence of jejunal morphological change, can confirm the diagnosis.

Patients should have pneumococcal vaccinations (because of splenic atrophy) once every 5 years (see p. 357).

**Complications**

A few patients do not improve on a strict diet and are said to have non-responsive coeliac disease. Many of these patients are still ingesting gluten. A few of the others may have concomitant problems, such as microscopic colitis, inflammatory bowel disease, small bowel bacterial overgrowth or lactase deficiency.

A very small percentage will have the rare complication of refractory coeliac disease (RCD):

- **Type 1 RCD** – the lymphocytes are normal and the T-cell receptors are polyclonal; 5-year survival is 93%.
- **Type 2** – there are abnormal clonal lymphocytes with loss of CD8 and CD3 surface markers. The 5-year survival rate is 40–60%. Very rarely, enteropathy-associated T-cell lymphoma (EATCL) (8–20% 5-year survival) or ulcerative jejunitis can occur as part of a spectrum of neoplastic T-cell disorders.

**Ulcerative jejunitis** presents with fever, abdominal pain, perforation and bleeding.

Diagnosis of these conditions is with MRI or barium studies, but laparoscopy with full-thickness small bowel biopsies is often required. Steroids and immunosuppressive agents, such as azathioprine, are used in ulcerative jejunitis.

The incidence of carcinoma of the oesophagus and small bowel adenocarcinoma, as well as that of extragastrointestinal cancers, is also increased. Malignancy seems to be unrelated to the duration of the disease but the incidence is reduced by a gluten-free diet.

**Dermatitis herpetiformis**

This is an uncommon, blistering, subepidermal eruption of the skin associated with a gluten-sensitive enteropathy (see also p. 687). Rarely, gross malabsorption occurs, but usually the jejunal morphological abnormalities are not as severe as in coeliac disease. The inheritance and immunological abnormalities are the same as for coeliac disease. The skin condition responds to dapsone but a gluten-free diet improves both the enteropathy and the skin lesion, and is recommended for long-term benefit.

**Non-coeliac gluten intolerance**

There is a recognized group of patients who are sensitive to dietary wheat and gluten-containing foods but do not have coeliac disease, in so far as their coeliac serology is negative and duodenal biopsies are normal. These patients have a range of symptoms, including diarrhoea, bloating and abdominal pain, which improve on avoidance of gluten. The mechanism is not yet clear.

**Tropical sprue**

This condition presents with chronic diarrhoea and malabsorption, and occurs in residents of or visitors to tropical areas where the disease is endemic: most of Asia, some Caribbean islands, Puerto Rico and parts of South America. Epidemics occur, lasting up to 2 years; in some areas, repeated epidemics are seen at varying intervals of up to 10 years.
The term tropical sprue is reserved for severe malabsorption (of two or more substances) accompanied by diarrhoea and malnutrition. A mild degree of malabsorption, sometimes following an enteric infection, is quite common in the tropics; it is usually asymptomatic and is sometimes called tropical malabsorption.

Aetiology

The aetiology is unknown but is likely to be infective because the disease occurs in epidemics and patients improve on antibiotics. A number of agents have been suggested but none has been unequivocally shown to be responsible. Different agents could be involved in different parts of the world.

Clinical features

These vary in intensity and consist of diarrhoea, anorexia, abdominal distension and weight loss. The onset is sometimes acute and occurs either a few days or many years after being in the tropics. Epidemics can break out in villages, affecting thousands of people at the same time. The onset can also be insidious, with chronic diarrhoea and evidence of nutritional deficiency. The clinical features of tropical sprue vary in different parts of the world, particularly as different criteria are used for diagnosis.

Diagnosis

Acute infective causes of diarrhoea must be excluded (Box 32.35), particularly Giardia, which can produce a syndrome very similar to tropical sprue. Malabsorption should be demonstrated, particularly of fat and vitamin B₁₂. The jejunal mucosa is abnormal, showing some villous atrophy (partial villous atrophy). In most cases, the lesion is less severe than that found in coeliac disease, although it affects the whole of the small bowel. Mild mucosal changes can be seen in asymptomatic individuals in the tropics.

Management

Many patients improve when they leave the sprue area and take folic acid (5 mg daily). Most patients also require an antibiotic to ensure a complete recovery (usually tetracycline 1 g daily for up to 6 months).

Severely ill patients require resuscitation with fluids and electrolytes for dehydration, and nutritional deficiencies should be corrected. Vitamin B₁₂ (1000 µg) is also given to all acute cases.

Prognosis

The prognosis is excellent. Mortality is usually associated with water and electrolyte depletion, particularly in epidemics.

Bacterial overgrowth

The gut contains many resident bacteria in the terminal ileum and colon. Anaerobic bacteria, e.g. Bacteroides, bifidobacteria, are 100–1000 times more abundant than aerobic bacterial (facultative anaerobes), such as Escherichia, Enterobacter and Enterococcus. This gut microflora has major functions, including metabolic ones, such as fermentation of non-digestible dietary residues into short-chain fatty acids as an energy source in the colon.

The microflora that influences epithelial cell proliferation is involved in the development and maintenance of the immune system and protects the gut mucosa from colonization by pathogenic bacteria. Bacteria also initiate vitamin K production.

The upper part of the small intestine is almost sterile, containing only a few organisms derived from the mouth. Gastric acid kills some ingested organisms and intestinal motility keeps bacterial counts in the jejunum low. The normal terminal ileum contains faecal-type organisms, mainly Escherichia coli and anaerobes, and the colon has abundant bacteria.

Bacterial overgrowth is normally found in association with a structural abnormality of the small intestine, such as a stricture or diverticulum, although it can occur occasionally in the elderly without such an abnormality. E. coli and/or Bacteroides, both in concentrations of greater than 10⁹/mL, are found as part of a mixed flora. These bacteria are capable of deconjugating and dehydroxylating bile salts, so that unconjugated and dehydroxylated bile salts can be detected in small bowel aspirates.

Clinical features

The clinical features of overgrowth are chiefly diarrhoea and steatorrhoea. There may also be symptoms caused by the underlying small bowel pathology. Steatorrhoea (see p. 1154) occurs because of conjugated bile salt deficiency. Some bacteria can metabolize vitamin B₁₂ and interfere with its binding to intrinsic factor, leading to mild B₁₂ deficiency (see p. 334); it is rarely severe enough to produce a neurological deficit. Some bacteria produce folic acid, giving a high serum folate. Bacterial overgrowth has only minimal effects on the absorption of other substances. Confirmation of bacterial overgrowth is with the hydrogen breath test:

- **Hydrogen breath test.** Bacteria are present in the oral cavity so the mouth should be rinsed out with an antiseptic mouthwash beforehand. The appearance of a breath hydrogen peak after oral glucose is used to estimate mouth-to-caecum transit time. An earlier rise in the breath hydrogen after glucose indicates bacterial breakdown in the small intestine.
This test is simple to perform and does not involve radioisotopes. However, interpretation is often difficult, and sensitivity and specificity are low.

**Management**

If possible, the underlying lesion should be corrected (e.g. a stricture should be resected). Where this is not possible, rotating courses of antibiotics are necessary, such as metronidazole, a tetracycline or ciprofloxacin. The response to antibiotics is unpredictable.

**Bile acid malabsorption**

Bile is released from the gall bladder after eating and is essential for fat digestion. In a healthy gut, most of the bile is reabsorbed in the small intestine and recycled (enterohepatic bile acid circulation). However, this reabsorption is interrupted in some patients leading to more bile passing through into the colon. The increased concentration of bile acids in the colon leads to diarrhea by reducing absorption of water and electrolytes as well as increasing secretion and colonic motility. Causes include:

- Crohn’s disease with ileal disease
- ileal resection
- HIV infection
- idiopathic/primary bile acid diarrhoea
- post-infective gastroenteritis
- post-cholecystectomy.

Diagnosis is made by either a trial of medication or with a SeHCAT scan. This is carried out by giving oral SeHCAT (a synthetic taurine conjugate) and measuring the retention of the bile acid by whole-body counting at 7 days. Patients are managed by giving bile acid sequestrants such as cholestyramine or colesvelam. These bind and inactivate the action of bile acids in the colon.

**Lactose intolerance**

This is a clinical syndrome where ingestion of lactose causes symptoms such as diarrhea, abdominal pain, bloating and flatulence. This is occasionally due to lactase deficiency but can also be due to secondary lactose malabsorption (usually due to underlying intestinal disease). There is a high incidence of lactase deficiency in many parts of the world (e.g. the Mediterranean countries and parts of Africa and Asia). There can be variability in symptoms amongst patients and a crossover with IBS symptoms. Formal diagnostic testing involves giving an oral dose of 50 g of lactose and serial measurement of blood glucose over 2 hours.

**Small intestinal resection**

Small intestinal resection is usually well tolerated, but massive resection leaving less than 1 m of small bowel in continuity is followed by the short bowel syndrome. The effects of resection depend on the amount and location of the resection and the presence or absence of the colon. Resection of the jejunum is better tolerated than ileal resection, where there is less adaptation, probably due to low levels of glucagon-like peptide 2 (GLP-2), which is a specific growth hormone for the enterocyte. Patients with an anatomically short small bowel after surgical resection should have close follow-up to ensure they do not become depleted of electrolytes or develop malnutrition. Management will depend on investigations, but might include the use of loperamide and codeine to reduce small intestinal transit time, high-dose PPI therapy to reduce gastric secretion, oral rehydration solution and, where necessary, parenteral electrolyte and calorie replacement.

**Ileal resection**

The ileum is the site of specific mechanisms for the absorption of bile salts and vitamin B<sub>12</sub>. Relatively small resections lead to malabsorption of these substances. Loss of the ileal brake (see p. 1154) leads to diarrhoea. Removal of the ileocaecal valve increases the incidence of diarrhoea (Fig. 32.34).

The following occur after ileal resection:

- **Bile-salt-induced diarrhoea.** Bile salts and fatty acids enter the colon and cause malabsorption of water and electrolytes (see p. 1185).
- **Steatorrhoea and gallstone formation.** Increased bile salt synthesis can compensate for loss of approximately one-third of the bile salts in the faeces. Greater loss than this results in decreased micelle formation and steatorrhoea, and lithogenic bile and gallstone formation.
- **Oxaluria and oxalate stones.** Bile salts in the colon cause increased oxalate absorption with oxaluria, leading to urinary stone formation.
- **B<sub>12</sub> deficiency.** Low serum B<sub>12</sub>, macrocytosis and other effects of B<sub>12</sub> deficiency are seen.

**Investigations**

These include imaging of the small bowel measurement of B<sub>12</sub>, and a bile salt retention (SeHCAT) test (see above). A hydrogen breath test may show rapid transit (p. 1192). Many patients require B<sub>12</sub> replacement and some need a low-fat diet if there is steatorrhoea. Diarrhoea is often improved by colestyramine, which binds bile salts and reduces the level of diarrhoeogenic bile salts in the colon.

**Jejunal resection**

The ileum can compensate for loss of jejunal absorptive function. Jejunal resection may lead to gastric hypersecretion with high gastric levels; the exact mechanism is unclear. Structural and functional
intestinal adaptation takes place over the course of a year, with an increase in the absorption per unit length of bowel in both jejunum and ileum.

Massive intestinal resection (short bowel syndrome)
Intestinal failure results from obstruction, dysmotility, surgical resection, congenital defect, or disease-associated loss of absorption. It is characterized by the inability to maintain protein-energy, fluid, electrolyte or micronutrient balance. This most often occurs following resection for Crohn’s disease, mesenteric vessel occlusion (see p. 1196), radiation enteritis (see later) or trauma. There are two common situations.

Shortened small intestine ending at a terminal small bowel stoma
The major problem is sodium and fluid depletion; the majority of patients with 100 cm or less of jejunum remaining will require parenteral supplements of fluid and electrolytes, often with nutrients. Sodium losses can be minimized by increasing salt intake, restricting hypotonic fluids between meals, and administering oral glucose–electrolyte mixture with a sodium concentration of 90 mmol/L. Jejunal transit time can be increased and stomal effluent loss reduced by treatment with the somatostatin analogue octreotide, often used in combination with a PPI, loperamide and codeine phosphate. There is no benefit from a low-fat diet, but fat assimilation can be increased on treatment with colestyramine and synthetic bile acids.

Teduglutide, a GLP-2 analogue, reduces stomal output and the number of days of parenteral nutrition.

Shortened small intestine in continuity with colon
Because of the absorptive capacity of the colon for fluid and electrolytes, only a small proportion of these patients require parenteral supplementation. Unabsorbed fat results in impairment of colonic fluid and electrolyte absorption, and so patients should be on a low-fat diet. A high carbohydrate intake is advised, as unabsorbed carbohydrate is metabolized anaerobically to short-chain fatty acids (SCFAs), which are absorbed; they also stimulate fluid and electrolyte absorption in the colon and act as an energy source (1.6 kcal/g). Patients are often treated with colestyramine to reduce diarrhoea and colonic oxalate absorption.

Whipple’s disease
Whipple’s disease is a rare infectious bacterial disease caused by Tropheryma whipplei. Some 87% of patients are males, and are usually white and middle-aged. Clinical features can progress over many years and can include:
- arthritis and arthralgia
- weight loss
- diarrhoea or steatorrhoea
- abdominal pain
- systemic symptoms of fever and weight loss
- peripheral lymphadenopathy and involvement of the heart, lung, joints and brain occur, simulating many neurological conditions.

Blood tests show features of chronic inflammation and malabsorption. Endoscopy typically shows pale, shaggy duodenal mucosa with eroded, red, friable patches.

Diagnosis
Diagnosis is made by small bowel biopsy. Periodic acid–Schiff (PAS)-positive macrophages are present but are non-specific. On electron microscopy, the characteristic trilaminar cell wall of T. whipplei can be seen within macrophages. T. whipplei antibodies can be identified by immunohistochemistry. A confirmatory polymerase chain reaction (PCR)-based assay is available.

Management
Treatment is with antibiotics that cross the blood–brain barrier, such as 160 mg trimethoprim and 800 mg sulfamethoxazole (co-trimoxazole) daily for 1 year. This is preceded by a 2-week course of streptomycin and penicillin or ceftriaxone. Treatment periods of less than 1 year are associated with relapse in about 40%. If left untreated, it can be fatal.

Radiation enteritis
Radiation of more than 40 Gy will damage the intestine. The chronic effects of radiation are muscle fibre atrophy, ulcerative changes due to ischaemia, and obstruction due to radiation-induced fibrotic strictures.

Pelvic irradiation is frequently used for gynaecological and urinary tract malignancies, and so the ileum and rectum are the areas most often involved.

At the time of the irradiation, there may be nausea, vomiting, diarrhoea and abdominal pain, usually improving within 6 weeks of completion of therapy.

Chronic radiation enteritis is diagnosed if symptoms persist for 3 months or more. The prevalence is higher than 15% of patients receiving radiotherapy that includes the abdomen. Abdominal pain due to obstruction is the main symptom. Malabsorption can be due to bacterial overgrowth in dilated segments and mucosal damage. Many patients suffer from increased bowel frequency. Management is symptomatic, although often unsuccessful in chronic radiation enteritis. Surgery should be avoided if possible, being reserved for obstruction or perforation. Hyperbaric oxygen has been shown to be beneficial but this is not available in many centres.

Acute radiation damage to the rectum produces a radiation proctitis with diarrhoea and tenesmus, with or without blood. Local steroids sometimes help initially. When the acute phase heals, mucosal telangiectases form and may cause persistent bleeding. If there is resistant anaemia, these can be treated with argon plasma coagulation or, under a light anaesthetic, by packing the rectum with a formalin-soaked swab for 2 minutes, both of which destroy the telangiectases.

Parasite infestation
- Giardia intestinalis (see p. 572) not only produces diarrhoea but also can produce malabsorption with steatorrhoea. Minor changes are seen in the jejunal mucosa and the organism can be found in the jejunal fluid or mucosa.
- Cryptosporidiosis (see p. 573) can also produce malabsorption.
- HIV infection causes patients to be particularly prone to parasitic infestation (Box 32.36).

Other causes of malabsorption
- Drugs that bind bile salts (e.g. colestyramine) and some antibiotics (e.g. neomycin) produce steatorrhoea.
- Orlistat is used in obesity to reduce fat absorption by inhibiting gastric and pancreatic lipase, so causing diarrhoea and steatorrhoea. A low-fat diet is also necessary, which leads to weight loss.
- Thyrotoxicosis causes diarrhoea, rarely with steatorrhoea, owing to increased gastric emptying and increased motility.
- Zollinger–Ellison syndrome is described on page 1336.
- Intestinal lymphangiectasia produces diarrhoea and, rarely, steatorrhoea.
• Lymphoma that has infiltrated the small bowel mucosa causes malabsorption.
• Diabetes mellitus (see p. 732) causes diarrhoea, malabsorption and steatorrhoea, sometimes due to bacterial overgrowth from autonomic neuropathy that leads to small bowel stasis.
• Hypogammaglobulinaemia, which is seen in a number of conditions including lymphoid nodular hyperplasia, causes steatorrhoea due either to an abnormal jejunal mucosa or to secondary infestation with Giardia intestinalis.

### Miscellaneous intestinal diseases

#### Protein-losing enteropathy

Protein-losing enteropathy refers to intestinal conditions that lead to protein loss, and usually manifest with hypoalbuminaemia. The causes include:
- Crohn’s disease
- tumours
- Ménétrier’s disease, a condition with giant rugal folds (Fig. 32.35)
- coeliac disease
- lymphatic disorders (e.g. lymphangiectasia).

Usually, protein-losing enteropathy forms a minor part of the generalized disorder but, occasionally, hepatic synthesis of albumin cannot compensate for the protein loss, and peripheral oedema dominates the clinical picture. Confirmation of the diagnosis is by measurement of α₁-antitrypsin clearance. It does not require an isotope. Alpha₁-antitrypsin is a large molecule (>50 000 daltons), which is resistant to proteolysis. Simultaneous measurements of serum and stool concentration (24-h collection) are made. The treatment is that of the underlying disorder.

#### Meckel’s diverticulum

This is the most common congenital abnormality of the gastrointestinal tract, affecting 2–3% of the population. The diverticulum projects from the wall of the ileum approximately 60 cm from the ileocaecal valve. It is usually symptomless. However, 50% contain gastric mucosa that secretes hydrochloric acid, and peptic ulcers can occur and may bleed (see p. 1181) or perforate.

Acute inflammation of the diverticulum also occurs and is indistinguishable clinically from acute appendicitis. Rarely, there is obstruction from an associated band.

Management is surgical removal, often laparoscopically.

#### Tuberculosis

Tuberculosis (TB; see also p. 967) can affect the intestine, as well as the peritoneum (see p. 1223). In developed countries, most patients are from ethnic minority groups, or are immunocompromised because of HIV or drugs. Intestinal TB is due to reactivation of primary disease caused by Mycobacterium tuberculosis. Bovine TB occurs in areas where milk is unpasteurized and is rare in Western countries.

**Clinical features**

These are abdominal pain, weight loss, anaemia, fever with night sweats, obstruction, right iliac fossa pain or a palpable mass. The ileocaecal area is most commonly affected, but the colon – and, rarely, other parts of the gastrointestinal tract – can be involved. One-third of patients present acutely with intestinal obstruction or generalized peritonitis; 50% have X-ray evidence of pulmonary TB.

**Diagnosis**

Differential diagnosis includes Crohn’s disease and caecal carcinoma.

- Small bowel follow-through may show transverse ulceration, and diffuse narrowing of the bowel with shortening of the caecal pole.

**Fig. 32.35** Protein-losing enteropathy showing giant rugal folds.
• **Ultrasound, MRI or CT** shows additional mesenteric thickening and lymph node enlargement.

• **Histology and culture of tissue** is desirable but not always possible. Specimens can be obtained by colonoscopy or laparoscopy but laparotomy is required in some cases. The histological findings include chronic inflammation with caseating granuloma. Acid-fast bacilli may be seen on dedicated stains. However, the histology is not always distinguishable from that of Crohn’s disease.

**Management**

Drug treatment is similar to that for pulmonary TB (see p. 969). Treatment should be started if there is a high degree of suspicion.

**Amyloidosis**

Systemic amyloidosis may affect any part of the gastrointestinal tract (see p. 1357). Rectal biopsy may be diagnostic. Occasionally, amyloid deposits occur as polypoid lesions. The symptoms depend on the site of involvement; amyloidosis in the small intestine gives rise to diarrhoea.

**Autoimmune rheumatic diseases**

Systemic sclerosis (see p. 460) most commonly affects the oesophagus (see p. 992), although the small bowel and colon are often found to be involved if investigated. There may be no symptoms of this involvement, but diarrhoea and steatorrhoea can occur due to bacterial overgrowth caused by reduced motility, dilation and the presence of diverticula.

**Intestinal ischaemia**

Intestinal ischaemia results from occlusion of arterial inflow, occlusion of venous outflow or failure of perfusion; these factors may act alone or in combination and usually occur in the elderly.

- **Arterial inflow occlusion** can be caused by atheroma, thrombosis and embolism (cardiac arrhythmia), including cholesterol emboli (see p. 1372), aortic disease (occluding ostia of mesenteric vessels) or vasculitis (see p. 464), thromboangiitis and Takayasu’s syndrome.

- **Venous outflow occlusion** occurs in 5–15% of cases, usually in sick patients with circulatory failure.

- **Infarction without occlusion** can occur due to reduced cardiac output, hypotension and shock, causing reduced intestinal blood flow.

**Acute small intestinal ischaemia**

An embolus from the heart in a patient with atrial fibrillation is the most common cause and usually occludes the superior mesenteric artery. Patients present with sudden abdominal pain and vomiting, with a distended and tender abdomen and absent bowel sounds. The patient is hypotensive and ill. Surgery is necessary to resect the gangrenous bowel. Mortality is high (up to 90%) and is related to coexisting disease, the development of multiorgan failure (MOF; see p. 219) and massive fluid and electrolyte losses in the postoperative period. Survivors may go on to develop nutritionally inadequate short bowel syndrome (see p. 1194).

**Ischaemic colitis**

See page 1211.

**Chronic small intestinal ischaemia**

This is due to atheromatous occlusion or cholesterol emboli of the mesenteric vessels, and is found particularly in the elderly. Good collateral circulation can minimize clinical effects. The characteristic symptom is postprandial abdominal pain and weight loss. Loud bruits may be heard but, as these are heard in normal subjects, they are of doubtful significance. The diagnosis is made using angiography.

**Eosinophilic gastroenteritis**

In this condition of unknown aetiology there is eosinophilic infiltration and oedema of any part of the gastrointestinal mucosa. The gastric antrum and proximal small intestine are usually involved, hosting either a localized lesion (eosinophilic granuloma) or diffuse sheets of eosinophils in the serosal and submucosal layers. There is an association with asthma, eczema and urticaria.

The condition occurs mainly in the third decade. The clinical presentation depends on the site of gut involvement. Abdominal pain, nausea and vomiting, and upper gastrointestinal bleeding occur. Peripheral eosinophilia is present in only 20% of patients. Endoscopic biopsy is useful for making the diagnosis histologically. Radiology may demonstrate mass lesions.

Treatment is with corticosteroids for the widespread infiltration, particularly if peripheral eosinophilia is present.

In some adults, the condition appears to be allergic (allergic gastroenteritis) and is associated with peripheral eosinophilia and high levels of plasma and tissue IgE. The relationship of eosinophilic oesophagitis (see p. 1170) to eosinophilic gastroenteritis is unclear.

**Intestinal lymphangiectasia**

Dilation of the lymphatics may be primary or secondary to lymphatic obstruction, such as occurs in malignancy or constrictive pericarditis. Hypoproteinaemia with ankle oedema is the main feature. The rare primary form may be detected incidentally as dilated lacteals on a jejunal biopsy or it can produce steatorrhoea of varying degrees. White-tipped villi are seen on capsule endoscopy. Serum immunoglobulin levels are reduced, with low circulating lymphocytes. Management is with a low-fat diet, mid-chain triglycerides and fat-soluble vitamin supplements as required. Octreotide has a dramatic effect in a few primary cases, although the mechanism of action is unknown.

**Abetalipoproteinaemia**

This rare congenital disorder is due to a failure of apo B-100 synthesis in the liver and apo B-48 in the intestinal cell, so that chylomicrons are not formed. This leads to fat accumulation in the intestinal cells, lending a characteristic histological appearance to the jejunal mucosa. Clinical features include acanthocytosis (spiky red cells owing to membrane abnormalities), a form of retinitis pigmentosa, and mental and neurological abnormalities. The latter can be prevented by vitamin E injections.

**Tumours of the small intestine**

The small intestine is relatively resistant to the development of neoplasia and only 3–6% of all gastrointestinal tumours and less than 1% of all malignant lesions occur here. The reason for the rarity of tumours is unknown. Explanations include the fluidity and relative sterility of small bowel contents and the rapid transit time, reducing the time of exposure to potential carcinogens. It is also possible that the high population of lymphoid tissue and secretion of IgA in the small intestine protect against malignancy.

**Adenocarcinoma and lymphoma**

**Adenocarcinoma of the small intestine** is rare and found most frequently in the duodenum (in the periampullary region) and in
the jejunum. It is the most common tumour of the small intestine, accounting for up to 50% of primary tumours.

**Lymphomas** are most frequently found in the ileum. These are of the non-Hodgkin’s type and must be distinguished from peripheral or nodal lymphomas involving the gut secondarily.

In developed countries, the most common type of lymphoma is the B cell type arising from MALT. These lymphomas tend to be annular or polyoid masses in the distal or terminal ileum, whereas most T cell lymphomas are ulcerated plaques or strictures in the proximal small bowel.

A tumour similar to Burkitt’s lymphoma also occurs and commonly affects the terminal ileum of children in North Africa and the Middle East.

### Predisposing factors for adenocarcinoma and lymphoma

#### Coeliac disease
There is an increased incidence of lymphoma of the T cell type and adenocarcinoma of the small bowel, as well as an unexplained increase in all malignancies, both in the gastrointestinal tract and elsewhere. The reason for the local development of malignancy is unknown. It is now accepted that coeliac disease is a pre-malignant condition but there is no association with the length of the symptoms. Management with a gluten-free diet can reduce the risk of both lymphoma and carcinoma.

#### Crohn’s disease
There is a small increase in the incidence of adenocarcinoma of the small bowel in Crohn’s disease.

### Immunoproliferative small intestinal disease

Immunoproliferative small intestinal disease (IPSID) is a rare B cell disorder in which there is proliferation of plasma cells in the lamina propria of the upper small bowel, producing truncated monoclonal heavy chains, without associated light chains. The α heavy chains are found in the gut mucosa on immunofluorescence and can also be detected in the serum. IPSID usually occurs in countries surrounding the Mediterranean, but it has also been found in developing countries in South America and the Far East. It predominantly affects people in lower socioeconomic groups in areas with poor hygiene and a high incidence of bacterial and parasitic infection of the gut. IPSID presents as a malabsorptive syndrome associated with diffuse lymphoid infiltration of the small bowel and neighbouring lymph nodes, progressing in some cases to a lymphoma. The condition has also been documented in the developed world.

*Clinically*, patients present with abdominal pain, diarrhoea, anorexia, weight loss and symptoms of anaemia. There may be a palpable mass, and an ultrasound followed by an MRI scan may detect a mass lesion. Endoscopic biopsy is useful where lesions are within reach. Ultrasound and CT may show bowel wall thickening and the involvement of lymph nodes, which is common with lymphoma. Wireless capsule endoscopy can be used where obstruction by the capsule is not likely, but cannot deliver histology.

### Management of small intestinal tumours

#### Adenocarcinoma
Most patients are treated surgically with a segmental resection. The overall 5-year survival rate is 20–35%; this varies with the histological grade and the presence or absence of lymph node involvement. Radiotherapy and chemotherapy are used in addition.

#### IPSID
If there is no evidence of lymphoma, antibiotics, such as tetracycline, should be tried initially. In the presence of lymphoma, combination chemotherapy is used; in one series, the 3–5-year survival rate was 58%.

#### Lymphoma
Most patients require surgery and radiotherapy with chemotherapy for more extensive disease. The prognosis varies with the type. The 5-year survival rate for T cell lymphomas is 25% but is better for B cell lymphomas, varying from 50% to 75%, depending on the grade of lymphoma.

#### Carcinoid tumours
These originate from the enterochromaffin cells (APUD cells) of the intestine. They make up 10% of all small bowel neoplasms, the most common sites being the appendix and terminal ileum. It is often difficult to be certain histologically whether a particular tumour is benign or malignant. A total of 10% of carcinoid tumours in the appendix present as acute appendicitis, secondary to obstruction. Surgical resection of the tumour is usually performed.

Most carcinoids do not secrete hormones or vasoactive compounds, and may present with liver enlargement due to metastases. **Carcinoid syndrome** occurs in only 5% of patients with carcinoid tumours and only when there are liver metastases. Patients complain of spontaneous or induced bluish-red flushing, predominantly on the face and neck, sometimes leading to permanent changes with telangiectases.

Gastrointestinal symptoms consist of abdominal pain and recurrent watery diarrhoea. Cardiac abnormalities are found in 50% of patients and take the form of pulmonary stenosis or tricuspid incompetence. Examination of the abdomen reveals hepatomegaly. The tumours secrete a variety of biologically active amines and peptides, including serotonin (5-hydroxytryptamine, 5-HT), bradykinin, histamine, tachykinins and prostaglandins. The diarrhoea and cardiac complications are probably caused by 5-HT itself, but the cutaneous flushing is thought to be produced by one of the kinins, such as bradykinin. This is known to cause vasodilation, bronchospasm and increased intestinal motility.

### Diagnosis of carcinoid syndrome

- **Ultrasound examination** confirms the presence of liver secondary deposits.
- **Urine** shows a high concentration of 5-hydroxyindoleacetic acid (5-HIAA), which is the major metabolite of 5-HT.
- **Serum chromogranin A** is raised in nearly all hindgut tumours and 80–90% of symptomatic foregut and midgut tumours.

### Management of carcinoid syndrome

Treatment is with octreotide and lanreotide; both are octapeptide somatostatin analogues that inhibit the release of many gut hormones. They alleviate flushing and diarrhoea, and can control a carcinoid crisis. Interferon and other chemotherapeutic regimens also occasionally reduce tumour growth, but have not been shown to increase survival.

Most patients survive for 5–10 years after diagnosis.

#### Peutz–Jeghers syndrome

This consists of mucocutaneous pigmentation (circumoral in 95% of patients, and on the hands in 70% and feet in 60%) and gastrointestinal polypos. It has an autosomal dominant inheritance. The gene STK11 (also known as LKB1) that is responsible for Peutz–Jeghers syndrome
codes for a serine protein kinase and can be used for genetic analysis. The brown buccal pigment is characteristic of the condition. The polyps, which are hamartomas, can occur anywhere in the gastrointestinal tract but are most frequent in the small bowel. They may bleed or cause small bowel obstruction or intussusception (50% of patients).

Management
Management is by endoscopic polypectomy. Balloon enteroscopy may be necessary to reach all the small bowel polyps. Bowel resection should be avoided if possible, but may be necessary in patients presenting with gangrenous bowel due to intussusception. Follow-up is with yearly pan-endoscopy. There is an increased incidence of gastrointestinal cancers. Non-gastrointestinal cancers also occur with increased frequency, so yearly screening for uterine, ovarian and cervical cancer should start in the teens, and breast and testicular screening by the age of 20.

Other tumours
Adenomas, lipomas and stromal tumours (see p. 1180) are rarely found and are usually asymptomatic and picked up incidentally. They occasionally present with iron deficiency anaemia. In familial adenomatous polyposis (FAP), duodenal adenomas form in one-third of patients and may progress to adenocarcinoma. This is the most common cause of death in FAP patients who have been treated by prophylactic colectomy.

Further reading

INFLAMMATORY BOWEL DISEASE

Two major forms of inflammatory bowel disease (IBD) are recognized:

• Crohn’s disease (CD), which can affect any part of the gastrointestinal tract
• Ulcerative colitis (UC), which affects only the colon

There is a degree of overlap between these two conditions in their aetiological pathogenesis, clinical features, histological and radiological abnormalities; in 10% of cases of IBD causing colitis, a definitive diagnosis of either UC or CD is not possible and the diagnosis is termed colitis of undetermined type (indeterminate colitis). It is clinically useful to distinguish between UC and CD because of differences in their management, although, in reality, they may represent two aspects of the same disease.

Another form of colitis related to microscopic inflammation is termed microscopic colitis; this is subdivided into lymphocytic and collagenous types (see p. 1208). The distinction between this and IBD is the absence of macroscopic evidence of inflammation.

Epidemiology

• The incidence of CD varies from country to country but is approximately 4–10 per 100 000 annually, with a prevalence of 25–100/100 000.
• The incidence of UC is stable at 6–15/100 000 annually, with a prevalence of 80–150/100 000.

Although both conditions have a worldwide distribution, the highest incidence rates and prevalence have been reported from Northern Europe, the UK and North America. Both race and ethnic origin affect the incidence and prevalence of CD and UC. Thus, in North America, prevalence rates of CD are lower in Hispanic and Asian people (4.1/100 000 and 5.6/100 000, respectively) compared with white individuals (43.6/100 000). Jewish people are more prone to IBD than any other ethnic group. Prevalence rates also change after migration; thus there is an increasing incidence of CD in the UK-born children of migrants from South-east Asia. Recent studies suggest that the incidence of both CD and UC is increasing in traditional low-prevalence areas such as South-east Asia.

Approximately 25% of patients are diagnosed before their 18th birthday and there is evidence that disease commencing in youth is more extensive and more aggressive than that occurring in older patients.

Aetiology and pathogenesis

Although the aetiology of IBD is unknown, it is increasingly clear that IBD represents the interaction between several co-factors: genetic susceptibility, the environment, the intestinal microbiota and host immune response (Fig. 32.36).

Genetic factors
CD and UC are complex polygenic diseases and having a positive family history is the largest independent risk factor for development of IBD. Up to 1 in 5 patients with CD and 1 in 6 patients with UC will have a first-degree relative with the disease. The monozygotic and dizygotic twin concordance rates for CD are 20–50% and 10%, respectively.

Genome-wide association studies have identified multiple susceptibility loci, and many of the underlying risk variants have been identified. The major genetic factors for CD include the NOD2 (CARD 15) gene (nucleotide oligomerization domain 2), the auto- phagy genes and the Th17 pathway (IL-23–type 17 helper T cells). The NOD2 protein on chromosome 16 is an intracellular sensor of bacterial peptidoglycan, present in bacterial cell walls (see below). NOD2 is expressed in epithelial cells, macrophages and endothelial cells. Individuals who are homozygote or compound heterozygote for one of several mutations in the NOD2 gene have a significantly increased risk of developing ileal CD. Likewise, mutations in the autophagy genes ATG16L1 and IRGM (immunity-related GTP-ase M-protein) and IL-23 receptor gene increase CD risk, and mutations in genes associated with the mucosal barrier increase UC risk. However, the presence of IBD-associated genes in many unaffected individuals and the failure of the approximately 71 genetic susceptibility loci identified thus far to explain more than around one-fifth of the genetic risk of CD highlight the complexity of the genetic basis of IBD. Specific genetic defects in the IL-10 receptor pathway are associated with a severe form of extremely early-onset colitis and perianal disease in children.

Apart from susceptibility, HLA genes on chromosome 6 also appear to have a role in modifying the disease. The DRB*0103 allele is linked to a particularly aggressive course of UC and the need for surgery, as well as with colonic CD. DRB*0103 and MICA*010 are associated with perianal disease, and DRB*0701 with ileal CD. For the extraintestinal disease complications and HLA links, see page 1202.

Environmental and other factors

• Smoking. Patients with CD are more likely to be smokers, and smoking has been shown to exacerbate CD and increase the risk
of disease recurrence after surgery. By contrast, there is an increased risk of UC in non- or ex-smokers and nicotine has been shown to be an effective treatment in one small clinical trial.

- **NSAIDs.** NSAID ingestion is associated with both the onset of IBD and flares of disease in patients with an established diagnosis.

- **Hygiene.** Poor and large families living in crowded conditions have a lower risk of developing CD. A ‘clean’ environment may not expose the intestinal immune system to pathogenic or non-pathogenic microorganisms such as helminths, which seems to alter the balance between effector and regulatory immune responses.

- **Nutritional factors.** Many foods and food components have been suggested as playing a role in the aetiopathogenesis of IBD (e.g. high sugar and fat intake) but, unfortunately, the results of numerous studies designed to define risk have been equivocal. However, breast-feeding may provide protection against the development of IBD in offspring.

- **Psychological factors.** Factors such as chronic stress and depression seem to increase relapses in patients with quiescent disease.

- **Appendicectomy.** This appears to be ‘protective’ against the development of UC, particularly if performed for appendicitis or for mesenteric lymphadenitis before the age of 20. It also influences the clinical course of UC, with a lower incidence of colectomy and reduced need for immunosuppressive therapy. By contrast, appendicectomy may increase the risk of development of CD.

**Intestinal microbiota**

The gut is colonized by 10 times more bacterial organisms than there are host cells, there being 300–400 distinct bacterial species within each host intestine. The intestinal microbiota plays a crucial role in perpetuating intestinal inflammation, in both animal models of disease and patients with IBD. The number of mucosal adherent bacteria is increased in patients with CD compared to healthy subjects, and diversion of the bacterial component of the faecal stream induces clinical remission. However, there is also evidence of an immunoregulatory role for the commensal microbiota, which protects against intestinal inflammation and upregulates epithelial defence mechanisms in animal models of colitis.

Mechanisms by which the intestinal microbiota may relate to the aetiology of IBD include:

- **Intestinal dysbiosis.** There is an alteration in the bacterial flora in patients with CD. Although results vary due to differences in both the patient groups studied and the microbiological method utilized, the most consistent finding in patients with IBD is a reduced diversity of microbial species. In addition, higher concentrations of *Bacteroides* and *E. coli*, and lower concentrations of bifidobacteria and *Faecalibacterium prausnitzii* have been reported in faecal and mucosal samples from patients with CD compared to healthy controls. Lower concentrations of *F. prausnitzii* have been found in patients with active compared with quiescent disease, and low levels of this organism in CD resection specimens predict subsequent endoscopic disease recurrence.

- **Specific pathogenic organisms.** It has been shown that there is increased *E. coli* adherence to the ileal epithelial cells in CD, with evidence of invasion into the mucosa. *E. coli’s* type 1 pili adhere to a protein called carcinoembryonic antigen-related cell adhesion molecule 6 (CEACAM6). Many authors have also suggested a link between CD and *Mycobacterium paratuberculosis* (MAP), although recent PCR-based studies have failed to confirm this and therapeutic trials of anti-*Mycobacterium tuberculosis* (MTB) therapy were not effective.

- **Bacterial antigens.** Bacteria exert their influence by the interaction of ligands such as peptidoglycan-polysaccharides (PG-PS) and lipopolysaccharides (LPS) with host pattern recognition receptors such as the Toll-like receptor family (cell surface) and the NOD family (intracellular).

- **Defective chemical barrier or intestinal defensins** (see p. 1155). Evidence suggests a decrease in human α defensin-1 (HD-1) in the mucosa of both CD and UC, and a lack of induction of HD-2, HD-3 and HD-5 in CD.
• **Impaired mucosal barrier function.** This may explain the presence of unusual and potentially pathogenic bacteria, such as MAP, *Listeria* and mucosal adherent *E. coli*. However, their presence does not necessarily imply causation of the disease, and they may reflect previous disease activity.

**Intestinal immune system**

IBD occurs when the mucosal immune system exerts an inappropriate response to luminal antigens, such as bacteria, which may enter the mucosa via a leaky epithelium (Fig. 32.37). Bacterial ligands interact with the innate and acquired mucosal immune system via Toll-like receptors expressed on both epithelial and antigen-presenting cells. Deficiencies occur in the clearance of invading bacteria by aspects of the innate immune system, such as neutrophils, which may allow inappropriate activation of the acquired immune system. In keeping with the genetic susceptibility loci identified, these findings highlight a deficiency in patients with IBD in a component of the inflammasome (an intracellular danger sensor of the innate immune system that can trigger caspase-1-dependent processing of inflammatory mediators, such as IL-1β and IL-18). In addition, individual bacterial species have distinct immunological effects mediated by dendritic cells (DCs), which sample bacteria from the intestinal lumen and direct the subsequent functional differentiation of naive T cells into effector or regulatory populations.

IBD is associated with an imbalance in the relative numbers of intestinal homing effector (Th1 and Th17) and regulatory T cell populations, which disturbs the normal tolerance to the luminal antigenic load.

The pro-inflammatory cytokines released by these activated effector T cells stimulate macrophages to secrete pro-inflammatory cytokines, such as tumour necrosis factor-alpha (TNF-α), IL-1 and IL-6 in large quantities. These mechanisms result in increased adhesion molecule expression on the intestinal vascular endothelium, which facilitates the recruitment of leukocytes from the circulation and the release of chemokines, all of which lead to tissue damage and also attract more inflammatory cells in a vicious circle.

**Pathology**

**CD** is a chronic inflammatory condition that may affect any part of the gastrointestinal tract from the mouth to the anus but has a particular tendency to affect the terminal ileum and ascending colon (ileocolonic disease) (Fig. 32.38). The disease can involve one small area of the gut, such as the terminal ileum, or multiple areas with relatively normal bowel in between (skip lesions). It may also involve the whole of the colon (total colitis), sometimes without macroscopic small bowel involvement. It is also associated with the development of perianal fistulae and fissures (Box 32.37).

![Cellular intestinal processes involved in inflammatory bowel disease.](image-url)

Fig. 32.37  Cellular intestinal processes involved in inflammatory bowel disease. Bacterial ligands attach to the epithelium and antigen-presenting cells (e.g. dendritic cells and macrophages) via Toll-like receptors and the NOD protein. The dendritic cells migrate to the Peyer’s patches and mesenteric lymph nodes. They present antigens to naive T cells, releasing a number of cytokines that cause damage. The T-cell subsets enter the blood vessels, where the enterotropic molecules α4β7 are induced and allow homing back to the gut, causing further damage. IFN-γ, interferon-gamma; IL, interleukin; TGF-β, transforming growth factor-beta; TNF-α, tumour necrosis factor-alpha. (Modified from Abraham C, Cho JH. Inflammatory bowel disease. N Engl J Med 2009; 361:2066–2078.)
Inflammatory bowel disease

**UC** can affect the rectum alone (proctitis), can extend proximally to involve the sigmoid and descending colon (left-sided colitis), or may involve the whole colon (extensive colitis) (Fig. 32.39). In a few of these patients, there is also inflammation of the distal terminal ileum (backwash ileitis).

**Macroscopic changes**

In **CD**, the involved bowel is usually thickened and is often narrowed. Deep ulcers and fissures in the mucosa produce a cobblestone appearance. Intra-abdominal fistulæ and abscesses may be seen, which reflect penetrating disease. An early feature is aphthoid ulceration in the colon, usually seen at colonoscopy (Fig. 32.40); later, larger and deeper ulcers appear in a patchy distribution, again producing a cobblestone appearance.

In **UC**, the mucosa looks reddened and inflamed, and bleeds easily ( friability). In severe disease, there may be extensive ulceration, with the adjacent mucosa appearing as post-inflammatory (pseudo-) polyps.

In fulminant colonic disease of either type, most of the mucosa is lost, leaving a few islands of oedematous mucosa (mucosal islands), and toxic dilation occurs. On healing, the mucosa can return to normal, although there is usually some residual scarring.

**Microscopic changes**

In **CD**, the inflammation extends through all layers (transmural) of the bowel, whereas in **UC** superficial inflammation limited to the mucosa is seen. In CD, there is an increase in chronic inflammatory cells and lymphoid hyperplasia, and in 50–60% of patients, granulomas are present. These granulomas are non-caseating epithelioid cell aggregates with Langhans’ giant cells.

In **UC**, the mucosa shows a chronic inflammatory cell infiltrate in the lamina propria. Crypt abscesses and goblet cell depletion are also seen.

These two diseases can usually be differentiated not only on the basis of clinical and radiological data but also on the histological differences seen in the rectal and colonic mucosa obtained by biopsy (Box 32.38).

It is occasionally not possible to distinguish between the two disorders, particularly if biopsies are obtained in the acute phase, and such patients are considered to have indeterminate colitis.

**Fig. 32.38 Sites of Crohn’s disease.**

**Fig. 32.39 Sites of ulcerative colitis (Montreal classification).**

(A) Extensive colitis (E3): pancolitis, total colitis: entire colon and rectum inflamed. (B) Distal colitis (E2): left-sided colitis: rectum, sigmoid and descending colon inflamed. (C) Proctitis (E1): rectum only inflamed.

**Fig. 32.40 Crohn’s disease: colonoscopic appearances.**

(A) Aphthoid ulcers typical of Crohn’s disease. (B) Deep, serpiginous ulceration in colonic Crohn’s disease.
Extraintestinal manifestations
These occur with both diseases (Box 32.39). Joint complications are most common; the peripheral arthropathies are classified as:

- **Type 1 (pauciarticular)** attacks are acute and self-limiting (<10 weeks), and occur with IBD relapses; they are associated with other extraintestinal manifestations of IBD activity.

- **Type 2 (polyarticular)** arthropathy lasts longer (months to years), independent of IBD activity and usually associated with uveitis.

Joint and other extragastrointestinal manifestations of IBD are shown in Box 32.39. There is an association of HLA DRB1*0103 with pauciarticular large-joint arthritis in UC and CD, and HLA-B44 with small-joint symmetrical arthritis. HLA-B27 is associated with sacroiliitis.

**Differential diagnosis**
Alternative causes of diarrhoea should be excluded (see Box 32.35) and stool cultures (including *Clostridium difficile* toxin assay) must always be performed. However, symptoms persisting beyond 5 days are unlikely to be caused by infective gastroenteritis. Stool microscopy for parasitic diseases such as amoebiasis should be carried out in patients with a relevant travel history. CD should be considered in all individuals with evidence of vitamin malabsorption (e.g. megaloblastic anaemia) or malnourishment, as well as in children with reduced growth velocity. Ileocolonic tuberculosis (p. 1195) is common in developing countries, such as India, which makes a diagnosis of CD difficult. Microscopy and culture for TB of any available tissue is essential in these countries. A therapeutic trial of anti-TB therapy may be required. Lymphomas can occasionally involve the ileum and caecum, although they are rare in the patient population at risk from IBD.

**Crohn’s disease**
**Clinical features**
The major symptoms are diarrhoea, abdominal pain and weight loss. Constitutional symptoms of malaise, lethargy, anorexia, nausea, vomiting and low-grade fever may be present and in 15% of these patients there are no gastrointestinal symptoms. Reduced growth velocity and delayed puberty may be the main presenting features in children. Despite the recurrent nature of this condition, some patients have an almost normal lifestyle. However, patients with extensive disease have frequent recurrences and progress from inflammatory to stricturing and penetrating disease. Approximately 50% of patients will require an intestinal resection within 5 years of diagnosis.

Clinical features are very variable and depend partly on the region of the bowel that is affected. The disease may present insidiously or acutely. Abdominal pain can be colicky, suggesting obstruction, but it usually has no special characteristics and sometimes in colonic disease only minimal discomfort is present. Diarrhoea occurs in 80% of all cases and in colonic disease it usually contains blood, making it difficult to differentiate from UC. Steatorrhoea may be present in small bowel disease. Diarrhoea can also be due to bile acid malabsorption, occurring as a consequence of ileal resection or ileal disease.

CD can also present as an emergency with acute right iliac fossa pain mimicking appendicitis. If laparotomy is undertaken, an oedematous, reddened terminal ileum is found. Other causes of an acute ileitis include infections such as *Yersinia* and TB.

CD is complicated by anal and perianal disease, and this is the presenting feature in 25% of cases, often preceding colonic and small intestinal symptoms (see Box 32.37). Enteric fistulae – for example, to bladder, vagina or abdominal wall – occur in 20–40% of cases.

**Examination**
Physical signs are few, apart from loss of weight and signs of malnutrition. Aphthous ulceration of the mouth is often seen. Abdominal examination may be normal, although tenderness and/or a right iliac fossa mass are occasionally found. The mass is due either to inflamed loops of bowel that are matted together or to an abscess, which may also cause psosas muscle irritation. The anus should always be examined to look for oedematous anal tags, fissures or perianal abscesses.

The presence of extraintestinal features of IBD should be assessed (see Box 32.39).

**Investigations**
**Blood tests**
- **Anaemia** is common and may be the normocytic, normochromic anaemia of chronic disease. However, deficiency of iron and/or folate also occurs. Despite terminal ileal involvement in CD, megaloblastic anaemia due to vitamin B12 deficiency is unusual, although serum B12 levels can be below the normal range.
- **Raised erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP)** are found, as are raised white cell and platelet counts.
- **Hypoalbuminaemia** is present in severe disease as part of an acute phase response to inflammation associated with a raised CRP.
- **Liver biochemistry** may be abnormal.
- **Blood cultures** are required if septicaemia is suspected.
- **Serological tests** may reveal negative perinuclear ANCA (pANCA) and positive ASCA (see p. 1201).

**Stool tests**
Stool cultures, including *C. difficile* toxin assay, should always be performed if diarrhoea is present. Microscopy for parasites is essential in patients with a relevant travel history. Faecal calprotectin and
lactoferrin are raised in active intestinal disease. Faecal calprotectin is useful for disease monitoring in IBD.

**Endoscopy and radiological imaging**

- **Colonoscopy** is performed if colonic involvement is suspected, except in patients presenting with severe disease (in whom a limited unprepared sigmoidoscopy should be carried out). The findings vary from mild, patchy, superficial (aphthoid) ulceration to more widespread, larger and deeper ulcers that produce a cobblestone appearance (see Fig. 32.40). Endoscopic assessment of the terminal ileum is essential in all patients with suspected CD. Two biopsies should be performed in five areas, including the rectum and terminal ileum.

- **Upper gastrointestinal endoscopy** is required to exclude oesophageal and gastroduodenal disease in patients with relevant symptoms and is increasingly being performed in all patients at diagnosis to define the extent of disease accurately as a guide to prognosis.

- **Small bowel imaging** is mandatory in patients with suspected CD. The technique used will depend on availability and local expertise. Techniques include barium follow-through, CT scan with oral contrast, small bowel ultrasound or MRI enteroclysis. An asymmetrical alteration in the mucosal pattern with deep ulceration, and areas of narrowing or structuring may be found. Although disease is commonly confined to the terminal ileum (Fig. 32.41), other areas of the small bowel can be involved, and skip lesions with normal bowel are seen between affected sites. Axial imaging allows the diagnosis of extraintestinal sepsis in patients presenting acutely and is therefore preferred in this situation.

- **Ultrasound scanning** provides a convenient radiation-free method for assessing disease activity in the ileum and colon and can be performed by appropriately trained gastroenterologists at the bedside.

- **Perianal MRI or endoanal ultrasound** is used to evaluate perianal disease.

- **Capsule endoscopy** is used in CD patients when radiological examination is normal. A patency capsule assessment is often performed first to exclude strictures of the small bowel that would constitute a contraindication to subsequent capsule endoscopy.

- **Radionuclide scans** with indium- or technetium-labelled leukocytes are used in some centres to identify small intestinal and colonic disease inflammation and to localize extraintestinal abscesses.

**Disease activity**

This can be assessed using simple parameters such as haemoglobin, white cell count, inflammatory markers (raised ESR, CRP and platelet count) and serum albumin. Formal clinical activity indices (e.g. CD Activity Index or Harvey Bradshaw Index) are used in research studies. Faecal calprotectin or lactoferrin has the potential to be a simple, cheap, non-invasive marker of disease activity in IBD and these tests are of value in predicting response to and failure of treatment.

**Medical management of Crohn's disease**

See Box 32.40.

**General considerations**

The aims of management are to induce and then maintain clinical remission and to achieve mucosal healing in order to prevent disease progression and complications. Alternative causes for symptoms, such as gastroenteritis, extraintestinal sepsis, stricture formation, functional gastrointestinal disease or bile salt malabsorption, must be excluded before commencing immunosuppressive therapy. Patients with mild symptoms and no evidence of extensive disease may require symptomatic treatment only. Cigarette smoking should be stopped. Anaemia, if due to vitamin B12, folic acid or iron deficiency, should be treated with the appropriate replacement. Patients who are intolerant of oral iron should receive an intravenous iron infusion. Most patients can be treated as outpatients, although severe attacks may require admission, and prophylaxis for thromboembolism (see p. 1013) should be given to all inpatients.

**Induction of remission**

**Glucocorticosteroids**

These are commonly used to induce remission in moderate and severe attacks of CD (oral prednisolone 30–60mg/day). Mild to moderate ileocaecal disease should be treated with controlled-release corticosteroids, such as budesonide, which has reduced systemic availability and is associated with a lower frequency and intensity of steroidal side-effects.

Overall remission/response rates vary from 60% to 90%, depending on type, site and extent of disease. Steroids should be avoided in patients with penetrating intestinal disease or perianal sepsis.

**Aminosalicylates**

These have been used but there is little evidence to support their efficacy in CD.

**Antibiotics**

Antibiotics (ciprofloxacin and metronidazole) are used for treating secondary complications of CD (e.g. abscess and perianal disease).

**Exclusive enteral nutrition**

This is the traditional treatment for moderate to severe attacks of CD in paediatric practice, but is under-utilized in adults due to issues with compliance to the diet. If administered as the sole source of nutrition for 28 days, rates of induction of remission are similar to those obtained with steroids. Relapse rates are high, however, particularly in those with colonic involvement.

**Refractory or fulminant disease**

Patients with symptoms that do not respond to conventional therapy should be re-assessed to exclude an alternative diagnosis such as a stricture or penetrating abscess. In patients with disease limited to the terminal ileum, surgical resection may be appropriate. In those with more extensive disease, remission should be induced with an anti-TNF agent, either as monotherapy or preferably in combination with an immunosuppressant such as azathioprine (see below).

**Maintenance of remission**

All patients require regular monitoring to exclude persistent intestinal inflammation. Patients with disease that has a good prognosis (older age at diagnosis, no perianal disease, limited ulceration at index investigations, non-smoker) may not require maintenance therapy. Patients with disease that has a poor prognosis (young age at diagnosis, extensive small bowel disease, deep colonic ulceration, perianal/rectal disease, smoker) or that flares up after induction therapy is withdrawn require long-term maintenance immunosuppression. The goal of maintenance therapy is to prevent
disease progression, as well as to reduce the need for corticosteroids, which are associated with a high burden of side-effects. Therapies that induce mucosal healing result in better outcomes. All maintenance therapies require careful monitoring to ensure optimal disease control and prevent side-effects. If there is ongoing evidence of disease activity, adherence should be confirmed and dose optimization or therapy escalation undertaken.

Conventional maintenance therapies
These include azathioprine (AZA; 2.5 mg/kg per day), mercaptopurine (MP; 1.5 mg/kg per day) and methotrexate (25 mg once a

**Fig. 32.41** Imaging of the small bowel in Crohn’s disease. (A) Barium follow-through showing an ulcerated stricture (arrowed), pre-stenotic dilation and separation of the small bowel loops due to fibro-fatty proliferation. Small bowel follow-through has generally been superseded by small bowel MRI. (B) Capsule endoscopy picture of an ileal ulcer in a patient with Crohn’s disease (arrowed). (C) Post-contrast T1 fat-suppressed coronal image from an MRI enterography examination demonstrates bowel wall thickening of the terminal ileum and mucosal hyperenhancement consistent with active inflammation (arrow). There is also fibrofatty proliferation (*) adjacent to the inflamed bowel consistent with chronic disease and, therefore, the overall appearances represent chronic active Crohn’s disease. (D) Capsule endoscopy showing an ileal Crohn’s disease stricture (arrowed).
week until remission, then reduced to 15 mg per week) (see Box 32.40). Long-term treatment with these drugs is necessary, as the rate of relapse on discontinuation is high. Patient education regarding side-effects and appropriate monitoring for complications is essential and may increase adherence. The key enzyme involved in AZA and MP metabolism is thiopurine methyl transferase (TPMT). This enzyme has a significant genetic variation and deficiencies can result in high circulating levels of thioguanine nucleotides with an increased risk of bone marrow depression. Assays of TPMT activity are available and should be performed before treatment. TPMT deficiency is not the only cause of bone marrow depression so 3-monthly blood counts should be performed on all patients. Metabolite measurement can be undertaken to assess adherence and ensure optimal dosing.

Anti-TNF agents

These have clear evidence of benefit in the induction and maintenance of remission in patients with CD. They are indicated in patients with disease refractory to conventional immunosuppressive therapy. Early use of anti-TNF therapy is indicated in selected patients with disease that has a poor prognosis (see above). They are also used to treat complex perianal/rectal disease once sepsis has been drained. Available anti-TNF agents include infliximab (a chimeric anti-TNF-α IgG1 monoclonal antibody), adalimumab (a fully humanized anti-TNF IgG1 monoclonal antibody) and certolizumab pegol (a PEgylated Fab’ fragment of a humanized anti-TNF antibody). They neutralize soluble TNF-α, bind to membrane-bound TNF-α and induce immune cell apoptosis, although the exact mechanism of action is not defined. In clinical trials, they have been shown to exert a steroid-sparing effect and bring about complete mucosal healing in up to one-third of patients in the long term. This results in a reduced need for hospital admission and surgery. These agents should always be used on a regular basis as maintenance therapy, as they are less effective and induce anti-drug antibodies if used episodically. In patients who are naive to azathioprine, combination therapy increases efficacy and reduces immunogenicity. Their use should be limited to clinicians experienced in the management of CD, as they are associated with significant complications, including opportunistic infections (such as TB), demyelination and malignancy.

Novel biological therapies

Novel therapies for the treatment of CD include the anti-α4β7 integrin therapy, vedolizumab, which acts to reduce leucocyte recruitment to the inflamed intestine. This is used in patients with moderately to severely active Crohn’s disease who are intolerant to an anti-TNF or in whom it is contraindicated, or in those patients who have had an inadequate response or lost response to an anti-TNF-α agent. Therapies that target the IL-12/IL-23 pathway, such as ustekinumab, are currently used to treat moderate to severely active Crohn’s disease, in those patients who cannot have, or have had an inadequate response to, an anti-TNF-α agent. Risankizumab is a human monoclonal antibody that targets the p19 subunit of interleukin-23, currently in phase 3 trials for patients with moderately to severely active Crohn’s disease. Recent preliminary studies using the oral anti-sense oligonucleotide, morgersen, have shown promise for the treatment of active Crohn’s disease. This agent binds to, and causes degradation of, SMAD7 messenger RNA, thereby restoring TGF-β1 signalling and decreasing the production of pro-inflammatory markers. Phase 3 studies are underway. Ozanimod is an oral agonist of the sphingosine-1-phosphate receptor subtypes 1 and 5 that decreases circulating activated lymphocytes, currently in phase 3 trials for the treatment of moderately to severe Crohn’s disease.

Advances in mucosal immunology have highlighted a variety of targets to resolve the inflammation and symptoms of the disease. Numerous investigational therapies concentrate on inhibiting, suppressing or altering T-cell differentiation.

Surgical management of Crohn’s disease

Studies prior to the introduction of biological agents suggest that up to 80% of patients will require an operation at some time during the course of their disease. Nevertheless, surgery should be avoided if possible and only minimal resections undertaken, as recurrence (15% per year) is almost inevitable without prophylactic maintenance therapy. The indications for surgery are:

- failure of medical therapy, with acute or chronic symptoms producing ill-health
- complications (e.g. toxic dilation, obstruction, perforation, abscesses, enterocutaneous fistula)
- failure to grow in children despite medical treatment
- presence of perianal sepsis; an examination is performed under anaesthetic, the sepsis is drained, and a seton is inserted to ensure ongoing drainage.

In patients with small bowel disease some strictures can be widened (stricturoplasty), whereas others require resection and anastomosis. It is essential to consider postoperative maintenance therapy in patients undergoing ileocolonic resection and anastomosis. All patients should refrain from smoking. There is some evidence that a 3-month course of metronidazole reduces relapse rates. Patients with a high risk of relapse (previous surgery, smoker, penetrating disease at the time of index surgery) should be evaluated for maintenance immunosuppressive therapy. Patients should undergo an ileocolonoscopy to assess the anastomosis for disease recurrence 6 months after surgery, when further therapy can be agreed with the patient.

When colonic CD involves the entire colon and the rectum is spared or minimally involved, a subtotal colectomy and ileorectal anastomosis may be performed. An eventual recurrence rate of 60–70% in the ileum, rectum or both is to be expected; however, two-thirds of these patients retain a functional rectum for 10 years. If the whole colon and rectum are involved, a panproctocolectomy with an end ileostomy is the standard operation. CD patients are not suitable for a pouch operation (see p. 1207), as recurrence in the pouch is high.

Problems associated with ileostomies include:

- mechanical problems
- dehydration, particularly if there is a short length of small bowel remaining
- psychological problems
- erectile dysfunction in men and reduced fecundity in women (due to prior pelvic surgery)
- recurrence of CD.

Prognosis

The majority of patients have inflammatory disease at diagnosis, although up to 20% will present with complicated disease, including strictures and penetrating disease. If disease is left untreated, its natural history is progression from inflammatory to stricturing and penetrating disease that may require surgery. Up to 50% of patients will require a surgical resection within the first 5 years of disease. The goal of therapy is to target early aggressive therapy at those patients with a poor prognosis. However, predicting disease prognosis at diagnosis is not easy. Features that imply a poor prognosis...
Ulcerative colitis
Clinical features
The major symptom in UC is diarrhoea with blood and mucus, sometimes accompanied by lower abdominal discomfort. General features include malaise, lethargy and anorexia with weight loss, although these features are not as severe as with CD. Aphthous ulceration in the mouth may be seen. The disease can be mild, moderate or severe (Box 32.41), and in most patients runs a course of remissions and exacerbations. Disease extent is defined as limited to the rectum (proctitis), left-sided or extensive (see Fig. 32.39).

Proctitis is characterized by the frequent passage of blood and mucus, urgency and tenesmus. There are normally few constitutional symptoms and the stool, when passed, may be solid. Patients are nevertheless greatly inconvenienced by the frequency of defecation.

In an acute attack of left-sided or extensive UC, patients have bloody diarrhoea, passing up to 10–20 liquid stools per day. Diarrhoea also occurs at night, with urgency and incontinence that is severely disabling for the patient. Patients with an acute severe flare of colitis (see Box 32.40) require urgent admission for intensive therapy.

Toxic megacolon is a serious complication associated with acute severe colitis. The plain abdominal X-ray shows a dilated, thin-walled colon with a diameter of more than 6 cm; it is gas-filled and contains mucosal islands (Fig. 32.42). It is a particularly dangerous stage of advanced disease, with impending perforation and a high mortality (15–25%). Urgent surgery is required in all patients in whom toxic dilation has not resolved within 48 hours, with intensive therapy as above. The differential diagnosis includes an infectious colitis, e.g. with C. difficile and cytomegalovirus.

Examination
In general, there are no specific signs in UC. The abdomen may be slightly distended or tender to palpation. Tachycardia and pyrexia are signs of severe colitis and mandate admission. The anus is usually normal. Rectal examination will reveal the presence of blood. Sigmoidoscopy is usually abnormal, showing an inflamed, bleeding, friable mucosa. Very occasionally, rectal sparing occurs, with normal proctoscopy.

Investigations

Blood tests
• **White cell and platelet counts** are commonly raised in moderate to severe attacks, and iron deficiency anaemia is present.
• **ESR and CRP** are often raised; liver biochemistry may be abnormal, with hypoalbuminaemia occurring in severe disease.
• **pANCA** may be positive. This is contrary to CD, where pANCA is usually negative (see p. 1202).

Stool tests and *C. difficile* toxin
These should always be performed to exclude infective causes of colitis. Stool microscopy to exclude amoebiasis is mandated in patients with a relevant travel history. Faecal calprotectin/lactoferrin will be elevated.

Colonoscopy
Endoscopy with mucosal biopsy is the ‘gold standard’ investigation for the diagnosis of UC. Colonoscopy also allows assessment of disease activity and extent. In patients with long-term colitis, chromoendoscopy is used to diagnose dysplasia. Full colonoscopy should not be performed in severe attacks of disease for fear of perforation; instead, a limited unprepared flexible sigmoidoscopy should be used to confirm diagnosis.

Imaging
A plain abdominal X-ray is essential in patients suffering acute severe attacks to exclude colonic dilation. However, the extent of disease is not reliably assessed using this investigation. Other imaging modalities are rarely used in the assessment of patients with UC, as endoscopy is preferred. However, inflammation of the colonic wall is detected on ultrasound, as is the presence of free fluid within the abdominal cavity.

Medical management of ulcerative colitis
Wherever possible, patients with IBD should be managed in patient-focused IBD clinics with access to a full multidisciplinary team. The mainstay of treatment for mild and moderate disease of any extent is an aminosalicylate, which acts topically in the colonic lumen. The
active moiety of these drugs is 5-aminosalicylic acid (5-ASA), which is absorbed in the small intestine. Therefore, the various aminosalicylate preparations are designed to deliver the active 5-ASA to the colon. This is achieved by binding of 5-ASA with an azo bond to sulfapyridine (sulfasalazine), 4-aminobenzoyl-D-alanine (balsalazide) or to 5-ASA itself (oolsalazine), coating with a pH-sensitive polymer, packaging of 5-ASA in microspheres, or a combination of these. The azo bonds are broken down by colonic bacteria to release 5-ASA within the colon.

The mode of action of 5-ASA in IBD is unknown, although it may involve the intracellular peroxisome proliferator-activated receptor (PPAR)-γ signalling pathway. The aminosalicylates have been shown to be effective in inducing remission in mild to moderately active disease, and maintaining remission in all forms of disease. There is also evidence that they are chemopreventive for UC-associated colorectal cancer. 5-ASA can rarely cause renal disease.

Proctitis
Rectal 5-ASA suppositories are the first-line treatment. Topical steroids are less effective than 5-ASA preparations. Oral 5-ASA can be added to increase remission rates. Some cases of proctitis do not respond to 5-ASA treatment and require oral prednisolone.

Left-sided colitis
Topical 5-ASA enemas are the first-line treatment. The addition of an oral 5-ASA will increase remission rates. Patients who do not respond to this or have worsening symptoms require oral prednisolone.

Extensive colitis
Patients with mild to moderate symptoms can be treated with an oral 5-ASA at an adequate dose. The additional of a 5-ASA enema increases remission rates. Patients who do not respond to this or have worsening symptoms require oral prednisolone.

Refractory/severe colitis of any extent
Patients with colitis that is refractory to standard conventional therapies should be investigated to ensure adherence to therapy, confirm active colitis and exclude infection, including biopsies to exclude reactivation of CMV colitis. They should then receive biological therapy with either an anti-TNF agent (infliximab, adalimumab or golimumab) or an anti-integrin therapy (vedolizumab), or tocilizab, an oral inhibitor of Janus kinase 1-3, which became available in 2018 for the treatment of adults with moderately to severely active UC.

Patients with severe colitis (see Box 32.41) and those who do not respond to oral prednisolone should be admitted to hospital and treated initially with hydrocortisone 100 mg i.v. 6-hourly, with s.c. low-molecular-weight heparin to prevent thromboembolism. Investigations to confirm the diagnosis and exclude enteric infection (see above) should be performed and full supportive therapy administered (intravenous fluids, and nutritional support via the enteral route if required). The incidence of concomitant C. difficile infection in patients admitted for severe colitis is increasing. This is associated with a significant increase in morbidity and must be excluded. The clinical status of patients should be monitored daily (fever, tachycardia, stool frequency), and daily FBC, CRP, and urea and electrolytes should be performed. Repeat abdominal X-rays are required if patients are not improving. Success or failure of medical treatment of a severe attack of UC must be judged by an experienced gastroenterologist and colorectal surgeon. If patients have not responded to intravenous steroids within 3 days, either salvage medical therapy or surgery is required. If patients respond to intravenous steroids, they should be switched to oral prednisolone after approximately 5 days, which they can be weaned off over 8–10 weeks. All patients who have been admitted for severe colitis should commence long-term maintenance therapy with a thiopurine (azathioprine/mercaptourine).

Salvage therapy
Salvage therapy to avoid colectomy is required for patients with a CRP higher than 45 mg/L or more than eight bowel motions after 3 days of intravenous hydrocortisone. Continuing steroid therapy alone in this situation will delay the inevitable colectomy and increase mortality. Salvage medical therapies with clear evidence of benefit in controlled clinical trials are intravenous cyclosporin 2 mg/kg per day as a continuous infusion or infliximab induction and maintenance therapy. Patients with extensive ulceration may require higher doses of induction infliximab. Patients with a low albumin level have been shown to have a lower response rate to salvage therapy. These agents should only be used by experienced gastroenterologists who are part of a multidisciplinary team with colorectal surgeons. Patients should be weaned off steroids rapidly, once salvage therapy has commenced, to reduce morbidity. Those who respond should be treated with oral ciclosporin or further infliximab infusions, as appropriate, while maintenance thiopurine therapy is commenced.

Novel therapies
Alicaforsen is an inhibitor of intracellular adhesion molecule-1. Alicaforsen enemas have demonstrated efficacy in the treatment of distal ulcerative colitis as well as pouchitis in clinical trials. An autologous stem cell transplantation trial in refractory Crohn’s disease – low intensity therapy evaluation (ASTIClite) is currently underway. It is looking to assess whether stem cell transplantation, with a low intensity treatment regimen, can reduce the symptoms and activity of Crohn’s disease and enhance quality of life, compared to current standard care. The trial will also assess the safety of the procedure, explore the mechanisms involved in immune reconstitution and whether patients who do experience recurrent disease after the stem cell transplant will respond to treatments that had not worked previously. Finally, the trial aims to assess the long-term safety and efficacy in patients undergoing stem cell transplantation over a minimum of a further 4 years.

Surgical management of ulcerative colitis
While the treatment of UC remains primarily medical, surgery continues to have a central role because it may be life-saving, is curative and eliminates the long-term risk of cancer. The main indications for surgery are severe colitis that fails to respond to medical therapy, and chronic active therapy-refractory disease. Other indications are listed in Box 32.42. In expert centres, laparoscopic surgery is often used to improve postoperative pain, recovery time and cosmesis.

In acute disease, subtotal colectomy with ileostomy and preservation of the rectum is the operation of choice. At a later date, a number of surgical options are available and are best carried out in a specialist colorectal centre. These include proctectomy with a permanent ileostomy; to avoid a permanent ileostomy, an ileo-anal pouch procedure can be performed (Fig. 32.43). The ileo-anal pouch is anastomosed to the anus at the dentate line following excision of the remaining rectum. One-third of patients, however, will experience ‘pouchitis’, inflammation of the pouch mucosa with clinical symptoms of diarrhoea, bleeding, fever and, at times, exacerbation of extracolonic manifestations (Fig. 32.44). The incidence of pouchitis is twice as high in patients with primary sclerosing cholangitis and is also raised in patients with a positive ANCA and backwash ileitis prior to colectomy. Two-thirds of pouchitis cases will recur as either acute relapsing or chronic unremitting forms. The mainstay of treatment is antibiotics (metronidazole with or without ciprofloxacin). Treatment is not always satisfactory and steroids may be required. The probiotic VSL#3 has been shown to be effective in preventing the onset of pouchitis and in maintaining remission in patients with antibiotic-treated pouchitis to induce mucosal healing.

Course and prognosis

One-third of patients with distal inflammatory proctitis due to UC will develop more proximal disease, with 5–10% developing total colitis. One-third of patients with UC will have a single attack and the others will follow a relapsing course. One-third of patients with UC will undergo colectomy within 20 years of diagnosis.

Cancer in inflammatory bowel disease

Patients with UC and extensive Crohn’s colitis have an increased incidence of developing dysplasia and subsequent colon cancer. The risk of dysplasia is related to the extent and duration of disease, as well as the presence of untreated mucosal inflammation. A family history of colorectal cancer and the presence of primary sclerosing cholangitis also increase the risk. Appropriate colonoscopic screening strategies according to guidelines are used by many, although evidence for overall benefit is still uncertain. A 40-year analysis of colonoscopy surveillance for neoplasia in UC, conducted at St Mark’s Hospital in the UK, suggested that surveillance may have a significant role in reducing the risk of advanced and interval colorectal cancer.

Mortality in inflammatory bowel disease

Population-based studies demonstrate that mortality in UC is similar to that in the general population. The two exceptions are patients with severe colitis, who have a slightly higher mortality in the first year after diagnosis, and patients aged over 60 at the time of diagnosis. Although it is currently unclear whether there is a slightly higher overall mortality in patients with CD, those with extensive jejunal and ileal disease and those with gastric and duodenal disease have been shown to have a relatively higher mortality.

Microscopic colitis

Patients with this group of disorders present with chronic or fluctuating watery diarrhoea. Although the macroscopic features on colonoscopy are normal, the histopathological findings on biopsy are abnormal. There are three distinct forms of microscopic inflammatory colitis:

- **Microscopic UC.** There is a chronic inflammatory cell infiltrate in the lamina propria, with deformed crypt architecture and goblet cell depletion, with or without crypt abscesses. Treatment is as for UC; many patients respond to treatment with aminosalicylates alone.

  - **Microscopic lymphocytic colitis.** There is surface epithelial injury, prominent lymphocytic infiltration in the surface epithelium and increased lamina propria mononuclear cells.

  - **Microscopic collagenous colitis.** There is a thickened subepithelial collagen layer (>10 μm) adjacent to the basal membrane, and increased infiltration of the lamina propria with lymphocytes and plasma cells, and surface epithelial cell damage. It is
predominantly a disorder of middle-aged or elderly females, and is associated with a variety of autoimmune disorders (arthritis, thyroid disease, limited cutaneous scleroderma and primary biliary cirrhosis).

The incidence of both microscopic lymphocytic and collagenous colitis is increased in patients with coeliac disease and this must be excluded. Treatment of microscopic and collagenous colitis is usually with budesonide. There is also evidence of benefit for amoxicillin, bismuth-containing preparations and, if refractory, prednisolone and azathioprine. A small number of patients with microscopic lymphocytic and collagenous colitis have coexisting bile acid malabsorption and can thus respond to cholestyramine. Prognosis is good.

Further reading

Constipation

‘Constipation’ is a very common symptom, particularly in women and the elderly. A consensus definition used in research (the Rome IV criteria) defines constipation as having two or more of the following for at least 3 months:

- infrequent passage of stools (<3/week),
- straining >25% of time,
- passage of hard stools (Bristol stool chart form 1-2) in >25% defecations
- incomplete evacuation and sensation of anorectal blockage in >25% defecations
- manual manoeuvres to facilitate >25% defecations (digital evacuation, support of the pelvic floor).

Other symptoms include abdominal bloating and/or discomfort (undistinguishable from the irritable bowel syndrome), as well as local and perianal pain. The causes of constipation are shown in Box 32.43.

Diagnosis

This relies on the history. When there has been a recent change in bowel habit in association with other significant symptoms (e.g. rectal bleeding), a colonoscopy or CT of the pneumocolon is indicated. By these means, gastrointestinal causes, such as colorectal cancer and narrowed segments due to diverticular disease, can be excluded.

Constipation can be classified into three broad categories but there is much overlap:

- normal transit through the colon (59%)
- defecatory disorders (25%)
- slow transit (13%).

Defecatory disorders with slow transit can occur together (3%).

Normal-transit constipation

In normal-transit constipation, stool traverses the colon at a normal rate, the stool frequency is normal and yet patients believe they are constipated. This is likely to be due to perceived difficulties of evacuation or the passage of hard stools. Patients may complain of abdominal pain or bloating. Normal-transit constipation can be distinguished from slow-transit constipation by undertaking marker studies of colonic transit. Capsules containing 20 radio-opaque shapes are swallowed on days 1, 2 and 3 and an abdominal X-ray obtained 120 hours after ingestion of the first capsule. Each capsule contains shapes of different configuration and the presence of more than 4 shapes from the first capsule, 6 from the second and 12 from the third denotes moderate to severe slow transit (Fig. 32.45).

Defecatory disorders

A ‘paradoxical’ contraction, rather than the normal relaxation of puborectalis and the external anal sphincter and associated muscles during straining, may prevent evacuation (pelvic floor dyssynergia, anismus). These are mainly due to dysfunction of the anal sphincter and pelvic floor. An anterior rectocele is a common problem where there is a weakness of the rectovaginal septum, resulting in protuberance of the anterior wall of the rectum with trapping of stool if the diameter is more than 3 cm. In some patients, the mucosa of the anterior rectal wall prolapses downwards during straining (see p. 1214), impeding the passage of stool, while in others there may be a higher mucosal intussusception.

In some patients, the rectum can become unduly sensitive to the presence of small volumes of stool, resulting in the urge to pass frequent amounts of small-volume stool and the sensation of incomplete evacuation.

The defecatory disorders can often be characterized by performing evacuation proctography and tests of anorectal physiology.

</table>
Slow-transit constipation occurs predominantly in young women who have infrequent bowel movements (usually less than once a week). The condition often starts at puberty and the symptoms include an infrequent urge to defecate, bloating, abdominal pain and discomfort. Some patients with severe slow-transit constipation have delayed emptying of the proximal colon and others a failure of ‘meal-stimulated’ colonic motility. Histopathological abnormalities have been demonstrated in the colons of some patients with severe slow-transit constipation, and some patients have coexisting disorders of small intestinal motility, consistent with a diagnosis of chronic idiopathic intestinal pseudo-obstruction (see p. 1223).

Management
Any underlying cause should be treated. In patients with normal and slow-transit constipation, the main focus should be directed towards increasing the fibre content of the diet in conjunction with increasing fluid intake.

The use of laxatives should be restricted to cases where symptoms impact on the patient’s quality of life. The types of laxatives available are listed in Box 32.44. Osmotic laxatives act by increasing the colonic inflow of fluid and electrolytes; this acts not only to soften the stool but also to stimulate colonic contractility. The polyethylene glycols (macrogols) have the advantage over the synthetic disaccharide lactulose in that they are not fermented anaerobically in the colon to gas that can distend the colon and cause pain. The osmotic laxatives are preferred to the stimulatory laxatives, which act by stimulating colonic contractility and by causing intestinal secretion. Prucalopride is a high-affinity 5-HT4 agonist that increases colonic transit and is an effective therapy for refractory constipation.

Linaclotide, a minimally absorbed peptide agonist of guanylate cyclase-C receptor, works by activating the cystic fibrosis transmembrane conductance regulator to stimulate chloride secretion and increase gastrointestinal fluid secretion. Significant benefit over placebo has been shown in clinical trials. Lubiprostone is an orally active agonist for type 2 chloride channels and therefore also increases gastrointestinal fluid secretion.

Patients with defecatory disorders should be referred to a specialist centre, as surgery may be indicated: for example, for anterior rectocele or internal anal mucosal intussusception. Anterior mucosal prolapse can be treated by injection, and those with pelvic floor dyssynergia (anismus) can benefit from biofeedback therapy.

Miscellaneous colonic conditions

Clostridium difficile-associated diarrhoea and pseudomembranous colitis

Clostridium difficile infection (CDI) is a common hospital-acquired infection and can be a significant cause of morbidity, especially amongst the elderly. It frequently occurs following antibiotic therapy due to disruption of the normal gut flora. The following antibiotics are particularly associated with CDI:

- fluoroquinolones
- clindamycin
- cephalosporins
- penicillins
- (macrolides and co-trimoxazole are less frequently associated).

Clinical features include profuse diarrhoea, which can lead to hypovolaemia and shock if severe. The white blood cell count is often significantly elevated and endoscopically there may be pseudomembranous colitis (severe inflammation of the bowel wall lining). Complications include ileus, toxic megacolon and bowel...
perforation. If megacolon or perforation is suspected then patients should have urgent imaging (X-ray or CT).

Diagnosis is made with a positive test for C. difficile toxin A and B. A positive test for glutamate dehydrogenase (GDH) antigen is not necessarily indicative of active infection, simply that the patient is a carrier of the pathogen.

**Treatment**

Initial treatment regimens are covered on page 1186. For recurrent or refractory CDI, antibiotics such as rifaximin or fidaxomicin can be useful. However, recently faecal microbiota transplantation (FMT) has become increasingly common. For this procedure, a solution of donor stool is given to the patient either through a nasogastric tube or via flexible sigmoidoscopy. The donor stool has been carefully selected from a centralized stool bank where all donors have had their blood and stool extensively screened for infection.

**Megacolon**

The term ‘megacolon’ is used to describe a number of congenital and acquired conditions in which the colon is dilated. In many instances, it is secondary to chronic constipation; in some parts of the world, Chagas’ disease is a common cause.

In all young patients with megacolon, Hirschsprung’s disease should be excluded. In this condition, which presents in the first years of life, an aganglionic segment of the rectum (megarectum) gives rise to constipation and subacute obstruction. Occasionally, Hirschsprung’s disease affecting only a short segment of the rectum can be missed in childhood. A preliminary rectal biopsy is performed and stained for ganglion cells in the submucosal plexus. In doubtful cases, a full-thickness biopsy should be obtained. A frozen section is stained for acetylcholinesterase, which is elevated in Hirschsprung’s disease. Manometric studies show failure of relaxation of the internal sphincter, which is diagnostic of Hirschsprung’s disease. This condition can be successfully treated surgically.

Treatment of other causes of a megacolon is similar to that of slow-transit constipation, but saline washouts and manual removal of faeces are sometimes required.

**Faecal incontinence**

Of the healthy population over the age of 65, 7% experience a degree of incontinence. Incontinence is classified as minor (inability to control flatus or liquid stool, causing soiling) or major (frequent and inadvertent evacuation of stool of normal consistency); see Box 32.45 for common causes. Obstetric injury is a common cause and sphincter defects have been found in up to 30% of primiparous women. Endoanal ultrasonography or pelvic MRI is the investigation of choice in the assessment of anal sphincter damage (Fig. 32.46). Neurophysiological investigation of pudendal nerve function, anal sensation and anal sphincter function may be required to elicit the cause of the problem.

Initial management of minor incontinence is bowel habit regulation. Loperamide is the most potent antidiarrhoeal agent, which also increases internal sphincter tone.

Biofeedback is effective in some people with faecal incontinence associated with impaired function of the puborectalis muscle and the external anal sphincter. Sacral spinal nerve stimulation has been shown to be effective in the treatment of patients with a functionally deficient but morphologically intact external anal sphincter. Surgery may be required for anal sphincter trauma and should only be carried out in specialist centres.

**Box 32.45 Aetiology of faecal incontinence**

- Congenital:
  - e.g. surgery for imperforate anus
- Anal sphincter dysfunction:
  - Structural damage:
    - surgery – anorectal, vaginal hysterectomy; obstetric injury during childbirth; trauma; radiation; perianal Crohn’s disease
  - Pudendal nerve damage:
    - childbirth
  - Perineal descent: prolonged straining at stool
- Rectal prolapse
- Faecal impaction with overflow diarrhoea
- Severe diarrhoea:
  - e.g. ulcerative colitis, functional diarrhoea, irritable bowel syndrome
- Neurological and psychological disorders:
  - Spinal trauma (S2–S4)
  - Spina bifida
  - Stroke
  - Multiple sclerosis
  - Diabetes mellitus (with autonomic involvement)
  - Dementia
  - Psychological illness

**Ischaemic disease of the colon (ischaemic colitis)**

Occlusion of branches of the superior mesenteric artery (SMA) or inferior mesenteric artery (IMA), often in the older age group, commonly presents with sudden onset of abdominal pain and the passage of bright red blood per rectum, with or without diarrhoea. There may be signs of shock and evidence of underlying cardiovascular disease. The anatomy of the vascular supply to the colon results in a watershed area at the splenic flexure, which is therefore the most common site affected. This condition has also been described in women taking the contraceptive pill, patients on nicorandil, and those with thrombophilia and small- or medium-vessel vasculitis.
Examination
On examination, the abdomen may be distended and tender. A straight abdominal X-ray often shows thumb-printing (a characteristic sign of ischaemic disease) at the splenic flexure. Patients are likely to display signs of cardiovascular shock and may have a lactic acidosis.

Differential diagnosis and investigations
The differential diagnosis includes other causes of acute colitis. Patients often require an urgent CT scan to exclude perforation. An unprepared flexible sigmoidoscopy is the diagnostic investigation of choice; biopsies showing epithelial cell apoptosis and lamina propria fibrosis are characteristic. A colonoscopy should be performed when the patient has fully recovered to exclude the formation of a stricture at the site of disease and confirm mucosal healing. Patients without evidence of underlying cardiovascular disease should be screened for thrombophilia and vasculitis.

Management
Most patients settle on symptomatic treatment. A few patients show progressive signs of peritonism and imminent perforation, and require urgent surgery.

Diverticular disease
Diverticula are frequently found in the colon and occur in 50% of patients over the age of 50 years. They are most frequent in the sigmoid, but can be present throughout the whole colon.

Terminology:
• diverticulosis indicates the presence of diverticula
• diverticulitis implies that these diverticula are inflamed
• diverticular colitis refers to crescentic inflammation on the folds in areas of diverticulosis.

It is perhaps better to use the more general term diverticular disease, as it is often difficult to be sure whether the diverticula are inflamed. The precise mechanism of diverticula formation is not known. There is thickening of the muscle layer and, because of high intraluminal pressures, pouches of mucosa extrude through the muscular wall through weakened areas near blood vessels to form diverticula. An alternative explanation is cholinergic denervation with increasing age, which leads to hypersensitivity and increased uncoordinated muscular contraction. Diverticular disease seems to be related to the low-fibre diet eaten in developed countries and is rare in rural Africa.

Diverticulitis occurs when faeces obstruct the neck of the diverticulum, causing stagnation and allowing bacteria to multiply and produce inflammation. This can then lead to bowel perforation (peridiverticulitis), abscess formation, fistulae into adjacent organs, haemorrhage and even generalized peritonitis.

Clinical features and investigations
Diverticular disease is asymptomatic in 95% of cases and is usually discovered incidentally on colonoscopy or barium enema examination. No treatment other than advice to increase dietary fibre is required in those patients. In symptomatic patients, intermittent left iliac fossa pain or discomfort and an erratic bowel habit commonly occur, which are difficult to differentiate from the irritable bowel syndrome. In severe disease, luminal narrowing results in severe pain and constipation. In the absence of clinical signs of acute diverticulitis, a colonoscopy or ‘virtual colonoscopy’ (see p. 1159) is the investigation of choice (Fig. 32.47). Barium enema combined with flexible sigmoidoscopy is also used.

Management
Management of uncomplicated symptomatic disease is with a well-balanced (soluble and insoluble) fibre diet (20 g/day), with smooth muscle relaxants if required. Antibiotics and admission to hospital are not required for uncomplicated disease.

Acute diverticulitis
The pathophysiology of diverticulitis is associated with altered gut motility, increased luminal pressure and a disordered colonic microenvironment. Acute diverticulitis most commonly affects diverticula in the sigmoid colon. It presents with severe pain in the left iliac fossa, often accompanied by fever and constipation. These symptoms and signs are similar to those of appendicitis but are located on the left side. On examination, the patient is often febrile with a tachycardia. Abdominal examination shows tenderness, guarding and rigidity on the left side of the abdomen. A palpable tender mass is sometimes felt in the left iliac fossa.
Investigations

- **Blood tests** often reveal a polymorphonuclear leucocytosis. The ESR and CRP are raised.
- **CT colonography** (Fig. 32.48) will show colonic wall thickening, diverticula and often pericolic collections and abscesses. There is usually a streaky increased density extending into the immediate pericolic fat with thickening of the pelvic fascial planes. These findings are diagnostic of acute diverticulitis (95% sensitivity and specificity) and differ from those of malignant disease. Sigmoidoscopy and colonoscopy are not performed during an acute attack.
- **Ultrasound examination** is often more readily available and is cheaper. It can demonstrate thickened bowel and large pericolic collections, but is less sensitive than CT.

Management

Mild attacks can be treated on an outpatient basis using oral antibiotics such as ciprofloxacin and metronidazole. Patients with signs of systemic upset (fevers, tachycardia), significant abdominal pain or co-morbidity require bowel rest, intravenous fluids and intravenous antibiotic therapy. Recent large trials of 5-ASA therapy have shown minor benefit in preventing recurrent diverticulitis. Repeat attacks often require surgery.

Complications of diverticular disease

- **Perforation** usually occurs in association with acute diverticulitis, and can lead to formation of a paracolic or pelvic abscess or generalized peritonitis. Surgery may be required.
- **Fistula formation** into the bladder, causing dysuria or pneumaturia, or into the vagina, causing discharge.
- **Intestinal obstruction** (see p. 1222), usually after repeated episodes of acute diverticulitis.
- **Bleeding** is sometimes massive. In most cases, the bleeding stops and the cause of the bleeding can be established by colonoscopy and sometimes angiography. In rare cases, emergency segmental colectomy is required.
- **Mucosal inflammation** occurs in areas of diverticula, giving the appearance of a segmental colitis at endoscopy that may resemble Crohn’s disease.

Anorectal disorders

**Pruritus ani**

Pruritus ani, or an itchy bottom, is common. Perianal excoriation results from scratching. Usually, the condition results from haemorrhoids or overactivity of sweat glands. **Management** consists of enhancing toilet hygiene, keeping the area dry and avoiding the use of perfumed moisturizing creams. Secondary causes include threadworm (*Enterobius vermicularis*) infestation, fungal infections (e.g. candidiasis) and perianal eczema, which should be treated appropriately.

**Haemorrhoids**

Haemorrhoids (primary – internal; second degree – prolapsing; third degree – prolapsed) usually cause rectal bleeding, discomfort and pruritus ani. Patients may notice red blood on their toilet paper and blood on the outside of their stools. They are the most common cause of rectal bleeding (see Fig. 32.31). Diagnosis is made by inspection, rectal examination and proctoscopy.

**Management**

If symptoms are minor, no treatment is required apart from advice about avoiding constipation. Suppositories containing a local anaesthetic and corticosteroids are helpful. If symptoms are more severe, rubber band ligation or injection of a sclerosant can be used. Haemorrhoidal artery ligation operation (HALO) uses Doppler ultrasound to identify and ligate feeding arteries to the haemorrhoids and is being used more frequently in place of surgery.

**Anal fissures**

An anal fissure is a tear in the sensitive skin-lined lower anal canal distal to the dentate line, which produces pain on defecation. It can be an isolated primary problem in young to middle-aged adults or may occur in association with Crohn’s disease or ulcerative colitis, in which case perianal abscesses and anal fistulae can complicate the fissure.
Diagnosis can usually be made on the history alone and confirmed on perianal inspection. Rectal examination is often not possible because of pain and sphincter spasm. The spasm not only causes pain but also impairs wound healing. In severe cases, proctoscopy and sigmoidoscopy should be performed under anaesthesia to exclude other anorectal disease. Initial treatment is with local anaesthetic gel and stool softeners. Use of 0.4% glyceryl trinitrate and 2% diltiazem ointments is of benefit. Botulinum toxin is used in chronic fissures but lateral subcutaneous internal sphincterotomy is also employed for severe cases.

**Fistula in ano and anorectal abscesses**

The anatomy of perianal fistulae may be simple or complex (Fig. 32.49). The fistulae usually present as abscesses and heal after the abscess is incised. In other cases, a small, discharging pilonidal sinus may be noted by the patient.

Endoanal ultrasonography, MRI and/or examination under anaesthetic are usually required to define the primary and any secondary tracks, exclude sepsis and detect any associated disease, such as Crohn’s disease and tuberculosis. Management is with surgical incision and drainage with antibiotics.

**Rectal prolapse, intussusception and solitary rectal ulcer syndrome**

All these conditions are thought to be related, rectal prolapse being the unifying pathology. Some patients with solitary rectal ulcer syndrome (SRUS) do not have prolapse but strain excessively and ulcerate the anterior rectal wall, which is forced into the anus during attempts at defecation. Constipation and chronic straining may be precipitating causes. Patients commonly present with slight bleeding and mucus on defecation, tenesmus and a sensation of anal obstruction.

SRUS is commonly located on the anterior wall of the rectum within 13 cm of the anal verge, and is sometimes difficult to distinguish from cancer and Crohn’s disease during endoscopic examination. SRUS has typical histological features of non-specific inflammatory changes with bands of smooth muscle extending into the lamina propria.

Asymptomatic SRUS should not be treated. Symptomatic patients should be advised to stop straining and measures should be taken to soften the stool. If rectal prolapse can be demonstrated during defecation, this should be repaired; in severe cases, surgical treatment by rectopexy may be indicated. Surgical treatment for complete rectal prolapse is also required.

**Colonic tumours**

**Colon polyps and polyposis syndromes**

A colonic polyp is an abnormal growth of tissue projecting from the colonic mucosa. Polyps range from a few millimetres to several centimetres in diameter and are single or multiple, pedunculated, sessile or ‘flat’ (Fig. 32.50).

Many histological types of polyp are found in the colon (Box 32.46). However, adenomas are the precursor lesions in most cases of colon cancer.

**Classification of colorectal polyps**

Classification is summarized in Box 32.46.

**Sporadic adenomas**

An adenoma is a benign, dysplastic tumour of columnar cells or glandular tissue. Adenomas have tubular, tubulovillous or villous morphology. The vast majority of adenomas are not inherited and are termed ‘sporadic’. Although many sporadic adenomas do not become malignant in the patient’s lifetime, they have a tendency to progress to cancer via increasing grades of dysplasia due to progressive accumulation of genetic changes (adenoma–cancer sequence). Factors favouring malignant transformation in colorectal polyps, and the relation between adenoma size and likelihood of cancer, are shown in Box 32.47. The progression from benign polyp to cancer is shown in Fig. 32.51.

The likelihood of an adenoma being present increases with age; it is rare before the age of 30 years. By the age of 60–70, 5% of asymptomatic subjects will have a polyp equal to or longer than 1 cm, or cancer with no symptoms, and up to 50% will have at least one small (less than 1 cm) adenoma. Removal of polyps at colonoscopy and subsequent surveillance reduce the risk of development of colon cancer by approximately 80%. Techniques such as chromoscopy, using dye spray or narrow band imaging, are being used to assist in their detection (flat adenomas account for approximately 12% of all adenomas).

Polyps in the rectum and sigmoid often present with rectal bleeding. More proximal lesions rarely produce symptoms and most are diagnosed on barium enema, CT colonography or on colonoscopy performed for screening or for other reasons. Large
villous adenomas can present with profuse diarrhoea with mucus and hypokalaemia.

Once a polyp has been found, it is almost always possible to remove it endoscopically. Surveillance guidelines dictate the frequency of repeat investigations:

- at 5 years, if 1 or 2 adenomas <1 cm are found
- at 3 years, if there are 3–4 small adenomas or at least 1 that is >1 cm
- at 1 year, if there are ≥5 small adenomas or there are ≥3, at least 1 of which is >1 cm.

If any doubt exists about the completeness of excision of any polyp, then an earlier repeat examination is suggested.

**Sessile serrated adenomas**

Serrated polyps form a heterogeneous group of colorectal lesions that includes the benign hyperplastic polyps (HPs), and the pre-malignant sessile serrated adenoma (SSA) and traditional serrated adenoma (TSA). They are characterized by the saw-tooth appearance of the crypt epithelium. It is now recognized that approximately 30% of colorectal cancers (particularly those in the right colon) originate from these lesions. Progression of serrated polyps is thought to occur via a distinct pathway from the adenoma–carcinoma sequence, with involvement of *BRAF* gene mutations and gene promoter hypermethylation (CpG island methylator phenotype, or CIMP; see p. 1217). Microsatellite instability can be detected in both the adenoma–carcinoma and the serrated pathways. Endoscopic resection of SSAs and TSAs with appropriate surveillance is recommended.

**Inherited polyposis syndromes**

About 5% of colorectal cancers have a well-defined single-gene basis.

**Familial adenomatous polyposis**

Familial adenomatous polyposis (FAP) is an autosomal dominant condition arising from germline mutations of the *APC* gene, located on chromosome 5q21–q22. More than 825 different mutations have been identified. Penetrance is virtually 100%. It is characterized by the presence of hundreds to thousands of colorectal and duodenal adenomas. The mean age of adenoma development is 16 years; the average age at which colorectal cancer develops is 39 years. Tracing and screening of relatives are essential, and affected individuals should be offered a prophylactic colectomy. Surgical options include colectomy and ileorectal anastomosis, which requires lifelong surveillance of the rectal stump, or a restorative proctocolectomy or pouch procedure with complete removal of rectal mucosa.

Cystic gland polyps, predominantly in the proximal stomach, and duodenal adenomas are frequently found in FAP, as well as other extraintestinal lesions such as osteomas, epidermoid cysts and desmoid tumours. The duodenal adenomas may progress to cancer and are the most common cause of death in colectomized patients with FAP. Congenital hypertrophy of the retinal pigment epithelium (CHRPE) occurs in many families with FAP. Other cancers in FAP include thyroid, pancreatic and hepatoblastomas.

*APC* gene mutations can be found in about 80% of families with FAP. Once the mutation has been identified in an index case, other family members can be tested for the mutation, and screening can then be directed at mutation carriers. If a mutation cannot be found in a known FAP case, all family members should undergo clinical screening with regular colonoscopy.

**Attenuated FAP** may be missed as it presents later (average age 44 years) and has fewer polyps (<100), which tend to occur on the right side of the colon rather than on the left. It may be indistinguishable from sporadic cases but the gene mutation is in the *APC* germline.

**MYH-associated polyposis**

*MUT Y* homologue-associated polyposis (MYH-AP) is an autosomal recessive inherited syndrome of multiple colorectal adenomas and cancer. *MYH* is a base-excision-repair gene that corrects oxidative DNA damage. MYH-AP may account for 7–8% of families with the FAP phenotype in whom *APC* mutations cannot be found. Subjects with multiple adenomas or an FAP phenotype without *APC* mutations and with a family history compatible with a recessive pattern of inheritance should be tested for MYH-AP.

**Lynch syndrome**

In Lynch syndrome (previously called hereditary non-polyposis colon cancer, HNPCC), polyps are formed in the colon and may...
progress rapidly to colon cancer. It affects 1:5000 people, causing 3–10% of colorectal cancer cases.

The disease is caused by a mutation in one of the DNA mismatch repair genes, usually hMSH2 or hMLH1, although others (hMSH6, PMS1, and PMS2) have been reported. Mismatch repair genes are responsible for maintaining the stability of DNA during replication. Inheritance is autosomal dominant. The defect in function of the mismatch repair mechanism causes naturally occurring, highly repeated, short DNA sequences known as microsatellites to be shorter or longer than normal, a phenomenon called microsatellite instability (MSI).

Onset of cancer is earlier than in sporadic cases, at age 40–50 or younger. Tumours have a predilection for the right colon, in contrast to sporadic cases. In contrast to FAP, the lifetime risk of colon cancer (penetrance of the gene) in mutation carriers is 70–80%. Other cancers are also more common in Lynch syndrome: stomach, small intestine, bladder, skin, brain and hepatobiliary system. Female patients are at risk for endometrial and ovarian cancer.

The diagnosis is made from the family history of colon cancer at a young age and the presence of associated cancers in the family. These are formalized in the various editions of the Amsterdam and the Bethesda criteria (Box 32.48).

**Turcot’s syndrome**

This consists of FAP or Lynch syndrome (HNPCC) with brain tumours.

**Gardner’s syndrome**

This involves, in addition to FAP, desmoid tumours, osteomas of the skull and other lesions.

**Hamartomatous polyps**

These are commonly large and stalked. The inherited syndromes show autosomal dominant inheritance and include:

- **Juvenile polyps**, which occur mainly in children and teenagers, and are found mainly in the colon; histologically, they show mucus retention cysts. Most are sporadic, but a syndrome of juvenile polyps is defined as: >3–5 juvenile colonic polyps, juvenile polyps throughout the gastrointestinal tract, or any number of polyps with a family history. This is an autosomal dominant condition and the relevant gene has been identified (see Box 32.46). The polyps are a cause of bleeding and intussusception in the first decade of life. There is also an increased risk of colon cancer (relative risk (RR) of 34), and surveillance and removal of polyps must be undertaken.
 Colon and rectum

32

Colon and rectum

• Peutz–Jeghers syndrome (see p. 1197).
• PTEN hamartoma–tumour syndrome (PHTS), which includes Cowden’s syndrome, Bannayan–Riley–Ruvalcaba syndrome and all syndromes caused by germline phosphatase and tensin homologue (PTEN) mutations. Cowden’s (multiple hamartoma) syndrome is associated with characteristic skin stigmata, and by intestinal polyps regarded as hamartomas but with a mixture of cell types. These patients have an increased risk of various extraintestinal malignancies (thyroid, breast, uterine and ovarian). These syndromes are uncommon and together account for less than 1% of colon cancer cases.

Colorectal carcinoma

Colorectal cancer (CRC) is the third most common cancer worldwide and the second most common cause of cancer death in the UK.

Each year approximately, 40 000 new cases are diagnosed in England and Wales (68% colon, 32% rectal cancer), and CRC is registered as the cause of death in about half this number. The prevalence rate per 100 000 (at all ages) is 53.5 for men and 36.7 for women. The incidence increases with age; the average age at diagnosis is 60–65 years. Approximately 20% of patients in the UK have distant metastases at diagnosis. The disease is much more common in Westernized countries than in Asia or Africa.

Factors related to risk of colorectal cancer are shown in Box 32.49.

Genetics

Most colorectal cancers develop as a result of progression from normal mucosa to adenoma to invasive cancer. This progression is controlled by the accumulation of abnormalities in a number of critical growth-regulating genes and can be divided into three main pathways:

• Chromosomal instability (CIN). CIN is the most common cause of conventional adenomas throughout the colon. This pathway involves the sequential accumulation of genetic mutations in tumour suppressor genes, usually initiated by a mutation in the gene encoding adenomatous polyposis coli (APC).

• Cpg island methylator phenotype. Cpg island methylator phenotype (CIMP) tumours arise via the serrated neoplasia pathway and have a marked predilection for the proximal colon. Following an initiating genetic mutation in the genes encoding BRAF or KRAS, these lesions progress via epigenetic silencing of tumour suppressor and mismatch repair (MMR) genes by promoter methylation (p. 1215). This pathway is epitomized by the serrated polyposis syndrome. The stepwise accumulation of genetic mutations in onco- and tumour suppressor genes that underpins the SCRC carcinogenesis pathway is well established and has significantly altered worldwide clinical practice. For example, mutations in KRAS appear to have importance as predictive factors for lack of response to certain oncological therapies. Activating KRAS mutations, which are identified in approximately 40–45% of CRCs, are associated with resistance to treatments that target the epidermal growth factor receptor (EGFR), such as cetuximab and panitumumab.

• Microsatellite instability. Microsatellite instability (MSI) tumours are also more commonly located in the proximal colon. They arise from defective DNA repair through inactivation of mismatch repair genes, epitomized by the germline mutation of MMR genes seen in Lynch syndrome (HNPCC).
This molecular classification can help to distinguish clinical characteristics, such as patient demographics, tumour distribution, response to therapy and prognosis.

Cancer families
A family history of CRC confers an increased risk to relatives. Family history is, next to age, the most common risk factor for CRC. FAP (Fig. 32.52) is the best-recognized syndrome predisposing to CRC but represents less than 1% of all colorectal cancers. Lynch syndrome (HNPCC) accounts for 3–10% of familial cancer (see p. 1215).

Additionally, some colon cancers arise, at least in part, from an inherited predisposition, so-called familial risk (Box 32.50). Estimates of their frequency range from 10% to 30% of all CRC but the genes involved have yet to be identified. The risk of CRC can be estimated from a family history matched with empirical risk tables, so that appropriate advice regarding screening can be offered.

Most CRCs are, however, sporadic and occur in individuals without a strong family history (Fig. 32.53).

Pathology
CRC, which usually takes the form of a polypoid mass with ulceration, spreads by direct infiltration through the bowel wall. It involves lymphatics and blood vessels with subsequent spread, most commonly to the liver and lung. Synchronous cancers are present in 2% of cases. Histology is adenocarcinoma with variably differentiated glandular epithelium and mucin production. ‘Signet ring’ cells, in which mucin displaces the nucleus to the side of the cell, are relatively uncommon and generally have a poor prognosis.

Clinical features
Symptoms suggestive of colorectal cancer include change in bowel habit with looser and more frequent stools, rectal bleeding, tenesmus and symptoms of anaemia. A rectal or abdominal mass may be palpable. Cancers arising in the caecum and right colon are often asymptomatic until they present as an iron deficiency anaemia. Cancer may present with intestinal obstruction.

Patients aged over 35–40 years presenting with new large bowel symptoms should be investigated. Digital examination of the rectum is essential and examination of the colon should be performed in all cases.

Investigations
- Colonoscopy is the “gold standard” for investigation and allows biopsy for histology. Biopsy of the tumour is mandatory, usually at endoscopy (Fig. 32.54).
- Double-contrast barium enema can visualize the large bowel but has now been superseded by CT colonography.
- Endoanal ultrasound and pelvic MRI are used for staging rectal cancer.
- Chest, abdominal and pelvic CT scanning evaluate tumour size, local spread, and liver and lung metastases, contributing to tumour staging.
- PET scanning is useful for detecting occult metastases and for evaluation of suspicious lesions found on CT or MRI.
- MRI is also useful for evaluating suspicious lesions found on CT or ultrasound, especially in the liver.
- Serum carcinoembryonic antigen (CEA) is of little use for primary diagnosis and should not be performed as a screening test. It is useful for follow-up; rising levels suggest recurrence.
- Faecal occult blood (FOB) tests are used for mass population screening.

| Box 32.50 Lifetime risk of colorectal cancer (CRC) in first-degree relatives of a CRC patient |
|---------------------------------|-----------------|
| Individuals affected            | Risk            |
| Population risk                 | 1 in 50         |
| One first-degree relative affected (any age) | 1 in 17         |
| One first-degree and one second-degree relative affected | 1 in 12         |
| One first-degree relative affected (age <45) | 1 in 10         |
| Two first-degree relatives affected | 1 in 6          |
| Autosomal dominant pedigree     | 1 in 2          |

Management

Management should be undertaken by multidisciplinary teams working in specialist units. About 80% of patients with CRC undergo surgery (often laparoscopically). The operative procedure depends on the cancer site. Long-term survival relates to the stage of the primary tumour and the presence of metastatic disease. There has been a gradual move from using Dukes’ classification to the TNM classification system (see Box 28.53). Long-term survival is only likely when the cancer is completely removed by surgery with adequate clearance margins and regional lymph node clearance.

- **Total mesorectal excision (TME)** is required for rectal cancers and removes the entire package of mesorectal tissue surrounding the cancer. A low rectal anastomosis is then performed. Abdomino-perineal excision, which requires a permanent colostomy, is reserved for very low tumours within 5 cm of the anal margin. TME combined with preoperative radiotherapy reduces local recurrence rates in rectal cancer to around 8% and improves survival. Pre- or postoperative chemotherapy reduces local recurrence rates but had no effect on survival in a recent study.
- **Segmental resection** and restorative anastomosis, with removal of the draining lymph nodes as far as the root of the mesentery, is used for cancer elsewhere in the colon. Surgery in patients with obstruction carries greater morbidity and mortality. Where technically possible, preoperative decompression by endoscopic stenting with a mesh-metal stent relieves obstruction, so surgery can be elective rather than emergency, and is probably associated with a decrease in morbidity and mortality.
- **Local transanal surgery** is very occasionally used for early superficial rectal cancers.
- **Surgical or ablative treatment of liver and lung metastases** prolongs life where treatment is technically feasible and the patient is fit enough to undergo the treatment.

- **Radiotherapy is not helpful** for colonic cancers proximal to the rectum because of difficulties in delivering a sufficient dose to the tumour without excess toxicity to adjacent structures, particularly the small bowel.
- **Adjuvant postoperative chemotherapy** improves disease-free survival and overall survival in stage III colon cancer (see p. 125). Those with stage II tumours and advanced features such as vascular invasion may also benefit. Genetic testing for KRAS mutations can help target appropriate chemotherapy regimens. Management of **advanced colorectal cancer** is discussed on page 124.

Follow-up

All patients who have surgery should have a total colonoscopy performed before surgery to look for additional lesions. If total colonoscopy cannot be achieved before surgery, a second ‘clearance’ colonoscopy within 6 months of surgery is essential. Patients with stage II or III disease should be followed up with regular colonoscopy and CEA measurements; rising levels of CEA suggest recurrence. Annual CT scanning of the chest and abdomen to detect operable liver metastases should be performed for up to 3 years post surgery.

Screening for CRC

- **FOB tests** have been studied as a screening test for colorectal cancer. Several large randomized studies have demonstrated a reduction in cancer-related mortality of 15–33%. Immunologically based FOB tests are superior to the conventional guaiac-based systems. The disadvantage of screening with FOB is its relatively low sensitivity, which means many negative colonoscopies. In FOB test screen-positive patients in the UK National Bowel Cancer Screening Programme (NHS BCSP), about 10% have cancer, 40% have adenomas and the colon is normal in 50%. Faecal immunochemical tests (FIT) for blood – FIT for haemoglobin are more specific than guaiac tests because FIT detects only human globin and therefore does not detect upper gastrointestinal bleeding (since the globin is digested in transit). Additionally, foods with peroxidase activity do not produce a positive reaction. FIT has replaced FOBt in the bowel cancer screening programme in the UK since April 2018.
- **Flexible sigmoidoscopy** screening has been shown to reduce the mortality from CRC, but not overall mortality.
- **Colonoscopy** is the ‘gold standard’ technique for examination of the colon and rectum and is the investigation of choice for high-risk patients. Universal screening strategies have been implemented in the UK for subjects between 60 and 69 who have a positive FOB. Cancer has been detected in 8–12% of patients, 75% of which was located in the left colon; 72% of detected cancers are at an ‘early’ stage (10% polyp cancer, 32% stage I and 30% stage II).
- **CT colonography** (‘virtual colonoscopy’, see Fig. 32.8) is increasingly being used.

THE ACUTE ABDOMEN

This section deals with the acute abdominal conditions that cause the patient to be hospitalized within a few hours of the onset of pain (Box 32.51). If they are recognized quickly as an emergency, a reduction in morbidity and mortality can be achieved. Although a specific diagnosis should be attempted, the immediate problem in management is to decide whether an ‘acute abdomen’ exists and whether surgery is required.

Diagnosis

History

This should include previous operations, any gynaecological problems and presence of any concurrent medical condition.

Pain

The onset, site, type and subsequent course of the pain should be determined as accurately as possible. In general, the pain of an acute abdomen can be either constant (usually owing to inflammation) or colicky (because of a blocked ‘tube’). The inflammatory nature of a constant pain will be supported by a raised temperature, tachycardia and/or a raised white cell count. If these are normal, then other causes (e.g. musculoskeletal, aortic aneurysm), even rare ones (e.g. porphyria), should be considered. Colicky pain can be due to an obstruction of the gut, biliary system, urogenital system or uterus. These cases will probably require conservative management initially, along with analgesics. If a colicky pain becomes a constant pain, then inflammation of the organ may have supervened (e.g. strangulated hernia, ascending cholangitis or salpingitis).

A **sudden onset** of pain suggests:

- perforation (e.g. of a duodenal ulcer)
- rupture (e.g. of an ectopic pregnancy)
- torsion (e.g. of an ovarian cyst)
- acute pancreatitis
- infarction (e.g. mesenteric).

Back pain suggests:

- pancreatitis
- rupture of an aortic aneurysm
- renal tract disease.

Inflammatory conditions (e.g. appendicitis) produce a more gradual onset of pain. With peritonitis, the pain is continuous and may be made worse by movement. Many inflammatory conditions can progress to those listed as having a sudden onset due to complications.

Vomiting

Vomiting may accompany any acute abdominal pain but, if persistent, suggests an obstructive lesion of the gut. The character of the vomit should be asked about. Does it contain blood, bile or small bowel contents?

Other symptoms

Any change in bowel habit or of urinary frequency should be documented and, in females, a gynaecological history, including last menstrual period, should be taken.

Physical examination

The general condition of the person should be noted. Do they look ill or shocked? Large volumes of fluid may be lost from the vascular compartment into the peritoneal cavity or into the lumen of the bowel, giving rise to hypovolaemia: that is, a pale, cold skin, a weak, rapid pulse and hypotension.

The abdomen

- **Inspection.** Look for the presence of scars, distension or masses.
- **Palpation.** The abdomen should be examined gently for sites of tenderness and the presence or absence of guarding. Guarding is involuntary spasm of the abdominal wall and indicates peritonitis. This can be localized to one area or may be generalized, involving the whole abdomen.
- **Bowel sounds.** Increased high-pitched, tinkling bowel sounds indicate fluid obstruction; this occurs because of fluid movement within the dilated bowel lumen. Absent bowel sounds suggest peritonitis. In an obstructed patient, absent bowel sounds may be due to strangulation, ischaemia or ileus. It is essential for the hernial orifices to be examined if intestinal obstruction is suspected.

Vaginal and rectal examination

Vaginal examination can be very helpful, particularly in diagnosing gynaecological causes of an acute abdomen (e.g. a ruptured ectopic pregnancy). Rectal examination is less helpful, as localized tenderness may be due to any cause; it may show blood on the glove.

Other observations

- **Temperature.** Fever is more common in acute inflammatory processes.
- **Urine.** Examine for:
  - blood – suggests urinary tract infection or renal colic
  - glucose and ketones – ketoacidosis can present with acute pain
  - protein and white cells – to exclude acute pyelonephritis.
- **Medical causes.** These should be borne in mind (Box 32.52).

Investigations

- **Blood count.** A raised white cell count occurs in inflammatory conditions.

*aPercentages are approximate and vary in different communities.*
Serum amylase. High levels (more than five times normal) indicate acute pancreatitis. Raised levels below this can occur in any acute abdomen and should not be considered diagnostic of pancreatitis.

Serum electrolytes. These are not particularly helpful for diagnosis but are useful for general evaluation of the patient.

Pregnancy test. A urine dipstick is used for women of childbearing age.

X-rays. An erect chest X-ray is useful to detect air under the diaphragm caused by a perforation (Fig. 32.55). Dilated loops of bowel or fluid levels are suggestive of obstruction on abdominal X-ray (Fig. 32.56).

Ultrasound. This is useful in the diagnosis of acute cholangitis, cholecystitis and aortic aneurysm, and in expert hands is reliable in the diagnosis of acute appendicitis. Gynaecological and other pelvic causes of pain can be detected.

CT scan. Spiral CT of the abdomen and pelvis is the most accurate investigation in most acute emergencies. It should be used more often to avoid unnecessary laparotomies.

Laparoscopy. This is used increasingly as a diagnostic tool prior to proceeding with surgery, particularly in men and women over the age of 50 years. In addition, therapeutic procedures, such as appendicectomy, can be performed.

**Acute appendicitis**

This is a common surgical emergency and affects all age groups. Appendicitis should always be considered in the differential diagnosis if the appendix has not been removed.

Acute appendicitis mostly occurs when the lumen of the appendix becomes obstructed with a faecolith; however, in some cases, there is only generalized acute inflammation. If the appendix is not removed at this stage, gangrene occurs with perforation, leading to a localized abscess or to generalized peritonitis.

**Clinical features**

Most patients present with abdominal pain; in many, it starts vaguely in the centre of the abdomen, becoming localized to the right iliac fossa in the first few hours. Nausea, vomiting, anorexia and occasional diarrhoea can occur.

Examination of the abdomen usually reveals tenderness in the right iliac fossa, with guarding due to the localized peritonitis. There may be a tender mass in the right iliac fossa. Although raised white cell counts, ESR and CRP are helpful, other laboratory tests can be less valuable. An ultrasound scan can detect an inflamed appendix and can also indicate an appendix mass or other localized lesion. CT is highly sensitive (98.5%) and specific (98%) negative predictive value; 99.5% positive predictive value), and reduces the incidence of removal of a ‘normal’ appendix. With the use of these investigations, the incidence of ‘normal’ appendix histology has fallen to 15–20%.

**Differential diagnosis**

- Non-specific mesenteric lymphadenitis – may mimic appendicitis.
- Acute terminal ileitis due to Crohn’s disease or *Yersinia* infection.
- Gynaecological causes:
  - Inflamed Meckel’s diverticulum
  - Functional bowel disease.
Management

The appendix is removed by laparoscopic surgery. If an appendix mass is present, the patient is usually treated conservatively with intravenous fluids and antibiotics. The pain subsides over a few days and the mass usually disappears over a few weeks. Interval appendicectomy is recommended at a later date to prevent further acute episodes.

Gynaecological causes of an acute abdomen

Ruptured ectopic pregnancy

The fallopian tube is the most common extrauterine site of implantation. Delayed diagnosis is the major cause of morbidity. Most patients will present with recurrent low abdominal pain associated with vaginal bleeding. Diagnosis is usually made with abdominal and transvaginal ultrasound. Most patients can be managed by laparoscopic salpingostomy or salpingectomy.

Ovarian causes

- Rupture of ‘functional’ ovarian cysts in the middle of the cycle (Mittelschmerz).
- Torsion or rupture of ovarian cysts.

Acute salpingitis

Most cases are associated with sexually transmitted infection. Patients commonly present with bilateral low abdominal pain, a fever and vaginal discharge. In the Fitz-Hugh–Curtis syndrome, Chlamydia infection tracks up the right paracolic gutter to cause a pericholangitis. Patients can present with acute right hypochondrial pain, fever and mildly abnormal liver biochemistry.

Acute peritonitis

Localized peritonitis

There is virtually always some degree of localized peritonitis with all acute inflammatory conditions of the gastrointestinal tract (e.g. acute appendicitis, acute cholecystitis). Pain and tenderness are largely features of this localized peritonitis. The treatment is for the underlying disease.

Generalized peritonitis

This is a serious condition, resulting from irritation of the peritoneum owing to infection (e.g. perforated appendix) or from chemical irritation due to leakage of intestinal contents (e.g. perforated ulcer). In the latter case, superadded infection gradually occurs; E. coli and Bacteroides are the most common organisms.

The peritoneal cavity becomes acutely inflamed, with production of an inflammatory exudate that spreads throughout the peritoneum, leading to intestinal dilation and paralytic ileus.

Clinical features

In perforation, the onset is sudden with acute, severe abdominal pain, followed by general collapse and shock. The patient may improve temporarily, only to become worse later as generalized toxaemia occurs.

When peritonitis is secondary to inflammatory disease, the onset is less rapid, the initial features being those of the underlying disease.

Investigations

Investigations should always include an erect chest X-ray. X-ray is used to detect free air under the diaphragm, and serum amylase is measured to diagnose acute pancreatitis, which is treated conservatively. Imaging with ultrasound and/or CT should always be performed for diagnosis.

Management

Peritonitis is treated surgically after adequate resuscitation and the re-establishment of a good urinary output. This includes insertion of a nasogastric tube, intravenous fluids and antibiotics. Surgery has a two-fold objective:

- peritoneal lavage of the abdominal cavity
- specific treatment of the underlying condition.

Complications

Any delay in the treatment of peritonitis produces more profound toxaemia and sepsis, which may lead to the development of multiorgan failure (see p. 219). Local abscess formation can occur and should be suspected if a patient continues to remain unwell postoperatively, with a swinging fever, high white cell count and continuing pain. Abscesses are commonly pelvic or subphrenic, and can be localized and drained using ultrasound and CT scanning techniques.

Intestinal obstruction

Most intestinal obstruction is due to a mechanical block. Sometimes the bowel does not function, leading to a paralytic ileus. This occurs temporarily after most abdominal operations and with peritonitis. The most common cause in adults is adhesions (Box 32.53).

Obstruction of the bowel leads to bowel distension above the block, with increased secretion of fluid into the distended bowel. Bacterial contamination takes place in the distended stagnant bowel. In strangulation, the blood supply is impeded, leading to gangrene, perforation and peritonitis unless urgent treatment of the condition is undertaken.

Clinical features

The patient complains of abdominal colic, vomiting and constipation without passage of wind. In upper gut obstruction the vomiting is profuse, but in lower gut obstruction it may be absent.

Examination of the abdomen reveals distension with increased bowel sounds. Marked tenderness suggests strangulation, and urgent surgery is necessary. Examination of the hernial orifices and rectum must be performed. X-ray of the abdomen reveals distended loops of bowel proximal to the obstruction. Fluid levels are seen in small bowel obstruction on an erect film. In large bowel obstruction, the caecum and ascending colon are distended. An instant, water-soluble Gastrografin enema without air insufflation may help to demonstrate the site of the obstruction. CT can localize the lesion accurately and is the investigation of choice.

Management

Initial management is by resuscitation with intravenous fluids (mainly 0.9% saline with potassium) and decompression. Many cases will settle on conservative management, but an increasing temperature, raised pulse rate, increasing pain and a rising white cell count require urgent scanning and possible exploratory laparotomy.

Box 32.53 Causes of intestinal obstruction

Small intestinal obstruction
- Adhesions (80% in adults)
- Hernias
- Crohn’s disease
- Intussusception
- Obstruction due to extrinsic involvement by cancer

Colonic obstruction
- Carcinoma of the colon
- Sigmoid volvulus
- Diverticular disease
Laparotomy with removal of the obstruction will be necessary in some cases of small bowel obstruction. If the bowel is gangrenous owing to strangulation, gut resection will be required. A few patients (e.g., those with Crohn’s disease) may have recurrent episodes of incomplete intestinal obstruction that can be managed conservatively. In large bowel obstruction due to malignancy, a self-expanding metal stent can be used, followed by elective surgery. In critically ill patients, a defunctioning colostomy may be needed. Volvulus of the sigmoid colon can be managed by the passage of a flexible sigmoidoscope or a rectal tube to un-kink and deflate the bowel, but recurrent volvulus may require sigmoid resection.

**Acute colonic pseudo-obstruction**

A clinical picture mimicking mechanical obstruction may develop in patients who do not have a mechanical cause. In more than 80% of cases, it complicates other clinical conditions, such as:

- intra-abdominal trauma, pelvic, spinal and femoral fractures
- postoperative states (abdominal, pelvic, cardiothoracic, orthopaedic, neurosurgical)
- intra-abdominal sepsis
- pneumonia
- metabolic disorders (e.g., electrolyte disturbances, malnutrition, diabetes mellitus, Parkinson's disease)
- drugs – opiates (particularly after orthopaedic surgery), antidepressants, antiparkinsonian drugs.

Patients present with rapid and progressive abdominal distension and pain. X-ray shows a gas-filled large bowel. Management is of the underlying problem (e.g., withdrawal of opiates analgesia), together with a trial of intravenous neostigmine therapy. Patients should be monitored and consideration should be given to surgery if the diameter of the caecum exceeds 14 cm.

**PERITONEUM**

**Anatomy and physiology**

The peritoneal cavity is a closed sac lined by mesothelial cells; these produce surfactant, which acts as a lubricant within the peritoneal cavity. The cavity contains <100 mL of serous fluid containing <30 g/L of protein.

The mesothelial cells lining the diaphragm have gaps that allow communication between the peritoneum and the diaphragmatic lymphatics. Approximately one-third of fluid drains through these lymphatics, the remainder through the parietal peritoneum. These mechanisms allow particulate matter to be removed rapidly from the peritoneal cavity.

Complement activation is an early defence mechanism and is followed rapidly by upregulation of the peritoneal mesothelial cells and migration of polymorphonuclear neutrophils and macrophages into the peritoneum.

Mast cells release potent mediators of inflammation, including histamine and eicosanoids, and interact with T cells to generate an immune response.

The peritoneum-associated lymphoid tissue includes the omental milky spots, the lymphocytes within the peritoneal cavity and the draining lymph nodes. B cells with a unique CD5+ are common. This defence system plays a major role in localizing peritoneal infection.

**Disorders affecting the peritoneum**

Conditions that can affect the peritoneum are shown in Box 32.54.

**Box 32.54 Diseases of the peritoneum**

---

**Infective (bacterial) peritonitis**
- Secondary to gut disease, e.g., appendicitis
- Perforation of any organ
- Chronic peritoneal dialysis
- Spontaneous, usually in ascites with liver disease
- Tuberculosis

**Neoplasia**
- Secondary deposits (e.g., from ovary, stomach)
- Primary mesothelioma

**Vasculitis**
- Rheumatic autoimmune disease
- Polyserositis (e.g., familial Mediterranean fever)

**Peritonitis** can be acute or chronic, as seen in TB. Most cases of infective peritonitis are secondary to gastrointestinal disease, but it occurs occasionally without intra-abdominal sepsis in ascites due to liver disease. Very rarely, fungal and parasitic infections (e.g., amoebiasis, candidiasis) can also cause primary peritonitis. Peritonitis is discussed further on page 1222.

The peritoneum can be involved by secondary malignant deposits, and the most common cause of ascites in a young to middle-aged woman is an ovarian carcinoma.

A subphrenic abscess is usually secondary to infection in the abdomen and is characterized by fever, malaise, pain in the right or left hypochondrium and shoulder-tip pain. An erect chest X-ray may show gas under the diaphragm, impaired movement of the diaphragm on screening and/or a pleural effusion. Ultrasound is usually diagnostic. Percutaneous catheter drainage inserted under CT or ultrasound guidance and antibiotics constitute highly successful therapy.

Ascites is associated with all diseases of the peritoneum. The fluid that collects is an exudate with a high protein content. It is also seen in liver disease. The mechanism, causes and investigation of ascites are discussed on page 1295.

**Peritoneal adhesions**

Adhesions form as a result of abdominal or pelvic surgery, or inflammation in the abdominoperitoneal cavity. They cause a variety of conditions, including adhesive small bowel obstruction (ASBO), chronic abdominal pain, complications during future surgery, and female infertility when they involve the fallopian tubes or ovaries. There is no satisfactory medical or surgical treatment and so surgical techniques have been developed to minimize peritoneal injury.

**Retroperitoneal fibrosis (peri-aortitis)**

This is a rare condition, in which there is a marked fibrosis over the posterior abdominal wall and retroperitoneum. It is associated with raised serum IgG4 levels (see p. 65) and is described on page 1379.

**Tuberculous peritonitis**

This is the second most common form of abdominal TB. Three subgroups can be identified: wet, dry and fibrous.

- In patients with the wet type, ascitic fluid should be examined for protein concentration (>20 g/L) and tubercle bacilli (rarely found).
- In the dry form, patients present with subacute intestinal obstruction, which is due to tuberculous small bowel adhesions.
- In the fibrous form, patients present with abdominal pain, distension and ill-defined, irregular, tender abdominal masses.

The diagnosis of peritoneal TB can be supported by findings on ultrasound or CT screening (mesenteric thickening and lymph node
enlargement). A histological diagnosis is not always required before instituting treatment. In some patients, careful laparoscopy (to avoid perforation) may have to be performed, and rarely laparotomy.

**Management**

Drug treatment is similar to that for pulmonary TB (see p. 969) and should be supervised by chest physicians who have experience in dealing with contacts.

Nutrition is a crucial but easily overlooked contributor to health. While more than half of the adult population in developed countries are overweight or obese, malnutrition or specific nutritional deficiencies may affect those with inadequate diet or with malabsorption syndromes. It is estimated that over one-third of adults over the age of 65 are at risk of malnutrition when they are admitted to hospital. Despite significant progress in eradicating extreme poverty globally, there are still parts of the developing world where malnutrition is a major population problem, often complicated by micronutrient deficiencies.

In well-resourced settings, dieticians monitor for malnutrition in inpatients, and recommend dietary supplements or clinically assisted nutrition to address this. This is especially relevant where patients cannot swallow, such as for patients who have suffered a stroke, or in those who are hypercatabolic (for instance during critical illness). Gastroenterologists with an interest in nutrition often advise in cases of malabsorption or where parenteral feeding is required.

Key skills in nutrition include:
- developing an awareness of patients at risk of malnutrition, and understanding the role of dietary supplements and clinically assisted nutrition in addressing this
- being aware of syndromes associated with specific micronutrient deficiencies
- understanding the consequences of obesity for health, and different ways of helping patients to lose weight.

Opportunities for learning about nutrition include shadowing dieticians reviewing patients in the community or as inpatients, attending specialist nutrition ward rounds led by gastroenterologists, or through attending obesity and bariatric surgery outpatient clinics.
INTRODUCTION

Nutrition is essential in health. Diseases in many organs have adverse effects on food intake and metabolism, leading to nutrition-related conditions associated with increased morbidity and mortality. Conversely, food intake determines health and plays a major role in diseases like cardiovascular disease, diabetes and cancer. There is no universally accepted definition of malnutrition, but a reasonable definition is as follows: ‘Malnutrition is a state of nutrition in which a deficiency, excess or imbalance of energy, protein and other nutrients causes measurable adverse effects on tissue/body form (body shape, size and composition) and function, and on clinical outcome.’

In developing countries, the lack of food and poor usage of the available food, often in association with ongoing inflammatory processes, result in what has traditionally been called protein–energy malnutrition (PEM). However, micro nutrient deficiencies often accompany PEM and they may contribute to its development. Worldwide, in 2011, 165 million children under 5 years of age were affected by stunting, and at least 52 million by wasting. Obesity has also been a growing problem in developing countries and the combination of stunting with obesity has been increasing. In developed countries, excess food is available, and overweight and obesity are the most common nutritional problems. However, under-nutrition (often referred to as ‘malnutrition’) continues to remain a major clinical and public health problem worldwide.

Diet and disease are inter-related in many ways:

• **Excess energy intake contributes to a number of diseases**, including ischaemic heart disease and diabetes, particularly when high in animal (saturated) fat content.

• **There is a relationship between food intake and cancer**, as found in many epidemiological studies. An excess of energy-rich foods (i.e. those containing fat and sugar), often combined with physical inactivity, plays a role in the development of certain cancers, while diets high in vegetables and fruits reduce the risk of most epithelial cancers. Numerous carcinogens, intentional and accidental, are found in many foods (i.e. nitrates for preserving foods) or accidental contaminants (e.g. moulds producing aflatoxin and fungi) may also be involved in the development of cancer.

• **The proportion of processed foods eaten may affect the development of disease.** Some processed convenience foods have a high sugar and fat content and therefore predispose to dental caries and obesity, respectively. They also have a low fibre content, and dietary fibre can help in the prevention of a number of diseases (see p. 1230).

• **Long-term under-nutrition is implicated in disease** by some epidemiological studies; for example, low growth rates in utero are associated with high death rates from cardiovascular disease in adult life.

In the UK, dietary reference values for food, energy and nutrients are stated as **reference nutrient intakes** (RNIs), on the basis of data from the Food and Agriculture Organization (FAO-WHO), United Nations University (UNU) expert committees and elsewhere. The RNI is sufficient, or more than sufficient, to meet the nutritional needs of 97.5% of healthy people in a population. Most people’s daily requirements are less than this, and so an **estimated average requirement (EAR)** is also given, which will certainly be adequate for most. A lower reference nutrient intake (LRNI), which fails to meet the requirements of 97.5% of the population, is also given. The RNI figures quoted in this chapter are for the age group 19–50 years. These represent values for healthy subjects and are not always appropriate for patients with disease.

WATER AND ELECTROLYTE BALANCE

Water and electrolyte balance is dealt with fully in Chapter 9. About 1 L of water is required in the daily diet to balance insensible losses but much more is usually drunk, the kidneys being able to excrete large quantities. The daily RNI for sodium is 70 mmol (1.6 g) but daily sodium intake varies in the range 90–440 mmol (2–10 g). These are needlessly high intakes of sodium, which are thought to play a role in causing hypertension (see Ch. 31). The World Health Organization (WHO) also recommends at least 90 mmol (3.5 g) potassium, which would reduce blood pressure and cardiovascular risk of stroke and coronary artery disease.

DIETARY REQUIREMENTS

Energy

Food is necessary to provide the body with energy (**Fig. 33.1**). The SI unit of energy is the joule (J), and 1 kJ = 0.239 kcal. The conversion factor of 4.2 kJ, equivalent to 1.00 kcal, is used in clinical nutrition.

Energy balance

Energy balance is the difference between energy intake and energy expenditure. Weight gain or loss is a simple but accurate way of estimating energy balance.

Energy requirements

There are two approaches to assessing energy requirements for subjects who are weight-stable and close to energy balance:

• assessment of energy intake

• assessment of total energy expenditure.

Energy intake

Energy intake can be estimated by dietary surveys and, in the past, this has been used to decide daily energy requirements. However, measurement of energy expenditure gives a more accurate assessment of requirements.

Energy expenditure

Daily energy expenditure (**Fig. 33.2** is the sum of:

• the basal metabolic rate (BMR)

• the thermic effect of food eaten

• occupational activities

• non-occupational activities.

**Total energy expenditure** can be measured using a double-labelled water technique. Water containing the stable isotopes $^2$H and $^{18}$O is given orally. As energy is expended, carbon dioxide and water are produced. The difference between the rates of loss of the two isotopes is used to calculate the carbon dioxide production, which is then used to calculate energy expenditure. This can be done on urine samples over a 2–3-week period with the subject ambulatory. The technique is accurate, but it is expensive and requires the availability of a mass spectrometer. An alternative tracer technique for measuring total energy expenditure is to estimate CO$_2$ production by isotopic dilution. A subcutaneous infusion of labelled bicarbonate is administered continuously by a minipump, and urine is collected to measure isotopic dilution by urea, which is formed from CO$_2$. Other methods for estimating energy expenditure, such as heart rate monitors or activity monitors, are also available but are less accurate.

**Basal metabolic rate** can be calculated by measuring oxygen consumption and CO$_2$ production, but it is more usually taken from

In the UK, the estimated ‘average’ daily energy requirement is:
- for a 55-year-old female – 8100 kJ (1940 kcal)
- for a 55-year-old male – 10600 kJ (2550 kcal).

This is at present made up of about 50% carbohydrate, 35% fat, 15% protein ± 5% alcohol. In developing countries, however, carbohydrate

...standardized tables (Box 33.1) that only require knowledge of the subject’s age, weight and sex.

The physical activity ratio (PAR) is expressed as multiples of the BMR for both occupational and non-occupational activities of varying intensities (Box 33.2).

Total daily expenditure

= BMR × [Time in bed + (Time at work × PAR) + Non–occupational time × PAR]

Thus, for example, to determine the daily energy expenditure of a 73-year-old, 50-kg female doctor, with a BMR of 4805 kJ/day, who spends one-third of a day sleeping, working and engaged in non-occupational activities, the latter at a PAR of 2.1, the following calculation ensues:

\[= 4805 \text{kJ/day} \times (0.3 \times 1.7) + 0.3 \times 2.10)\]

\[= 6919 \text{kJ (1655 kcal/day)}\]

Fig. 33.1 The production of energy from the main constituents of food. Alcohol produces up to 5% of total calories but the variation between individuals is wide. One mol of glucose produces 36 mol of adenosine triphosphate (ATP). CoA, coenzyme A; NEFA, non-esterified fatty acids; TCA, tricarboxylic acid.

Fig. 33.2 Daily energy expenditure in an active and a sedentary 70-kg adult. BMR, basal metabolic rate; DIT, dietary-induced thermogenesis; PAR, physical activity ratio.
may be more than 75% of the total energy input, and fat less than 15% of the total energy input.

Energy requirements increase during the growing period, with pregnancy and lactation, and sometimes following infection or trauma. In general, the increased BMR associated with inflammatory or traumatic conditions is counteracted or more than counteracted by a decrease in physical activity, so that total energy requirements are not increased.

In the basal state, energy demands for resting muscle are 20% of the total energy required, those for abdominal viscera 35–40%, those for brain 20% and those for heart 10%. There can be more than a 50-fold increase in muscle energy demands during exercise.

**Energy stores**

Although virtually all body fat and glycogen are available for oxidation, less than half the protein is available for oxidation. Fig. 33.3 shows that fat accounts for the largest reserves of energy in both lean and obese subjects. The size of the stores determines survival during starvation.

**Body weight**

Body weight depends on energy balance. Intake depends not only on food availability but also on a number of complex interrelationships that include the stimulus of good food, the role of hunger, metabolic changes (e.g. hypoglycaemia), and the pleasure and habit of eating. Some people are able to keep their body weight constant within a few kilograms for many years, but most gradually increase their weight owing to a small but continuous increase of intake over expenditure. A gain or loss of energy of 25–29 MJ (6000–7000 kcal) would, respectively, increase or decrease body weight by approximately 1 kg.

**Protein**

In the UK, the adult daily RNI for protein is 0.75 g/kg, with protein representing at least 10% of the total energy intake. Most affluent people eat more than this, consuming 80–100 g of protein per day.

The total amount of nitrogen excreted in the urine represents the balance between protein breakdown and synthesis. In order to maintain nitrogen balance, at least 40–50 g of dietary protein are needed. The amount of protein oxidized can be calculated from the amount of nitrogen excreted in the urine over 24 hours using the following equation:

\[
\text{Grams of protein required} = \text{Urinary nitrogen} \times 6.25
\]

(most proteins contain about 16% of nitrogen)

In practice, urinary urea is more easily measured and forms 80–90% of the total urinary nitrogen (N). In healthy individuals, urinary nitrogen excretion reflects protein intake. However, excretion does not match intake in catabolic conditions (negative N balance), or during growth or repletion following an illness (positive N balance). Protein contains many amino acids:

- **Indispensable (essential)**. There are nine amino acids that cannot be synthesized and must be provided in the diet: tryptophan, histidine, methionine, threonine, isoleucine, valine, phenylalanine, lysine and leucine.
- **Dispensable (non-essential)**. These are amino acids that can be synthesized in the body (some may still be needed in the diet unless adequate amounts of their precursors are available). Animal proteins (e.g. in milk, meat and eggs) contain a good balance of all the indispensable amino acids, but many proteins from vegetables are deficient in at least one indispensable amino acid. In developing countries, protein intake derives mainly from vegetable proteins. By combining foodstuffs with different low concentrations of indispensable amino acids (e.g. maize with legumes), protein intake can be adequate, provided enough vegetables are available.

Loss of protein from the body (negative N balance) occurs not only because of inadequate protein intake, but also because of inadequate energy intake. When there is loss of energy from the body, more protein is directed towards oxidative pathways and, eventually, gluconeogenesis for energy.

**Role of amino acids**

- **Glutamine** is quantitatively the most significant amino acid in the circulation and in inter-organ exchange.
- **Alanine** is released from muscle; it is deaminated and converted into pyruvic acid before entering the citric acid cycle.
- **Homocysteine** is a sulphur-containing amino acid that is derived from methionine in the diet. A raised plasma concentration is an independent risk factor for vascular disease.

Amino acids are utilized to synthesize products other than protein or urea. For example:

- **Glycine** is required for haem production.
- **Tyrosine** is required for melanin and thyroid hormones.
- **Glutamine, aspartate and glycine** are required for nucleic acid bases.
- **Glutamate, cysteine and glycine** are required for glutathione, which is part of the defence system against free radicals.

**Fat**

Dietary fat is chiefly in the form of triglycerides, which are esters of glycerol and free fatty acids. Fatty acids vary in chain length and in saturation (Box 33.3). The hydrogen molecules related to the double bonds can be in the cis or the trans position; most natural fatty acids in food are in the cis position (Box 33.4).

The **essential fatty acids** (EFAs) are linoleic and α-linolenic acid, both of which are precursors of prostaglandins. Eicosapentaenoic and docosahexaenoic acid are also necessary, but can be made to a limited extent in the tissues from linoleic and linolenic acid, and thus a dietary supply is not essential.

**Synthesis of triglycerides,** sterols and phospholipids is very efficient. Even with low-fat diets, subcutaneous fat stores can be normal.

**Dietary fat** provides 37 kJ (9 kcal) of energy per gram. A high-fat intake has been implicated in the causation of:
- cardiovascular disease
- cancer (e.g. breast, colon and prostate)
- obesity
- type 2 diabetes.

The data on causation are largely epidemiological and disputed by many. Nevertheless, it is often suggested that the consumption of saturated fatty acids should be reduced, accompanied by an increase in mono-unsaturated fatty acids, such as those in olive oil (the ‘Mediterranean diet’), or polyunsaturated fatty acids. Any increase in polyunsaturated fats should not, however, exceed 10% of the total food energy, particularly as this requires a big dietary change.

**Trans fats (partly hydrogenated fatty acids)**

Increased consumption of hydrogenated vegetable and fish oils in margarines has led to increased trans fatty acid consumption. Trans fatty acids (also called trans fats) behave as if they were saturated fatty acids, increasing circulating low-density lipoprotein (LDL) and decreasing high-density lipoprotein (HDL) cholesterol concentrations, which, in turn, raise the risk of cardiovascular disease. In most countries, nutrition labels for all conventional foods and supplements must indicate the trans fatty acid content. The usage of trans fatty acids from partially hydrogenated oils has now been banned in many countries.

**Polyunsaturated fatty acids**

The **n-6 polyunsaturated fatty acids (PUFAs)** are components of membrane phospholipids, influencing membrane fluidity and ion transport. They also have antiarrhythmic, antithrombotic and anti-inflammatory properties, all of which are potentially helpful in preventing cardiovascular disease.

The **n-3 PUFAs** increase circulating HDL cholesterol and lower triglycerides, both of which might reduce cardiovascular risk. Some of the actions of n-3 PUFAs are mediated by a range of leukotrienes and eicosanoids, which differ in pattern and functions from those produced from n-6 PUFAs.

**Epidemiological studies and clinical intervention studies** suggest that n-3 PUFAs may have effects in the secondary prevention of cardiovascular disease and all-cause mortality (e.g. a 20–30% reduction in mortality from cardiovascular disease, according to some studies). The benefits, which have been noted as early as 4 months after intervention, have been attributed largely to the antiarrhythmic effects of n-3 PUFAs, but some work suggests that n-3 PUFAs, administered as capsules, can be rapidly incorporated into atheromatous plaques, stabilizing them and preventing rupture. Whether these effects are due directly to n-3 PUFAs or other changes in the diet is still debated.

**Recommendations for fat intake**

The British Nutrition Foundation and the American Heart Association presently recommend a two-fold increase of the current intake of total n-3 PUFAs (a several-fold increase in the intake of fish oils, and a 50% increase in the intake of α-linolenic acid). Implementing this recommendation will mean either a major change in the dietary habits of populations that eat little fish, or ingestion of capsules containing fish oils. Some government agencies have warned of the hazards of eating certain types of fish, which increase the risk of mercury poisoning and possibly other toxicities.

The current recommendations for fat intake for the UK are shown in Box 33.5.

**Cholesterol**

Cholesterol is found in all animal products. Eggs are particularly rich in cholesterol, which is virtually absent from plants. The average daily intake in the UK is 300–500 mg. Cholesterol is also synthesized (see Fig. 34.5), and only very high or low dietary intakes will significantly affect blood levels.

**Essential fatty acid deficiency**

Essential fatty acid deficiency may accompany PEM, and it has been clearly defined as a clinical entity in patients on long-term parenteral nutrition given glucose, protein and no fat. Alopecia, thrombocytopenia, anaemia and dermatitis occur within weeks, with an increased ratio of triene (n-9) to tetraene (n-6) in plasma fatty acids.
### Health promotion

Many chronic diseases – particularly obesity, diabetes mellitus and cardiovascular disease – cause premature mortality and morbidity, and are potentially preventable by dietary change. This is a global problem; for example, obesity affects 1 in 9 adults in the world, and the body mass index (BMI) is now similar in high- and middle-income groups. Reduction in salt and fat intake, combined with exercise and stopping smoking, would have a major effect on the health of the population.

**Box 33.5** suggests the composition of the 'ideal healthy diet'. The values given are based on the principle of:
- reducing total fat in the diet, particularly saturated fat
- increasing consumption of fish, which contains n-3 (or e-3) PUFAs
- increasing intake of wholegrain cereals and green and orange vegetables and fruits, leading to an increase in fibre and antioxidants.

Reductions in dietary sodium and cholesterol have also been suggested. There would be no disadvantage in this, and most studies have suggested some benefit.

### Fortification of foods

Fortification of foods with specific nutrients is common. In the UK, margarine and milk are fortified with vitamins A and D, flour with calcium, iron, thiamine and niacin, and breakfast cereals with several vitamins and iron.

### Nutrient goals and dietary guidelines

The interests of the individual are often different from those associated with government policy. A distinction needs to be made between nutrient goals and dietary guidelines:
- **Nutrient goals** refer to the national intakes of nutrients that are considered appropriate for optimal health in the population.
• Dietary guidelines refer to the dietary methods used to achieve these goals. Since dietary habits vary in different countries, dietary guidelines may also differ, even when the nutrient goals are the same. Nutrient goals are based on scientific information that links nutrient intake to disease. Although the information is incomplete, it includes evidence from a wide range of sources, including experimental animal studies, clinical studies, and both short-term and long-term epidemiological studies.

Pathophysiology of starvation
In the first 24 h following low dietary intake, the body relies for energy on the breakdown of hepatic glycogen to glucose (Fig. 33.4). Hepatic glycogen stores are small and therefore gluconeogenesis is soon necessary to maintain glucose levels. Gluconeogenesis takes place mainly from pyruvate, lactate, glycerol and amino acids, especially alanine and glutamine. The majority of protein breakdown takes place in muscle, with eventual loss of muscle bulk.

Lipolysis, the breakdown of the body’s fat stores, also occurs. It is inhibited by insulin, but the level of this hormone falls off as starvation continues. The stored triglyceride is hydrolysed by lipase to glycerol, which is used for gluconeogenesis, and also to non-esterified fatty acids, which can be used directly as a fuel or oxidized in the liver to ketone bodies.

Adaptive processes take place as starvation continues, to prevent the body’s available protein being completely utilized. There is a decrease in metabolic rate and total body energy expenditure. Central nervous metabolism changes from glucose as a substrate to ketone bodies. Gluconeogenesis in the liver decreases, as does protein breakdown in muscle, both of these processes being inhibited directly by ketone bodies. Most of the energy at this stage is seen in very poor areas. Most nutritional problems occurring in the population at large are due to eating wrong combinations of foodstuffs, such as an excess of refined carbohydrate or a diet low in fresh vegetables. Under-nourishment associated with disease is common in hospitals and nursing homes, and Box 33.6 gives a list of conditions in which malnutrition is often seen. Surgical complications, with sepsis, are a common cause. Many patients are admitted to hospital under-nourished, and a variety of chronic conditions predispose to this state (Box 33.7).

Most of the weight loss, leading to malnutrition, is due to poor intake secondary to the anorexia associated with the underlying condition. Disease may also contribute by causing malabsorption and increased catabolism, which is mediated by complex changes in cytokines, hormones, side-effects of drugs, and immobility. The elderly are particularly at risk of malnutrition because they often suffer from diseases and psychosocial problems, such as social isolation or bereavement (see Box 33.7).
comes from adipose tissue, with some gluconeogenesis from amino acids, particularly from alanine in the liver and glutamine in the kidney.

The **metabolic response to prolonged starvation** differs between lean and obese individuals. One of the major differences concerns the proportion of energy derived from protein oxidation, which determines the proportion of weight loss from lean tissues. This proportion may be up to three times smaller in obese subjects than lean subjects. It can be regarded as an adaptation that depends on the composition of the initial reserves (see Fig. 33.3). This means that deterioration in body function is more rapid in lean subjects, and survival time shorter in lean subjects (approximately 2 months) compared with the obese (in whom it can be at least several months).

**Following trauma or shock**, some of the adaptive changes do not take place. Glucocorticoids and cytokines (see below) stimulate the ubiquitin–proteasome pathway in muscle, which is responsible for accelerated proteolysis in muscle in many catabolic illnesses. In starvation, there is a decrease in BMR, while in inflammatory and traumatic disease, there is often an increase in BMR. These changes all result in continuing gluconeogenesis with massive muscle breakdown, and further reduction in survival time.

**Regulation of metabolism**

Tissue metabolism is regulated by multiple coordinated processes. Some are rapid, involving nerves, whilst others are slower, involving circulating substrates and hormones. Factors include:

- **Circulating substrate concentrations.** The uptake and metabolism of ketone bodies, which serve as the major fuel for the brain during prolonged starvation, are primarily determined by the circulatory concentration, which can increase up to 5 mmol/L or more. The liver is responsible for the production of ketone bodies, which is, in turn, controlled by the availability of fatty acids derived from adipose tissue. Substrates may also compete with each other for metabolism; e.g. glucose competes with non-esterified fatty acids for uptake and metabolism in muscle and heart (the glucose–fatty acid cycle), and this is independent of hormones.

- **Blood flow.** The delivery of substrates to tissues depends not only on their circulating concentration but also on the blood flow to tissues. In many tissues, there is coupling between metabolic activity and blood flow, with arterioles regulating blood flow to the tissue according to demand; e.g. blood flow to muscle increases during exercise.

- **Signals.** Hormones and other signals, such as cytokines (see below), regulate intracellular metabolism.

**Insulin/glucagon ratios in the fed and fasted state**

**In the fed state**, insulin/glucagon ratios are high. Insulin promotes synthesis of glycogen, protein and fat, and inhibits lipolysis and gluconeogenesis.

**In the fasted state**, insulin/glucagon ratios are low. Glucagon acts mainly on the liver and has no action on muscle. It increases glycogenolysis and gluconeogenesis, as well as increasing ketone body production from fatty acids. It also stimulates lipolysis in adipose tissue. Catecholamines have a similar action to glucagon but also affect muscle metabolism. These agents both act via cyclic adenosine monophosphate (cAMP) to stimulate lipolysis, producing free fatty acids that can then act as a major source of energy.

**Proportion of lean to fat tissue**

**During weight loss** uncomplicated by disease, the proportion of lean to fat tissue loss (or proportion of energy derived from protein metabolism) is greater in lean than overweight/obese individuals.

**During acute disease**, loss of lean tissue, which is associated with protein oxidation, can be particularly rapid. Hormones such as corticosteroids, pro-inflammatory cytokines and insulin resistance are all involved.

**Role of cytokines**

The metabolic response to trauma, injury and inflammation depends on the balance between pro-inflammatory (e.g. tumour necrosis factor, TNF; interleukin-2, IL-2) and anti-inflammatory cytokines (e.g. IL-10), and the production of many of these cytokines is influenced by genetic polymorphisms. Since many chronic diseases, including atherosclerosis, have an inflammatory component, these changes have wide-reaching metabolic implications.

Cytokines such as IL-1, IL-6 and TNF play a significant role in regulating metabolism. In acute diseases, they contribute to the
Protein–energy malnutrition

Box 33.8 Keys to detecting chronic protein–energy malnutrition (PEM) in developed countries

1. Body mass index (BMI)
   - Probable chronic PEM: <18.5 kg/m²
   - Possible chronic PEM: 18.5–20 kg/m²
   - Little or no risk of chronic PEM: >20 kg/m²

2. Weight loss in previous 3–6 months
   - >10%: high risk of developing PEM
   - 5–10%: possible risk of developing PEM
   - <5%: low/no risk of developing PEM

3. Acute disease effect
   - Diseases that have resulted or are likely to result in no dietary intake for >5 days (e.g., prolonged unconsciousness, persistent swallowing problems after a stroke, or prolonged ileus after abdominal surgery): high risk of malnutrition

catabolic process, glycogenolysis and acute phase protein synthesis. TNF, which inhibits lipoprotein lipase, is one of a number of ‘cachexia factors’ in patients with cancer.

It is unclear how these cytokines interact with central feeding pathways to cause anorexia. However, in animal models of both cancer and inflammatory bowel disease, many peripheral and central mediators of appetite are involved. For example, neuropeptide Y levels in the hypothalamus are often inappropriately low, so there is a reduced drive to feed.

Clinical features

Patients are sometimes seen with loss of weight or malnutrition (failure to thrive in children) as the primary symptom. Mostly, however, malnourishment is only seen as an accompaniment of some other disease process, such as malignancy. Severe malnutrition is seen mainly with advanced organic disease or after surgical procedures followed by complications. Three key features that help in the detection of chronic protein–energy malnutrition (PEM) in adults are listed in Box 33.8.

Other factors that may suggest PEM include:
- history of decreased food intake/loss of appetite
- clothes becoming loose-fitting (weight loss) and a general appearance indicating obvious wasting
- physical and psychosocial disturbances likely to have contributed to the weight loss.

The factors listed in Box 33.8 act as a link between detection and management (see also Fig. 33.5, the Malnutrition Universal Screening Tool). If the underlying physical or psychosocial problems are not addressed adequately, treatment may not be successful.

PEM leads to a depression of the immunological defence mechanism, resulting in a decreased resistance to infection. It also detrimentally affects muscle strength and fatigue, reproductive function (e.g., in anorexia nervosa, which is common in adolescent girls; see p. 797), wound healing and psychological function (depression, anxiety, hypochondriasis, loss of libido).

In children, growth failure is a key element in the diagnosis of PEM. WHO standards for optimal growth in children of 0–4 years have been adopted by developing and developed countries. They aim to reflect optimal rather than prevailing growth in both developed and developing countries, since they involved a healthy pregnancy and children born to non-smoking, relatively affluent mothers who breast-fed their children exclusively or predominantly for the first 6 months of life. The general principles of management of severe PEM in children are similar in developed and developing countries but resources are required to manage the problems once they have been identified (see p. 1236).

Management

When malnutrition is obvious and the underlying disease cannot be corrected at once, some form of nutritional support is necessary (see also p. 1253). Nutrition should be given enterally if the gastrointestinal tract is functioning adequately. This can be done most easily by encouraging the patient to eat more often and by giving a high-calorie supplement. If this is not possible, a liquefied diet may be given intragastrically via a fine-bore tube or by a percutaneous

![Fig. 33.5 Malnutrition Universal Screening Tool (MUST).](http://www.bapen.org.uk)
endoscopic gastrostomy (PEG). If both of these measures fail, parenteral nutrition is given.

### Developing countries

The International Union of Nutritional Sciences, with support from the International Pediatric Association, launched a global Malnutrition Task Force in 2005 to ensure that an integrated system of prevention and treatment of malnutrition is actively supported.

In many areas of the world, people are on the verge of malnutrition due to extreme poverty. In addition, if events such as drought, war or changes in political climate occur, millions suffer from starvation.

### Clinical features

Although the basic condition of PEM is the same in all parts of the world, whatever the cause, malnutrition resulting from long periods of near-total starvation produces unique clinical appearances in children that are virtually never seen in high-income countries. The term ‘protein–energy malnutrition’ covers the spectrum of clinical conditions seen in adults and children. Children under 5 years may present with the following:

- **Kwashiorkor** occurs typically in a young child displaced from breast-feeding by a new baby. It is often precipitated by infections such as measles, malaria and diarrhoeal illnesses. The child is apathetic and lethargic with severe anorexia. There is generalised oedema with skin pigmentation and thickening (Fig. 33.6B). The hair is dry and sparse, and may become reddish or yellow in colour. The abdomen is distended owing to hepatomegaly and/or ascites. The serum albumin is always low. The exact cause is unknown, but theories related to diet (low in protein and high in carbohydrate) and free radical damage in the presence of inadequate antioxidant defences have been proposed.

- **Marasmus** is the childhood form of starvation, which is associated with obvious wasting. The child looks emaciated, and there is obvious muscle wasting and loss of body fat. There is no oedema. The hair is thin and dry (Fig. 33.6A). The child is not as apathetic or anorexic as with kwashiorkor. Diarrhoea is frequently present and signs of infection must be looked for carefully.

The WHO classification of severe malnutrition (Box 33.9) makes no distinction between kwashiorkor and marasmus because the approach to treatment is similar in both. The WHO classification of chronic under-nutrition in children is based on standard deviation (SD) scores. Thus, children with an SD score between −2 and −3 (between 3 and 2 SD scores below the median, corresponding to a value between 0.13 and 2.3 centiles) can be regarded as being at moderate risk of under-nutrition; below an SD score of −3, there is a risk of severe malnutrition. A low weight-for-height is a measure of thinness (wasting when pathological) and a low height-for-age is a measure of shortness (stunting when pathological). Those with oedema and clinical signs of severe malnutrition are classified as having oedematous malnutrition.

**Starvation in adults** may lead to extreme loss of weight, depending on the severity and duration. They may crave food, are apathetic, and complain of cold and weakness with a loss of subcutaneous fat and muscle wasting. The WHO classification is based on BMI, with a value less than 18.5 kg/m² indicating malnutrition (severe malnutrition if <16.0 kg/m²).

Severely malnourished adults and children are very susceptible to respiratory and gastrointestinal infections, leading to an increased mortality in these groups.

### Investigations

These are not always practicable in certain settings in the developing world.

- **Blood tests** may demonstrate the following results:
  - Anaemia due to folate, iron and copper deficiency is often present, but the haematocrit may be high owing to dehydration.
  - Eosinophilia suggests parasitic infestation.
  - Electrolyte disturbances are common.
  - Malarial parasites should be sought.
  - Human immunodeficiency (HIV) tests should be performed.

---

**Fig. 33.6 Malnourished children. (A) Marasmus. (B) Kwashiorkor. (Courtesy of Dr Paul Kelly.)**
- **Stools** should be examined for parasitic infestations.
- **Chest X-ray** may reveal tuberculosis, which is common and easily missed if a chest X-ray is not performed.

### Management

Management must involve the provision of protein and energy supplements and the control of infection. The approach to the treatment of children is described below. Adults do not usually suffer such severe malnutrition but the same general principles of treatment should be followed.

### Resuscitation and stabilization

The severely ill child will require:
- correction of fluid and electrolyte abnormalities, avoiding intravenous therapy, if possible, because of the danger of fluid overload
- treatment of shock

- treatment of hypoglycaemia (blood glucose <3 mmol/L), hypothermia (reduce heat loss, and provide additional heat if necessary) and infection (antibiotics) – these often coexist.

The standard WHO **oral hydration solution** has a high sodium and low potassium content and is not suitable for severely malnourished children. Instead, the rehydration solution for malnutrition (ReSoMal) is recommended. It is commercially available but can also be produced by modification of the standard WHO oral hydration solution.

**Infection** is common (Box 33.10). Diarrhoea is often due to bacterial or protozoal overgrowth; metronidazole is very effective and is often given routinely. Parasites are also common and, as facilities for stool examination are usually not available, mebendazole 100 mg twice daily should be given for 3 days. In high-risk areas, antimalarial therapy is given. A recent study in Malawi suggests that the addition of antibiotics to therapeutic regimens for uncomplicated severe acute malnutrition in children less than 5 years of age is associated with a significant improvement in recovery and mortality.

Large doses of **vitamin A** are also given because deficiency of this vitamin is common. After the initial resuscitation, further stabilization over the next few days is undertaken, as indicated in Box 33.11.

### Re-feeding

This needs to be planned carefully. During the initial management of the acute situation, a balanced diet with sufficient protein and energy is given to maintain a steady state. Large increases in energy can lead to heart failure, circulatory collapse and death (re-feeding syndrome). Initial feeding involves the administration of feeds that are low in osmolarity and low in lactose. WHO recommendations are 100 kcal/kg per day; 1.0–1.5 g protein/kg per day; and 130 mL liquid/kg per day (100 mL/kg per day if the child has marked oedema). Attempts should be made to give the feeds slowly and frequently (e.g. 2-hourly during days 1–2; 3-hourly during days 3–5; and 4-hourly thereafter), although anorexia is often a problem and can be exacerbated by excessive feeding. If necessary, fluids and food should be given by nasogastric tube. The child is then gradually weaned to liquids and then solids by mouth. All severely malnourished children have vitamin and mineral...
deficiencies. Although anaemia is common, the WHO recommends giving iron only after the child develops a good appetite and starts gaining weight, because of concern about detrimental effects during the acute phase of illness (iron is a pro-oxidant). The child should be given daily micronutrient supplements for at least 2 weeks. These should include a multivitamin supplement with folic acid, zinc and copper.

**Rehabilitation**

Gradually, as the child improves, more energy can be given, and during rehabilitation, weight gain is achieved by providing extra energy and protein (‘catch-up weight gain’). Children who have been severely ill need constant attention right through the convalescent period, as home conditions are often poor and feeds are refused. Sensory stimulation and emotional support are major components of management during both the stabilization and the rehabilitation phases. The treatment of underlying chronic infective conditions, such as HIV, malaria and tuberculosis, is also necessary.

**Care setting**

In some parts of the world where malnutrition is widespread, there are not enough hospitals or therapeutic feeding centres to cope with the problem; this emphasizes the need for outpatient and community-based programmes, although these require investment and time to build to full capacity. The programmes may involve the use of ready-to-use therapeutic foods, such as energy-dense pastes with minerals and vitamins, without the need to add water, which could potentially contaminate the food.

**Prognosis**

Children with extreme malnutrition have a mortality of over 50%. By careful management, this can be reduced significantly to less than 10%, depending on the availability of facilities and trained staff. Treatment of underlying disease is essential. Brain development takes place in the first years of life, a time when severe PEM is frequently seen. There is evidence that intellectual impairment and behavioural abnormalities occur in severely affected children. Physical growth is also impaired. Probably both of these effects can be alleviated if it is possible to maintain a high standard of living with a good diet and freedom from infection over a long period.

**Prevention**

Prevention of PEM depends not only on the availability of adequate nutrients but also on the education of both governments and individuals in the importance of good nutrition and immunization (Box 33.12). Short-term programmes are useful for acute shortages of food, but long-term programmes involving improved agriculture are equally necessary. Bad feeding practices and infections are more prevalent than actual shortage of food in many areas of the world. However, good surveillance is necessary to avoid periods of famine.

---

**Box 33.12 Prevention of protein–energy malnutrition – GOBIF (a WHO priority programme)**

- Growth monitoring: the WHO has a simple growth chart that the mother keeps
- Oral rehydration, particularly for diarrhea
- Breast-feeding supplemented by food after 6 months
- Immunization: against measles, tetanus, pertussis, diphtheria, polio and tuberculosis (see also Box 20.20)
- Family planning

Food supplements (and additional vitamins) should be given to ‘at-risk’ groups by adding high-energy food (e.g. milk powder, meat concentrates) to the diet. Pregnancy and lactation are times of high energy requirement and supplements have been shown to be beneficial.

**Further reading**

---

**VITAMINS**

Deficiencies due to inadequate intake associated with PEM (Box 33.13) are commonly seen in developing countries. This is not, however, invariable. For example, vitamin A deficiency is not seen in Jamaica, but is common in PEM in Hyderabad, India. In the West, deficiency of vitamins is less common but prominent in the specific groups shown in Box 33.14. The widespread use of vitamins as ‘tonics’ is unnecessary. Toxicity from excess fat-soluble vitamins is occasionally seen.

**FAT-SOLUBLE VITAMINS**

**Vitamin A**

Vitamin A (retinol) is part of the family of retinoids, which is present in food and the body as esters combined with long-chain fatty acids. The richest food source is liver, but it is also found in milk, butter, cheese, egg yolks and fish oils. Retinol or carotene is added to margarine in the UK and other countries.

Beta-carotene is the main carotenoid found in green vegetables, carrots and other yellow and red fruits. Other carotenoids, lycopene and lutein, are probably of little quantitative importance as dietary precursors of vitamin A.

Beta-carotene is cleaved in the intestinal mucosa by carotene dioxygenase, yielding retinaldehyde, which can be reduced to retinol. Between one-quarter and one-third of dietary vitamin A in the UK is derived from retinoids. Nutritionally, 6 μg of β-carotene is equivalent to 1 μg of preformed retinol; vitamin A activity in the diet is given as retinol equivalents.

**Function**

Retinol is stored in the liver and is transported in plasma bound to an α-globulin, retinol-binding protein (RBP). Vitamin A has several metabolic roles:

- Retinaldehyde in its cis form is found in the opsin proteins in the rods (rhodopsin) and cones (iodopsin) of the retina (see p. 913).

### Box 33.14 Some causes of vitamin deficiency in developed countries

**Decreased intake**
- Alcohol dependency: chiefly B vitamins (e.g., thiamine)
- Small bowel disease: chiefly folate, occasionally fat-soluble vitamins
- Vegans: vitamin D (if no exposure to sunlight), vitamin B₁₂
- Elderly with poor diet: chiefly vitamin D (if no exposure to sunlight), folate
- Anorexia from any cause: chiefly folate

**Decreased absorption**
- Ileal disease/resection: only vitamin B₁₂
- Liver and biliary tract disease: fat-soluble vitamins
- Intestinal bacterial overgrowth: vitamin B₁₂
- Oral antibiotics: vitamin K

**Miscellaneous**
- Long-term enteral or parenteral nutrition: usually vitamin supplements are given
- Renal disease: vitamin D
- Drug antagonists (e.g. methotrexate interfering with folate metabolism)

Light causes retinaldehyde to change to its trans isomer, and this leads to changes in membrane potentials that are transmitted to the brain.

- Retinol and retinoic acid are involved in the control of cell proliferation and differentiation.
- Retinyl phosphate is a co-factor in the synthesis of most glycoproteins containing mannose.

### Vitamin A deficiency

Worldwide, vitamin A deficiency and xerophthalmia (see below) are major causes of blindness in young children, despite intensive preventative programmes.

Xerophthalmia has been classified by the WHO (Box 33.15). Impaired adaptation, followed by night blindness, is the first effect. There is dryness and thickening of the conjunctiva and the cornea (xerophthalmia occurs as a result of keratinization). Bitot’s spots – white plaques of keratinized epithelial cells – are found on the conjunctiva of
young children with vitamin A deficiency. These spots can, however, be seen without vitamin A deficiency, possibly caused by exposure. Corneal softening, ulceration and dissolution (keratomalacia) eventually occur, superimposed infection is a frequent accompaniment and both lead to blindness (Fig. 33.7). In PEM, retinol-binding protein is reduced, along with other proteins. This suggests vitamin A deficiency, although body stores are not necessarily reduced.

**Vitamin A in malnourished children**

Vitamin A supplementation (single oral dose of 60 mg retinol palmitate) appears to improve morbidity and mortality from measles. It has also been suggested that similar supplementation reduces morbidity and/or mortality from diarrhoeal diseases and respiratory infections, and improves growth.

**Diagnosis**

In parts of the world where deficiency is common, diagnosis is made on the basis of the clinical features, and deficiency should always be suspected if any degree of malnutrition is present. Blood levels of vitamin A will usually be low, but the best guide to diagnosis is a response to replacement therapy.

**Management**

Urgent treatment with retinol palmitate 30 mg orally should be given on two successive days. In the presence of vomiting and diarrhoea, 30 mg of vitamin A is given intramuscularly. Associated malnutrition must be treated, and superadded bacterial infection should be treated with antibiotics. Referral for specialist ophthalmic treatment is necessary in severe cases.

**Prevention**

Most Western diets contain enough dairy products and green vegetables, but vitamin A is added to foodstuffs (e.g. margarine) in some countries. Vitamin A is not destroyed by cooking.

In some developing countries, vitamin A supplements are given at the time a child attends for measles vaccination. Food fortification programmes are another approach. Education of the population is necessary and people should be encouraged to grow their own vegetables. In particular, pregnant women and children should be encouraged to eat green vegetables and yellow fruits.

**Other effects of vitamin A**

In a chronically malnourished population, maternal repletion with vitamin A before, during and after pregnancy may improve lung function in the offspring at 9–13 years. It may also reduce maternal mortality. Administration of vitamin A to young children at risk of deficiency reduces mortality, although to a lesser extent than previously thought. The effect of β-carotene in cardiovascular and other diseases is discussed below in the section entitled ‘Dietary antioxidants’ (see p. 1242). Retinoic acid and some synthetic retinoids are used in dermatology (see Box 20.9).

**Possible adverse effects**

- **High intakes of vitamin A.** Chronic ingestion of retinol can cause liver and bone damage, hair loss, double vision, vomiting, headaches and other abnormalities. Single doses of 300 mg in adults or 100 mg in children can be harmful.
- **Retinol is teratogenic.** The incidence of birth defects in infants is high with vitamin A intakes of more than 3 mg a day during pregnancy. In pregnancy, extra vitamin A or consumption of liver is not recommended in the UK. However, β-carotene is not toxic.

**Vitamin D**

Vitamin D is discussed in more detail on pages 483–444, where the most common manifestations of deficiency are outlined (rickets and osteomalacia). Vitamin D status is assessed by measurement of 25-hydroxyvitamin D in the serum. Vitamin D receptors are distributed widely in human tissues but their function in many non-musculoskeletal tissues still remains poorly understood. Vitamin D status has been linked to a wide range of diseases, including:

- cardiovascular disorders (ischaemic heart disease, heart failure, hypertension)
- respiratory disorders (chest infections)
- renal disorders (progression of renal disease)
- endocrine disorders (type 1 and type 2 diabetes)
- neuropsychiatric disorders (depression, cognitive deficits)
- cancer (e.g. prostate, breast, colon) and mortality from various causes.
- multiple sclerosis (see p. 864).

It has therefore been suggested that vitamin D may have a role in global health, and not just the health of the musculoskeletal system. Studies of the relationship between vitamin D serum levels (25-hydroxyvitamin D) and the risk of the conditions listed above have led to different definitions of the optimal level of 25-hydroxyvitamin D for adequate status. This also implies that there are different requirements for vitamin D in different diseases. However, randomized controlled trials (RCTs) of vitamin D supplementation have not been as promising in averting some of these conditions as might have been anticipated from the observational relationships. Reduced circulating concentrations of vitamin D can result not only from lack of exposure to sunlight and a poor diet, but also from inflammation, smoking and obesity.

**Vitamin K**

Vitamin K is found as phylloquinone (vitamin K₁) in green, leafy vegetables, dairy products, and rapeseed and soya bean oils. Intestinal bacteria can synthesize the other major form of vitamin K, menaquinone (vitamin K₃), in the terminal ileum and colon. Vitamin K is absorbed in a similar manner to other fat-soluble substances in the upper small gut. Some menaquinones must also be absorbed, as this is the major form found in the human liver.
**Function**

Vitamin K is a co-factor that is necessary for the production not only of blood clotting factors (II, VII, IX and X, and other proteins involved in coagulation), but also of proteins that are necessary for the formation of bone.

Vitamin K is a co-factor for the post-translational carboxylation of specific protein-bound glutamate residues in γ-carboxyglutamate (Gla). Gla residues bind calcium ions to phospholipid templates, and this action on factors II, VII, IX and X, and on proteins C and S, is required for coagulation to take place.

Bone osteoblasts contain three vitamin K-dependent proteins: osteocalcin, matrix Gla protein and protein S, which have a role in bone matrix formation. Osteocalcin contains three Gla residues, which bind tightly to the hydroxyapatite matrix, depending on the degree of carboxylation; this leads to bone mineralization. There is, however, no convincing evidence that vitamin K deficiency or antagonism affects bone other than rapidly growing bone.

**Vitamin K deficiency**

Vitamin K deficiency results in inadequate synthesis of clotting factors, which leads to an increase in the prothrombin time and haemorrhage. It has also been linked to bone health, but there is inadequate evidence to support the routine use of vitamin K to prevent osteoporosis and reduce fracture risk. Deficiency occurs in the newborn, in cholestatic jaundice, and with concomitant use of vitamin K antagonists.

**The newborn**

Deficiency occurs in the newborn owing to:

- poor placental transfer of vitamin K
- the fact that there is little vitamin K in breast milk
- the lack of hepatic stores of menaquinone (no intestinal bacteria in the neonate).

Deficiency leads to a haemorrhagic disease of the newborn, which can be prevented with prophylactic vitamin K. Vitamin K (phytomenadione 1 mg, i.m.) is given to all neonates after the risks have been discussed with parents and consent has been obtained.

**Cholestatic jaundice**

When bile flow into the intestine is interrupted, malabsorption of vitamin K occurs, as no bile salts are available to facilitate absorption and the prothrombin time increases. This can be corrected by giving 10 mg of phytomenadione intramuscularly. (Note that an increased prothrombin time caused by liver disease does not respond to vitamin K injection, there being no shortage of vitamin K – just poor liver function.) In patients with chronic cholestasis (e.g. primary biliary cholangitis), oral therapy with a water-soluble preparation, menadiol sodium phosphate 10 mg daily, is used.

**Concomitant vitamin K antagonists**

Oral anticoagulants, such as warfarin, antagonize vitamin K. Antibacterial drugs also interfere with the bacterial synthesis of vitamin K.

**Vitamin E**

Vitamin E includes eight naturally occurring compounds that may be divided into tocopherols and tocotrienols. The most active compound and the most widely available in food is the natural isomer d-d-α-tocopherol (or RRR-α-tocopherol), which accounts for 90% of vitamin E in the human body. Vegetables and seed oils, including soya bean, saffron, sunflower, cereals and nuts, are the main sources. Animal products are poor sources of the vitamin. Vitamin E is absorbed with fat, transported in the blood largely in LDLs.

An individual’s vitamin E requirement depends on the intake of polyunsaturated fatty acids (PUFAs). Since this varies widely, no daily requirement is given in the UK. The requirement stated in the USA is approximately 7–10 mg/day, but average diets contain much more than this. If PUFAs are taken in large amounts, more vitamin E is required.

**Function**

The biological activity of vitamin E results principally from its antioxidant properties. In biological membranes, it contributes to membrane stability. It protects cellular structures against damage from a number of highly reactive oxygen species, including hydrogen peroxide, superoxide and other oxygen radicals. Vitamin E may also affect cell proliferation and growth.

**Vitamin E deficiency**

The first deficiency to be demonstrated was a haemolytic anaemia described in premature infants. Infant formulations now contain vitamin E.

Deficiency is seen only in children with abetalipoproteinaemia (see p. 1196) and in patients on long-term parenteral nutrition. The severe neurological deficit (gross ataxia) can be prevented with vitamin E injections.

 Plasma or serum levels of α-tocopherol can be measured and should be corrected for the level of plasma lipids by expressing the value as milligrams per milligram of plasma lipid.

**Epidemiological data and clinical trials**

Animals fed an atherogenic diet supplemented with α-tocopherol develop far fewer new atheromatous lesions than those fed an atherogenic diet alone; there may be regression of existing lesions.

There is also evidence for vitamin E intake and blood α-tocopherol levels as an independent risk factor for the development of ischaemic heart disease in healthy, well-nourished individuals eating a Western diet. This has been shown in comparisons of different communities in the WHO ‘MONICA’ observational study.

Randomized trials involving vitamin E supplementation have produced conflicting results, possibly due to factors such as short duration of treatment, use of suboptimal doses or lack of concurrent administration of vitamin C. There are very few trials to assess the role of vitamin E in prevention of peripheral vascular disease and cancer.

**WATER-SOLUBLE VITAMINS**

Water-soluble vitamins are non-toxic and relatively cheap; they can therefore be given in large amounts if a deficiency is possible. The daily requirements for water-soluble vitamins are given in Box 33.13.
pyruvate) and in the Krebs cycle, TPP is the key enzyme for the
decarboxylation of α-ketoglutarate to succinyl CoA. TPP is also the
cofactor for transketolase, a key enzyme in the hexose monophos-
phate shunt.

Thiamine is found in many foodstuffs, including cereals, grains, beans and nuts, as well as pork and duck. It is often added to food (e.g. in cereals) in developed countries. The dietary requirement (see Box 33.13) depends on energy intake, more being required if the diet is high in carbohydrates.

Following absorption, thiamine is found in all body tissues, the majority being in the liver. Body stores are small and signs of deficiency quickly develop with inadequate intake.

There is no evidence that a high oral intake is dangerous but ataxia has been reported after high parenteral therapy.

**Thiamine deficiency**

Thiamine deficiency is seen:

- **As beriberi**, where the only staple food consumed is polished rice.
- In **chronic alcohol-dependent patients** who are consuming virtually no food at all.
- In **starved patients** (e.g. with carcinoma of the stomach), and in severe prolonged hyperemesis gravidarum, anorexia nervosa and prolonged total starvation in healthy subjects (e.g. fasts for political reasons). It can also occur in patients given parenteral nutrition with little or no thiamine, as large doses of glucose increase requirements for thiamine and can precipitate deficiency (e.g. during re-feeding).

**Beriberi**

This is now confined to the poorest areas of South-east Asia. It can be prevented by eating under-milled or parboiled rice, or by fortification of rice with thiamine. The prevention of beriberi needs a general increase in overall food consumption so that the staple diet is varied and includes legumes and pulses, which contain a large amount of thiamine. There are two main clinical types of beriberi, which, surprisingly, only rarely occur together.

- **Dry beriberi** usually presents insidiously with a symmetrical polyneuropathy. The initial symptoms are heaviness and stiffness of the legs, followed by weakness, numbness, and pins and needles. The ankle jerk reflexes are lost and eventually all the signs of polyneuropathy that may involve the trunk and arms are found (see p. 891). Cerebral involvement occurs, producing the picture of the Wernicke–Korsakoff syndrome (p. 891). In endemic areas, mild symptoms and signs may be present for years without unduly affecting the patient.
- **Wet beriberi** causes oedema. Initially, this is of the legs, but it can extend to involve the whole body, with ascites and pleural effusions. The peripheral oedema may mask the accompanying features of dry beriberi.

Thiamine deficiency impairs pyruvate dehydrogenase with accumulation of lactate and pyruvate, producing peripheral vasodilatation and eventually oedema. The heart muscle is also affected and heart failure occurs, causing a further increase in the oedema. Initially, there are warm extremities, a full, fast, bounding pulse and a raised venous pressure (“high-output state”), but eventually heart failure advances and a poor cardiac output ensues. The electrocardiogram may show conduction defects.

**Infantile beriberi** occurs, usually acutely, in breast-fed babies at approximately 3 months of age. The mothers show no signs of thiamine deficiency but presumably their body stores must be virtually nil. The infant becomes anorexic, develops oedema and has some degree of aphony. Tachycardia and tachypnoea develop and, unless treatment is instituted, death occurs quickly.

**Diagnosis**

In endemic areas, the diagnosis of beriberi should always be suspected; if it is in doubt, treatment with thiamine should be instituted. A rapid disappearance of oedema after thiamine (50 mg i.m.) is diagnostic. Other causes of oedema must be considered (e.g. renal or liver disease), and the polyneuropathy is indistinguishable from that due to other causes. The diagnosis is confirmed by measurement of the circulating thiamine concentration or transketolase activity in red cells using fresh heparinized blood.

**Management**

Thiamine 50 mg i.m. is given for 3 days, followed by 50 mg of thiamine daily by mouth. The response in wet beriberi is seen in hours, providing a dramatic improvement, but in dry beriberi improvement is often slow to occur. In most cases, all the B vitamins are given because of multiple deficiency. Infantile beriberi is treated by giving thiamine to the mother, which is then passed on to the infant via the breast milk.

**Thiamine deficiency in people with alcohol dependence or acute illness**

In the developed world, alcohol-dependent people and those with severe acute illness receiving high-carbohydrate infusions without vitamins are the only major groups to suffer from thiamine deficiency. Rarely, they develop wet beriberi, which must be distinguished from alcoholic cardiomyopathy. More usually, however, thiamine deficiency presents with polyneuropathy or with the Wernicke–Korsakoff syndrome.

This syndrome, which consists of dementia, ataxia, varying ophthalmoplegia and nystagmus (see p. 891), presents acutely and should be suspected in all heavy drinkers. If treated promptly, it is reversible; if left, it becomes irreversible. It is a major cause of dementia in the USA.

**Urgent treatment** with thiamine 250 mg i.m. or i.v. infusion once daily is given for 3 days, often combined with other B-complex vitamins. Anaphylaxis can occur. Thiamine must always be given before any intravenous glucose infusion.

**Riboflavin**

Riboflavin is widely distributed throughout all plant and animal cells. Good sources are dairy products, offal and leafy vegetables. Riboflavin is not destroyed appreciably by cooking but is destroyed by sunlight. It is a flavo-protein that is a co-factor for many oxidative reactions in the cell.

There is no definite deficiency, although many communities have low dietary intakes. Studies in volunteers taking a low-riboflavin diet have produced:

- angular stomatitis or cheilosis (fissuring at the corners of the mouth)
- a red, inflamed tongue
- seborrhoeic dermatitis, particularly involving the face (around the nose) and the scrotum or vulva

Conjunctivitis with vascularization of the cornea and opacity of the lens has also been described. It is probable, however, that many of the above features are due to multiple deficiencies rather than lack of riboflavin itself.

Riboflavin 5 mg daily can be tried for the above conditions, usually given as the vitamin B complex.
Niacin

This is the generic name for the two chemical forms, nicotinic acid and nicotinamide, the latter being found in the two pyridine nucleotides, nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP). Both act as hydrogen acceptors in many oxidative reactions, and in their reduced forms (NADH and NADPH) act as hydrogen donors in reductive reactions. Many oxidative steps in the production of energy require NAD and NADP.

Niacin can be synthesized in humans from tryptophan, 60 mg of tryptophan being converted to 1 mg of niacin. The amount of niacin in food is given as the ‘niacin equivalent’, which is equal to the amount of niacin plus one-sixtieth of the tryptophan content. Eggs and cheese contain tryptophan.

Kynureninase and kynurenine hydroxylase, key enzymes in the conversion of tryptophan to nicotinic acid, are both B₆ and riboflavin-dependent, and deficiency of these B vitamins can also produce Pellagra.

Pellagra

This is rare but is found in people who eat virtually only maize: for example, in parts of Africa. Maize contains niacin in the form of niacytin, which is biologically unavailable and has a low content of tryptophan. In Central America, pellagra has always been rare because maize (for the cooking of tortillas) is soaked overnight in calcium hydroxide, which releases niacin. Many of the features of pellagra (Fig. 33.8) can be explained purely by niacin deficiency, but some are probably due to multiple deficiencies, including deficiencies of proteins and of other vitamins.

Clinical features

The classical features are dermatitis, diarrhoea and dementia. Although this is an easily remembered triad, not all features are always present and the mental changes are not a true dementia.

Fig. 33.8 Pellagra. Hyperpigmentation with desquamation of the dorsal aspects of the hands and forearms. (From Bologna JL, Jorizzo JL, Schaffer JV (eds). Dermatology, 3rd edn. St Louis: Mosby; 2012, with permission.)

• Dermatitis. In the areas of skin exposed to sunlight, there is redness initially, followed by cracks with occasional ulceration. Chronic thickening, dryness and pigmentation develop. The lesions are always symmetrical and often affect the dorsal surfaces of the hands. The perianal skin and vulva are frequently involved. Casal’s necklace or collar is the term given to the skin lesion around the neck, which is confined to this area by the clothes worn.

• Diarrhoea. This is often a feature but constipation is occasionally seen. Other gastrointestinal manifestations include a painful, red, raw tongue, glossitis and angular stomatitis. Recurring mouth infections occur.

• Dementia. This occurs in chronic disease. In milder cases, there are symptoms of depression, apathy and sometimes thought disorders. Tremor and an encephalopathy frequently occur. Hallucinations and acute psychosis are also seen with more severe cases.

Pellagra may also occur in the following circumstances:

• Isoniazid therapy. This can lead to a deficiency of vitamin B₆, which is needed for the synthesis of nicotinamide from tryptophan. Vitamin B₆ is now given concomitantly with isoniazid.

• Hartnup’s disease, a rare inborn error in which basic amino acids, including tryptophan, are not absorbed by the gut. There is also loss of this amino acid in the urine.

• Generalized malabsorption (rare).

• Alcohol-dependent patients who eat little.

• Very-low-protein diets

• Carcinoid syndrome and phaeochromocytomas. In these disorders, tryptophan metabolism is diverted away from the formation of nicotinamide to form amines.

Diagnosis and management

In endemic areas, diagnosis and management are based on the clinical features, remembering that other vitamin deficiencies can produce similar changes (e.g. angular stomatitis). Niacinamide (approximately 300 mg daily by mouth) is given, with a maintenance dose of 50 mg daily, and produces a dramatic improvement in the skin and diarrhoea. Mostly, however, vitamin B complex is given, as other deficiencies are often present.

An increase in the protein content of the diet, and treatment of malnutrition and other vitamin deficiencies, are essential.

Vitamin B₆

Vitamin B₆ exists as pyridoxine, pyridoxal and pyridoxamine, and is found widely in plant and animal foodstuffs. Pyridoxal phosphate is a co-factor in the metabolism of many amino acids. Dietary deficiency is extremely rare. Some drugs (e.g. isoniazid, hydralazine and penicillamine) interact with pyridoxal phosphate, producing B₆ deficiency. The polynuropathy occurring after isoniazid usually responds to vitamin B₆.

Sideroblastic anaemia may respond to vitamin B₆ (see p. 332).

A polynuropathy has occurred after high doses (>200 mg) given over many months.

Biotin and pantothenic acid

Biotin is involved in a number of carboxylase reactions. It occurs in many foodstuffs and the dietary requirement is small. Deficiency is extremely rare and is confined to a few people who consume raw
Vitamin C

Ascorbic acid is a powerful reducing agent that controls the redox potential within cells. It is involved in the hydroxylation of proline to hydroxyproline, which is necessary for the formation of collagen. The failure of this biochemical pathway in vitamin C deficiency accounts for virtually all of the clinical effects seen.

Humans, along with a few other animals (e.g. primates and the guinea-pig), are unusual in not being able to synthesize ascorbic acid from glucose.

Vitamin C is present in all fresh fruit and vegetables. Unfortunately, ascorbic acid is easily leached out of vegetables when they are placed in water and it is also oxidized to dehydro-ascorbic acid during cooking or exposure to copper or alkalis. Potatoes are a good source, as many people eat a lot of them, but vitamin C is lost during storage.

It has been suggested that ascorbic acid in high dosage (1–2 g daily) will prevent the common cold. While there is some scientific support for this, clinical trials have shown no significant effect. Vitamin C supplements have also been advocated to prevent atherosclerosis and cancer, but again a clear benefit has not been demonstrated.

Vitamin C deficiency is seen mainly in infants fed boiled milk and in people who do not eat vegetables, such as those consuming rice-only diets.

Scurvy

In adults, the early symptoms of vitamin C deficiency may be non-specific, with weakness and muscle pain. Other features are shown in Box 33.16. Parafolllicular haemorrhages and corkscrew hairs (Fig. 33.9) occur. In infantile scurvy, there is irritability, painful legs, anaemia and characteristic subperiosteal haemorrhages, particularly into the ends of long bones.

Diagnosis

The anaemia is usually hypochromic but, occasionally, a normochromic or megaloblastic anaemia is seen. The type of anaemia depends on whether iron deficiency (owing to decreased absorption or loss due to haemorrhage) or folate deficiency (folate being largely found in green vegetables) is present.

Plasma ascorbic acid is very low in obvious deficiency and a vitamin C level of below 11 μmol/L (0.2 mg/100 mL) indicates vitamin C deficiency. The leucocyte-platelet layer (buffy coat) of centrifuged blood corresponds to vitamin C concentrations in other tissues. The normal level of leucocyte ascorbate is 1.1–2.8 pmol/10⁶ cells.

Management

Initially, the patient is given 250 mg of ascorbic acid daily and encouraged to eat fresh fruit and vegetables. Subsequently, 40 mg daily will maintain a normal exchangeable body pool of about 900 mg (5.1 mmol).

Prevention

Orange juice should be given to bottle-fed infants. The intake of breast-fed infants depends on the mother’s diet. In the elderly, eating adequate fruit and vegetables is the best way to avoid scurvy. Careful surveillance of the elderly, particularly those who live alone, is necessary. Ascorbic acid supplements should be necessary only occasionally.

Vitamin B₁₂ and folate

These are dealt with on page 334 and daily requirements are shown in Box 33.13.

Folate

In many developed countries, up to 15% of the population have a partial deficiency of 5,10-methylene tetrahydrofolate reductase, a key folate-metabolizing enzyme. This is due to a point mutation and is associated with an increase in neural tube defects and hyperhomocysteinaemia, which has been linked to cardiovascular disease. Autoantibodies against folate receptors have been found in serum from women who have had a pregnancy complicated by neural tube defects. However, the role of this in the pathogenesis is unclear.

In the USA and some other countries, enriched cereals are fortified with folic acid 1.4 mg/kg of grain to increase daily intake.

DIETARY ANTIOXIDANTS

Free radicals are generated during inflammatory processes, radiotherapy, smoking and in the course of a wide range of diseases. They may cause uncontrolled damage of multiple cellular components, the most sensitive of which are unsaturated lipids, proteins and DNA, and they also disrupt the normal replication process. They have been implicated as a cause of a wide range of diseases, including malignant, acute inflammatory and traumatic diseases, cardiovascular disease, neurodegenerative conditions such as Alzheimer’s disease, senile macular degeneration, and cataract. Defence against uncontrolled damage by free radicals is provided by antioxidant enzymes (e.g. catalase, superoxide dismutase) and antioxidants, which may be endogenous (e.g. glutathione) or
exogenous (e.g., vitamins C and E, carotenoids). A possible causal link between lack of antioxidants and cardiovascular disease has emerged from epidemiological studies, although several RCTs have not confirmed this.

**Epidemiology**

**Dietary intake**

- A high intake of fruits and vegetables has been linked to a reduced risk of heart disease, cerebrovascular disease and total cardiovascular morbidity and mortality.
- A high intake of nuts (rich in vitamin E) and dietary components, such as red wine, onions and apples (rich in flavonoids), which are strong scavengers of free radicals, has also been linked to a reduced risk of cardiovascular disease.
- The seasonal variation in cardiovascular disease, which is higher in winter, has been related to a decreased intake of fresh fruit and vegetables at that time of year.
- The decline in cardiovascular disease in the USA since the 1950s has been associated with a simultaneous increase in the intake of fresh fruit and vegetables.

**Status of antioxidant nutrients**

The level of antioxidant nutrients in the circulation has been reported to be inversely related to cardiovascular morbidity and mortality, the extent of atherosclerosis as assessed by intra-arterial ultrasound, and clinical signs of ischaemic heart disease. The tissue content of lycopene, a marker of vegetable intake, has been reported to be low in patients with myocardial infarction.

Antioxidants, especially vitamin E, have been shown to prevent the initiation and progression of atherosclerotic disease in animals. They also reduce the oxidation of LDL in the arterial wall *in vitro*. Oxidation of LDL is an initial event in the atherosclerotic process (see p. 1079). However, these epidemiological studies show an association rather than a causal link, and RCTs comparing the antioxidant against a control group are necessary.

The results of RCTs (see also p. 72) have been formally evaluated through a series of systematic reviews and meta-analyses.

- For *primary or secondary prevention* of cardiovascular disease, intervention with β-carotene, α-tocopherol (vitamin E) and ascorbic acid (vitamin C) has demonstrated no significant benefit.
- Vitamin E or β-carotene given in, for example, stroke and fatal and non-fatal myocardial infarction has also not yielded benefits.
- There is a report of increased risk of intracerebral and subarachnoid haemorrhage in healthy individuals receiving carotene and α-tocopherol.
- A meta-analysis has shown a small but significant overall increased risk of cardiovascular death and all-cause mortality in individuals treated with β-carotene (compared with the control group).
- There is an increased risk of developing lung cancer when large doses of β-carotene are administered to subjects with a history of heavy smoking.
- Although administration of antioxidant nutrients has been proposed in a wide range of acute (e.g. critical illness, pancreatitis) and chronic diseases, the evidence base from RCTs is generally not strong.
- In some cases, improvement in indices of free radical damage has been demonstrated (e.g. in acute inflammatory conditions), but with little evidence of clinical benefit.

Epidemiological studies are also confounded by other associated variables, such as eating a low-fat diet or undertaking more exercise. The latter may be more valuable in the causal pathway than the intake of antioxidants. Diets rich in fresh fruit and vegetables also contain a range of antioxidants that were not tested in the clinical trials. Therefore, the results of large-scale RCTs using various combinations and doses of antioxidant nutrients are awaited.

In the meantime, the policy of encouraging ‘healthy’ behaviour, which includes increased physical activity and a varied diet rich in fresh fruit and vegetables, and nuts, is still generally recommended both for the population as a whole and for those at risk of cardiovascular disease.

**HOMOCYSTEINE, CARDIOVASCULAR DISEASE AND B VITAMINS**

The circulating concentration of the amino acid homocysteine is an independent risk factor for cardiovascular disease. A high concentration is related to ischaemic heart disease, stroke, thrombosis, pulmonary embolism, coronary artery stenosis and heart failure. The strength of the association is similar to that in smoking or hyperlipidaemia.

Proposed mechanisms, based on experimental evidence, by which homocysteine detrimentally affects vascular function, include:

- the direct damaging effects of homocysteine on endothelial cells of blood vessels
- an increase in blood vessel stiffness
- an increase in blood coagulation

Homocysteine is not found in food, but results from metabolism within the body, which depends on folic acid, vitamin B₁₂ and pyridoxine (vitamin B₆) (Fig. 33.10). Deficiency of one or more of these vitamins is common in the elderly, which would increase the concentration of homocysteine. If an elevated homocysteine concentration were causally linked to cardiovascular disease, then it should be possible to lower the risk by administering one or more of these vitamins to decrease the homocysteine concentration. However, several studies suggest that lowering homocysteine concentrations in this way does not reduce the risk of cardiovascular disease.

MINERALS

A number of minerals have been shown to be essential in animals, and an increasing number of deficiency syndromes are becoming recognized in humans. Long-term total parenteral nutrition allowed trace element deficiency to be studied in controlled conditions; now trace elements are always added to long-term parenteral nutrition regimens. It is highly probable that trace-element deficiency is also a frequent accompaniment of all PEM states, but this is difficult to study because of multiple deficiencies. Sodium, potassium, magnesium and chloride are discussed in Chapter 9. Reference nutrient intake (RNI) values are shown in Box 33.17. However, in disease, the requirements of specific nutrients may increase (e.g. sodium potassium, magnesium and chloride in patients with persistent diarrhoea or other gastrointestinal fluid losses) or decrease (e.g. phosphate, potassium and sodium in chronic kidney disease).

Iron

Iron deficiency (see also p. 330) is common worldwide, affecting both developing and developed countries. It is particularly prevalent in women of reproductive age. Dietary iron overload is seen in South African men who cook and brew in iron pots.

Copper deficiency

Menkes’ kinky hair syndrome is a rare condition caused by malabsorption of copper. The Menkes’ disease gene (ATP7A) encodes a copper-transporting ATPase and has a homology to the gene in Wilson’s disease. Infants with this sex-linked recessive abnormality develop growth failure, mental retardation, bone lesions and brittle hair. Anaemia and neutropenia also occur. This condition, which serves as a model for copper deficiency, supports the idea that some of the clinical features seen in PEM are due to copper deficiency. Breast and cow’s milk are low in copper, and supplementation is occasionally necessary when first treating PEM.

Copper toxicity

This occurs in Wilson’s disease; see page 862.

Zinc

Zinc is involved in many metabolic pathways, often acting as a coenzyme; it is essential for the synthesis of RNA and DNA. In young children in developing countries, death attributable to zinc deficiency is lower than previously thought. One study found significant improvements when extra zinc was provided with several other micronutrients.

Zinc deficiency

Acrodermatitis enteropathica is an inherited disorder caused by malabsorption of zinc. Infants develop growth retardation, severe diarrhoea, hair loss and a skin rash, which can occur anywhere on the body but is most often found around the mouth, genitalia and hands (a similar rash occurs in adults suffering from zinc deficiency due to other causes; see below). There are also associated Candida and bacterial infections (Fig. 33.11). This condition provides a model for zinc deficiency. Zinc supplementation results in a complete cure. Zinc deficiency probably also plays a role in PEM and in many diseases in children in the developing world. Zinc supplementation has been demonstrated as being of some benefit in, for example, the prevention of diarrhoeal diseases and acute respiratory infections; it also improves growth.

Levels of zinc have also been shown to be low in some patients with malabsorption or skin disease, and in patients with the acquired immunodeficiency (AIDS), but its exact role in these
situations is disputed. Zinc has low toxicity, but high zinc levels from water stored in galvanized containers interfere with iron and copper absorption. Conversely, administration of copper or iron to treat deficiencies such as iron deficiency anaemia can precipitate zinc deficiency. Wound healing is impaired with moderate zinc deficiency and is improved by zinc supplements. Impaired taste and smell, hair loss and night blindness are also features of severe zinc deficiency.

Iodine

Iodine exists in foodstuffs as inorganic iodides, which are efficiently absorbed. Iodine is a constituent of the thyroid hormones (see Box 21.25).

Iodine deficiency

Many areas throughout the world lack iodine in the soil, and so iodine deficiency, which impairs brain development, is a WHO priority. Two billion people worldwide (one-third of whom are children) have insufficient iodine intake. Endemic goitre (Fig. 33.12) occurs in remote areas where the daily intake is below 70 μg, and in those parts 1–5% of babies are born with congenital hypothyroidism (with severe stunting, learning difficulty and a goitre). In these areas, iodized oil should be given intramuscularly to all reproductive women every 3–5 years. Salt iodization is now practiced in many countries and is a simple, cost-effective way to prevent deficiency.

Selenium

Clinical deficiency of selenium is rare, except in areas of China where Keshan disease, a selenium-responsive cardiomyopathy, occurs. Selenium deficiency may also cause a myopathy. Interactions between selenium and viruses have also been implicated. Toxicity has been described with very high intakes.

Calcium

Calcium absorption (see also p. 474) from the gastrointestinal tract is vitamin D-dependent. Some 99% of body calcium is in the skeleton. Increased calcium is required in pregnancy and lactation, when dietary intake must be increased. Calcium deficiency is usually due to vitamin D deficiency.

Phosphate

Phosphates (see also p. 192) are present in all natural foods, and dietary deficiency has not been described. Patients taking large amounts of aluminium hydroxide can, however, develop phosphate
deficiency owing to binding in the gut lumen. It can also be seen in total parenteral nutrition. Symptoms include anorexia, weakness and osteoporosis.

### Other trace elements

The possible significance of chromium, cobalt, manganese, molybdenum and nickel is shown in Box 33.18.

### NUTRITION AND AGEING

**Early origins of health and disease in older adults**

A low birth weight (and/or length) is associated with reduced height, as well as reduced mass and fat-free mass in adult life. These relationships are independent of genetic factors; the smaller of identical twins becomes a shorter and lighter adult.

Relationships have also been reported between growth of the fetus and a variety of diseases and risk factors for disease in adults and older people. These include cardiovascular disease (especially ischaemic heart disease), hypertension, diabetes, and even obesity and fat distribution. However, the strength of association for some of these conditions is weak. Animal studies involving dietary modifications (e.g. protein and zinc, even within the normal range) during pregnancy or in early postnatal life have clearly demonstrated effects, such as on rates of hypertension. The effects can not only persist through the lifetime of the offspring, but also be passed through to their offspring.

The extent to which these findings apply to humans is uncertain and the mechanisms are poorly understood. Since relationships have been reported between cardiovascular disease in old age and growth in the first few years of life, as well as starvation during puberty, it is likely that cumulative environmental stresses, including nutritional stress, from the time of implantation of the fertilized egg, to fetal and postnatal growth and development, and into adult life, summate to produce an overall disease risk (Fig. 33.13). Although high birth weight and length are associated with a reduced risk of cardiovascular disease in later life, they may also be associated with an increased risk of cancer.

### Nutritional requirements in the elderly

These are qualitatively similar to the requirements of younger adults; the diet should contain approximately the same proportions of nutrients, and essential nutrients are still needed. However, the RNIs stated earlier (see Boxes 33.13 and 33.17) are intended for healthy people without disease; specific requirements in disease, which is common in older people, are less well defined. Furthermore, the extent to which muscle loss is due to ageing, malnutrition and disease continues to be debated, as do the boundaries between sarcopenia, cachexia, malnutrition and frailty. Sarcopenia is defined as loss of skeletal muscle bulk, accompanied by decreased strength; unlike cachexia, it occurs without an underlying illness. Sarcopenia leads to disability with an increase in falls (see Ch 15).

Maintenance of physical activity continues to be necessary for overall health, regardless of age. However, energy expenditure by the elderly is less, so they have a lower energy requirement. For people aged 60 and above, irrespective of age, the daily energy requirement has been set at approximately 1.5 × BMR. Because they have reduced fat-free mass – from an average of 60 kg to 50 kg in men, and from 40 kg to 35 kg in women – their BMR is reduced.

Nutritional deficits in the elderly are common and may be due to many factors, such as dental problems, depression and lack of motivation. Significant malnourishment in developed countries is usually secondary to social problems or disease. In elderly people who are in institutions, multiple nutrient deficiencies are common. Vitamin D supplements (colecalciferol 20 μg (800 units) daily) may be required because of poor diet, and elderly people may not receive adequate exposure to sunlight. Owing to the high prevalence of osteoporosis in elderly people, an increased daily calcium intake (1–1.5 g/day) is often recommended.

### Further reading

Obesity is almost invariable in developed countries and almost all people accumulate some fat as they get older. The WHO acknowledges that obesity (BMI >30 kg/m²) is a worldwide problem that also affects many developing countries. Obesity implies an excess storage of fat and this can most easily be detected by looking at the undressed patient. Not all obese people eat more than the average person but all obviously eat more than they need.

The present obesity epidemic is mainly due to changes in lifestyle behaviour (although genetic factors may be involved in some individuals). There has been a trebling in the prevalence of obesity over the last three decades in the UK, as well as a vast increase in developing countries. The growing obesity problem in humans has affected children, adults and older people. Clinical and public health interventions require a multi-level approach: for example, by altering the cumulative environmental experience during the lifespan. Strategies to prevent and treat obesity in children can influence obesity in adults, and this in turn influences obesity in old age. Ultimately, all depend on changing energy balance through effects on food intake and/or energy expenditure.

Most patients suffer from simple obesity, but in certain conditions, obesity is an associated feature (Box 33.19). Even in the latter situation, the intake of calories must have exceeded energy expenditure over a prolonged period of time. Hormonal imbalance is often incriminated in women (e.g. after the menopause or when taking contraceptive pills), but most weight gain in such cases is usually small and due to water retention.

Pathophysiology

Genetic and environmental factors

These have always been difficult to separate in the study of obesity but there is little doubt that the recent obesity ‘epidemic’, which has developed over a few decades, is predominantly due to changes in lifestyle (various environmental factors) and unlikely to be caused by rapid changes in the gene pool over this period of time. This is consistent with the view that evolution during times of limited food resources has tended to defend more against under-nutrition than over-nutrition. However, observational studies in both monozygotic and dizygotic twins, reared together or apart, suggest that strong genetic influences account for the difference in BMI later in life, and that the influence of the childhood environment is weaker. These observations also showed that weight gain did not occur in all pairs of twins, suggesting that environmental factors operate.

A search for genetic factors led to the identification of a putative gene, first in the obese (ob ob) mouse and now in humans. The ob gene was shown to be expressed solely in both white and brown adipose tissue. The ob gene is found on chromosome 7 and produces a 16 kDa protein called leptin. In the ob ob mouse, a mutation in the ob gene leads to production of a non-functioning protein. Administration of normal leptin to these obese mice reduces food intake and corrects the obesity. A similar situation has been described in a very rare genetic condition that causes obesity in humans, in which leptin is not expressed.

In massively obese subjects, leptin mRNA in subcutaneous adipose tissue is 80% higher than in controls. Plasma levels of leptin are also very high, correlating with the BMI. Weight loss due to food restriction decreases plasma levels of leptin. However, in contrast to the ob ob mouse, the leptin structure is normal, and abnormalities in leptin are not the prime cause of human obesity.

Leptin secreted from fat cells was thought to act as a feedback mechanism between the adipose tissue and the brain, acting as a

Food intake

Many factors related to the home environment, such as finance and the availability of sweets and snacks, will affect food intake. Some individuals eat more during periods of heavy exercise or during pregnancy, and are unable to return to their former eating habits. The increase in obesity in social class 5 can usually be related to the type of food consumed (i.e. food containing sugar and fat). Measures to reduce obesity in social class 5 can usually be related to the type of food consumed (i.e. food containing sugar and fat). There are a large number of other peripheral appetite-suppressing signals, including GLP-1 and oxyntomodulin, which, like PYY, are produced by the gut in a nutrient-dependent manner.

**Peripheral appetite-stimulating signals.** Ghrelin is a 28-amino-acetylated peptide produced by the oxyntic cells of the fundus of the stomach. It is the first known gastrointestinal tract peptide that stimulates appetite by activating the central appetite-stimulating pathway. The circulatory concentration is high before a meal and is reduced rapidly by ingestion of a meal or glucose (compare PYY, which increases after a meal). It may also act as a long-term signal, as its circulating concentration in weight-stable individuals is inversely related to BMI over a wide range (compare insulin and leptin, which are positively related to BMI; see below). Ghrelin is also increased in several situations in which there is a negative energy balance, such as long-term exercise, very-low-calorie diets, anorexia nervosa, and both cancer and cardiac cachexia (an exception is vertical banded gastric bypass surgery, where its concentration is low rather than high). The peptide, obestatin, produced by the same gene that encodes ghrelin, counteracts the increase in food intake induced by ghrelin.

**Central pathways (2nd order in Fig. 33.14)**
There are two main pathways in the arcuate nucleus:

- The **central appetite-stimulating (orexigenic) pathway** in the ventromedial part of the arcuate nucleus, which expresses neuropeptide Y (NPY) and agouti pathway-related protein (AgRP). Animal studies suggest that this pathway also decreases energy expenditure.

- The **central appetite-suppressing pathway (anorexigenic pathway or leptin–melanocortin pathway)** in the dorsolateral part of the arcuate nucleus, which expresses pro-opiomelanocortin/cocaine-and-amphetamine-regulated transcript (POMC/CART). In this pathway, α-melanocyte-stimulating hormone (α-MSH), formed by cleavage of POMC by prohormone convertase (PC1), exerts its appetite-suppressing effect via the melanocortin-4 receptors (MC4R) in areas of the brain that regulate food intake and autonomic activity. Animal studies suggest that this pathway also increases energy expenditure.

These pathways interact with each other and feed into the lateral hypothalamus, which communicates with other parts of the brain, and influence the autonomic nervous system and ingestive behaviour.

These central pathways are in turn influenced by a variety of peripheral signals, which can also be classified as appetite-stimulating or appetite-suppressing.

**Other factors**
The single gene mutations affecting the appetite-suppressing pathway in humans, e.g. leptin, leptin receptor, POMC, Mc4R, PC1 and SIM1, are rare and recessive, with the exception of Mc4R, which is common and dominant with incomplete penetrance. It appears that the Mc4R mutation accounts for 2–6% of human obesity. Affected individuals are obese without disturbances in pituitary function or resting energy expenditure, although children tend to be tall. However, these mutations are of little significance, as obesity is predominantly polygenic in origin (the human obesity gene map has already identified several hundreds of candidate genes).

The endocannabinoid system is also involved in both central and peripheral regulation of food intake and control of energy balance. There are two receptors: endocannabinoid (CB1) in the brain and CB2 in the periphery. CB1 receptors are located in the cerebral cortex, cerebellum and hippocampus.

The control of appetite is extremely complex. To take just one signal, leptin, as an example, there can be leptin resistance, in which obese individuals have high circulating leptin but appetite is not reduced. In contrast, in acute starvation, leptin concentrations decrease to lower levels than could be expected from the prevailing adipose tissue mass. It is known that cytokines, such as TNF and IL-2, which are elevated in a wide range of inflammatory and traumatic conditions, also suppress appetite, although the exact pathways involved are not entirely clear. Finally, a range of transmitters in the central nervous system appear to affect appetite:

- appetite inhibitors: dopamine, serotonin, γ-aminobutyric acid
- appetite stimulators, e.g. opioids.

**Energy expenditure**

**Basal metabolic rate**
Basal metabolic rate (BMR) in obese subjects is higher than in lean subjects, which is not surprising since obesity is associated with an increase in lean body mass.

**Physical activity**
Obese patients tend to expend more energy during physical activity, as they have a larger mass to move. On the other hand, many obese patients decrease their amount of physical activity. The energy expended on walking at 3 miles/hour is only 15.5 kJ/min (3.7 kcal/min); therefore, a mild to moderate increase in physical activity plays only a small part in losing weight. Nevertheless, because increased body fat develops insidiously over many years, any change in energy balance is helpful.

**Thermogenesis**
About 10% of ingested energy is dissipated as heat and is uncon- nected with physical activity. This dietary-induced thermogenesis has been reported to be lower in obese and post-obese subjects than in lean subjects. This would tend to favour energy deposition in obesity and those predisposed to obesity. However, other reports have identified no difference in dietary-induced thermogenesis between lean and obese subjects.

When stimulated by cold or food, brown adipose tissue in animals dissipates the energy derived from ingested food into heat. This can be a major component of overall energy balance in small mammals but the effect is likely to be very small and of doubtful clinical significance in adult humans, even though brown adipose tissue is found in humans. The principal receptors mediating catecholamine-stimulated lipolysis in brown adipose tissue, and to a lesser extent at other sites, are the β2-adrenergic receptors. Drugs with β2-adrenergic activities have been developed but side-effects have limited their use.

**Clinical features**
Most patients recognize the problem posed by their weight, but feel trapped and unable to take steps to address it. Many symptoms are related to psychological problems or social pressures.

The degree of obesity can be assessed by comparing the patient with tables of ideal weight for height, calculating the BMI (Box 33.20) and measuring skinfold thickness. The latter should be measured over the middle of the triceps muscle; normal values are 20 mm in a man and 30 mm in a woman. A central distribution of body fat (a waist/hip circumference ratio of >1.0 in men and >0.9 in women) is associated with a higher risk of morbidity and
mortality than a more peripheral distribution of body fat (waist/hip ratio <0.85 in men and <0.75 in women). This is because fat located centrally, especially inside the abdomen, is more sensitive to lipolytic stimuli, with the result that the abnormalities in circulating lipids are more severe.

Box 33.21 shows the conditions and complications that are associated with obesity. The relationship between cardiovascular disease (hypertension or ischaemic heart disease), hyperlipidaemia, smoking, physical exercise and obesity is complex. Difficulties arise in interpreting mortality figures because of the number of factors involved. Many studies do not differentiate between the types of physical exercise taken nor do they take into account the cuff-size artefact in the measurement of blood pressure (an artefact will occur if a large cuff is not used in patients with a large arm). Nevertheless, obesity almost certainly plays a part in all of these diseases and should be treated. An exception is that stopping smoking, even if accompanied by weight gain, is more beneficial than any of the other factors. Physical fitness is also helpful, and there is some evidence to suggest that a fit obese person may have a similar cardiovascular risk to a leaner, unfit person, or even a lower risk.

Morbidity and mortality

Obese patients are at risk of early death, mainly from diabetes, coronary heart disease and cerebrovascular disease. The greater the obesity, the higher are the morbidity and mortality rates. For example, men who are 10% overweight have a 13% increased risk of death, while the increase in mortality for those 20% overweight is 25%. The rise is less in women, and in men over 65, obesity is not an independent risk factor. Weight reduction reduces this mortality and therefore should be strongly encouraged. The benefits are probably greater in more obese subjects (Box 33.22).

Metabolic syndrome

There are two classification systems, which are shown in Box 33.23. The differences are as follows:

- A large waist is an absolute requirement for the International Diabetes Federation (IDF) but not for the Adult Treatment Panel 3 National Cholesterol Education Programme (ATP III NCEP).
- The IDF criteria use lower cut-off values for waist circumference (close to values for people with a BMI of 25 kg/m²) and lower fasting blood glucose concentrations.

This means that the prevalence of metabolic syndrome will be higher using the IDF criteria, and that the IDF criteria will identify at-risk patients at an earlier stage. This could lead to further investigations following on from the initial screening, and earlier institution of preventative as well as therapeutic measures.

Overweight/central obesity and insulin resistance, which causes glucose and lipid disturbances including non-alcoholic fatty liver disease, seem to form the basis of many features of the metabolic syndrome. Early treatment of obesity and the metabolic syndrome can prevent the development of clinical diabetes and its complications.

The metabolic syndrome is a combination of risk factors (see Box 33.23). Its overall role in the prediction of the risk of cardiovascular disease has been questioned, as the sum of the combined risk factors involved in the syndrome does not offer more than the individual factors added together.

Management

Dietary control

This largely depends on a reduction in calorie intake. The most common diets allow a daily intake of approximately 4200 kJ (1000 kcal), although this may need to be nearer 6300 kJ (1500 kcal) for someone engaged in physical work. Very-low-calorie diets are also advocated by some, usually over shorter periods of time, but unless they are accompanied by changes in lifestyle, weight regain is likely. Patients must realize that prolonged dieting is necessary for large amounts of fat to be lost. Furthermore, a permanent change in eating habits is required to maintain the new low weight. It is relatively easy for most people to lose the first few kilograms but long-term success in moderate obesity is poor (no more than 10%). Most obese people oscillate in weight; they often regain the lost weight but many manage to lose weight again. This “cycling” in body weight may play a role in the development of coronary artery disease.
There are some potential long-term concerns with low-carbohydrate diets (high in fat and protein), including increased risk of osteoporosis, renal stones and atheroma (due to high intake of saturated fat, high trans fat and cholesterol, and the lack of fruits, vegetables and whole grains), but long-term studies are lacking.

Low-energy-density diets, often bulky and rich in fibre and complex carbohydrates, may be more satiating but they are often less palatable than high-energy-dense diets, which may affect long-term compliance.

Liquids, such as soft drinks, appear to be less satiating than solid foods.

A study has shown that Mediterranean and low-carbohydrate diets are as effective as a low-fat diet for weight loss.

**Behavioural modification**

The aim of behavioural modification is to encourage the patient to take personal responsibility for changing lifestyle, which will determine dietary habits and physical activity. Family therapy may also be useful, especially when it involves obese children, but can be time-consuming and expensive. Cognitive behavioural therapy is even more time-consuming and expensive.

**Drug therapy**

Drugs can be used in the short term (e.g. up to 3 months and then reviewed), as an adjunct to the dietary regimen, but they do not substitute for strict dieting. The pancreatic lipase inhibitor, orlistat, is the only drug licensed specifically for weight loss in the UK.

Centrally acting drugs include:

- Drugs acting on both *serotoninergic* and *noradrenergic pathways*, e.g. sibutramine (now withdrawn in Europe due to side-effects). Other drugs are being evaluated.
- **Cannabinoid-1 receptor blockers**, e.g. rimonabant (now withdrawn due to depression/suicide risk), acting on the endocannabinoid system.
- **Drugs acting on the noradrenergic pathways**. These do suppress appetite but all have been withdrawn, at least in the UK, because of cardiovascular side-effects. 

*Peripherally acting* drugs are as follows:

- **Orlistat** is an inhibitor of pancreatic and gastric lipases. It reduces dietary fat absorption and aids weight loss. Weight regain occurs after the drug is stopped. It has been used continuously in a large-scale trial for up to 2 years. Patients complain of diarrhoea during treatment and, to avoid this, take a low-fat diet, resulting in weight loss.
- **GLP-1 receptor agonists** suppress appetite; injections have been used to treat obesity (see Fig. 33.14) and type 2 diabetes mellitus (see p. 719).
- **Sodium-glucose cotransporter-2 (SGLT-2) inhibitors** such as canagliflozin are used to treat diabetes, and have also been demonstrated to reduce body weight and improve cardiovascular outcomes (see p. 719).

A systematic review of long-term pharmacotherapy concluded that there was a paucity of long-term studies with anti-obesity agents, and that in weight loss trials of 1 year’s duration, these studies
agents appear to be only modestly effective in promoting weight loss (about 3 or 4 kg greater weight loss, respectively, than the control group). Other randomized trials show that a combination of lifestyle modification and pharmacotherapy produces greater weight loss than either treatment alone, but the withdrawal of several anti-obesity drugs from the market suggests that a pharmacotherapeutic ‘magic bullet’ to treat obesity without substantial short-term and long-term effects is not yet available.

Surgical management (bariatric surgery, metabolic surgery)

Surgery is now performed laparoscopically in patients with morbid obesity (BMI >40 kg/m²), or in patients with a BMI higher than 35 kg/m² and obesity-related complications, after conventional lifestyle approaches have failed. Fitness for surgery should be checked, especially in older people. Some centres may insert a balloon into the stomach to initiate weight loss prior to bariatric surgery for morbid obesity. A variety of gastrointestinal surgical procedures have been used, which fall into three main groups (Fig. 33.15):

- **Restrictive procedures**, which restrict the ability to eat (e.g. adjustable gastric banding, vertical banded gastroplasty and sleeve gastrectomy).

- **Malabsorptive procedures**, which reduce the ability to absorb nutrients (e.g. biliopancreatic diversion and Roux-en-Y gastric bypass). The malabsorptive procedures cause nutrient deficiencies, malnutrition and, in some cases, anastomotic leaks and the dumping syndrome (e.g. with the duodenal switch).

- **Restrictive plus malabsorptive procedures** (e.g. duodenal switch, Roux-en-Y gastric bypass, intragastric balloon).

The procedures all have advantages and disadvantages, and there is controversy about the procedure of choice for specific groups of patients. The restrictive procedures are more straightforward than the complex bypass procedures. The adjustable gastric banding procedure is attractive in concept, especially since it can be undertaken laparoscopically with a lower perioperative mortality (<0.3%) than the other procedures (approximately 1%); it can, however, be associated with erosion and slippage of the band, as well as problems with the port, making repeat operations a frequent requirement (>10% of cases). The sleeve gastrectomy is associated with heartburn and greater risk of weight regain, but a biliary pancreatic diversion (duodenal switch) can be added later.

Postoperatively, there is a need to monitor nutrient status carefully and to provide supplements of vitamins and minerals (including iron and calcium), as nutrient deficiencies are common. Weight loss following the combined restrictive and malabsorptive procedures tends to be greater than with either procedure alone.

A systematic analysis of several bariatric surgical procedures concluded that, in comparison to non-surgical treatments, they produced significantly more weight loss (23–37 kg), which was maintained up to 8 years and associated with improvement in quality of life and co-morbidities. There is now evidence showing that the risk of myocardial infarction, stroke, cardiovascular events and mortality is reduced by about half compared to non-surgical controls over a follow-up period of 2–15 years. Although fertility is improved after bariatric surgery, women are advised to delay pregnancy for a year or more after rapid and substantial weight loss, while the safety of pregnancy is being elucidated. A recent study has shown a reduction in risk of gestational diabetes and earlier than expected birth but the benefits and risks of bariatric surgery still need further study. The commissioning of specialist obesity services should be multidisciplinary and should not focus on the surgical treatment only.

**Liposuction**, the removal of large amounts of fat by suction, does not deal with the underlying problem and weight regain frequently occurs. There appears to be no reduction in cardiovascular risk factors with the procedure.

Prevention

Preventing obesity must always be the goal because most obese people find it difficult to maintain any weight loss they manage to achieve. All health professionals must be aware of the dangers of obesity and encourage children, and young as well as older adults, from gaining too much weight. A small gain each year over a long period produces an obese individual for whom treatment is difficult. Public health policies should consider the creation of public places to encourage physical activity and fitness, education about the benefits of losing weight or not gaining it, and changes in food composition (alternatives to high-fat, high-energy-dense foods and sugar reduction).

Since the present obesity epidemic has resulted from lifestyle changes, it is appropriate to promote lifestyle changes, not only as

---

**Fig. 33.15 Examples of surgical procedures to treat morbid obesity.** (A) Restrictive procedure: gastric banding with a subcutaneous port attached to the anterior abdominal wall so that fluid can be injected into the adjustable band around the upper stomach. (B) Restrictive plus malabsorptive procedure: Roux-en-Y gastric bypass, in which food passes through a small stomach pouch and bypasses the proximal small bowel. (C) Gastric sleeve.
the first-line therapy for most overweight and obese individuals, but also in the prevention of overweight and obesity. Lifestyle modification may include reducing the proportion of time spent in physical inactivity (for instance, watching television); building physical activity into daily routines (for instance, through cycling to work), and encouraging patterns of healthy eating.

NUTRITIONAL SUPPORT

Support in the hospital patient

Nutritional support is recognized as being necessary in many hospitalized patients. The pathophysiology and hallmarks of malnutrition have been described earlier (see p. 1231) but malnutrition is often not immediately clinically apparent. Screening tools can be used to identify adults who are malnourished or at risk of malnutrition. The Malnutrition Universal Screening Tool (MUST score) is widely used (see Fig. 33.5) to identify patients that require nutritional support. In the UK, up to 40% of patients are malnourished on acute admission to hospital and up to 70% of patients are malnourished on discharge. Here, the forms of nutritional support that are available are discussed, along with special nutritional requirements in some diseases.

Principles

Some form of nutritional supplementation is required in those patients who cannot eat, should not eat, will not eat or cannot eat enough. All patients should be screened for malnutrition on admission and the findings linked to a care plan, preferably under the supervision of a trained multidisciplinary team, including a dietitian. Plans are discussed with patients and consent is taken for any invasive procedure (e.g. nasogastric tube, parenteral nutrition). If the patient is unable to give consent, the healthcare team should act in the patient’s best interest, considering any previously expressed wishes of the patient and views of the family. It is usually necessary to provide nutritional support for:

- all severely malnourished patients on admission to hospital
- moderately malnourished patients who, because of their physical illness, are not expected to eat for more than 5 days
- normally nourished patients expected not to eat for more than 5 days or expected to eat less than half their intake for more than 8–10 days.

Enteral rather than parenteral nutrition should be used if the gastrointestinal tract is functioning normally.

In the re-feeding syndrome, the shifts of water and electrolytes that occur during parenteral and enteral nutrition can be life-threatening. Carbohydrate intake stimulates insulin release, which leads to a cellular uptake of phosphate, potassium and magnesium. Complications include hypophosphataemia, hypokalaemia, hypomagnesaemia and fluid overload because of sodium retention (decreased renal excretion of sodium and water). Biochemical abnormalities can result in cardiac arrhythmias and respiratory insufficiency, and are associated with a raised mortality. Any electrolyte deficiency should be replaced and monitored, and patients who have eaten little or nothing for more than 5 days should initially receive no more than 50% of their energy requirements (National Institute for Health and Care Excellence (NICE) guidelines). Patients at risk of the re-feeding syndrome should be given high potency vitamins daily for 10 days and oral or enteral thiamine 50mg 4 times daily for 10 days, along with multivitamins.

Nutritional requirements for adults

The exact nutrient requirements in many disease states are not clearly defined and vary with the stage and severity of disease, as well as nutritional status. The optimal protein and energy intakes needed to produce the best clinical outcomes in acute critical illness continue to be debated. The following general guidance is provided for specific nutrients or groups of nutrients:

<table>
<thead>
<tr>
<th>Nutrient</th>
<th>Requirements</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Fluid</strong></td>
<td>Typical requirements are approximately 2–3 L/day (&gt;60 years = 30 mL/kg, 18–60 years = 35 mL/kg). Requirements are increased in patients with large-output stomas, nasogastric aspirations, diarrhoea and fever. Requirements are reduced in patients with oedema, hepatic failure and renal failure.</td>
</tr>
<tr>
<td><strong>Energy</strong></td>
<td>Typical requirements are approximately 7.5–10.0 MJ/day (1800–2400 kcal/day). Disease increases resting energy expenditure but decreases physical activity. Extra energy is given for repletion and reduced energy for obesity.</td>
</tr>
<tr>
<td><strong>Protein</strong></td>
<td>Typical requirements are 9–15 g N/day (56–94 g protein/day) or 0.15–0.25 g N/kg per day (0.94–1.56 g protein/kg per day). Extra protein may be needed in severely catabolic conditions, such as extensive burns, sepsis and major trauma.</td>
</tr>
<tr>
<td><strong>Major minerals</strong></td>
<td>Typical requirements for sodium and potassium are 60–100 mmol/day (1.0–1.5 mmol/kg). Requirements are increased in patients with gastrointestinal effluents. The excretion of these minerals in various effluents can provide an indication of the additional requirements (see Box 9.12). Requirements may be lower in patients with fluid overload (or those with hypernatraemia and hyperkalaemia). The requirements for calcium and magnesium are higher in enteral than in parenteral nutrition because only a proportion of these minerals is absorbed by the gut.</td>
</tr>
<tr>
<td><strong>Trace elements</strong></td>
<td>For trace elements such as iodine, fluoride and selenium, which are well absorbed, the requirements are similar in enteral and parenteral nutrition. For other trace elements, such as iron, zinc, manganese and chromium, the requirements in parenteral nutrition are substantially lower than in enteral nutrition (Fig. 33.16).</td>
</tr>
</tbody>
</table>
**Vitamins.** Many vitamins are given in greater quantities in patients receiving parenteral nutrition than in those receiving enteral nutrition (Fig. 33.17). This is because patients on parenteral nutrition may have increased requirements, partly because of severe disease, partly because they may already have depleted pools of vitamins, and partly because some vitamins degrade during storage. Vitamin K is usually absent from parenteral nutrition regimens and therefore it may need to be administered separately.

### Enteral nutrition

In enteral nutrition, feeds can be given by various routes:
- By mouth (food can be supplemented with solid or liquid supplements with multiple benefits).
- By fine-bore nasogastric tube (Box 33.25).
- By percutaneous endoscopic gastrostomy (PEG). This is useful for patients who need enteral nutrition for a prolonged period (e.g. >30 days), such as those with swallowing problems following a head injury, or elderly people after a stroke. A catheter is placed percutaneously into the stomach under endoscopic control (Fig. 33.18).
- By needle catheter jejunostomy. In this technique, a fine catheter is inserted into the jejunum at laparotomy and brought out through the abdominal wall.

### Diet formulation

A polymeric diet with whole protein and fat can be used (Box 33.26), except in patients with severely impaired gastrointestinal function, who may require a pre-digested (i.e. semi-elemental/elemental) diet. In these patients, the nitrogen source is purified low-molecular-weight peptides or amino acid mixtures, the fat sometimes being given partly as medium-chain triglycerides (MCTs).

### Management of enteral nutrition

Daily amounts of fluid vary between 1.5 and 2.5 L, but small amounts are started in patients with suspected poor gastric emptying and severe malnutrition (to avoid the re-feeding syndrome). Hypercatabolic patients require a high supply of nitrogen (0.25–0.35 g/kg daily) and often will not achieve positive nitrogen balance until the primary injury is resolved.
The success of enteral feeding depends on careful supervision of the patient, with monitoring of weight, biochemistry and diet charts.

Parenteral nutrition

This should only be used if the enteral route cannot be used. The need for major improvements in the practice of parenteral nutrition in UK hospitals has been emphasized by the National Confidential Enquiry into Patient Outcome and Death (NCEPOD). This included a requirement for improvements at every level: assessment, monitoring and follow-up, including appropriate care of lines to avoid catheter-related sepsis and documentation.

Peripheral parenteral nutrition

Specially formulated mixtures for peripheral use are available; these have a low osmolality (<800 mosmol/L) and contain lipid emulsions. Heparin and corticosteroids can be added to the infusion and local application of glyceryl trinitrate patches reduces the occurrence of thrombophlebitis and prolongs catheter life.

- A peripheral cannula can be inserted into a mid-arm vein (20 cm) and can be left for up to 5 days.
- A longer (60 cm), peripherally inserted central catheter (PICC) placed into an antecubital fossa vein has its distal end lying in a central vein; here, there is less risk of thrombophlebitis and hyperosmolar solutions can be given. With careful management, PICCs can be used for up to a month or so.

Peripheral parenteral nutrition is often preferred initially, allowing time to consider the necessity for insertion of a central venous catheter.

Parenteral nutrition via a central venous catheter

A silicone catheter is placed into a central vein, usually adopting an infraclavicular approach to the subclavian vein (Box 33.27). The skin-entry site should be dressed carefully and not disturbed unless there is a suggestion of catheter-related sepsis. Complications of catheter placement include central vein thrombosis, pneumothorax and embolism, but one of the most common problems is catheter-related sepsis. Organisms, mainly staphylococci, enter along the side of the catheter, leading to septicemia. Sepsis can be prevented by ensuring careful and sterile placement of the catheter, not removing the dressing over the catheter entry site, and not giving other substances (e.g. blood products, antibiotics) via the central vein catheter.

Sepsis should be suspected if the patient develops fever and leucocytosis. In two-thirds of cases, organisms can be grown from the catheter tip after removal. Treatment involves removal of the catheter and appropriate systemic antibiotics.

Nutrients

With parenteral nutrition, it is possible to provide sufficient nitrogen for protein synthesis and calories to meet energy requirements. Electrolytes, vitamins and trace elements are also necessary. All these substances are infused simultaneously.

Nitrogen source

Most patients receive at least 11–15 g N/day, in the form of synthetic L-amino acids.
Energy source

Energy is supplied by glucose, with additional calories provided by a fat emulsion. Fat infusions give a greater number of calories in a smaller volume than can be provided by carbohydrate. Fat infusions are not hypertonic and they also prevent essential fatty acid deficiency, which has been reported in long-term parenteral nutritional regimens without fat emulsions. Deficiency causes a scaly skin, hair loss and a delay in healing.

Electrolytes, vitamins and trace elements

Initially, the electrolyte status should be monitored daily and electrolyte solutions given as appropriate. Fat- and water-soluble vitamins and minerals, including trace elements, should be given routinely (see Figs. 33.16 and 33.17).

Management of parenteral nutrition

Peripheral parenteral nutrition is administered via 3-L bags over 24 hours, the constituents being premixed under sterile conditions. Box 33.28 shows the composition that provides 9 g of nitrogen and 7206 kJ (1700 kcal) in 24 hours.

For a central venous parenteral nutrition regimen, most hospitals now use premixed 3-L bags. A standard parenteral nutrition regimen that provides 14 g of nitrogen 9305 kJ (2250 kcal) over 24 hours is also given in Box 33.28.

Monitoring includes:

- **Blood tests.** Plasma electrolytes and glucose are checked daily (at least initially); full blood count, liver biochemistry and function, calcium and phosphate twice weekly; and magnesium, zinc and triglycerides weekly.
- **Nutritional status.** Weight and skinfold thickness are monitored on a weekly basis if appropriate calipers are available. Daily weight changes reflect changes in fluid balance.
- **Nitrogen balance assessment** (see p. 1228). This requires complete collections of urine.

Complications

- **Mechanical:** insertional trauma and catheter-related (see above).
- **Metabolic:** e.g. hyperglycaemia (insulin therapy is often necessary), fluid and electrolyte disturbances, hypercalcaemia, nutrient deficiencies (if inadequately provided).

### Box 33.28 Examples of parenteral nutrition regimens

**Peripheral**

- **Nitrogen**
  - l-amino acids 9 g/L: 1 L

- **Energy**
  - Glucose 20%: 1 L
  - Lipid 20%: 0.5 L
  - + Trace elements, electrolytes, water-soluble and fat-soluble vitamins, heparin 1000 U/L and hydrocortisone 100 mg; insulin is added if required. Nitrogen 9 g, non-protein calories 7206 kJ (1700 kcal)

**Central**

- **Nitrogen**
  - l-amino acids 14 g/L: 1 L

- **Energy**
  - Glucose 50%: 0.5 L
  - Glucose 20%: 0.5 L
  - + Lipid 10% as either Intralipid or Lipofundin: 0.5 L; fractionated soya oil 100 g/L, soya oil 50 g, medium-chain triglycerides 50 g/L
  - + Electrolytes, water-soluble and fat-soluble vitamins, trace elements; heparin and insulin may be added if required. Nitrogen 14 g, non-protein calories 9305 kJ (2250 kcal)

- **Organ or tissue dysfunction:** e.g. abnormal liver dysfunction, respiratory distress and metabolic bone disease.
- **Others:** e.g. rare allergic reactions to lipid, and psychological disturbances.

### Support in the home patient

In both high- and low-income countries, there is considerably more under-nutrition in the community than in hospital. However, the principles of care are very similar: detection of malnutrition and the underlying risk factors; treatment of underlying disease processes and disabilities; correction of specific nutrient deficiencies; and provision of appropriate nutritional support. This typically begins with dietary advice, and may involve the provision of ‘meals on wheels’ by social services. A systematic review of the use of nutritional supplements in the community came to the following conclusions:

- Supplements are generally of more value in **patients with a BMI <20 kg/m² and children with growth failure** (weight for height <85% of ideal) than in those with better anthropometric indices. They are likely to be of little or no value in patients with little weight loss and a BMI >20 kg/m². The supplemental energy intake in such subjects largely replaces oral food intake.

- Supplements may be of value in **weight-losing patients** (e.g. >10% weight loss compared with pre-illness) with a BMI >20 kg/m², and in **children with deteriorating growth performance** without chronic protein-energy under-nutrition.

- The functional benefits vary according to the patient group. In patients with **chronic obstructive airways disease**, the observed functional benefits were increases in respiratory muscle strength, handgrip strength, and walking distance/duration of exercise. In the **elderly**, the benefits were reduction in number of falls, or increase in activities of daily living, and reduction in pressure ulcer surface area. In patients with **HIV/AIDS**, there were changes in immunological function and improved cognition. Patients with **liver disease** experienced a lower incidence of severe infections and had a lower frequency of hospitalization.

- **Acceptability and compliance** are likely to be better when a choice of supplements (of type, flavour, consistency) and the schedule are decided in conjunction with the patient and/or carer. Adjustments to these may be necessary when there is a change in patterns of daily activities, disease status, and ‘taste fatigue’ with prolonged use of the same supplement.

- Nutritional **counselling and monitoring** are recommended before and after the start of supplements (see below). Some patients receive enteral tube feeding or parenteral nutrition at home. Indeed in developed countries, enteral tube feeding occurs more frequently at home than in hospital.

### Home enteral nutrition

In adults, the most common reason for starting home tube feeding is for swallowing difficulties. This involves patients with neurological disorders, such as motor neurone disease, multiple sclerosis and Parkinson’s disease, but the most common single diagnosis is cerebrovascular disease. Approximately 2% of patients who have had a stroke in the UK receive home enteral tube feeding (HETF). However, in a British Nutrition survey of patients with these disorders (apart from Parkinson’s), only 15% in total were able to return to oral feeding after 1 year.
Food allergy and food intolerance

Many people ascribe their various symptoms to food, and many such sufferers are seen and started on exclusion diets. The scientific evidence that food does harm is weak, in most instances, although adverse reactions to food certainly exist. These can be divided into those that involve immune mechanisms (food allergy) and those that do not (food intolerance).

Food allergy

Food allergy, which is estimated to affect up to 5–7% of young children and 1–2% of adults (with a rising prevalence), may be mediated by immunoglobulin E (IgE) or not mediated by IgE (T cell-mediated). The IgE-mediated reactions tend to occur early after a food challenge (within minutes to an hour). Adults tend to be allergic to fish, shellfish and peanuts, while children tend to be allergic to cow’s milk, egg white, wheat and soy. Peanuts are very allergenic to fish, shellfish and peanuts, while children tend to be allergic to egg and are IgE-mediated.

Acute hypersensitivity. An example is urticaria, vomiting or diarrhoea after eating nuts, strawberries or shellfish. These IgE-mediated reactions do not usually produce clinical problems, as the patients have already learned to avoid the suspected food. Inadvertent ingestion of the incriminating food can sometimes occur, leading to angio oedema or anaphylaxis (see p. 668).

Eczema and asthma. These tend to affect young children; they are often due to egg and are IgE-mediated.

Rhinitis and asthma. These have been produced by foods such as milk and chocolate, mainly in atopic subjects.

Chronic urticaria. This has been treated successfully by an exclusion diet.

Food-sensitive enteropathy. This may manifest itself as coeliac disease (gluten (wheat) sensitive enteropathy) and cow’s milk enteropathy (in infants); it is T cell-mediated.

Food intolerance

Migraine. This sometimes follows the intake of foods such as chocolate, cheese and alcohol, which are rich in certain amines, such as tyramine. Patients on monoamine oxidase inhibitors, which are involved in the metabolism of these amines, are particularly vulnerable.

Irritable bowel syndrome. In some patients, this seems to be related to ingestion of certain food items, such as wheat, but the mechanisms are not clearly defined.

Chinese restaurant syndrome. Monosodium glutamate, a flavour enhancer used in cooking Chinese food, may produce dizziness, faintness, nausea, sweating and chest pains.

Lactose intolerance. Patients develop abdominal bloating and diarrhoea following ingestion of lactose, which is present in milk (see p. 1193). This is probably the most common form of food intolerance worldwide, and may be genetic in origin.

A number of other inborn errors of metabolism can also be regarded as forms of food intolerance.

Food intolerance may be caused by a constituent of food (e.g. the histamine in mackerel or canned food, or the tyramine in cheeses); by chemical mediators released by food (e.g. histamine may be released by tomatoes or strawberries); or by toxic chemicals found in food (e.g. the food additive tartrazine). Many other additives and compounds with certain E numbers have been implicated as causing reactions but the evidence is poor.

There is little or no evidence to suggest that diseases such as arthritis, behavioural and affective disorders, and Crohn’s disease are due to ingestion of a particular food. Multiple vague symptoms, such as tiredness or malaise, are also not caused by food allergy, and psychiatric evaluation may be indicated (see p. 772).

Management

The history may help to delineate the causative agent, particularly when the effects are immediate.

Skin-prick testing with allergen and measurement in the serum of antigen or antibodies do not generally correlate with symptoms and are usually misleading.

Diagnostic exclusion diets are sometimes used but are time-consuming. They can occasionally be of value in identifying a particular food that is causing problems.

Dietary challenge consists of the food and the test being given sublingually or by inhalation in an attempt to reproduce the symptoms. Again, this may be helpful in a few cases.

Most people who have acute reactions to food realize it and stop eating the food; they do not require medical attention. In the remainder of patients, a small minority seem to be helped by modifying their diet but there is no good scientific evidence to support these exclusion diets. A recent study showed that the introduction of peanuts decreased the frequency of peanut allergy in children at high risk of developing this allergy, and moderated immune responses to peanuts.

Increasing evidence suggests that many children with milk and egg allergies are able to tolerate the food when heat-modified, and this may speed up resolution of the allergy.

There is no good evidence to recommend that pregnant or breast-feeding women should change their diet to prevent allergies in infants at high risk or normal risk.

**ALCOHOL**

Although alcohol is not a nutrient, it is consumed in large quantities all over the world. In many countries, alcohol consumption is a major medical and social problem (see p. 790). It increases morbidity and mortality in a variety of ways, including effects on heart disease, stroke, cancers, liver and neurological/psychiatric problems, and is associated with nutritional deficiencies and abnormal metabolism of drugs.

Ethanol (ethyl alcohol) is oxidized, in the steps shown in Box 33.29, to acetaldehyde. Acetaldehyde is then converted to acetate, 90% in the liver mitochondria. Acetate is released into the blood and oxidized by peripheral tissues to carbon dioxide and water.

Alcohol dehydrogenases are found in many tissues and it has been suggested that enzymes present in the gastric mucosa may contribute substantially to ethanol metabolism.

Ethanol itself produces 29.3kJ/g (7 kcal/g), but many alcoholic drinks also contain sugar, which increases their calorific value. For example, 1 pint of beer provides about 1045kJ (250kcal), so heavy drinkers will be unable to lose weight if they continue to drink.

**Effects of excess alcohol consumption**

Excess consumption of alcohol leads to two major problems, both of which can be present in the same patient:

- Alcohol dependence syndrome (see p. 790)
- Physical damage to various tissues.

Each unit of alcohol (defined as 10mL (7.9g) of pure ethanol) corresponds to about half a pint of normal beer, one single measure of spirit or half a glass of wine (Fig. 33.19). An intake of less than 14 units per week is generally considered to be safe. All the long-term effects of excess alcohol consumption are due to excess ethanol, irrespective of the type of alcoholic beverage; that is, beer and spirits are no different in their long-term effects. Short-term effects, such as hangovers, depend on additional substances, particularly other alcohols such as isomyl alcohol, which are known as congeners. Brandy and bourbon contain the highest percentage of congeners.

The amount of alcohol that produces damage varies and not everyone who drinks heavily will suffer physical damage. For example, only 20% of people who drink heavily develop cirrhosis of the liver. The effect of alcohol on different organs of the body is not the same; in some patients, the liver is affected; in others, the brain or muscle. The differences may be genetically determined.

Thiamin deficiency contributes to neurological (confusion, Wernicke–Korsakoff syndrome; see p. 891) and some of the non-neurological manifestations (cardiomyopathy). The susceptibility of different organs to damage is variable and the figures given in Box 33.30 are provided only as a guide to sensible drinking. Heavy drinkers who persist for many years are at greater risk than heavy sporadic drinkers.

**Liver disease**

In general, the effects of a given intake of alcohol seem to be worse in women. The following figures are for men and should be reduced by about 30% for women:

- **High risk:** 160g ethanol per day (20 single drinks)
- **Medium risk:** 80g ethanol per day (10 single drinks)
- **Little risk:** 40g ethanol per day (5 single drinks).

**Alcohol consumption in pregnancy**

Women are advised not to drink alcohol at all during pregnancy because consumption of even small amounts of alcohol can lead to fetal growth restriction and may also increase the risk of miscarriage. The fetal alcohol syndrome is characterized by mental retardation, dysmorphic features and growth impairment; it occurs in fetuses of alcohol-dependent women.

A summary of the physical effects of alcohol is given in Box 33.31. Details of these diseases are discussed in the relevant

**Box 33.29 The main pathways of ethanol oxidization**

Alcohol dehydrogenase

\[ 	ext{CH}_3	ext{CH}_2	ext{OH} + 	ext{NAD}^+ \rightarrow 	ext{CH}_3	ext{CHO} + 	ext{NADH} + 	ext{H}^+ \]  

Liver microsomal ethanol oxidizing system (MEOS)

- Includes the specific P450 enzyme, CYP2E1, which is induced by ethanol

\[ 	ext{CH}_3	ext{CH}_2	ext{OH} + 	ext{NADPH} + 	ext{H}^+ + 	ext{O}_2 \rightarrow 	ext{CH}_3	ext{CHO} + 	ext{NADP} + 2	ext{H}_2	ext{O} \]

---

**Box 33.30 Guide to sensible alcohol drinking**

**Weekly maximum**

- 14 units for both men and women

**To help achieve this**

- Use a standard measure
- Do not drink during the daytime
- Have alcohol-free days each week

**Remember**

- Health can be damaged without being ‘drunk’. Regular heavy intake is more harmful than occasional binges
- Do not drink to ‘drown sorrows’
- In the UK, the drink-before-driving limit of alcohol in the blood is 800mg/L
- 1 unit of alcohol is eliminated per hour; therefore spread drinking time
- Food decreases absorption and therefore results in a lower blood alcohol level
- 4–5 units are sufficient to put the blood alcohol level over the legal driving limit in a 70kg man (less in a lighter person)
The effects of alcohol withdrawal are discussed on page 791. Specific public health and clinical guidance on prevention and management of alcohol-related disorders has been produced by NICE. The clinical guidelines specifically address alcohol withdrawal, Wernicke’s encephalopathy, and both alcohol-related liver and pancreatic disease.

Drugs and the liver

Key skills in hepatology include:
- managing patients with decompensated chronic liver disease, including variceal bleeding, ascites and encephalopathy, and those presenting with acute liver failure
- appreciating the role of history, examination, imaging, blood tests and liver biopsy in the diagnosis of patients newly presenting with evidence of liver disease
- understanding the natural history of hepatitis B and C infection and how to use the recently licensed and older medications available for their management.

Opportunities to learn hepatology include attending ward rounds on inpatient liver units, participating in outpatient hepatology clinics, observing the work of specialist nurses who manage patients with chronic liver disease in the community, learning how to perform paracentesis safely on medical day units, and watching ERCP procedures being performed.

### CLINICAL SKILLS FOR LIVER DISEASE

#### History

Both acute and chronic liver disease are often asymptomatic, especially in the early stages. Taking a history in hepatology involves not only asking about symptoms but also establishing the presence of common risk factors for liver disease to help establish a diagnosis (Box 34.1).

**Asking about alcohol**

This requires gentleness and tact (Box 34.2). Patients often underestimate their alcohol intake or degree of dependence. This history should be non-judgemental, and help should be offered through referral to alcohol support services if patients express a desire to become abstinent.

#### Examination

In acute liver disease there may be few signs, apart from jaundice and an enlarged liver. In the cholestatic phase of the illness, pale stools and dark urine are present.

The figure on p. 1263 illustrates the many signs associated with chronic liver disease, although physical examination is occasionally normal in patients with advanced disease.

#### Investigations

A detailed overview of the diagnostic investigations used in liver disease begins on page 1268. Fig. 34.1 illustrates how these investigations may be employed in an outpatient setting for a patient referred from primary care with raised liver transaminases.
Symptoms of acute liver disease
- May be asymptomatic and anicteric
- Symptomatic disease, often viral, producing malaise, anorexia and fever
- Jaundice (see later), often appearing as the illness progresses

Symptoms of chronic liver disease
- Non-specific symptoms, particularly weakness, anorexia and fatigue
- Right hypochondrial pain due to liver distension
- Abdominal distension due to ascites
- Ankle swelling due to fluid retention
- Haematomeisis and melena from variceal haemorrhage
- Pruritus due to cholestasis – often an early symptom of primary biliary cholangitis (PBC)
- Endocrine dysfunction: gynaecomastia, loss of libido and amenorrhoea
- Confusion and drowsiness due to hepatic encephalopathy

Past medical history
- Any previous disease affecting the liver, biliary tract, pancreas or gut
- Heart failure
- History of autoimmune disease
- Features of metabolic syndrome: obesity, diabetes, gout, hypercholesterolaemia

Medications
- Recent antibiotic use (several cause cholestasis)
- Paracetamol overdose
- Full medication history, establishing whether any cause liver damage

Family history
- History of jaundice, liver disease or specific diseases such as haemochromatosis

Alcohol use
- Take a detailed history (see later)

Risk factors for viral hepatitis
- Childhood spent in countries where hepatitis B or C is endemic
- Contaminated needles – unsafe tattoos, injecting drug use
- High-risk unprotected sexual activity

Box 34.1 Taking a history in liver disease

Extent of use
- Preferred type of alcohol (beer, wine, spirits); strength where relevant
- ‘Super-strength’ beers can be up to 10% ethanol
- Daily consumption (in cans, bottles or glasses, subsequently converted to units)
- Number of abstinent days per week
- Frequency of consuming >8 units on one occasion
- Duration of alcohol use, and changing use over this time

Degree of dependence
- Number of times alcohol has interfered with regular activities (e.g. going to work)
- Number of times the person has been unable to stop drinking once they have started

Need for a morning drink to ‘get going’
- Feelings of guilt about alcohol consumption
- Concern on the part of family and friends about alcohol use
- Injuries to self or others caused by alcohol

Views on abstinence
- Awareness of risks of current level of alcohol use (if this exceeds target levels)
- Willingness to cut down versus abstaining completely
- Previous attempts to give up
- Previous experiences of support groups, including Alcoholics Anonymous, and cognitive behavioural therapy
- Sources of support: family members, close friends, social or religious groups

Box 34.2 Taking an alcohol history in patients with liver disease

Screening blood tests
- Hepatitis B and C testing
- Autoantibodies
- Ferritin (haemochromatosis)
- Alpha-1-anti-trypsin levels
- Caeruloplasmin (in younger patients)

Ultrasound
- Assess for steatohepatitis or cirrhosis
- Exclude bile duct obstruction
- Masses
- Evidence of hepatic congestion or portal vein thrombosis
- Assess for ascites

Specialist non-invasive tests
- Transient elastography (liver stiffness, raised in cirrhosis)
- Liver MRI or magnetic resonance cholangiopancreatogram (MRCP)
- Echocardiogram
- CT abdomen

Invasive tests
- Liver biopsy
- ERCP

Fig. 34.1 Use of diagnostic investigations in an outpatient setting. This scheme would be appropriate for a patient referred from primary care with raised liver transferases.
Skin
- Scratch marks

Eyes
- Jaundice
- Kayser–Fleischer rings (Wilson’s disease)
- Xanthelasma (on eyelids)

General
- Jaundice
- Smell of alcohol/fetor hepaticus
- Encephalopathy
- Weight loss

Hands
- Flapping tremor
- Palmar erythema
- Dupuytren’s contracture (alcohol)
- Nails
  - Clubbing
  - Leuconychia

Abdomen
- Scars
- Distension (ascites – shifting dullness)
- Dilated superficial veins
- Hepatomegaly (small in cirrhosis)
- Splenomegaly
- Tumour
- Palpable gall bladder

Testicular atrophy

Oedema (pitting)
- Bruises

NB: Often patients with liver disease have very few signs.
INTRODUCTION

The aetiology of liver disease differs from region to region. In the developed world, liver inflammation is most often due to obesity, the metabolic syndrome (non-alcoholic fatty liver disease, NAFLD), non-alcoholic steatohepatitis (NASH) and alcohol excess. In the developing world, chronic viral infection with either hepatitis B or hepatitis C is the leading cause of liver mortality. In England, liver disease is the fifth most common cause of premature mortality. Globally, about half a billion people suffer from chronic viral hepatitis. Health education and the improvement in public health, along with vaccination programmes, should help to stop the spread of viral infections and reduce risk factors for the metabolic syndrome.

Cirrhosis represents the final common pathway for liver diseases and is characterized by progressive fibrosis of the liver parenchyma, which leads to portal hypertension and deterioration of liver function. In decompensated cirrhosis the median overall survival is 2 years, which is a far worse prognosis than for many cancers.

Imaging techniques enable the liver, biliary tree and pancreas to be visualized with precision, resulting in earlier diagnosis. Liver transplantation is an established therapy for both acute and chronic liver disease.

ANATOMY OF THE LIVER AND BILIARY SYSTEM

Liver

The liver is the body’s largest internal organ (1.2–1.5 kg) and is situated in the right hypochondrium. A functional division into the larger right lobe (containing caudate and quadrate lobes) and the left lobe is made by the middle hepatic vein. The liver is further subdivided into eight segments (Fig. 34.2) by divisions of the right, middle and left hepatic veins. Each segment has its own portal pedicle, permitting individual segment resection at surgery.

The hepatic blood supply constitutes 25% of the resting cardiac output and is delivered via two main vessels, entering via the liver hilum (porta hepatitis):

- **The hepatic artery**, a branch of the coeliac axis, supplies 25% of the hepatic blood flow. The hepatic artery autoregulates flow, ensuring a constant total blood flow.
- **The portal vein** drains most of the gastrointestinal tract and the spleen. It supplies 75% of hepatic blood flow. The normal portal pressure is 5–8 mmHg; flow increases after meals.

The blood from these vessels is distributed to the segments and flows into the sinusoids via the portal tracts. Blood leaves the sinusoids, entering branches of the hepatic vein, which join into three main branches before entering the inferior vena cava.

The **caudate lobe** is an autonomous segment, as it receives an independent blood supply from the portal vein and hepatic artery, and its hepatic vein drains directly into the inferior vena cava.

**Lymph**, formed mainly in the perisinusoidal space, is collected in lymphatics that are present in the portal tracts. These small lymphatics enter larger vessels, which eventually drain into the portal system.

The **acinus** is the functional hepatic unit. This consists of parenchyma supplied by the smallest portal tracts containing portal vein radicles, hepatic arterioles and bile ductules (Fig. 34.3). The hepatocytes near this triad (zone 1) are well supplied with oxygenated blood and are more resistant to damage than the cells nearer the terminal hepatic (central) veins (zone 3). The **sinusoids** lack a basement membrane and are loosely surrounded by specialist fenestrated endothelial cells and Kupffer...
cells (phagocytic cells). Sinusoids are separated by plates of liver cells (hepatocytes). The subendothelial space between the sinusoids and hepatocytes is the space of Disse, which contains a matrix of basement membrane constituents and stellate cells (see Fig. 34.21).

**Stellate cells** store retinoids in their resting state and contain the intermediate filament, desmin. When activated (to myofibroblasts, they are contractile and regulate sinusoidal blood flow. Endothelin and nitric oxide play a major role in modulating stellate cell contraction. Stellate cells are activated by a wide variety of inflammatory cytokines (such as tumour necrosis factor-alpha, TNF-α); once activated, they generate extracellular matrix proteins, including collagen, leading to fibrosis and eventually cirrhosis. Under appropriate conditions, stellate cells can also produce proteases that degrade the extracellular matrix, leading to reversal of fibrosis. The balance between collagen production and degradation is critical to the progression of liver scarring and cirrhosis development/resolution (see p. 1289).

**Biliary system**

Bile canaliculi form a network between the hepatocytes. These join to form thin bile ductules near the portal tract, which, in turn, enter the bile ducts in the portal tracts. These then combine to form the right and left hepatic ducts, which leave each liver lobe. The hepatic ducts join at the porta hepatis to form the common hepatic duct. The cystic duct connects the gall bladder to the lower end of the common hepatic duct. The gall bladder lies under the right lobe of the liver and stores and concentrates hepatic bile; its capacity is approximately 50 mL. The common bile duct is formed at the junction of the cystic and common hepatic ducts and is 8 mm in diameter or less, passing through the head of the pancreas, and narrowing at its lower end to pass into the duodenum. The common bile duct and pancreatic duct open into the second part of the duodenum, most often through a common channel at the ampulla of Vater, which contains the muscular sphincter of Oddi. This contracts rhythmically and prevents all of the bile from entering the duodenum, by maintaining a higher pressure than the gall bladder in the fasting state.

**FUNCTIONS OF THE LIVER**

**Protein metabolism**

See also page 1228.

**Synthesis and storage**

The liver is the principal site of synthesis of all circulating proteins, apart from γ-globulins (produced in the reticuloendothelial system). The liver receives amino acids from the intestine and muscles and, by controlling the rate of gluconeogenesis and transamination, regulates plasma levels. Plasma contains 60–80 g/L of protein, mainly albumin, globulin and fibrinogen.

Albumin has a half-life of 16–24 days, and 10–12 g is synthesized daily. Its main functions are to maintain intravascular oncotic (colloid osmotic) pressure, and to transport water-insoluble substances such as bilirubin, hormones, fatty acids and drugs. Reduced synthesis of albumin over prolonged periods produces hypoalbuminaemia and is seen in chronic liver disease and malnutrition. Hypoalbuminaemia is also found in hypercatabolic states (e.g. trauma, burns and sepsis) and in diseases associated with an excessive loss (e.g. nephrotic syndrome or protein-losing enteropathy).

Transport or carrier proteins, such as transferrin and caeruloplasmin, acute phase and other proteins (e.g. α1-antitrypsin and α-fetoprotein) are also produced in the liver.

The liver also synthesizes all coagulation factors (except for one-third of factor VIII) – that is, fibrinogen, prothrombin, factors V, VII, IX, X and XII, proteins C and S, and antithrombin (see pp. 368–369), as well as components of the complement system. The liver stores large amounts of certain vitamins, particularly A, D and B12, lesser amounts of others (vitamin K and folate), and minerals – iron in ferritin and haemosiderin, and copper.

**Degradation (nitrogen excretion)**

Amino acids are degraded by transamination and oxidative deamination to produce ammonia, which is then converted to urea and excreted by the kidneys. This is the major pathway for the elimination of nitrogenous waste. Failure of this process occurs in severe liver disease.

**Carbohydrate metabolism**

Glucose homeostasis and maintenance of blood sugar are major functions of the liver. It stores approximately 80 g of glycogen. In the immediate fasting state, blood glucose is maintained either by glucose release from glycogen breakdown (glycogenolysis) or by synthesis of new glucose (gluconeogenesis). Sources for gluconeogenesis are lactate, pyruvate, amino acids from muscles (mainly alanine and glutamine), and glycerol from lipolysis of fat stores. In prolonged starvation, ketone bodies and fatty acids are used as alternative sources of fuel as body tissues adapt to a lower glucose requirement (see p. 1231).

**Lipid metabolism**

Fats are insoluble in water and are transported in plasma as protein–lipid complexes (lipoproteins). These are discussed in detail on page 744.

The liver has a major role in the metabolism of lipoproteins. It synthesizes very-low-density lipoproteins (VLDLs) and high-density lipoproteins (HDLs). HDLs are the substrate for lecithin-cholesterol acyltransferase (LCAT), which catalyses the conversion of free cholesterol to cholesterol ester (see later). Hepatic lipase removes triglyceride from intermediate-density lipoproteins (IDLs) to produce low-density lipoproteins (LDLs), which are degraded by the liver after uptake by specific cell-surface receptors (see Fig. 24.3).

Triglycerides are mainly of dietary origin but are also formed in the liver from circulating free fatty acids (FFAs) and glycerol, and incorporated into VLDLs. Oxidation or de novo synthesis of FFAs occurs in the liver, depending on availability of dietary fat.

Cholesterol may be of dietary origin but most is synthesized from acetyl-coenzyme A (acetyl-CoA) in the liver, intestine, adrenal cortex and skin. It either occurs as free cholesterol or is esterified with fatty acids; this reaction is catalysed by LCAT. This enzyme is reduced in severe liver disease, increasing the ratio of free cholesterol to ester, which alters membrane structures. One result of this is the red cell abnormalities (e.g. target cells) seen in chronic liver disease. Phospholipids (e.g. lecithin) are synthesized in the liver. The complex interrelationships between protein, carbohydrate and fat metabolism are shown in Fig. 34.4.
Bile secretion and bile acid metabolism

Bile secretion and bile acid metabolism

Bile consists of water, electrolytes, bile acids, cholesterol, phospholipids and conjugated bilirubin. Two processes are involved in bile secretion across the canalicular membrane of the hepatocyte – bile salt-dependent and bile salt-independent processes – each contributing about 230 mL/day. Another 150 mL/day is produced by bile ductule epithelial cells.

Bile formation requires uptake of bile acids and other organic and inorganic ions across the basolateral (sinusoidal) membranes by multiple transport proteins (sodium taurocholate co-transporting polypeptide (NTCP) and sodium-independent organic anion-transporting polypeptide 2 (OATP2); Fig. 34.5). This process is driven by sodium/potassium adenosine triphosphatase (Na+/K+-ATPase) in the basolateral membranes. Intracellular transport across hepatocytes is partly through microtubules and partly by cytosol transport proteins.

Bile acids are also synthesized in hepatocytes from cholesterol, the rate-limiting step being those catalysed mainly by cholesterol-7α-hydroxylase and the P450 enzymes (CYP7A1 and CYP8B1).

The farnesoid X bile acid receptor blocks bile acid formation from cholesterol and also regulates the transport proteins (NTCP, OATP2) that increase bile acid uptake by the liver. It is a target for a new class of therapeutic drugs, farnesoid X receptor (FXR) agonists.

The canalicular membrane contains multispecific organic anion transporters, mainly ATPase-dependent (ATP binding cassette), the multidrug-resistant protein 2 (MRP2), multidrug-resistant protein 3 (MDR3) and the bile salt excretory pump (BSEP), which carry a broad range of compounds including bilirubin diglucuronide, glucuronidated and sulphated bile acids, and other organic anions against a concentration gradient into the biliary canaliculus. Na+ and water follow the passage of bile salts by diffusion across the tight junction between hepatocytes (a bile salt-dependent process). In the bile salt-independent process, water flow is due to other osmotically active solutes such as glutathione and bicarbonate.

Secretion of a bicarbonate-rich solution is stimulated mainly by secretin and inhibited by somatostatin. This involves several membrane proteins, including the Cl-/HCO3− exchanger and the cystic fibrosis transmembrane conductance regulator that controls Cl− secretion, and water channels (aquaporins) in cholangiocyte membranes.

The bile acids are excreted into bile and pass via the common bile duct into the duodenum. The two primary bile acids – cholic acid and chenodeoxycholic acid (see Fig. 34.5) – are conjugated with glycine or taurine, which increases their solubility. Intestinal bacteria convert these acids into secondary bile acids, deoxycholic and lithocholic acid. Fig. 34.6 shows the enterohepatic circulation of bile acids.

The average total bile flow is 600 mL/day. During fasting, half flows into the duodenum and half is diverted into the gall bladder. The gall bladder mucosa absorbs 80–90% of the water and electrolytes but is impermeable to bile acids and cholesterol. Following a meal, the I cells of the duodenal mucosa secrete cholecystokinin, which stimulates contraction of the gall bladder and relaxation of the sphincter of Oddi, allowing bile to enter the duodenum. An adequate bile flow is dependent on bile salts being returned to the liver by the enterohepatic circulation.

Bile acids act as detergents; their main function is lipid solubilization. Bile acid molecules have both a hydrophilic and a hydrophobic end. In aqueous solutions they form micelles, with their hydrophobic (lipid-soluble) ends in the centre. Micelles are expanded by cholesterol and phospholipids (mainly lecithin), forming mixed micelles.

Bile acid receptors in liver disease

Bile acids have been identified as crucial cell signalling molecules that regulate multiple biological processes. Bile acids are endogenous ligands for FXR and TGR5, a G-protein coupled receptor. Gain- and loss-of-function studies have demonstrated that both are involved in the regulation of lipid and carbohydrate metabolism and inflammatory responses. These receptors may therefore be potential targets for treatment of NAFLD, and phase III trials of the FXR agonist obeticholic acid are nearing completion in NASH (see p. 1288). Furthermore, obeticholic acid has been approved for the second-line treatment of PBC following trial results demonstrating an improvement in liver blood tests. Finally, obeticholic acid showed potential beneficial effect for primary sclerosing cholangitis and a long-term multicentre study is ongoing. In cirrhotic animal models, this drug reduced both portal hypertension and gut bacterial translocation. However, hepatic decompensation, liver failure and death have been reported when Child B or C cirrhosis patients are dosed more frequently than recommended and so it remains uncertain whether it will emerge as a treatment for portal hypertension.

Bilirubin metabolism

Bilirubin is produced mainly from the breakdown of mature red cells by Kupffer cells in the liver and reticuloendothelial system; 15% of bilirubin is formed from catabolism of other haem-containing proteins, such as myoglobin, cytochromes and catalases.

Normally, 250–300 mg (425–510 mmol) of bilirubin are produced daily. The iron and globin are removed from haem and reused. Biliverdin is formed from haem and reduced to form bilirubin. The bilirubin produced is unconjugated and water-insoluble, due to internal hydrogen bonding, and is transported to the liver.
Functions of the liver

attached to albumin. Bilirubin dissociates from albumin and is taken up by hepatic cell membranes and transported to the endoplasmic reticulum by cytoplasmic proteins, where it is conjugated with glucuronic acid and excreted into bile. The microsomal enzyme uridine diphosphoglucuronosyl transferase catalyses the formation of bilirubin monoglucuronide and then diglucuronide. This conjugated bilirubin is water-soluble; it is actively secreted into biliary canaliculi and excreted into the intestine within bile (see Fig. 16.5). It is not absorbed from the small intestine because of its large molecular size. In the terminal ileum, bacterial enzymes hydrolyse the molecule, releasing free bilirubin, which is then reduced to urobilinogen; some of this is excreted in the stools as stercobilinogen. The remainder is absorbed by the terminal ileum, passes to the liver via the enterohepatic circulation, and is re-excreted into bile. Urobilinogen bound to albumin enters the circulation and is excreted in urine via the kidneys. When hepatic excretion of conjugated bilirubin is impaired, a small amount is strongly bound to serum albumin and is not excreted by the kidneys; it accounts for persisting hyperbilirubinaemia after cholestasis has resolved.

Hormone and drug inactivation

The liver catabolizes hormones such as insulin, glucagon, oestrogens, growth hormone, glucocorticoids and parathyroid hormone. It is also the prime target organ for many hormones (e.g. insulin). It is the major site for the metabolism of drugs (see p. 1310) and alcohol (see p. 1258). Fat-soluble drugs are converted to water-soluble substances that facilitate their excretion in the bile or urine. Cholecalciferol is converted to 25-hydroxycholecalciferol.
Liver disease

Primary biliary cholangitis
Hepatocellular carcinoma
- e.g. Hepatitis A, B, C, D, E and others
- Disease
Autoimmune hepatitis
Disease

Liver function tests

Useful blood tests for certain liver diseases are shown in Box 34.3.

Blood tests

Liver ‘function’ tests: serum albumin and bilirubin; prothrombin time (PT).
Liver biochemistry: serum aspartate (AST) and alanine aminotransferases (ALT) – an increase reflects hepatocellular damage; serum alkaline phosphatase (ALP) and gamma-glutamyl transpeptidase (γ-GT) – an increase reflects cholestasis; total protein.
Viral markers.
Additional blood investigations: haematological, biochemical, immunological, markers of liver fibrosis and genetic analysis.

Imaging techniques – to define gross anatomy.
Liver biopsy – for histology.

Blood tests ordered for ‘liver function’ are usually processed by an automated multichannel analyser to produce serum levels of bilirubin, aminotransferases, ALP, γ-GT and total proteins. These routine tests are markers of liver damage but not actual tests of ‘function’ per se. Subsequent investigations are often based on these tests.

Liver tests

Useful blood tests for certain liver diseases are shown in Box 34.3.

Liver function tests

Serum albumin
This is a marker of synthetic function and is useful for gauging the severity of chronic liver disease: a falling serum albumin is a bad prognostic sign. In acute liver disease, initial albumin levels may be normal. Interpretation of a low albumin can be difficult when other causes of hypoalbuminaemia (e.g. malnutrition, urinary protein loss or sepsis) are present.

Bilirubin
Serum bilirubin is normally almost all unconjugated. In liver disease, increased serum bilirubin is usually accompanied by other abnormalities in liver biochemistry. Differentiation between conjugated or unconjugated bilirubin is necessary only in congenital disorders of bilirubin metabolism (see later) or to exclude haemolysis.

Prothrombin time

Prothrombin time (PT) is also a marker of synthetic function. Because of its short half-life, it is a sensitive indicator of both acute and chronic liver disease. Vitamin K deficiency should be excluded as the cause of a prolonged PT by giving an intravenous bolus (10 mg) of vitamin K. Vitamin K deficiency commonly occurs in biliary obstruction, as the low intestinal concentration of bile salts results in poor absorption of vitamin K.

Prothrombin times vary in different laboratories, depending on the thromboplastin used in the assay. The international normalized ratio (INR) was developed to standardize anticoagulation with coumarin derivatives but is very variable in liver disease and causes large differences when included in prognostic scores for cirrhosis across different centres. A rising INR in patients with liver disease that is not corrected by vitamin K is a poor prognostic sign.

Liver biochemistry

Aminotransferases
These enzymes (often referred to as transaminases) are contained in hepatocytes and leak into the blood with liver cell damage. Two enzymes are measured:

INVESTIGATIONS IN THE PATIENT WITH LIVER DISEASE

Investigative tests can be divided into:

- Blood tests:
  - Liver ‘function’ tests: serum albumin and bilirubin; prothrombin time (PT).
  - Liver biochemistry: serum aspartate (AST) and alanine aminotransferases (ALT) – an increase reflects hepatocellular damage; serum alkaline phosphatase (ALP) and gamma-glutamyl transpeptidase (γ-GT) – an increase reflects cholestasis; total protein.
  - Viral markers.
  - Additional blood investigations: haematological, biochemical, immunological, markers of liver fibrosis and genetic analysis.

- Imaging techniques – to define gross anatomy.
- Liver biopsy – for histology.

Blood tests

Useful blood tests for certain liver diseases are shown in Box 34.3.

Liver function tests

Serum albumin
This is a marker of synthetic function and is useful for gauging the severity of chronic liver disease: a falling serum albumin is a bad prognostic sign. In acute liver disease, initial albumin levels may be normal. Interpretation of a low albumin can be difficult when other causes of hypoalbuminaemia (e.g. malnutrition, urinary protein loss or sepsis) are present.

Bilirubin
Serum bilirubin is normally almost all unconjugated. In liver disease, increased serum bilirubin is usually accompanied by other abnormalities in liver biochemistry. Differentiation between conjugated or unconjugated bilirubin is necessary only in congenital disorders of bilirubin metabolism (see later) or to exclude haemolysis.

Prothrombin time

Prothrombin time (PT) is also a marker of synthetic function. Because of its short half-life, it is a sensitive indicator of both acute and chronic liver disease. Vitamin K deficiency should be excluded as the cause of a prolonged PT by giving an intravenous bolus (10 mg) of vitamin K. Vitamin K deficiency commonly occurs in biliary obstruction, as the low intestinal concentration of bile salts results in poor absorption of vitamin K.

Prothrombin times vary in different laboratories, depending on the thromboplastin used in the assay. The international normalized ratio (INR) was developed to standardize anticoagulation with coumarin derivatives but is very variable in liver disease and causes large differences when included in prognostic scores for cirrhosis across different centres. A rising INR in patients with liver disease that is not corrected by vitamin K is a poor prognostic sign.

Liver biochemistry

Aminotransferases
These enzymes (often referred to as transaminases) are contained in hepatocytes and leak into the blood with liver cell damage. Two enzymes are measured:
• **Aspartate aminotransferase** (AST) is primarily a mitochondrial enzyme (80%; 20% in cytoplasm) and is also present in heart, muscle, kidney and brain. High levels are seen in hepatic necrosis, myocardial infarction, muscle injury and congestive cardiac failure.

• **Alanine aminotransferase** (ALT) is a cytosol enzyme, more specific to the liver, so that a rise occurs only with liver disease. The ALT:AST ratio is a useful clinical indicator:
  - In viral hepatitis, ALT is greater than AST unless cirrhosis is present, in which case AST is greater than ALT.
  - In alcoholic liver disease and steatohepatitis, the AST is often greater than the ALT.
  - In patients with viral hepatitis, an AST:ALT ratio of more than 1 indicates cirrhosis.
  - In patients with liver disease without cirrhosis, in whom AST is greater than ALT, alcohol or obesity is the most likely aetiological agent.

**Alkaline phosphatase**

Alkaline phosphatase (ALP) is present in hepatic canalicular and sinusoidal membranes, and also in bone, intestine and placenta. If necessary, its origin can be determined by electrophoretic separation of isoenzymes or bone-specific monoclonal antibodies. In clinical practice, if the γ-GT is also abnormal, the ALP is presumed to come from the liver.

Serum ALP is raised in both intrahepatic and extrahepatic cholestatic disease of any cause, due to increased synthesis. In cholestatic jaundice, levels may be 4–6 times the normal limit. Raised levels also occur with hepatic infiltrations (e.g. metastases) and in cirrhosis, frequently in the absence of jaundice.

**Gamma-glutamyl transpeptidase**

This is a microsomal enzyme present in liver and also in many tissues. Its activity can be induced by numerous drugs such as phenytoin, warfarin and rifampicin, and by alcohol. If the ALP is normal, a raised serum γ-GT can be a useful guide to alcohol intake (see p. 790). However, mild elevations of γ-GT are common, even with minimal alcohol consumption, and it is also raised in fatty liver disease. In the absence of other liver function test abnormalities, a slightly raised γ-GT can safely be ignored. In cholestasis, the γ-GT rises in parallel with the ALP, as it has a similar pathway of excretion.

**Total proteins and globulin fraction**

The globulin fraction is often raised in autoimmune hepatitis; if it falls, it indicates successful therapy.

**Viral markers**

Viruses are a major cause of liver disease. Virological studies have a key role in diagnosis; markers are available for most common viruses that cause hepatitis.

**Haematological tests**

A full blood count may show thrombocytopenia. Thrombocytopenia is a common finding in cirrhosis and is often aggravated by alcohol-induced bone marrow suppression. A low platelet count (below the lower limit of normal – 150 x 10^9/L) should be regarded as indicative of cirrhosis, unless another cause can be found. In alcohol excess, red blood cells are often macrocytic.

**Biochemical tests**

- **α1-Antitrypsin** enzyme deficiency can produce cirrhosis.
- **α-Fetoprotein** is normally produced by the fetal liver. Its reappearance in increasing and high concentrations in adults indicates hepatocellular carcinoma. Increased concentrations in pregnancy and amniotic fluid suggest fetal neural tube defects. Blood levels are also slightly raised with regenerative liver tissue in patients with hepatitis, chronic liver disease and also teratomas.

- **Urinary copper** is raised, and serum copper and caeruloplasmin are low in Wilson’s disease (see p. 1301).

**Immunological tests**

**Serum immunoglobulins**

Increased γ-globulins are thought to result from reduced phagocytosis by sinusoidal and Kupffer cells of the gut-absorbed antigens. These antigens then stimulate antibody production in the spleen, lymph nodes and portal tract lymphoid and plasma cell infiltrates. In PBC the predominant raised serum immunoglobulin is IgM, while in autoimmune hepatitis it is IgG. IgG4 is raised in autoimmune pancreatitis/cholangitis (see p. 1330 and Box 3.10).

**Serum autoantibodies**

- **Anti-mitochondrial antibody (AMA)** in serum is found in over 95% of patients with PBC (see p. 1298). Several different AMA subtypes are described, depending on their antigen specificity, and are also found in autoimmune hepatitis and other autoimmune diseases. AMA is demonstrated by an immunofluorescent technique and is neither organ- nor species-specific. The M2 subtype is specific for PBC.
- **Nucleic, smooth muscle (actin), liver/kidney microsomal antibodies** can be found in serum, often in high titre, in patients with autoimmune hepatitis. These serum antibodies are also present in other autoimmune conditions and other liver diseases.
- **Anti-nuclear cytoplasmic antibodies (ANA)** can be found in the serum of patients with primary sclerosing cholangitis (see p. 1299).

**Markers of liver fibrosis**

Fibrosis plays a key role in the outcome of many chronic liver diseases, and accurate assessment of fibrosis is critical for the appropriate management of many liver disorders. A variety of systems have been developed to assess the extent of liver fibrosis and these range from algorithms of varying degrees of complexity that use standard haematological and biochemical tests, to novel biomarkers. Simple algorithms include the APRI (aspartate aminotransferase to platelet ratio index) score, while more complex commercial tests include the fibrotest algorithm. Novel biomarker-based algorithms include those based on measurements of hyaluronic acid, procollagen III amino terminal peptide and tissue inhibitor of metalloproteinase 1 (TIMP-1), all combined in the enhanced liver fibrosis (ELF) test. In general, these markers have been developed for chronic hepatitis C but they are often successfully applied to other liver disorders. The current assays have a high sensitivity/specificity for the detection or absence of cirrhosis but are less effective at detecting intermediate levels of fibrosis. Combining mechanical non-invasive fibrosis tests, such as transient elastography (see p. 1270), with fibrosis markers allows many patients to avoid a liver biopsy to assess fibrosis.

**Genetic analysis**

These tests are performed routinely for haemochromatosis (HFE gene) and for α1-antitrypsin deficiency. Markers are also available for the most frequent abnormal genes in Wilson’s disease (see p. 1301).

**Imaging techniques**

**Ultrasound examination**

This non-invasive, safe and relatively cheap technique involves analysis of the reflected ultrasound beam detected by a probe moved across the abdomen. The normal liver appears as a relatively homogeneous structure. The gall bladder, common bile duct, pancreas, portal vein and other structures in the abdomen can be visualized. **Abdominal ultrasound** is useful in:

- Detection of extrahepatic obstruction (the bile duct is usually dilated, particularly in advanced disease). Note that opiates may cause biliary dilation without obstruction, and so scans in injecting drug users often show extrahepatic biliary dilation.
- Assessment of a jaundiced patient (to exclude obstruction) (see p. 1273).
- Assessment of hepatomegaly/splenomegaly.
- Detection of gallstones (see Fig. 35.2).
- Assessment of focal liver disease – lesions >1 cm.
- Assessment of portal and hepatic vein patency.
- Assessment of the hepatic parenchyma – diffuse fatty infiltration often leads to a ‘bright’ appearance on ultrasound but experience is required to distinguish this from normal variation.
- Identification of cirrhosis – in advanced cirrhosis, the liver edge is irregular and the spleen is often enlarged. Note that a normal ultrasound does not exclude cirrhosis.
- Assessment of lymph node enlargement.

Other abdominal masses can be delineated and biopsies obtained under ultrasonic guidance.

**Colour Doppler ultrasound**

This will demonstrate vascularity within a lesion, and the direction of portal and hepatic vein blood flow.

**Hepatic stiffness (transient elastography)**

Using an ultrasound transducer, a vibration of low frequency and amplitude is passed through the liver, the velocity of which correlates with hepatic stiffness. Stiffness (measured in kPa) increases with worsening liver fibrosis (sensitivity and specificity 80–95%, compared to liver biopsy). Elastography can reliably exclude cirrhosis and, in cirrhosis, increasing liver stiffness is associated with a higher risk of complications. Elastography is less effective for determining lesser degrees of fibrosis but, particularly when combined with non-invasive fibrosis tests (see earlier), it can be used to exclude cirrhosis reliably. It cannot be employed in the presence of ascites and morbid obesity, and is affected by inflammatory tissue and congestion.

Acoustic radiation force impulse is incorporated into standard B mode ultrasonography and has similar physical principles to transient elastography.

**Computed tomography examination**

Computed tomography (CT), during or immediately after intravenous contrast, shows both arterial and portal venous phases of enhancement, enabling more precise characterization of a lesion and its vascular supply (Fig. 34.7). Retrospective analysis of data allows multiple overlapping slices to be obtained with no increase in the radiation dose, providing excellent visualization of the size, shape and density of the liver, pancreas, spleen, lymph nodes and lesions in the porta hepatitis. Multiplanar and three-dimensional reconstruction in the arterial phase can create a CT angiogram, often making formal invasive angiography unnecessary. CT also provides guidance for biopsy. It has advantages over ultrasound in detecting calcification and is useful in obese subjects, although

---

**Fig. 34.7** Triple phase liver CT showing a hepatocellular carcinoma. The liver has an irregular contour consistent with cirrhosis and there are splenic and gastric varices. The arterial phase (A) demonstrates an enhancing lesion, which is poorly seen on the portal venous phase (B) but demonstrates washout on the delayed phase imaging (C) consistent with hepatocellular carcinoma. (1) Liver; (2) spleen; (3) lesion; (4) aorta; (5) stomach; (6) portal vein; (7) varices; (8) washout of lesion.
ultrasound is usually the first imaging modality to be used to investigate liver disease.

**Magnetic resonance imaging**

Magnetic resonance imaging (MRI) produces cross-sectional images in any plane within the body and does not involve radiation. It is the most sensitive investigation for focal liver disease but can also assess fibrosis. Diffuse liver disease alters the T1 and T2 characteristics. Other fat-suppression modes, such as **short T1 inversion recovery (STIR)**, allow good differentiation between haemangiomias and other lesions. Contrast agents such as intravenous gadolinium, which allow further characterization of lesions, are suitable for those with iodine allergy, and provide angiography and venography of the splanchic circulation. Use of these agents has superseded direct arteriography.

**Magnetic resonance cholangiopancreatography**

Magnetic resonance cholangiopancreatography (MRCP) involves the manipulation of data acquired by MRI. A heavily T2-weighted sequence enhances visualization of the ‘water-filled’ bile ducts and pancreatic ducts to produce high-quality images of ductal anatomy. This non-invasive technique is replacing diagnostic (but not therapeutic) endoscopic retrograde cholangiopancreatography (see p. 1325) and is usually the next test to be applied if a biliary abnormality is present on ultrasound examination.

**Radionuclide imaging – scintiscanning**

In a 99mTc-IODIDA scan, technetium-labelled iododiethyl IDA is uptake by the hepatocytes and excreted rapidly into the biliary system. Its main uses are in the diagnosis of:

- acute cholecystitis
- jaundice due to either biliary atresia or hepatitis in the neonatal period.

**Endoscopy**

**Upper gastrointestinal endoscopy** is used for diagnosis and treatment of varices, detection of portal hypertensive gastropathy, and detection of associated lesions such as peptic ulcers. Colonoscopy may show portal hypertensive colopathy. Capsule endoscopy can identify small intestinal varices.

**Endoscopic retrograde cholangiopancreatography**

Endoscopic retrograde cholangiopancreatography (ERCP) outlines the biliary and pancreatic ducts (see p. 1325).

**Angiography**

This is performed by selective catheterization of the coeliac axis and hepatic artery. It outlines the hepatic vasculature and the abnormal vasculature of hepatic tumours, but spiral CT and MRI have replaced diagnostic angiography. The portal vein can be demonstrated with increased definition using subtraction techniques that have replaced splenoportography (by direct splenic puncture).

In **digital vascular imaging** (DVI), contrast given intravenously or intra-arterially can be detected in the portal system using computerized subtraction analysis.

**Hepatic venous cannulation** allows abnormal hepatic veins to be diagnosed in patients with Budd–Chiari syndrome and is also used to measure portal pressure indirectly. There is a 1 : 1 relationship of occluded (by balloon) hepatic venous pressure with portal pressure in patients with alcoholic or viral-related cirrhosis. The height of portal pressure has prognostic value for survival in cirrhosis: a difference of the occluded minus the free hepatic venous pressure (hepatic venous pressure gradient, HVPG) of 20% or more from baseline values, or below 12 mmHg, has been associated with protection from rebleeding and prevention of other complications of cirrhosis.

**Liver biopsy**

Histological examination of the liver is valuable in the differential diagnosis of diffuse or localized parenchymal disease and its severity. Liver biopsy can be performed on a day-case basis. The indications and contraindications are shown in **Box 34.4**. The mortality rate is less than 0.02% when the technique is performed by experienced operators.

Liver biopsy guided by ultrasound or CT is performed under a local anaesthetic via a percutaneous approach in the right intercostal space. A transjugular approach is used when liver histology is essential for management but coagulation abnormalities or ascites prevent the percutaneous approach.

Most complications of liver biopsy occur within 24 hours (usually in the first 2 hours). They are often minor and include abdominal or shoulder pain that settles with analgesics. Minor intraperitoneal bleeding can occur but this settles spontaneously. Rare complications include major intraperitoneal bleeding, haemothorax and pleurisy, biliary peritonitis, haemobilia and transient septicaemia. Haemobilia produces biliary colic, jaundice and melaena within 3 days of the biopsy.

**Further reading**

---

**JAUNDICE**

Jaundice (icterus) is detectable clinically when the serum bilirubin is over 50 μmol/L (3 mg/dL). It may be divided into:

- **haemolytic jaundice** – increased bilirubin load for the liver cells
- **congenital hyperbilirubinaemias** – defects in conjugation
- **cholestatic jaundice** – including hepatocellular (parenchymal) liver disease and large duct obstruction.
Haemolytic jaundice
The increased breakdown of red cells (see Fig. 16.5) leads to an increase in production of bilirubin. The resulting jaundice is usually mild (serum bilirubin of 68–102 μmol/L, or 4–6 mg/dL), as normal liver function can easily manage the increased bilirubin. Unconjugated bilirubin is not water-soluble and therefore does not pass into urine: hence 'acholuric jaundice'. Urinary urobilinogen is increased. The causes are those of haemolytic anaemia (p. 338), and clinical features of anaemia, jaundice, splenomegaly, gallstones and leg ulcers may be seen.

Investigations show haemolysis and elevated unconjugated bilirubin, but normal serum ALP, transferases and albumin. Serum haptoglobulins are low.

Congenital hyperbilirubinaemias (non-haemolytic)
Unconjugated types

Gilbert's syndrome
This is the most common familial conjugated hyperbilirubinaemia and affects 2–7% of the population. It is asymptomatic and usually detected incidentally with a raised bilirubin (17–102 μmol/L, or 1–6 mg/dL). All other liver biochemistry is normal and there are no signs of liver disease. There is a family history of jaundice in 5–15% of patients. Most patients have reduced levels of UDP-glucuronosyl transferase (UGT-1) activity; this is the enzyme that conjugates bilirubin with glucuronic acid.

Mutations occur in the gene (UGT1A1 promoter region) encoding this enzyme, with an expanded nucleotide repeat consisting of two extra bases in the upstream 5' promoter element. This abnormality appears to be required for the syndrome to occur but is not in itself sufficient for clinical manifestation (phenotypic expression).

Establishing the diagnosis is necessary to provide reassurance and prevent unnecessary investigations. The raised unconjugated bilirubin is diagnostic and rises on fasting and during mild illness. The reticulocyte count is normal, excluding haemolysis, and no treatment is necessary.

Crigler–Najjar syndrome
This is very rare. Only patients with type II (autosomal dominant) disease, with a decrease in, rather than absence (type I – autosomal recessive) of, UGT survive into adult life. Liver histology is normal. Transplantation is the only effective treatment.

Conjugated types

Dubin–Johnson and Rotor's syndromes
Dubin–Johnson and Rotor's syndromes (autosomal recessive) are due to defects in hepatic bilirubin handling. The prognosis is good in both. In the Dubin–Johnson syndrome the liver is black owing to melanin deposition.

Benign recurrent intrahepatic cholestasis
This is rare and presents in early adulthood. Recurrent attacks of acute cholestasis occur without progression to chronic liver disease. Jaundice, severe pruritus, steatorrhoea and weight loss develop. Serum γ-GT is normal. Benign recurrent intrahepatic cholestasis may be associated with intrahepatic cholestasis of pregnancy (see p. 1455). Genetic testing is available and there are two forms: BRIC1 is caused by mutations in the ATP8B1 gene and BRIC2 by mutations in the ABCB11 gene. Both are autosomal recessive. Treatment includes medications to manage symptoms and occasionally specialized therapies, such as nasobiliary drainage, to shorten episodes.

Progressive familial intrahepatic cholestasis syndromes
Progressive familial intrahepatic cholestasis (PFIC) syndromes are a heterogeneous group of autosomal recessive conditions defined by defective secretion of bile acids (see Figs 34.5 and 35.1).
- In type 1 (PFIC1), with cholestasis in the first weeks of life, the γ-GT is normal.
- In type 2 (PFIC2), there is frequently a non-specific giant cell hepatitis that progresses to cholestasis; again, γ-GT is normal.
- In type 3 (PFIC3), deficient canalicular phosphatidylcholine transport and accumulation of toxic bile acids cause liver damage, which can lead to cirrhosis.
Liver transplantation is the only cure for these syndromes.

Cholestatic jaundice (acquired)
This condition can be divided into extrahepatic and intrahepatic cholestasis. The causes are shown in Fig. 34.8.
• **Extrahepatic cholestasis** is due to large duct obstruction of bile flow at any point in the biliary tract distal to the bile canaliculi.

• **Intrahepatic cholestasis** occurs because of failure of bile secretion, which may be caused by intrinsic defects in bile secretion or inflammation in the intrahepatic ducts.

Clinically, in both types, there is jaundice with pale stools and dark urine, and the serum bilirubin is conjugated. However, intrahepatic and extrahepatic cholestatic jaundice must be differentiated, as their clinical management is entirely different.

### Differential diagnosis of jaundice

Jaundice (see p. 1263) may occur in previously healthy people who have an acute hepatic illness or may develop in patients with cirrhosis who have “decompensated”. The management of decompensated cirrhosis is described on page 1290 but all patients with jaundice should be questioned closely about risk factors for chronic liver disease to determine whether this is a true acute presentation rather than an ‘acute on chronic’ illness. The history often gives a clue to the diagnosis. Certain causes of jaundice are more likely in particular categories of people. For example, a young person is more likely to have infectious hepatitis, so questions should be asked about drug and alcohol misuse, and sexual behaviour. An elderly person with gross weight loss is more likely to have a carcinoma. All patients may complain of malaise. Abdominal pain occurs in patients with biliary obstruction, and sometimes with an enlarged liver there is pain resulting from distension of the capsule.

Questions should be appropriate to the particular situation, and the following aspects of the history should be covered:

- **Country of origin**. The incidence of hepatitis B virus (HBV) and hepatitis C virus (HCV) infection is increased in many parts of the world (see pp. 1277 and 1282).

- **Duration of illness**. A history of jaundice with prolonged weight loss in an older patient suggests malignancy. A short history, particularly with a prodromal illness of malaise, suggests an infectious hepatitis.

- **Recent outbreak of jaundice**. An outbreak in the community suggests hepatitis A virus (HAV).

- **Intravenous drug use, or recent injections or tattoos**. These all increase the chance of HBV and HCV infection.

- **Men having sex with men**. There is an increased chance of HBV and HCV infection.

- **Female sex workers**. There is an increased chance of HBV infection.

- **Medical treatment in the developing world**. There is an increased risk of HBV and HCV due to poorly sterilized equipment or administration of unscreened blood or blood products.

- **Alcohol consumption**. A history of drinking habits should be taken, although many patients often understate their consumption.

- **Drugs (particularly those taken in the previous 2–3 months)**. Many drugs, including over-the-counter and herbal preparations, cause jaundice (see p. 1310).

- **Travel**. Certain areas have a high risk of HAV infection, as well as hepatitis E virus (HEV), but HAV is common in the UK and HEV is common in travellers to the Indian subcontinent.

- **Family history**. Patients with, for example, Gilbert’s disease may have family members who experience recurrent jaundice.

- **Recent surgery**. Surgery on the biliary tract or for carcinoma is relevant.

- **Environment**. People engaged in recreational activities in rural areas, as well as farm and sewage workers, are at risk for leptospirosis, hepatitis E and exposure to chemicals.

- **Fever or rigors**. These are suggestive of cholangitis or possibly a liver abscess.

### Clinical features

The signs of acute and chronic liver disease should be looked for (see p. 1263). Certain additional signs may be helpful:

- **Hepatomegaly**. A smooth, tender liver is seen in hepatitis and in extrahepatic obstruction, but a knobbly, irregular liver suggests metastases or cirrhosis. Causes of hepatomegaly are shown in Box 34.5.

- **Splenomegaly**. This indicates portal hypertension when signs of chronic liver disease are present. The spleen can also be “tipped” occasionally in viral hepatitis. In alcoholic cirrhosis, in particular, the spleen may not be grossly enlarged and may not be palpable.

- **Ascites**. This is found in cirrhosis but can also be due to other causes (see Box 34.21).

- **Palpable gall bladder**. This occurs with a carcinoma of the pancreas obstructing the bile duct.

- **Generalized lymphadenopathy**. This suggests a lymphoma.

- **Cold sores** are often seen with a herpes simplex virus hepatitis.

### Investigations

Jaundice is not itself a diagnosis and the cause should always be sought. The two most useful tests are the **viral markers** (for HAV, HBV and HCV), and an ultrasound examination. Liver biochemistry confirms the jaundice and may help in the diagnosis.

An **ultrasound examination** should always be performed to exclude an extrahepatic obstruction and to diagnose any features compatible with chronic liver disease. Ultrasound will demonstrate:

- the size of the bile ducts, which are dilated in biliary obstruction (Fig. 34.9)
- the level of the obstruction
- the cause of the obstruction in virtually all patients with tumours and in 75% of patients with gallstones.

The pathological diagnosis of any mass lesion can be made by fine-needle aspiration cytology (sensitivity approximately 60%) or by needle biopsy (sensitivity approximately 90%).

A flow diagram for the general investigation of the jaundiced patient is shown in Fig. 34.10.

### Liver biochemistry

In hepatitis, serum AST and ALT tend to be high early in the disease, with only a small rise in serum ALP. Conversely, in extrahepatic obstruction, the ALP is high, with a smaller rise in aminotransferases. However, these findings alone cannot be relied on to make a diagnosis in an individual case. The PT is often prolonged in long-standing liver disease and the serum albumin is low.
Liver ultrasound. (A) Markedly dilated intrahepatic ducts (arrowed). (B) A dilated common bile duct (red arrow). A duct with a diameter of 6 mm or less is normal; however, it can be of larger calibre and still not represent pathology in some circumstances, such as in elderly patients and after cholecystectomy. Several factors must therefore be considered when deciding what is normal for a patient. Normal colour flow is demonstrated in the portal vein (green arrow).

Fig. 34.10 Approach to the patient with jaundice. CBD, common bile duct; MRCP, magnetic resonance cholangiopancreatography; US, ultrasound. * Proceed as in bottom left box (Re-check drug history...).
can be caused by many agents (Fig. 34.11). Chronic hepatitis is defined as any hepatitis lasting for 6 months or longer and is classified according to the aetiology (Box 34.6). Chronic viral hepatitis is the principal cause of chronic liver disease, cirrhosis and hepatocellular carcinoma worldwide.

Acute hepatitis

Pathology

Although some histological features are suggestive of the aetiological factor, most changes are non-specific. Hepatocytes show degenerative changes (swelling, cytoplasmic granularity, vacuolation) and undergo necrosis (becoming shrunken, containing eosinophilic Councilman bodies). The distribution of these changes may vary with aetiology but necrosis is usually maximal in zone 3. The extent of the damage is very variable between individuals, even when they are affected by the same agent; at one end of the spectrum, single and small groups of hepatocytes die (spotty or focal necrosis), while at the other end, there is multicinar necrosis involving a substantial part of the liver (massive hepatic necrosis) and resulting in acute hepatic failure. Between these extremes, there is limited confluent necrosis with collapse of the reticulin framework, leading to linking (bridging) between the central veins, between the central veins and portal tracts, and between the portal tracts. The extent of the inflammatory infiltrate is also variable but portal tracts and lobules are infiltrated mainly by lymphocytes. Other variable features include cholestasis in zone 3 and fatty change, the latter being prominent in hepatitis due to alcohol or certain drugs.

Chronic hepatitis

Pathology

The pathological features are often diagnostic. Chronic inflammatory cell infiltrates, comprising lymphocytes, plasma cells and sometimes lymphoid follicles, are usually present in the portal tracts. The amount of inflammation varies from mild to severe. In addition, there may be:

- loss of definition of the portal/periportal limiting plate – interface hepatitis (damage is due to apoptosis rather than necrosis)
- lobular change, focal lytic necrosis, apoptosis and focal inflammation
- confluent necrosis
- fibrosis, which may be mild, bridging (across portal tracts) or severe cirrhosis.

The overall severity of the hepatitis is judged by the degree of hepatitis and inflammation (grading), and the severity of fibrosis or cirrhosis (staging). In chronic viral hepatitis there are various scoring systems. For example, the Knodell scoring system (histological activity index) uses the sum of four factors (periportal or bridging necrosis, intralobular degeneration and focal necrosis, portal inflammation and fibrosis). The Ishak score stages fibrosis from 0 (none) to 6 (cirrhosis). The METAVIR system has four stages. Scoring systems are used for drug trials and for assessing progression of disease, but are not quantitative measures of fibrosis and different systems may be used for different diseases (for example, the Brunt scoring system is usually applied to NAFLD, and the METAVIR system is reserved for hepatitis C).

Viral hepatitis

The differing features of the common forms of viral hepatitis are summarized in Box 34.7. Two different patterns are recognized: acute hepatitis with rapid onset of infection and, usually, rapid resolution; and chronic viral hepatitis, which is asymptomatic and often detected on routine blood tests or during screening for infection. Hepatitis A always and hepatitis E usually cause acute infections, while hepatitis B, C and D may cause acute or chronic disease.
Hepatitis A

Epidemiology

Hepatitis A is common worldwide, often occurring in epidemics. The disease is usually seen in the autumn and affects children and young adults. Spread of infection is mainly by the faeco-oral route and arises from ingestion of contaminated food or water (e.g. shellfish). Overcrowding and poor sanitation facilitate spread, and outbreaks of infection have occurred in men who have sex in men. There is no carrier state. In the UK it is a notifiable disease.

Hepatitis A virus

Hepatitis A virus (HAV) is a picornavirus (Fig. 34.12). It has a single serotype, as only one epitope is immunodominant. It replicates in the liver, is excreted in bile, and then excreted in the faeces for about 2 weeks before the onset of clinical illness and for up to 7 days after. The disease is maximally infectious just before the onset of jaundice. HAV particles can be demonstrated in the faeces by electron microscopy.

Clinical features

The viraemia causes the patient to feel unwell, with non-specific symptoms that include nausea and anorexia. Many recover at this stage and remain anicteric. An anicteric infection is common in children and confers lifetime immunity. In the developing world, improvements in hygiene have reduced early infection and, paradoxically, led to an increase in symptomatic infection in exposed adults.

After 1 or 2 weeks, some patients become jaundiced and symptoms often improve. Persistence of nausea, vomiting or any mental confusion warrants assessment in hospital. As the jaundice deepens, the urine becomes dark and the stools are pale. The liver is moderately enlarged and the spleen may be palpable. Occasionally, tender lymphadenopathy is seen, with a transient rash in some cases. Thereafter, the jaundice lessens and, in the

Fig. 34.12 Hepatitis A. (A) The hepatitis A (HAV) virion consists of four polyepitopes (VP1–VP4), which form a tight protein shell, or capsid, containing the RNA. The major antigenic component is associated with VP1. (B) Arrangement of the HAV genome.
majority of cases, the illness is over within 3–6 weeks. Extrahepatic complications are rare but include arthritis, vasculitis, myocarditis and acute kidney injury. A biphasic illness occasionally occurs, with the return of jaundice and, classically, a more severe ‘second phase’, which is cholestatic (cholestatic viral hepatitis) with an increase in the ALP rather than the aminotransferases; thus, it runs a prolonged course of 7–20 weeks. Rarely, the disease may be very severe with acute hepatitis, liver coma and death; this is more common in the elderly. The typical sequence of events after HAV exposure is shown in Fig. 34.13.

Investigations
Liver biochemistry
- **Prodromal stage**: The serum bilirubin is usually normal. A raised serum AST or ALT, which can sometimes be over many thousands, precedes the jaundice.
- **Icteric stage**: The serum bilirubin reflects the level of jaundice. Serum AST reaches a maximum 1–2 days after the appearance of jaundice, and may rise above 500 IU/L. Serum ALP is usually less than 300 IU/L.
  
  After the jaundice has subsided, the aminotransferases may remain elevated for some weeks and occasionally for up to 6 months.

Haematological tests
There is leucopenia with a relative lymphocytosis. Very rarely, there is a Coombs’-positive haemolytic anaemia or an associated aplastic anaemia. The PT is prolonged in severe cases. The erythrocyte sedimentation rate (ESR) is raised.

Viral markers: antibodies to HAV
IgG antibodies are common in the general population over the age of 50 years but an anti-HAV IgM means an acute infection. In areas of high prevalence, most children have antibodies by the age of 3 years following asymptomatic infection.

Other tests
Further tests are not necessary in the presence of an IgM antibody but liver biochemistry must be followed to establish a return to normal levels.

**Differential diagnosis**
Differentiation must be made from all other causes of jaundice, but in particular from other types of viral and drug-induced hepatitis.

**Prognosis**
The prognosis is excellent, with most patients making a complete recovery. The mortality in young adults is 0.1% but increases with age. Death is due to acute hepatic necrosis.

There is no reason to stop alcohol consumption, other than for the few weeks when the patient is ill. Patients may complain of debility for several months following resolution of the symptoms and biochemical parameters. This is known as the post-hepatitis syndrome and treatment is by reassurance. HAV hepatitis never progresses to chronic liver disease.

**Management**
There is no specific treatment, and rest and dietary measures are unhelpful. Corticosteroids have no benefit. Admission to hospital is not usually necessary.

**Prevention**
Control of hepatitis depends on good hygiene. The virus is resistant to chlorination but is killed by boiling water for 10 minutes.

**Active immunization**
A formaldehyde-inactivated HAV vaccine is given to people travelling frequently to endemic areas, patients with chronic liver disease, those with haemophilia, and workers in frequent contact with hepatitis cases (e.g. in residential institutions for patients with learning difficulties). Community outbreaks can be interrupted by vaccination. A single dose produces antibodies that persist for at least 1 year, with immunity lasting beyond 10 years. This obviates the need for a booster injection in healthy individuals.

**Passive immunization**
Normal human immunoglobulin (0.02 mL/kg i.m.) is used if exposure to HAV is for less than 2 weeks. HAV vaccine should also be given.

**Hepatitis B**

**Epidemiology**
The hepatitis B virus (HBV) is present worldwide and there are an estimated 220 million carriers. The UK and the USA have a low carrier rate (0.5–2%) but this rises to 10–20% in parts of Africa and the Middle and Far East.

**Vertical transmission** from mother to child, usually during parturition or soon after birth, and rarely in utero, is the usual means of transmission worldwide, although in Africa transmission from other infected children is common during the early childhood years. HBV is not transmitted by breast-feeding.

**Horizontal transmission** occurs, particularly in children, through minor abrasions or close contact with other children, and HBV can survive on household articles, such as toys or toothbrushes, for prolonged periods. Childhood chronic HBV is associated with very high levels of viral replication (up to 10^{12} IU/mL), ensuring that high levels of virus are present in minute amounts of blood and thus facilitating viral spread.

HBV spread also occurs by the intravenous route (e.g. by transfusion of infected blood or blood products, or by contaminated needles employed by drug users, tattooists or acupuncturists) or by close personal contact, such as during sexual intercourse, particularly in men who have sex with men. The virus can be found in semen and saliva.

**Figs. 34.13** Hepatitis A virus (HAV): sequence of events after exposure. ALT, alanine aminotransferase; Ig, immunoglobulin.
**Hepatitis B virus**

The complete infective virion or Dane particle is a 42 nm particle comprised of an inner core or nucleocapsid (27 nm), surrounded by an outer envelope of surface protein (hepatitis B surface antigen, HBsAg). This surface coat is produced in excess by the infected hepatocytes and can exist separately from the whole virion in serum and body fluid as 22 nm particles or tubules.

The HBV genome is variable, and genetic sequencing can be used to define the different HBV genotypes, A–H. There is a strong correlation between genotypes and geographical areas. **Genotype A** is found in north-west Europe, North America and Central Africa; **B** in South-east Asia (including China, Taiwan and Japan); **C** in South-east Asia; **D** in southern Europe, India and the Middle East; **E** in West Africa; **F** in South and Central America, in American Indians and in Polynesia; **G** in France and the USA; and **H** in Central and South America. These genotypes may influence the chance of responding to interferon treatment (A more than B; C more than D) but all genotypes respond equally well to nucleoside analogues.

The core or nucleocapsid is formed of core protein (HBcAg), containing incompletely double-stranded circular DNA and DNA polymerase/reverse transcriptase. One strand is almost a complete circle and contains overlapping genes that encode both structural proteins (pre-S, surface (S), core (C)) and replicative proteins (polymerase (P) and X). The other strand is variable in length. DR1 and DR2 are direct repeats necessary for HBV synthesis during viral replication (Fig. 34.14).

HBsAg is a protein formed via specific self-cleavage of the pre-core/core gene product, which is secreted separately by the cell.

**Hepatitis B mutants**

Mutations occur in the various reading frames of the HBV genome (Fig. 34.14). These mutants can emerge in patients with chronic HBV infection (escape mutants) or can be acquired by infection. **HBsAg mutants** are produced by alterations in the ‘a’ antigenic determinants of the HBsAg proteins, usually with a substitution of glycine for arginine at position 145. This results in changes in the antibody-binding domain and may render the vaccine ineffective. In patients with some HBV genotypes (particularly genotype D), a mutation in the **pre-core region**, when a guanosine (G) to adenosine (A) change creates a stop codon (TAG), prevents the production of HBsAg (the secreted form of HBcAg) but the synthesis of HBcAg is unaffected. This mutation may be associated with HBsAg-negative disease but other mutations in the core promoter region of the virus also give rise to HBsAg-negative disease. To detect infectivity in HBsAg-negative disease, HBV DNA must always be measured, as no HBsAg will be present.

**DNA polymerase mutants** occur, particularly following treatment with the first generation of directly acting antiviral drugs, such as lamivudine.

**Pathogenesis**

**Pre-S, and pre-S₂, regions** are involved in attachment to the hepatocyte receptor – the sodium taurocholate co-transporting polypeptide (NTCP). After penetration into the cell the virus loses its coat and the virus core is transported to the nucleus without processing. The transcription of HBV into messenger RNA takes place when the HBV DNA is converted into a closed circular form (cccDNA), which acts as a template for RNA transcription. The transcribed RNA is then reverse-transcribed by the viral polymerase protein to HBV DNA, which is circularized and packaged. Hence HBV, like HIV, replicates via reverse transcription that introduces errors into the replication cycle (reverse transcriptase enzymes are error-prone) but allows production of viral DNA that can integrate into the host genome. Unsurprisingly, some drugs (e.g. lamivudine and tenofovir) that are active against the HIV polymerase also have effects on the HBV polymerase.

**Translation into HBV proteins** (Box 34.8), as well as replication of the genome, takes place in the endoplasmic reticulum; the proteins are then packaged together and exported from the cell. There is excess production of non-infective HBsAg particles, which are extruded into the circulation.

The HBV is not usually directly cytopathic (although high replication levels in immunosuppressed individuals can lead to direct toxicity) and liver damage is produced by the host immune response.

HBV-specific cytotoxic CD8 T cells recognize the viral antigen via human leucocyte antigen (HLA) class I molecules on the infected hepatocytes. However, suppressor or regulatory T cells inhibit these cytotoxic cells, leading to viral persistence and chronic HBV infection. Th1 responses (IL-2, interferon-gamma) are thought to be associated with viral clearance, and Th2 (IL-4, 5, 6, 10, 13) responses with the development of chronic infection and disease severity. Viral persistence in patients with a very poor cell-mediated...
response leads to an asymptomatic, inactive, chronic HBV infective state. However, a better response results in continuing hepatocellular damage, with the development of chronic hepatitis.

Chronic HBV infection progresses through a series of four distinct phases (Fig. 34.15).

- **Phase 1 HBeAg-positive chronic HBV infection.** The natural history of childhood-acquired HBV is shown in the figure. In this first early phase there is high-level viral replication, with HBeAg, which is not associated with an immune-mediated liver injury response and does not cause liver damage. This was previously called the ‘immunotolerant phase’ of HBV but it is now clear that an immune response does develop, although why this does not lead to an obvious hepatitis has not yet been established. Management is not indicated but close follow-up is required. This phase matures into the next adolescent phase.

- **Phase 2 HBeAg-positive chronic HBV infection.** During adolescence, liver damage often develops, with fluctuating raised transaminases (ALT) in the presence of high levels of HBeAg-positive infection. This was previously termed the ‘immunoactive phase’ but it is now recognized that the change from ‘inactive’ to ‘active’ disease is complex and not simply related to changes in immune tolerance. In some patients, this disease phase will progress to cirrhosis and therapy is therefore indicated to reduce the development of fibrosis. Management in this phase may lead to seroconversion from HBeAg-positive to HBeAg-negative.

- **Phase 3 HBeAg-negative chronic HBV infection.** In many patients the disease evolves to a quiescent phase (previously termed the ‘inactive carrier’ phase), when host immune responses suppress viral replication, leading to low-level HBV DNA (<2000 IU/mL), absence of HBeAg and normal ALTs. In some patients the virus is eventually cleared, with the loss of HBsAg; in many, however, viral reactivation occurs with viral mutations, leading to HBeAg-negative disease with high levels of viral replication (HBV DNA 10^5/10^6) and ALT in the absence of HBeAg. Note that, in this phase, fluctuating ALTs may lead to misdiagnosis, and so the ALTs and HBV DNA should be tested four times a year to establish the diagnosis in patients who are HBeAg-negative.

- **Phase 4 HBeAg-negative chronic HBV infection.** In a proportion of patients with inactive HBV, disease will reactivate as they age, and this final phase is characterized by high-level viral replication (HBV DNA 10^5/10^6) but negative HBeAg and raised ALT. In this phase, fluctuating ALT levels may lead to misdiagnosis and so liver function and HBV DNA should be tested four times a year to establish the diagnosis in patients who are HBeAg-negative. Therapy for HBeAg-negative disease is indicated to prevent disease progression. Hepatocellular carcinoma (HCC) can develop at all stages of disease but is more common in those with high levels of HBV DNA.

Immunosuppression, such as occurs during chemotherapy, aggravates all phases of HBV and a particular problem is seen in patients with HBeAg-negative, inactive disease, where the presence of normal liver biochemistry provides a false sense of security. HBV reactivation is common in such patients and has a high mortality. It is essential for all those due to receive chemotherapy to be screened for HBsAg, and those who have chronic HBV should receive prophylactic antiviral therapy, such as tenofovir or entecavir. Profound immunosuppression, such as occurs during bone marrow transplantation or rituximab therapy, can lead to disease reactivation in patients who have lost all traces of HBV, and in those with evidence of HBV exposure (i.e. those with antibodies against hepatitis B core or anti-hepatitis B surface antibodies) consideration of prophylactic therapy or close monitoring is required.
Liver disease

Immunity to HBV; previous exposure; vaccination - Implies viral replication

Significance

Acute hepatitis B

Acute hepatitis B (high titre)

Seroconversion - Acute or chronic infection

The majority of patients recover completely; acute hepatic failure occurring in up to 1%. Some patients go on to develop chronic hepatitis and the outcome depends on several factors, chiefly the age of the patient.

Management of acute hepatitis

This is mainly symptomatic. However, patients should have their HBV markers monitored. Several experts suggest that entecavir or tenofovir should be given for the persistent presence of HBeAg beyond 12 weeks, and in some patients who are very ill.

Prevention

Prevention depends on vaccination. In countries that do not vaccinate all citizens, prevention depends on avoiding risk factors (see earlier). These include not sharing needles and having safe sex. Vertical transmission is discussed later. Infectivity is highest in those with the e antigen and/or HBV DNA in their blood.

Immunization

Vaccination is obligatory in most developed countries (the UK recently added HBV to the childhood vaccination schedule), as well as countries with high endemicity, and has been shown to reduce mortality and morbidity. In countries that do not have a universal vaccination policy, groups at high risk are vaccinated. These include all healthcare personnel; members of emergency and rescue teams; morticians and embalmers; children in high-risk areas; people with haemophilia; patients in some psychiatric units; patients with chronic kidney disease/on dialysis units; long-term travellers; men who have sex with men, bisexual men and sex workers; and intravenous drug users.

Active and passive (combined) prophylaxis with vaccination and immunoglobulin should be given to healthcare staff with accidental needlestick injury; all newborn babies of HBsAg-positive mothers; and regular sexual partners of HBsAg-positive patients who have been found to be HBV-negative.

For adults, a dose of 500IU of specific hepatitis B immunoglobulin (HB Ig) (200IU for newborns) is given; the vaccine (i.m.) is given at another site.

Prevention of mother-to-child transmission of HBV offers the potential to arrest transmission of this infection but the logistics of delivering the vaccine in a timely manner to babies born to high-risk mothers in developing countries (such as rural Africa and China) have, so far, prevented an effective campaign.

Active immunization

This is with a recombinant yeast vaccine, produced by insertion of a plasmid containing the gene of HBsAg into a yeast.
Dosage regimen
Three injections (at 0, 1 and 6 months) are given into the deltoid muscle; this gives short-term protection in over 90% of patients. People who are over 50 years of age or clinically ill and/or immunocompromised (including those with human immunodeficiency virus (HIV) infection or acquired immunodeficiency syndrome (AIDS)) have a poor antibody response; more frequent and larger doses are required. Antibody levels should be measured at 7–9 months after the initial dose in all at-risk groups. Antibody levels fall steadily after vaccination, and booster doses may be required after approximately 3–5 years. It is not cost-effective to check antibody levels prior to active immunization. There are few side-effects from the vaccine.

Chronic hepatitis B virus infection
Following an acute HBV infection, which may be subclinical, approximately 1–10% of patients will not clear the virus and will develop a chronic HBV infection. The features are described on page 1280.

Investigations
These may show a moderate rise in aminotransferases but infection with normal aminotransferases is common. The serum bilirubin is often normal. HBsAg and HBV DNA are found in the serum, sometimes with HBeAg.

Histologically, there is a full spectrum of changes, from near normal with only a few lymphocytes and interface hepatitis to full-blown cirrhosis. HBsAg may lend a ‘ground-glass’ appearance to the cytoplasm on haematoxylin and eosin staining, and this can be confirmed on orcein staining or, more specifically, immunohistochemical staining. HBeAg can also be demonstrated in hepatocytes by appropriate immunohistochemical staining.

Management of chronic hepatitis B

Indications for therapy are similar to those for HBeAg-positive and negative patients with chronic hepatitis. Three criteria are used: serum HBV DNA levels, serum ALT levels and histological grade and stage. Increasingly, non-invasive assessment of liver fibrosis by, for example, transient elastography is replacing liver biopsy:

- Patients with moderate to severe active necroinflammation and/or fibrosis in the liver, with HBV DNA above 2000 IU/mL (approximately 10 000 copies/mL) and/or ALT above the upper limit of normal, are usually offered therapy. Age and comorbidities also affect the decision to treat and the choice of agents.
- If cirrhosis is present, treatment should be given, independent of ALT or HBV DNA levels. Patients with decompensated cirrhosis can also be treated with oral antiviral agents but liver transplantation may be required. All patients, regardless of disease phase, need long-term follow-up, as transition to an active phase is common; the lifetime risk of malignancy is increased in all patients who are HBsAg-positive, and men over 40 and women over 50 should be offered 6-monthly ultrasound screening.

Aim of therapy
The goals are to prevent disease progression and, ideally, eliminate HBsAg.
- Interferon is an immunostimulator that induces an immune response, leading to prolonged remission after discontinuation of therapy.
- Oral nucleotides suppress viral replication and are used for prolonged periods of time.

In patients receiving long-term oral antiviral agents, liver fibrosis regresses. Even those with cirrhosis may recover, and the liver may remodel and lose all traces of fibrosis.

Antiviral agents
Interferon, entecavir and tenofovir are the most commonly used drugs.

Pegylated interferon-alfa-2a (180 µg once a week s.c.) is most often used in patients who are HBeAg-positive with active disease. Some patients (25–45%, depending on genotype – A and B respond best) lose HBeAg and move to the ‘inactive’ HBeAg-negative phase of disease. A proportion then goes on to lose HBsAg some years after treatment discontinuation. Patients with higher serum aminotransferase values (three times the upper limit of normal), who are younger and have viral loads below 10^7 IU/mL, respond best to treatment. Patients with concomitant HIV respond poorly and those with cirrhosis should not receive interferon. Response can be assessed during therapy by measuring the serum levels of HBsAg: if these fall after 3 months, a favourable outcome is likely, and most doctors stop therapy after 3 months if the HBsAg level remains unchanged. In patients with HBeAg-negative HBV, pegylated interferon-alfa-2a is occasionally used, as it offers a finite duration of therapy. A proportion of patients with active disease (high ALT, increased HBV DNA) convert to inactive disease, and response can be assessed by an early decline in HBsAg.

Side-effects of treatment include an acute influenza-like illness occurring 6–8 hours after the first injection. This usually disappears after subsequent injections but malaise, headaches and myalgia are common; depression, reversible hair loss and bone marrow depression and infection may also occur.

Oral antiviral therapy for HBV (entecavir and tenofovir) is very effective and almost all compliant patients respond with a decrease in HBV DNA to undetectable levels and a reduction in liver inflammation (Box 34.10). Both HBeAg-positive and HBeAg-negative patients respond equally well. Long-term viral suppression has been shown to reverse fibrosis, and even patients with cirrhosis respond with reversion of fibrosis. Resistance is rarely seen with third-generation drugs, and older, more resistance-prone drugs, like lamivudine, are no longer recommended. A small proportion of patients develop an immune response leading to loss of HBeAg and, very rarely, loss of HBsAg. However, the majority of patients who commence oral antiviral agents will require very prolonged treatment, perhaps life-long. Studies are in progress to determine whether antiviral therapy can ever be safely discontinued. Entecavir and tenofovir are the drugs of choice for HBV, and both agents are associated with very few side-effects and an excellent response. Combination therapy has little benefit and a single drug should be used. New treatments that target alternative steps in the viral life cycle (e.g. polymerization of the core protein) or augment...
Liver disease

The prevalence rate of infection ranges from 0.4% in Europe and 1–3% in Southern Europe (possibly linked to intramuscular injections of vaccines or other medicines) to 6% in Africa; in Egypt, the rates are as high as 19%, owing to parental antimony treatment for schistosomiasis. The virus is transmitted by blood and blood products, and was common in people with haemophilia treated before screening of blood products was introduced. The incidence in intravenous drug users is high (40–60%). The low rate of HCV infection in high-risk groups – such as men who have sex with men, sex workers and attendees at sexually transmitted infection clinics – suggests a limited role for sexual transmission. Vertical transmission from a healthy mother to child can occur but is rare (approximately 5%). Other routes of community-acquired infection (e.g. close contact) are extremely rare. In 20% of cases the exact mode of transmission is unknown.

Hepatitis C virus (HCV)
Hepatitis C virus (HCV) is a single-stranded RNA virus of the Flaviviridae family. The RNA genome is approximately 10kb in length, encoding a polyprotein product consisting of structural (capsid and envelope) and non-structural viral proteins (Fig. 34.17). Comparisons of subgenomic regions, such as E1, NS4 or NS5, have allowed variants to be classified into six genotypes, which have differing geographical distributions. Variability is distributed throughout the genome, with the non-structural gene of different genotypes showing 30–50% nucleotide sequence disparity. Genotypes 1a and 1b account for 70% of cases in the USA and 50% in Europe, while genotype 3 is common in the Indian subcontinent and genotype 4 is prevalent in Egypt. There is a rapid change in envelope proteins, making it difficult to develop a vaccine. Antigens from the nucleocapsid regions have been used to develop enzyme-linked immunosorbent assays (ELISAs). The current assay, ELISA-3, incorporates antigens NS3, NS4 and NSS regions.

Clinical features
Most acute infections are asymptomatic, about 10% of patients having a mild influenza-like illness with jaundice and a rise in serum aminotransferases. Most patients will not be diagnosed until they present, years later, with evidence of abnormal transferase values at health checks or with chronic liver disease.

Investigations
Investigation is by evaluation of HCV, RNA and HCV antibodies; HCV RNA can be detected from 1 to 8 weeks after infection. Anti-HCV tests are usually positive 8 weeks from infection. Patients with acute HCV infection should be tested on several occasions, as many have fluctuating viraemia during the first few months of infection, with periods of undetectable HCV RNA followed by virological relapse. Viral clearance is confirmed by multiple tests for HCV RNA over a period of many months.

Management
In acute infection, most experts recommend a period of monitoring for a few weeks with serial assessments of HCV RNA. If the viral load is falling, treatment may not be required, but the patient should be observed for several months to confirm true viral clearance. If the HCV RNA level does not decline, therapy is indicated. Needle-stick injuries must be followed and treated early, although the vast majority (>97%) do not go on to develop viraemia. For the treatment of patients with co-infection with HIV, see page 1445.

Prognosis
Some 85–90% of asymptomatic patients develop chronic liver disease. A higher percentage of symptomatic patients ‘clear’ the virus, with only 48–75% going on to chronic liver disease.
Chronic hepatitis C infection

Pathogenesis
As with hepatitis B infection, cytokines in the Th2 phenotypes are profibrotic and cause the development of chronic infection. A dominant CD4 Th2 response, with a weak CD8 interferon-gamma response, may lead to rapid fibrosis. Th1 cytokines are antifibrotic and thus a dominant CD4 Th1 and CD8 cytolytic response may cause less fibrosis.

Clinical features
Patients with chronic HCV infection are usually asymptomatic, the disease only being discovered following a routine biochemical test when mild elevations in the aminotransferases (usually ALT) are noticed (50%). The elevation in ALT may be minimal and fluctuating, and some patients have a persistently normal ALT (25%), the disease being detected by checking HCV antibodies (e.g. in blood donors). Non-specific malaise and fatigue are common in chronic infection and often reverse following viral clearance. Extrahepatic manifestations are seen, including arthritis, cryoglobulinaemia with or without glomerulonephritis, and porphyria cutanea tarda. There is a higher incidence of diabetes, and associations with lichen planus, sicca syndrome and non-Hodgkin lymphoma.

Chronic HCV infection causes slowly progressive fibrosis that leads, over decades, to cirrhosis. After 20 years of infection, 16% of patients have developed cirrhosis; the proportion that will ultimately develop cirrhosis after a lifetime of infection remains unknown but is likely to be higher than the proportions reported after short-term follow-up. Factors associated with rapid progression of HCV fibrosis include excess alcohol consumption, co-infection with HIV, obesity, diabetes and infection with genotype 3. Once cirrhosis has developed, some 3–4% per year will develop decompensated cirrhosis and approximately 1% will develop liver cancer. Unlike HBV infection, HCV rarely causes liver cancer in the absence of cirrhosis. In most parts of the world, HCV was spread (either by injection drug use or by poorly sterilized medical devices) in the 1970s. Given the slow development of cirrhosis, current mathematical models of disease burden predict a massive increase in HCV-related end-stage liver disease over the next decade.

Investigations
Diagnosis is made by finding HCV antibody in the serum using third-generation ELISA-3 tests. A proportion of patients with spontaneous clearance will have undetectable HCV RNA in the serum (measured by PCR) but most individuals who are antibody-positive will be viremic. The level of viraemia varies from a few thousand to many millions of viral copies per millilitre, although current practice is to present viral load measurements in international units (IU). Disease progression and treatment outcome are not influenced by the viral load.

The HCV genotype should be characterized in patients who are to be given treatment (see next section), and assessment of fibrosis (by either liver biopsy or non-invasive methods) is required in those who would prefer to defer therapy. Cirrhosis should be excluded in all patients who have been infected for more than 20 years and a liver biopsy or non-invasive marker should be used.

Management
The aim of treatment is to eliminate the HCV RNA from the serum in order to:
• stop the progression of active liver disease
• prevent the development of HCC.

A clinical cure is determined by a sustained virological response (SVR), defined by a negative HCV RNA by PCR 6 months after the end of therapy. Additional public health benefits may accrue from a reduction in the pool of infected people, and campaigns to eliminate HCV in populations at high risk of infection (such as people who inject drugs) are under way.

Antiviral agents
Treatment for HCV infection is now based on direct-acting antiviral agents that are administered orally. These drugs target enzymes in
Liver disease

Therapy may involve a nucleotide inhibitor of the polymerase (sofosbuvir) combined with an NS5a inhibitor. This combination may be pan-genotypic (sofosbuvir/velpatasvir) or specific for genotypes 1 and 4 (sofosbuvir/ledipasvir), and involves a single tablet given once a day for 8–12 weeks. An alternative strategy is to use a protease inhibitor-based regimen (either glecaprevir or grazoprevir) combined with an NS5a inhibitor. Glecaprevir is combined with pibrentasvir and involves three tablets a day for 8 weeks in patients without cirrhosis or for 12 weeks in those with cirrhosis. The regimen is effective in all viral genotypes. Grazoprevir is combined with elbasvir and is used as a single tablet that is taken for 12 weeks and is effective in patients with genotypes 1 and 4. All of the treatment regimens eliminate virus in more than 95% of patients; in the very few who do not respond to therapy a ‘rescue’ treatment involving sofosbuvir/velpatasvir and the pan-genotypic protease inhibitor voxilaprevir is licensed and eliminates virus in over 90% of patients. Following viral clearance, liver fibrosis progression is halted and may even reverse, but in patients with cirrhosis the risk of liver cancer persists (albeit at a reduced level). Patients who do not have cirrhosis can be discharged from follow-up after successful therapy, defined as undetectable virus 12 weeks after discontinuation of treatment.

The extraordinary effectiveness of the oral antiviral regimens against HCV, combined with their excellent safety programme, has led to campaigns to identify and treat all patients with HCV, and the World Health Organization has a goal of eliminating HCV by 2030. If this can be achieved, it will represent the first time that a viral infection has been controlled without an effective vaccine.

Hepatitis E

Hepatitis E virus (HEV) is an RNA virus (Hepeviridae family; Fig. 34.19); it causes disease that is clinically very similar to hepatitis A. It is enterally transmitted, usually by contaminated water, with 30% of dogs, pigs and rodents carrying the virus. Epidemics have been seen in many developing countries, and sporadically in developed countries, in patients who have had contact with farm animals or have travelled abroad. In some developing countries, zoonotic infection from contaminated pork has led to acute HEV infection becoming relatively common. It has a mortality from fulminant hepatic failure of 1–2%, which rises to 20% in pregnant women. There is no carrier state and infection does not progress to chronic liver disease, except in some immunosuppressed patients. An ELISA for IgG and IgM anti-HEV is available for diagnosis. HEV RNA can be detected in the serum or stools by PCR. Prevention and control depend on good sanitation and hygiene; a vaccine has been developed and used successfully in China. Over the last few years it has become clear that HEV infection is common in many domestic animals, particularly pigs. Contamination of meat is not uncommon and acute infection with HEV is now the most common cause of acute viral hepatitis in the UK and many EU countries. The infection with animal-derived HEV is usually less aggressive than the water-borne infections in the Indian subcontinent and the symptoms and outcomes are similar to those of hepatitis A infection. A large proportion of the adult population in England have evidence of infection with hepatitis E, suggesting that subclinical infection is common. In patients who are immunocompromised, HEV infection may lead to chronic infection, which is treated by reduction of the immunosuppression and/or introduction of the broad-spectrum antiviral agent ribavirin.

Hepatitis non-A–E

Approximately 10–15% of acute viral hepatitides cannot be typed and are described as hepatitis non-A–E. GB agent (hepatitis G virus, HGV) and transfusion-transmitted virus (TTV) agents have not been documented as causing disease in humans.

Abnormal liver biochemistry is frequently found in a number of acute infections. The abnormalities are usually mild and have no clinical significance.

Infectious mononucleosis

Infectious mononucleosis (see also p. 524) is due to the Epstein–Barr (EB) virus. Mild jaundice, associated with minor abnormalities
Acute hepatic failure

Acute liver failure (ALF) is defined as acute liver injury with encephalopathy and deranged coagulation (INR >1.5) in a patient with a previously normal liver. The time intervals are variable. The time of development to jaundice to encephalopathy varies from 7 days (hyper-acute) to 8–28 days (acute) and 21–26 weeks (subacute). Occasionally, patients may have previous liver damage: for example, D virus superinfection in a previous carrier of HBsAg, Budd-Chiari syndrome or Wilson’s disease.

ALF is a rare but often life-threatening syndrome that is due to acute hepatitis from many causes (Box 34.11). These causes vary throughout the world; most involve viral hepatitis but paracetamol overdose is common in the UK (50% of cases). HCV does not usually cause acute hepatic failure, although exceptional cases have been reported from Japan and India.

Histologically, there is multiacinar necrosis involving a substantial part of the liver. Severe fatty change is seen in pregnancy (see p. 1455) and Reye’s syndrome (p. 1310), or following intravenous tetracycline administration.

Clinical features

Examination shows a jaundiced patient with a small liver and signs of hepatic encephalopathy. The mental state varies from slight...
Liver disease

drowsiness, confusion and disorientation (grades I and II) to unresponsive coma (grade IV) with convulsions. Fetal hepaticus is common but ascites and splenomegaly are rare. Fever, vomiting, hypotension and hypoglycaemia occur. Neurological examination shows spasticity and hyper-reflexia; plantar responses remain flexor until late. Cerebral oedema develops in 80% of patients with ALF but is far less common with subacute failure; its consequences, intracranial hypertension and brain herniation, account for about 25% of the causes of death. Other complications include bacterial and fungal infections, gastrointestinal bleeding, respiratory arrest, kidney injury (hepatorenal syndrome and acute tubular necrosis) and pancreatitis.

Investigations

- Routine tests (see p. 1268).
- There is hyperbilirubinaemia, high serum aminotransferases and low levels of coagulation factors including prothrombin and factor V. Aminotransferases are not useful indicators of the course of the disease, as they tend to fall along with the albumin with progressive liver damage.
- An electroencephalogram (EEG) is sometimes helpful in grading the encephalopathy.
- Ultrasound will define liver size and may indicate underlying liver pathology.

Management

There is no specific treatment but patients should be managed in a specialized unit. Transfer criteria to such units are shown in Box 34.12. Supportive therapy, as for hepatic encephalopathy, is necessary (see p. 1297). When signs of raised intracranial pressure (which may be measured directly) are present, 20% mannitol (1 g/kg body weight) should be infused intravenously; this dose may need to be repeated. Dexamethasone is not of value. Hypoglycaemia, hypokalaemia, hypomagnesaemia, hypophosphataemia and hypocalcaemia should be anticipated and corrected with a 10% glucose infusion (checked by 2-hourly dipstick testing), potassium, calcium, phosphate and magnesium supplements. Hypoanaemia should be corrected with hypertonic saline. Coagulopathy is managed with intravenous vitamin K, platelets, blood or fresh frozen plasma. Haemorrhage may be a problem and patients are given a proton pump inhibitor (PPI) to prevent gastrointestinal bleeding. Prophylaxis against bacterial and fungal infection is routine, as infection is a frequent cause of death and may preclude liver transplantation. Suspected infection should be treated immediately with suitable antibiotics. Renal and respiratory failure should be treated as necessary. Liver transplantation has been a major advance for patients with ALF. It is difficult to judge the timing or the necessity for transplantation, but there are guidelines based on validated prognostic indices of survival (see later).

Prognosis

In mild cases (grades I and II encephalopathy with drowsiness and confusion), two-thirds of patients will survive. The outcome of severe cases (grades III and IV encephalopathy with stupor or deep coma) is related to aetiology. In specialist units, 70% of patients with paracetamol overdose and grade IV coma will survive, as will 30–40% patients with HAV or HBV hepatitis. Poor prognostic variables indicating a need to transplant the liver are shown in Box 34.13.

AUTOIMMUNE HEPATITIS

Autoimmune hepatitis (AIH) is a progressive inflammatory liver condition with a 75% female preponderance. Approximately 40% of AIH patients have a family history of autoimmune disease (e.g. pernicious anaemia, thyroiditis or coeliac disease), and at least 20% have concomitant autoimmune diseases or will develop them during follow-up.

Pathogenesis

The pathogenesis of AIH is incompletely understood, although evidence increasingly demonstrates that genetic susceptibility, molecular mimicry and impaired immunoregulatory networks contribute to the initiation and perpetuation of the autoimmune attack. Liver damage is thought to be mediated primarily by T cell–mediated events (CD4+ T cells) against liver antigens, producing a progressive necro-inflammatory process that leads to fibrosis and cirrhosis. However, no clear trigger mechanism has been found.

Clinical features

There are two peaks in presentation. In the peri- and postmenopausal group, patients may be asymptomatic, or present with fatigue and abnormalities in liver biochemistry or the presence of chronic liver disease on examination. In the teens and early twenties, the disease (often type II) presents as an acute hepatitis with jaundice and very high aminotransferases, which do not improve with time. This age group often has clinical features of cirrhosis and patients who are ill may also have features of an autoimmune disease, such as fever, migratory polyarthritides, glomerulonephritis, pleurisy, pulmonary infiltration or lung fibrosis.

There are rare overlap syndromes with primary biliary cholangitis and primary sclerosing cholangitis, existing concomitantly or developing consecutively.

**Box 34.12 Transfer criteria to specialized units for patients with acute liver injury**

- INR >3.0
- Presence of hepatic encephalopathy
- Hypotension after resuscitation with fluid
- Metabolic acidosis
- Prothrombin time (seconds) > interval (hours) from overdose (paracetamol cases)

INR, international normalized ratio.

**Box 34.13 Poor prognostic variables in acute hepatic failure indicating liver transplantation**

**Non-paracetamol (acetaminophen) causes**

Three of the following five:

- Drug or A–E hepatitis
- Age <10 and >40 years
- Interval from onset of jaundice to encephalopathy >7 days
- Serum bilirubin >300 μmol/L
- Prothrombin time >50 sec (or >100 sec in isolation)

**Paracetamol overdose**

- Arterial pH <7.3 (after resuscitation, 7.25 on acetylcysteine)
- Serum creatinine >300 μmol/L and
- Prothrombin time >100 sec and
- Grade III–IV encephalopathy
treatment is started (see p. 1204). Other agents that have been used in resistant cases include budesonide (in non-cirrhotic patients), mycophenolate, ciclosporin and tacrolimus.

**Prognosis**

Steroid and azathioprine therapy induce remission in over 80%; indeed, this response forms part of the diagnostic criteria. Treatment is life-long in most, although withdrawal may be considered after 2–3 years of biochemical remission. Those with initial cirrhosis are more likely to relapse following withdrawal and require indefinite therapy. Liver transplantation is performed if treatment fails, although the disease may recur. HCC occurs less frequently than with viral-induced cirrhosis. The risk of malignancy associated with chronic low-dose azathioprine therapy has been reported to be 1.4 times normal.

**Further reading**

**DRUG-INDUCED CHRONIC HEPATITIS**

Several drugs can cause a chronic hepatitis similar to autoimmune hepatitis (see Box 34.25). Patients are often female, present with jaundice and hepatomegaly, and have raised serum aminotransferases and globulin levels. Improvement follows drug withdrawal but exacerbations can occur with re-introduction. Isoniazid, amiodarone and methotrexate can cause chronic histological changes. With rare exceptions, patients with pre-existing chronic liver disease are not more susceptible to drug injury.

**CHRONIC HEPATITIS OF UNKNOWN CAUSE**

As increasing numbers undergo routine blood tests, mild elevations in serum aminotransferases and γ-GT are commonly found. Many will have no symptoms or signs of liver disease. All known aetiological agents should be excluded, risk factors for NAFLD evaluated, and tests carried out to exclude liver diseases. Liver biopsy should be performed if the elevation in aminotransferases (&gt;100 IU/L) persists for over a year but often only non-specific changes are found.

**NON-ALCOHOLIC FATTY LIVER DISEASE**

Non-alcoholic fatty liver disease (NAFLD) is now the most common cause of chronic liver disease in many developed countries. It is often detected on routine abdominal ultrasound examination, and steatosis is found in up to one-third of these patients. NAFLD is a spectrum of liver diseases comprised of non-alcoholic fatty liver (NAFL) and non-alcoholic steatohepatitis (NASH). Whereas NAFL has negligible risk of progression, 10–30% of NASH patients may develop cirrhosis or HCC. NAFL and NASH have traditionally been considered as two separate clinical entities, rather than two points on a disease continuum. However, studies that have evaluated sequential liver biopsies are challenging this notion and have found that both patients with NAFL and those with NASH have the potential to develop progressive liver disease, suggesting that
Liver disease

NAFL, NASH and fibrosis progression are a continuum rather than separate diagnoses. Indeed, one large study showed no difference in liver-related adverse events between definite NASH and severe steatosis. However, patients with advanced fibrosis at presentation were much more likely to progress than those without, and these patients therefore require follow-up. In this cohort, complications of cirrhosis were the third most common cause of death, following cardiovascular events and non-hepatic malignancies.

Risk factors for NAFLD are obesity, hypertension, type 2 diabetes and hyperlipidaemia, such that NAFLD is considered to be the liver component of the metabolic syndrome (see p. 1250). Most patients are asymptomatic, although hepatomegaly may be present. Mild increases in serum aminotransferases and/or γ-GT (with ALT greater than AST) are frequently the sole liver biochemical abnormality. Despite the high prevalence of NAFLD, well-defined screening recommendations are currently lacking.

Pathogenesis

Histological changes follow a spectrum similar to that of alcohol-induced hepatic injury, and range from simple fatty change to fat and inflammation (NASH), fibrosis and cirrhosis.

Oxidative stress injury and other factors lead to lipid peroxidation in the presence of fatty infiltration and inflammation. Fibrosis may then occur, enhanced by insulin resistance, which induces connective tissue growth factor.

Investigations

- Ultrasound demonstration of steatosis in the absence of other injurious causes, such as alcohol, usually provides the diagnosis.
- Liver biopsy allows staging of the disease. Although no definitive guidelines exist, many clinicians perform a biopsy if a diagnosis of NASH or advanced fibrosis is considered likely.
- Elastography (see p. 1270) is used to evaluate the degree of fibrosis but may not be technically possible in the morbidly obese.

Management

- All NAFLD patients require lifestyle advice aimed at weight loss, increased physical activity and attention to cardiovascular risk factors. Calorie restriction is recommended, aimed at losing 0.5–1 kg per week until target weight is achieved. A reduction of more than 7–9% in body weight has been associated with reduced steatosis, hepatocellular injury and hepatic inflammation. However, less than 15% of patients will achieve significant long-term weight loss.
- Orlistat, an enteric lipase inhibitor causing malabsorption of dietary fat, is used with a low-fat diet as an adjunct in subjects with a body mass index (BMI) of more than 30 kg/m². The effects are modest and only those achieving a greater than 5% loss of body weight in 3 months should continue orlistat, and then for only 1 year, as fat-soluble vitamin deficiency may occur.
- Pioglitazone or vitamin E may be used for those with biopsy-proven NASH, when lifestyle intervention has failed. Meta-analysis data demonstrated that pioglitazone significantly improved liver steatosis, inflammation and, to a lesser degree, fibrosis. However, it is associated with weight gain and reports of congestive cardiac failure, bladder cancer and reduced bone density. Conversely, pioglitazone reduces death, myocardial infarction and stroke in diabetes patients. The risks and benefits to each patient should be evaluated accordingly and pioglitazone is infrequently used in clinical practice.
- Vitamin E (800 IU/day) is an antioxidant that improves steatohepatitis. A meta-analysis showed an increase in all-cause mortality at doses over 400 IU/day, and an increased risk of haemorrhagic stroke and prostate cancer has also been reported. Again, this is not frequently used.
- Weight loss following bariatric surgery leads to reduced steatosis, steatohepatitis and fibrosis. The optimum technique is unknown and long-term data are lacking, although initial concerns about worsening fibrosis have not been borne out. Bariatric surgery should be avoided in those with advanced cirrhosis and portal hypertension, but gastric bypass and sleeve gastrectomy (p. 1250) have been shown to achieve weight loss and improve obesity-related co-morbidities in Child–Pugh A cirrhotic patients.

Hepatocellular carcinoma

The yearly cumulative incidence of HCC is 2.6% in patients with NASH cirrhosis and ultrasound surveillance should therefore be performed 6-monthly. Hyperinsulinaemia and obesity are risk factors for many malignancies and HCC can occur in NAFL/NASH patients in the absence of cirrhosis.

Liver transplantation

NASH cirrhosis is the most rapidly growing indication for transplantation in the US, the leading cause in women and the second leading cause overall. Survival is comparable to that in other indications, and although recurrence occurs post transplant (4–25%), it does not appear to have an impact on graft survival. Patients frequently have multiple cardiovascular risk factors that must be managed aggressively. UK guidelines suggest that bariatric surgery could be considered at transplantation for the morbidly obese.

New treatments for NASH

There has been substantial industry investment in pharmacotherapies for NASH, with the pipeline currently crowded at mid-stage. However, there are several phase III studies that are due to complete in the early 2020s and all of these agents showed potential clinical benefit in phase II trials. They include elafibranor, a dual peroxisome proliferator-activated receptor (PPAR)γ/δ agonist; obeticholic acid, the FXR agonist; cenicriviroc, a dual antagonist of C-C chemokine receptor types 2 and 5; selonsertib, an apoptosis signal-regulating kinase 1 inhibitor; and tiraglateotide, a glucagon-like peptide. It is highly likely that the landscape of treatments for NASH will change substantially by 2025.

However, it is imperative to tackle obesity at source: for example, through public health campaigns, taxation of high-sugar food, reduction in processed food within the diet, education, increased activity and vegetable consumption. Prevention of obesity, especially in children and adolescents, will most likely be far superior to the effects of these drugs.

CIRRHOSIS

In cirrhosis, the liver architecture is diffusely abnormal and interferes with liver blood flow and function; this leads to the clinical manifestations of portal hypertension and liver failure.
Liver injury causes necrosis and apoptosis, releasing cytokines and inflammatory mediators. These activate stellate cells to myofibroblasts and platelet-derived growth factor-β (TGF-β); this leads to transdifferentiation of stellate cells to myofibroblasts and production of tissue inhibitors of metalloproteinases (MMPs), but this is inhibited by concurrent myofibroblast factor (PDGF), which stimulates myofibroblast proliferation. Macrophages phagocytose necrotic and apoptotic cell contents and reactive oxygen species (ROS). This activates hepatic stellate cells and tissue macrophages through the CC-chemokine ligand 2–CC-chemokine receptor 2 (CCL2–CCR2) axis (see p. 1264). These cells phagocytose necrotic and apoptotic cells and secrete pro-inflammatory mediators, including transforming growth factor-beta (TGF-β); this leads to transdifferentiation of stellate cells to myofibroblasts and platelet-derived growth factor (PDGF), which stimulates myofibroblast proliferation. Macrophages degrade scar matrix by secretion of matrix metalloproteinases (MMPs), but this is inhibited by concurrent myofibroblast and macrophage production of tissue inhibitors of metalloproteinases (TIMPs). This results in progressive matrix deposition and scar accumulation. Increased gut permeability and hepatic lipopolysaccharide–Toll-like receptor 4 (LPS–TLR4) signalling also promotes fibrogenesis. Repetitive or chronic injury and inflammation perpetuate this process.

If the cause of fibrosis is eliminated (e.g. through treatment of viral hepatitis), resolution (complete reversal to near-normal liver architecture) of early fibrosis can occur. In cirrhosis, regression (improvement, not reversal) occurs, which improves clinical outcomes. Antifibrotic therapies are emerging (including stem cell transplant strategies) but currently liver transplantation is the only available treatment for liver failure.

**Pathology**

The characteristic features of cirrhosis are regenerating nodules separated by fibrous septa, and loss of lobular architecture within the nodules (Fig. 34.22A–C). Two types are described:

- **Micronodular cirrhosis.** Regenerating nodules are usually <3mm in size with uniform involvement of the liver; often caused by alcohol or biliary tract disease.
- ** Macronodular cirrhosis.** The nodules are of variable size and normal acini may be seen within larger nodules; often caused by chronic viral hepatitis.

A mixed picture with small and large nodules occurs occasionally. Symptoms and signs are described on page 1263.

**Investigations**

Investigations aim to assess the severity and type of liver disease.

**Severity**

- **Liver function.** Serum albumin and PT are the best indicators of liver function; the outlook is poor if the albumin level is <28/L. The degree to which the PT is prolonged is commensurate with disease severity.
- **Liver biochemistry.** This may be normal, depending on the severity of disease. In most cases, there is a slight elevation in the serum ALP and serum aminotransferases. In decompensated cirrhosis, all biochemistry is deranged.
- **Serum electrolytes.** A low sodium indicates severe liver disease due to a defect in free water clearance or excess diuretic therapy.
- **Serum creatinine.** An elevated concentration of >130 μmol/L is a marker of poor prognosis.
- **Biomarkers.** In the Enhanced Liver Fibrosis (ELF) test, which assesses fibrosis, a value of <7.7 indicates none to mild, 7.7–9.8 moderate and ≥9.8 severe disease. In addition, a serum α-fetoprotein of >200ng/mL is strongly suggestive of HCC.

**Type**

This can be determined by:

- viral markers
- serum autoantibodies
- serum immunoglobulins
- iron indices and ferritin
- copper and caeruloplasmin (see p. 1301)
- α1-antitrypsin (see p. 1302).
- genetic markers.

Serum copper and serum α1-antitrypsin should always be measured in young cirrhotics. Total iron-binding capacity (TIBC) and ferritin should be measured to exclude hereditary haemochromatosis; genetic markers are also available (see p. 1300).

**Imaging**

- **Ultrasound examination** can demonstrate changes in the size and shape of the liver. Fatty change and fibrosis produce a diffusely increased echogenicity. In established cirrhosis, there may be marginal nodularity of the liver surface and distortion.
Liver disease of the arterial vascular architecture. The patency of the portal and hepatic veins can be evaluated. Ultrasound is useful for detecting HCC.

- **Transient elastography** is increasingly used to avoid liver biopsy (see p. 1270). Technical limitations preclude its use in patients with ascites or morbid obesity but it is suitable for most. If the reading is high (>25), portal hypertension is likely, and some experts recommend that endoscopy to identify varices should be restricted to patients with high fibroscan scores.

- **CT scanning** (see p. 1270) is also helpful. Fig. 34.22D–E shows hepatosplenomegaly and the dilated collaterals seen in chronic liver disease. Arterial phase contrast-enhanced scans are useful for detecting HCC.

- **Endoscopy** is performed for the detection and treatment of varices and portal hypertensive gastropathy. If identified, varices can be treated by banding or injection sclerotherapy. Colonoscopy is occasionally carried out for colopathy.

- **MRI scanning** is useful in the diagnosis of both malignant and benign tumours such as haemangiomas. MR angiography can demonstrate the vascular anatomy, and MR cholangiography the biliary tree.

**Liver biopsy**

This remains the ‘gold standard’ for confirming the type and severity of liver disease. Adequate samples, in terms of length and number of complete portal tracts, are necessary for diagnosis and staging/grading of chronic viral hepatitis; in macronodular cirrhosis, the core of liver may fragment, causing sampling errors. Immunocytochemical stains can identify viruses, bile ducts, angiogenic structures and oncogenic markers. Chemical measurement of iron and copper is necessary to confirm a diagnosis of iron overload or Wilson’s disease. Digital image analysis of picosirius red staining can be used to quantitate collagen in biopsy specimens (see Fig. 34.22C).

**Management**

Management is that of the complications of decompensated cirrhosis. Patients should undergo 6-monthly ultrasound to screen for the early development of HCC (see p. 1308), as all therapeutic strategies work best with small, single tumours.

Treatment of the underlying cause may arrest or reverse cirrhosis. Patients with compensated cirrhosis should lead a normal life. Those at risk should receive hepatitis A and B vaccination. The only dietary restriction is reduction of salt intake (≤2 g sodium per day). Alcohol should be avoided, as should aspirin and non-steroidal anti-inflammatory drugs (NSAIDs), which may precipitate gastrointestinal bleeding or renal impairment.

**Prognosis**

Prognosis is extremely variable. In general, the 5-year survival rate is approximately 50%, depending on the stage at which diagnosis is made. Poor prognostic indicators are shown in Box 34.15. Development of any complication usually worsens the prognosis.

There are a number of prognostic classifications based on modifications of Child’s grading (A, B and C; Box 34.16) and the Model for End-stage Liver Disease (MELD; Box 34.17); these focus on serum bilirubin, creatinine and the INR, which is widely used as a predictor of mortality in patients awaiting liver transplantation. Modifications of the MELD score (e.g. UKELD) are used in some countries.

**Acute-on-chronic liver failure**

Acute-on-chronic liver failure (ACLF) refers to the condition of patients hospitalized for an acute complication of cirrhosis...
accompanied by organ failure(s); it has a high short-term mortality. ACLF is believed to be distinct from traditional decompensated cirrhosis, based not only on the presence of organ failure(s) and high mortality rate, but also on younger age, alcohol aetiology, higher prevalence of certain precipitating events (e.g., bacterial infections or active alcohol excess), and a higher level of systemic inflammation. It is estimated to occur in 31% of patients hospitalized with an acute complication of cirrhosis.

Liver assist devices

As the liver has great potential to regenerate, extracorporeal liver support devices may allow patients with liver failure to be bridged to recovery or even liver transplantation. Current approaches include the use of biological devices that contain hepatocytes and those that function as detoxification devices, and artificial liver support systems. However, no device is currently available routinely.

Gut–liver axis

The liver is exposed to gut-derived bacterial components that have little consequence in health, as an effective gut barrier limits the amount of bacterial components transported to the liver. In advanced liver disease the intestinal barrier function is compromised due to changes in gut motility, an increase in intestinal permeability, and suppression of gut immunological functions. This leads to bacteria and bacterial components (e.g., lipopolysaccharide) entering the portal circulation and being transported to the liver, activating Toll-like receptors and producing an inflammatory response. This cross-talk between the intestinal microbiota and the liver is referred to as the gut-liver axis; it is seen as a key pathophysiological mechanism in the progression of liver disease and development of the complications of cirrhosis. Antibiotics and non-selective beta-blockers intercept the gut-liver axis by blocking bacterial translocation, which is likely to account for their beneficial effects in reducing portal pressure, variceal haemorrhage and spontaneous bacterial peritonitis. However, absorbable antibiotics will lead to the selection of resistant bacteria. Rifaximin, a poorly absorbed antibiotic used for encaphalopathy, specifically affects the gut flora and has a low risk for inducing resistance; it may therefore have a role in this indication.

Liver transplantation

This is the only established treatment for advanced liver disease. Shortage of donors is a major problem in all developed countries and in some, such as Japan or South Korea, living related donors form the majority.

Indications

These include:

- **Acute liver disease**: acute hepatic failure of any cause (see p. 1286)
- **Chronic liver disease**: usually for complications of cirrhosis that are no longer responsive to therapy.

The timing of transplantation depends on donor availability. All patients with end-stage cirrhosis (Child’s grade C; MELD score ≥20; UKELD score ≥49) and those with debilitating symptoms should be referred to a transplant centre. In addition, specific extrahepatic complications of cirrhosis, even with preserved liver function, such as hepatopulmonary syndrome and porto-pulmonary hypertension, can be reversed by transplantation.

- **Primary biliary cholangitis**. Patients should be transplanted when their serum bilirubin is persistently >100μmol/L or when they have symptoms such as intractable pruritus.
- **Chronic hepatitis B if HBV DNA-negative** or levels are falling with effective therapy. Following transplantation, recurrence of hepatitis is prevented by hepatitis B immunoglobulin and nucleoside analogues in combination.
- **Chronic hepatitis C**. Following the introduction of the directly acting antiviral drugs, rates of transplantation for HCV have fallen substantially; for example, a reduction from 10.5% in 2013 to 4.7% in 2016 was seen in the UK.
Liver disease

- **Autoimmune hepatitis.** In patients who have failed to respond to medical treatment, the disease can recur.

- **Alcoholic liver disease.** Well-motivated patients who have stopped drinking without improvement of liver disease are offered a transplant, with frequent counselling. It has been shown that transplantation may represent life-saving treatment in patients with severe alcoholic hepatitis who are not responding to medical therapy. However, further studies are awaited. Early liver transplantation is an emerging therapy for acute severe alcoholic hepatitis, and multiple small studies have demonstrated that ‘highly selected’ patients have comparable 1- and 3-year survival to those with chronic liver disease following transplantation. However, not all caregivers agree that the usual expectation of demonstrated alcohol abstinence prior to transplantation should be waived and further data are needed.

- **Primary metabolic disorders.** Examples are Wilson’s disease, hereditary haemochromatosis and α1-antitrypsin deficiency.

- **NASH cirrhosis.** In view of the increasing rates of obesity, this is highly likely to become the most frequent indication for transplantation.

- **Other conditions,** such as primary sclerosing cholangitis, polycystic liver disease and metabolic diseases such as primary oxaluria.

### Contraindications

Absolute contraindications include active sepsis outside the hepatobiliary tree, malignancy outside the liver, liver metastases (except neuroendocrine) and a lack of psychological commitment on the part of the patient.

Relative contraindications are mainly anatomical considerations that make surgery more difficult, such as extensive splanchic venous thrombosis. With exceptions, patients aged 70 years or over are not usually given a transplant. In HCC the recurrence rate is high, unless there are fewer than three small (<3 cm) lesions or a solitary nodule of less than 5 cm (Milan criteria).

### Preparation for surgery

Pre-transplant work-up includes confirmation of the diagnosis, ultrasound and cross-sectional imaging, and radiological demonstration of the hepatic arterial and biliary trees, as well as assessment of cardiorespiratory and renal status. In view of the ethical and financial implications of transplantation, regular psychosocial and possibly psychiatric support is vital.

The donor should be ABO-compatible (HLA matching is not necessary) and have no evidence of active sepsis, malignancy, or HIV, HBV or HCV infection. Younger donors (<50 years) experience better graft function. The donor liver is cooled and stored on ice; its preservation time may be up to 20 hours. The recipient operation takes approximately 8 hours and rarely requires a large blood transfusion. Cadaveric donor livers (from heart-beating or non-heart-beating donors) may consist of whole graft, split grafts (for two recipients) or reduced grafts. Live donors may be healthy individuals or patients with, for example, familial amyloid polyneuropathy, whose livers can be transplanted into others (domino transplant). The mortality of right lobe donors is between 1 in 200 and 1 in 400. Recent advances in devices for storing donated liver prior to transplantation may allow livers to be used that were previously considered unsuitable.

The operative mortality is very low and most postoperative deaths occur in the first 3 months. Sepsis and haemorrhage can be serious complications. Opportunistic infections occur owing to immunosuppression. Various immunosuppressive agents have been used: tacrolimus – alone or in combination with azathioprine or mycophenolate mofetil – steroids, sirolimus and micro-emulsified ciclosporin are the most common.

### Rejection

- **Acute or cellular rejection** usually occurs 5–10 days post-transplant; it can be asymptomatic or there may be a fever. On biopsy, a pleomorphic portal infiltrate is seen with prominent eosinophils, bile duct damage and endothelialitis of the blood vessels. This responds well to immunosuppressive therapy.

- **Chronic ductopenic rejection** is seen between 6 weeks and 9 months post transplant, with disappearing bile ducts (vanishing bile duct syndrome, VBDS), and an arteriopathy with narrowing and occlusion of the arteries. Early ductopenic rejection is rarely reversed by immunosuppression and often requires retransplantation.

- **Graft-versus-host disease** is extremely rare.

### Prognosis

Elective liver transplantation in low-risk patients has a 90% 1-year survival and a 70–85% 5-year survival. Patients require life-long immunosuppression, although doses can be reduced over time without significant problems. Future strategies to reduce immunosuppression requirements after transplant may include infusion of autologous regulatory T cells. HCV cirrhosis, primary sclerosing cholangitis and HCC are conditions in which long-term survival after transplantation is compromised by disease recurrence.

### Complications and effects of cirrhosis

These are shown in Box 34.18.

### Portal hypertension

The portal vein is formed by the union of the superior mesenteric and splenic veins. Normal pressure is 5–8 mmHg with only a small gradient across the liver to the hepatic vein, in which blood is returned to the heart via the inferior vena cava. Portal hypertension is classified according to the site of obstruction:

- **pre-hepatic** – blockage of the portal vein before the liver
- **intrahepatic** – distortion of the liver architecture, either pre-sinusoidal (e.g. schistosomiasis) or post-sinusoidal (e.g. cirrhosis)
- **post-hepatic** – venous blockage outside the liver (rare).

As portal pressure rises above 10–12 mmHg, the compliant venous system dilates and collaterals form within the systemic venous system. The main sites of collaterals are the gastro-oesophageal junction, rectum, left renal vein, diaphragm, retroperitoneum and the anterior abdominal wall via the umbilical vein.

The collaterals at the gastro-oesophageal junction (varices) are superficial and tend to rupture. Portosystemic anastomoses at other sites rarely cause symptoms. Rectal varices are frequently found (30%) if looked for and can be differentiated from haemorrhoids, which are lower in the anal canal. The microvasculature of the gut becomes congested, giving rise to portal hypertensive gastropathy and colopathy, in which there is punctate erythema and erosions, which can bleed.

Pathophysiology

Following liver injury and fibrogenesis, the contraction of activated myofibroblasts (mediated by endothelin, nitric oxide and prostaglandins) contributes to increased resistance to blood flow. This increased resistance leads to portal hypertension and opening of portosystemic anastomoses in both pre-cirrhotic and cirrhotic livers. Neo-angiogenesis also occurs. The hyperdynamic circulation of cirrhosis (caused by nitric oxide, cannabinoids and glucagon) leads to peripheral and splanchnic vasodilation. This, combined with plasma volume expansion due to sodium retention (see p. 1295), has a significant effect on maintaining portal hypertension.

Aetiology

The most common cause is cirrhosis (Box 34.19). Others are described here.

Pre-hepatic causes

Extrahepatic blockage due to portal vein thrombosis can be caused by congenital portal venous abnormalities, neonatal sepsis of the umbilical vein or inherited prothrombotic conditions, such as factor V Leiden or primary myeloproliferative disorders with or without JAK2 mutations (see p. 394).

Patients present with gastrointestinal bleeding, often at a young age. They have normal liver function and prognosis following bleeding is therefore excellent.

The portal vein blockage can be identified by ultrasound with Doppler imaging; CT and MR angiography are also used.

Treatment for variceal bleeding is usually repeated endoscopic therapy or non-selective beta-blockade. Splanctectomy is performed only if there is isolated splenic vein thrombosis. Anticoagulation prevents further thrombosis and intestinal infarction, and does not increase the risk of bleeding.

Intrahepatic causes

Cirrhosis is by far the most common cause but others include:

- **Non-cirrhotic portal hypertension** is characterized by mild portal tract fibrosis on liver histology. The aetiology is unknown but arsenic, vinyl chloride, anti-retroviral therapy and other toxins have been implicated. A similar disease is frequently found in India. The liver lesion does not progress and prognosis is good.

- **Schistosomiasis** with extensive pipe-stem fibrosis occurs in endemic areas such as Egypt and Brazil. Often there is concomitant liver disease, such as HCV infection, which was transmitted by non-sterile equipment.

- **Other causes** include congenital hepatic fibrosis, and nodular regenerative hyperplasia and partial nodular transformation.

Post-hepatic causes

Prolonged severe heart failure with tricuspid incompetence or constrictive pericarditis can cause portal hypertension. The Budd–Chiari syndrome is described on page 1304.

Clinical features

Patients are often asymptomatic, the only clinical evidence being splenomegaly, although features of chronic liver disease may exist (see p. 1263).

Variceal haemorrhage

Approximately 90% of patients with cirrhosis will develop gastroesophageal varices over 10 years but only one-third of these will bleed. Bleeding is likely to occur with large varices, or in those with red signs at endoscopy, and in severe liver disease.

Management

Management can be divided into:

- the active bleeding episode
- prevention of rebleeding
- prophylactic measures to prevent the first haemorrhage.

Despite the therapeutic techniques available, prognosis ultimately depends on the severity of the underlying liver disease; overall 6-week mortality from variceal haemorrhage is 15–25%, reaching 50% in Child's grade C.

Initial management of acute variceal bleeding

See Fig. 34.23, and also the general management of gastrointestinal haemorrhage on page 1181.

Resuscitation

- **Assess** the patient: pulse, blood pressure and conscious state.
- **Insert a large-bore intravenous line** and obtain **blood** for group and crossmatching, haemoglobin, PT/INR, serum creatinine and electrolytes, liver biochemistry and blood cultures.
- **Restore blood volume** with plasma expanders or, if possible, blood transfusion. See the treatment of shock for more detail (p. 221). Prompt correction, but not over-correction, of hypovolaemia is necessary in cirrhosis patients, as their baroreceptor reflexes are diminished. A target haemoglobin of 80g/L is sufficient and this lessens the likelihood of early rebleeding.
- **Perform an ascitic tap**.
- **Monitor for alcohol withdrawal and treat with lorazepam or oxazepam** (the half-life of chlordiazepoxide will increase in advanced liver disease, amplifying the risk of adverse events). Give intravenous thiamine.
- **Start prophylactic antibiotics. These treat and prevent infection, and reduce early rebleeding and mortality.**

Urgent endoscopy

Endoscopy (Fig. 34.24) should be performed to confirm the diagnosis and to exclude bleeding from other sites (e.g. gastric ulceration) and portal hypertensive gastropathy/gastric antral vascular ectasia (GAVE). The latter describes chronic gastric congestion, punctate erythema and gastric erosions, which may contribute to
chronic anaemia. Portal hypertensive gastropathy and GAVE are distinct entities; management of portal hypertensive gastropathy is centred on reduction in portal pressures with beta-blockers, whereas treatment of GAVE is endoscopic and uses various ablative techniques.

Variceal banding or injection sclerotherapy

Banding of oesophageal varices is performed by mounting a band on the tip of the endoscope, sucking the varix into the end of the scope, and dislodging the band over the varix using a trip-wire mechanism.

Between 15% and 20% of bleeding comes from gastric varices, which are associated with a greater mortality (up to 40%); endoscopic injection of cyanoacrylate is the best treatment.

Overall, haemostasis is achieved in 80–90% of patients. Best practice is to perform the endoscopy with the patient under general anaesthetic to provide appropriate airway support, and with critical care support.

Injection sclerotherapy is now rarely performed for oesophageal varices.

Other measures

Vasoconstrictor therapy

This is used to restrict portal inflow by splanchnic arterial constriction and has shown benefit when used in combination with endoscopic techniques.

- **Terlipressin.** This is the only vasoconstrictor proven to reduce mortality. The dose is 2 mg 6-hourly, reducing to 1 mg 4-hourly after 48 hours if a prolonged regimen is required (up to 5 days). Terlipressin should not be given to patients with ischaemic heart disease. The patient may complain of abdominal colic, and may defecate and have facial pallor owing to generalized vasoconstriction. If haemostasis has been achieved at endoscopy, there is probably little added benefit with this therapy, and treatment should be tapered accordingly.

- **Somatostatin.** This has few side-effects. Infusion of 250–500 μg/h reduces bleeding and is reserved for patients with contraindications to terlipressin.

A recent prospective, multicentre study showed that haemostatic effects and safety at day 5 of treatment did not differ significantly between terlipressin, somatostatin and octreotide when utilized as adjuvants to endoscopic treatment.

Balloon tamponade

Balloon tamponade is used if endoscopic therapy has failed or if there is exsanguinating haemorrhage. The usual balloon tube is a four-lumen Sengstaken–Blakemore, which should be left in place for no more than 12 hours and removed in the endoscopy room prior to follow-up endoscopy. The tube is passed into the stomach and the gastric balloon inflated with air and pulled back. It should be positioned in close apposition to the gastro-oesophageal junction to prevent the cephalad variceal blood flow to the bleeding point. The oesophageal balloon should be inflated only if bleeding is not controlled by the gastric balloon alone.

Haemostasis is achieved in up to 90%. However, the balloon may cause serious complications, such as aspiration pneumonia, oesophageal rupture and mucosal ulceration. The procedure is also very unpleasant for the patient.

A self-expanding covered metal stent (Danis), which has a wire loop to enable removal and is introduced orally or endoscopically, can be placed over the varices. This is effective and has the advantages that it does not impair swallowing, cannot be removed by uncooperative patients and allows post-endoscopic investigation. The stent is removed 7 days after insertion. A randomized trial in 28 patients showed that oesophageal stents may have greater efficacy with less adverse events than balloon tamponade in the control of variceal bleed following endoscopic failure.

Additional management of the acute episode

- **Measures to prevent encephalopathy.** Portosystemic encephalopathy (PSE) can be precipitated by a large bleed (blood contains protein). Management is as outlined on page 1297.
"Nursing. Patients require high-dependency/intensive care nursing. They should remain nil by mouth until bleeding has stopped.

Reduction in acid secretion. Ranitidine may be preferable to PPIs, as it lessens the risk of *Clostridium difficile* infection; PPIs are widely used, however. Sucralfate 1g four times daily can reduce oesophageal ulceration following endoscopic therapy.

Management of an acute rebleed
Rebleeding occurs in approximately 15–20% within 5 days. The source should be established by endoscopy and sometimes takes the form of ulceration or slippage of a ligation band. Endoscopy should be performed once only to control rebleeding. If haemostasis cannot be achieved, then transjugular intrahepatic portocaval shunting will be necessary.

Transjugular intrahepatic portocaval shunt
Transjugular intrahepatic portocaval shunt (TIPS) is used when bleeding cannot be controlled either acutely or following a rebleed. Under X-ray guidance, a guidewire is passed from the jugular vein into the liver and the portal vein. After balloon expansion of the tract between the hepatic and portal veins, an expandable, covered metal shunt is placed over the wire to form a channel between the systemic and portal venous systems. It reduces the hepatic sinusoidal and portal vein pressure by creating a total shunt. There is an increased risk of portal systemic encephalopathy. Stent stenosis or thrombosis is far less frequent now that ‘covered’ stents are used, as opposed to the ‘bare metal’ stents employed previously. Collaterals arising from the splenic or portal veins can be selectively embolized.

A recent observational study in 671 patients validated the survival benefit of ‘pre-emptive’ TIPS (within 72 hours of admission) in those with cirrhosis and acute variceal haemorrhage, and at high risk for treatment failure. Most of the benefit was seen in patients with Child-Pugh class C disease. However, widespread implementation of this approach represents a significant challenge for many healthcare systems, and despite strong supporting evidence, most centres have not adopted it at present.

Emergency surgery
This is performed very rarely when other measures fail. Oesophageal transection and ligation of the feeding vessels to the bleeding varices or acute portosystemic shunt surgery is performed.

Prevention of recurrent variceal bleeding (secondary prophylaxis)
The risk of bleeding recurring without prophylaxis is 60–80% over a 2-year period, with an approximate mortality of 20% per episode.

Prophylactic long-term measures
Non-selective beta-blockade
Oral propranolol or carvedilol to reduce the resting pulse rate by 25% decreases portal pressure. Portal inflow is reduced by a decrease in cardiac output (β1) and by blockade of β2 vasodilator receptors on the splanchnic arteries, leaving an unopposed vasoconstrictor effect. Significant reduction of hepatic venous pressure gradient (HVPG, measured by hepatic vein catheterization) is associated with very low rates of rebleeding, particularly if below 12mmHg. Data have emerged demonstrating that additional α1-adrenoergic blockade, causing vasodilation with carvedilol, may increase the number of patients with a reduction in HVPG compared to propranolol.

Endoscopic treatment
Repeated courses of banding at 2-weekly intervals lead to obliteration of varices. This markedly reduces rebleeding, most instances occurring before the varices have been fully obliterated. Between 30% and 40% of varices return per year, so follow-up endoscopy should be performed at 1–3 months after obliteration and then every 6–12 months. Complications of banding include oesophageal ulceration, mediastinitis and, rarely, strictures.

Combination therapy reduces overall bleeding compared to endoscopic therapy alone but with no overall improvement in mortality. A pragmatic approach is therefore to give combination therapy to those who can tolerate beta-blockade, and band ligation alone to those who cannot.

Surgery
• Surgical portosystemic shunting is associated with an extremely low risk of rebleeding and is used if TIPS is not available. Hepatic encephalopathy is a significant complication. The ‘shunts’ are usually an end-to-side portocaval Anastomosis or a selective distal splenorenal shunt (Warren shunt).

• Devascularization procedures, including oesophageal transection, do not produce encephalopathy and can be used when there is splanchnic venous thrombosis.

• Liver transplantation (see p. 1291) is the best option when there is poor liver function.

Prophylactic measures (primary prophylaxis)
Patients with cirrhosis and significant varices that have not bled should be prescribed non-selective beta-blockers. This reduces the chances of upper gastrointestinal bleeding by approximately 50%, may increase survival and is cost-effective. If there are contraindications, variceal banding is an option. Two large-scale trials were due to start in the UK in 2020 and aimed to clarify the best approach for primary prophylaxis. It was anticipated that these studies would complete by 2026.

Ascites
Ascites, fluid within the peritoneal cavity, is a common complication of cirrhosis. Several factors underlie its pathogenesis:

• Sodium and water retention results from peripheral arterial vasodilatation (secondary to nitric oxide, atrial natriuretic peptide and prostaglandins), which causes a reduction in the effective blood volume. This reduction activates the sympathetic nervous system and the renin–angiotensin system, promoting salt and water retention (see Fig. 9.6).

• Portal hypertension exerts a local hydrostatic pressure, leading to increased hepatic and splanchnic production of lymph, and transudation of fluid into the peritoneal cavity.

• Low serum albumin (due to poor liver function) may further contribute by reducing plasma oncotic pressure.

In patients with ascites, urine sodium excretion rarely exceeds 5mmol in 24 hours. Loss of sodium from extrarenal sites accounts for approximately 30mmol in 24 hours. Under these circumstances, a normal daily sodium intake of 120–200mmol results in a positive sodium balance of approximately 90–170mmol in 24 hours (equivalent to 600–1300mL of fluid retained).

Clinical features
Abdominal swelling may develop over days or several weeks. Precipitating factors include continued excessive alcohol consumption, infection/sepsis, development of an HCC or splanchnic vein thrombosis. Mild abdominal pain and discomfort are common but, if more
Liver disease

severe, should raise the suspicion of SBP (see later). Respiratory distress and difficulty eating accompany tense ascites.

The presence of fluid is confirmed clinically by demonstrating shifting dullness. Many patients also have peripheral oedema. A pleural effusion (usually right-sided) may infrequently be found and arises from the passage of ascites through congenital diaphragmatic defects.

Investigations

A diagnostic aspiration of 10–20 mL of fluid should be obtained for:

- **Cell count.** A neutrophil count >250 cells/mm³ is indicative of an underlying (usually spontaneous) bacterial peritonitis.
- **Gram stain and culture.**
- **Protein measurement.** A high serum–ascites albumin gradient of >11 g/L suggests portal hypertension, while a low gradient of <11 g/L is associated with non-liver disease-related abnormalities of the peritoneum, such as neoplasia (Box 34.20).
- **Cytology.** A search should be made for malignant cells.
- **Amylase.** Pancreatic ascites should be excluded.

The differential diagnosis of ascites is listed in Box 34.21.

Management

The aim is both to reduce sodium intake and to increase renal sodium excretion, producing a net reabsorption of fluid from the ascites into the circulating volume. The maximum rate at which ascites can be mobilized is 500–700 mL in 24 hours (see later).

- **Serum electrolytes, creatinine and estimated glomerular filtration rate (eGFR).** Check on alternate days; weigh the patient and measure urinary output daily.
- **Bed rest.** This will cause a diuresis by improving renal perfusion but is rarely helpful.
- **Dietary sodium restriction.** It is possible to reduce sodium intake to 40 mmol in 24 hours and still maintain an adequate protein and calorie intake with a palatable diet.
- **Drugs.** Many contain significant amounts of sodium (up to 50 mmol daily). Examples include antacids and antibiotics (particularly penicillins and cephalosporins). Sodium-retaining drugs (NSAIDs, corticosteroids) should be avoided.
- **Fluid restriction.** This is unnecessary unless the serum sodium is <128 mmol/L (see later).
- **Diuretics.** The diuretic of choice is the aldosterone antagonist spironolactone, starting at 100 mg daily. Chronic administration produces gynaecomastia. Eplerenone 25 mg once daily does not cause gynaecomastia.

The aim of diuretic therapy should be to produce a net loss of fluid approaching 700 mL in 24 hours (0.7 kg weight loss, or 1.0 kg if peripheral oedema is present). Although 60% of patients respond on this regimen, the spironolactone can be increased gradually to 400 mg daily if necessary, providing there is no hyperkalaemia. Urinary sodium may be used to titrate the dose. A loop diuretic, such as furosemide 20–40 mg or bumetanide 0.5 mg or 1 mg daily, is added if response is poor. These loop diuretics have several potential disadvantages, including hyponatraemia, hypokalaemia and volume depletion.

Diuretics should be temporarily discontinued if a rise in serum creatinine occurs, representing over-diuresis and hypovolaemia, or if there is hyperkalaemia or worsening encephalopathy. Hyponatraemia almost always represents haemodilution secondary to a failure to clear free water (usually a marker of reduced renal perfusion), and diuretics should be stopped if the sodium falls below 128 mmol/L. Vaptans (see p. 180), vasopressin V₂-receptor antagonists that increase free water clearance, have a small beneficial effect on hyponatraemia and ascites but do not affect mortality, complications of cirrhosis or renal failure; routine use in cirrhosis cannot be recommended.

Paracentesis

This is used when symptomatic tense ascites needs to be relieved or diuretic therapy is insufficient to control accumulation of fluid. The main complications are hypovolaemia and renal dysfunction (post-paracentesis circulatory dysfunction), predominantly due to an accentuation of the arteriolar vasodilatation already present in these patients; this is more likely when more than 5 L are removed and with worse liver function. In patients with normal renal function and without hyponatraemia, this is overcome by infusing albumin (8 g/L of ascitic fluid removed). In practice, up to 20 L can be removed over 4–6 hours, with albumin infusion.

Shunts

A TIPS may be inserted to treat resistant ascites, providing there is no spontaneous portosystemic encephalopathy and there is minimal disturbance of renal function. Frequency of paracentesis and diuretic use is reduced and nutrition is enhanced. Survival may also improve.

A peritoneo-bladder conduit, by means of an implantable, rechargeable, battery-powered pump, has been developed for use in patients with advanced cirrhosis and resistant ascites (Alfapump). This removes ascites from the peritoneal cavity into the urinary bladder, to be eliminated through urination. Early studies have shown a reduction in the need for large-volume paracentesis but several complications, including pain and infection, occur.

**Straw-coloured**

- Malignancy (most common cause)
- Cirrhosis
- Infective:
  - Tuberculosis
  - Following intra-abdominal perforation – any bacterium may be found (e.g. Escherichia coli)
  - Spontaneous in cirrhosis
- Hepatic vein obstruction (Budd–Chiari syndrome) – protein level high in fluid
- Chronic pancreatitis
- Congestive cardiac failure
- Constrictive pericarditis

**Chylous**

- Obstruction of main lymphatic duct (e.g. by carcinoma) – chylomicrons are present
- Cirrhosis

**Haemorrhagic**

- Malignancy
- Ruptured ectopic pregnancy
- Abdominal trauma
- Acute pancreatitis

In patients requiring end-of-life care, insertion of a long-term abdominal drain (LTADs) may allow ascites management outside of a hospital setting. Although not formally evaluated in cirrhosis, they have been used successfully in patients whose ascites is due to malignancy.

**Spontaneous bacterial peritonitis**

Spontaneous bacterial peritonitis (SBP) represents a serious complication that is an indication for referral for transplant assessment; it occurs in up to 18% of patients with ascites who have undergone decompensation. The infecting organisms gain access to the peritoneum by haematogenous spread; most are *Escherichia coli*, *Klebsiella* or enterococci. The condition should be suspected in any patient with ascites who deteriorates, as pain and pyrexia are frequently absent. Diagnostic aspiration should always be performed. A raised neutrophil count in ascites is sufficient evidence alone to start immediate treatment. A broad-spectrum antibiotic is used, with subsequent alteration according to culture results in combination with infusions of human albumin solution. Evidence has emerged that non-selective beta-blockers should be stopped following diagnosis of SBP, as prescription increases the risk of renal impairment. Mortality is 10–15%. Recurrence is common (70% within a year) and secondary prevention – for example, with norfloxacin 400mg daily – prolongs survival. Primary prophylaxis of SBP in patients with ascites protein below 10g/L or severe liver disease may prevent hepatorenal syndrome and improve survival.

**Portosystemic encephalopathy**

Portosystemic encephalopathy (PSE) is a chronic neuropsychiatric syndrome that is secondary to cirrhosis. Acute encephalopathy can occur in acute hepatic failure (see p. 1285). PSE can arise in portal hypertensive patients due to spontaneous ‘shunting’, or in those with surgical or TIPS shunts.

**Pathogenesis**

In cirrhosis, the portal blood bypasses the liver via collaterals, and ‘toxic’ metabolites pass directly to the brain to produce encephalopathy. Ammonia-induced alteration of brain neurotransmitter balance, especially at the astrocyte–neurone interface, is considered to be the leading pathophysiological mechanism. Ammonia is produced by the breakdown of protein by intestinal bacteria. Other implicated substances are free fatty acids and mercaptans; accumulation of false neurotransmitters (octopamine) or activation of the γ-aminobutyric acid (GABA) inhibitory neurotransmitter system may also be responsible. Increased blood levels of aromatic amino acids (tyrosine and phenylalanine) and reduced branched-chain amino acids (valine, leucine and isoleucine) also occur. The factors precipitating PSE are shown in Box 34.22.

**Clinical features**

An acute onset often has a precipitating factor (Box 34.22). The patient becomes increasingly drowsy and comatose.

Chronically, there is a disorder of personality, mood and intellect, with a reversal of normal sleep rhythm. These changes may fluctuate and a collateral history should be obtained. The patient is irritable, confused and disorientated, and has slow, slurred speech. General features include nausea, vomiting and weakness. There is hyper-reflexia and increased tone. Coma occurs as the encephalopathy becomes more marked. Convulsions are very rare, and if they do occur, other causes must be considered.

Signs include:

- fetor hepaticus (a sweet smell to the breath)
- a coarse flapping tremor seen when the hands are outstretched and wrists hyperextended (asterixis)
- constructional apraxia, with the patient being unable to write or draw a five-pointed star, for example
- decreased mental function, which can be assessed by using the serial sevens test or a trail-making (or connection) test.

**Investigations**

*Diagnosis* is clinical.

**Additional investigations**

- *EEG* shows a decrease in the frequency of the normal α-waves (8–13Hz) to 1.5–3Hz. These changes occur before coma supervenes.
- *Visual evoked responses* (see p. 830) also detect subclinical encephalopathy.
- *Arterial blood ammonia* can be useful for the differential diagnosis of coma and for following a patient with PSE, but is not always available.

**Management**

- **Identify and remove the possible precipitating cause**, such as cerebral depressant drugs, constipation or electrolyte imbalance due to over-diuresis.
- **Give purgation and enemas** to empty the bowels of nitrogenous substances. Lactulose (10–30mL three times daily) is an osmotic purgative that reduces the colonic pH and limits ammonia absorption. Lactitol (1g-galactoside sorbitol 30g daily) is metabolized by colonic bacteria and is comparable in efficacy.
- **Maintain nutrition**, if necessary via a fine-bore nasogastric tube, and do not restrict protein for more than 48 hours.
- **Give antibiotics**. Rifaximin is a poorly absorbed semisynthetic antibiotic based on rifamycin that has a beneficial effect on secondary prevention of PSE. Metronidazole (200mg four times daily) may be effective acutely. Neomycin should be avoided.
- **Stop or reduce diuretic therapy**.
- **Give intravenous fluids** as necessary (beware of too much sodium).
- **Treat infection**.
- **Increase protein** in the diet to the limit of tolerance as encephalopathy improves.
- **Embolize collaterals**. In selected patients, embolization of collaterals that bypass the liver may improve liver blood flow and reduce encephalopathy but careful case selection is mandatory.

**Prognosis**

Acute encephalopathy in acute hepatic failure has a very poor prognosis associated with that of the disease itself. In cirrhosis,
chronic PSE adversely affects prognosis but the course is very variable. Very rarely with chronic portosystemic shunting, an organic syndrome with cerebellar signs or choreoathetosis develops, as well as myelopathy leading to a spastic paraparesis due to demyelination. These patients require referral to a liver transplant centre.

**Renal failure (hepatorenal syndrome)**

The hepatorenal syndrome typically occurs in patients with advanced cirrhosis, portal hypertension, jaundice and ascites. The urine output is low with a low urinary sodium concentration, a maintained capacity to concentrate urine (i.e. intact tubular function) and almost normal renal histology. The renal failure is therefore described as ‘functional’. It is often precipitated by over-vigorous diuretic therapy, NSAIDs, diarrhoea, paracentesis and infection, particularly SBP.

The mechanism is similar to that of ascites, with extreme peripheral vasodilatation leading to decreased effective blood volume and consequent hypotension (see p. 1295). This causes increased plasma renin, aldosterone, noradrenaline (norepinephrine) and vasopressin, leading to renal vasoconstriction. There is an increased pre-glomerular vascular resistance that causes blood to be directed away from the renal cortex. This leads to a reduced GFR and plasma renin remains high. Salt and water retention occurs, with reabsorption of sodium from the renal tubules.

Eicosanoids have been incriminated in the pathogenesis, supported by precipitation of the syndrome by inhibitors of prosta
glandin synthase, such as NSAIDs.

Diuretic therapy should be stopped and intravascular hypovolaemia corrected, preferably with albumin. Terlipressin or noradrenaline with intravenous albumin improves renal function in approximately 50%. Liver transplantation is the best option. In patients who are candidates for transplantation, haemodialysis can be used as a bridging option but is frequently difficult to perform, and survival is generally limited by the severity of the hepatic failure.

**Hepatopulmonary syndrome**

This is hypoxaemia in patients with advanced liver disease due to intrapulmonary vascular dilation with no evidence of primary pul
dmonary disease. The patients have features of cirrhosis with spider naevi and clubbing, as well as cyanosis. Most are asymptomatic, but with more severe disease become breathless on standing. Transthoracic echocardiography shows intrapulmonary shunting and arterial blood gases confirm hypoxaemia. These changes are improved with liver transplantation.

**Porto-pulmonary hypertension**

This occurs in 1–2% of patients with cirrhosis and portal hyper
tension. It may respond to medical therapy (e.g. intravenous epoprostenol, or oral bosentan and sildenafil). Severe pulmonary hypertension is a contraindication to liver transplantation.

**Primary hepatocellular carcinoma**

This is discussed on page 1308.

**Further reading**

**Types of cirrhosis**

**Alcoholic cirrhosis**

This is discussed on page 1303.

**Primary biliary cholangitis**

Primary biliary cholangitis (PBC; [Fig. 34.25]) is a chronic disorder with progressive destruction of small interlobular bile ducts, leading to cirrhosis. Women aged 40–50 years constitute 90% of patients. PBC is diagnosed increasingly frequently in its milder forms. The prevalence is approximately 7.5 per 100 000, with a 1–6% increase in first-degree relatives. PBC has been called ‘chronic non-suppurative destructive cholangitis’, a term more descriptive of the early lesion, which emphasizes the fact that true cirrhosis occurs only in the later stages.

**Aetiology**

The aetiology is unknown but an immunological basis is well described. Serum anti-mitochondrial antibodies (AMA) are found in almost all patients. The mitochondrial antigen M2 is specific to PBC and five M2-specific antigens have been identified. The presence of AMA in high titre is unrelated to the clinical or histological picture and its role in pathogenesis is unclear. Antibodies against nuclear antigens, such as anti-gp210, are present in 50% of patients and correlate with progression towards liver failure.

It seems likely that an environmental factor acts on a genetically predisposed host via molecular mimicry, initiating autoimmunity. *E. coli* and *Novosporangium aromaticivorans* antibodies are present in high titre.

Synthesis of IgM is increased, thought to be due to failure of the switch from IgM to IgG antibody synthesis. No specific associated class II major histocompatibility complex (MHC) loci have been found.

**Clinical features**

Asymptomatic patients are discovered on routine examination or screening, and may have hepatomegaly, a raised serum ALP or autoantibodies.

Pruritus is often the earliest symptom. Fatigue, which is fre
quently disabling, may accompany the pruritus, particularly in pro
gressive cases. When jaundice appears, hepatomegaly is usually
associated disorders

Autoimmune disorders (e.g. Sjögren’s syndrome, scleroderma, thyroid disease) occur with increased frequency. Keratoconjunctivitis sicca (dry eyes and mouth) is seen in 70% of cases. Renal tubular acidosis, membranous glomerulonephritis, coeliac disease and interstitial pneumonitis are also associations.

Investigations

- **Mitochondrial antibodies** – measured routinely by ELISA (in titres >1:160) – are present in over 95% of patients; M2 antibody is 98% specific. Other non-specific antibodies (e.g. anti-nuclear factor and smooth muscle) may also be present.
- **High serum alkaline phosphatase** is often the only liver biochemistry abnormality.
- **Serum cholesterol** is raised.
- **Serum IgM** can be very high.
- **Ultrasound** can show a diffuse alteration in liver architecture.
- **Liver biopsy** shows characteristic histological features of a portal tract infiltrate, mainly of lymphocytes and plasma cells; approximately 40% have granulomas. Most of the early changes are in zone 1. Later, there is damage to and loss of small bile ducts with ductular proliferation. Portal tract fibrosis and, eventually, cirrhosis are seen.
- **Hepatic granulomas** are also seen in sarcoidosis, tuberculosis, schistosomiasis, drug reactions, brucellosis and parasitic infestation (e.g. strongyloidiasis).

Differential diagnosis

The classical picture presents little difficulty with diagnosis (and can be confirmed by biopsy, although this is necessary only in doubtful cases). A group of patients with the histological changes of PBC but the serology of autoimmune hepatitis are termed as having autoimmune hepatitis and respond to steroids and azathioprine.

In the jaundiced patient, extrahepatic biliary obstruction should be excluded by ultrasound or MRCP.

Management

- **Ursodeoxycholic acid** (10–15 mg/kg) improves bilirubin and aminotransferase levels. It should be given early in the asymptomatic phase, as these patients benefit, whereas no benefit is achieved in advanced disease. In patients who do not respond to ursodeoxycholic acid, obeticholic acid may be considered, but this drug is associated with increases in cholesterol and may exacerbate itching.
- **Steroids** improve biochemical and histological disease but cause osteoporosis and other side-effects, and so should not be used.
- Malabsorption of fat-soluble vitamins (A, D and K) occurs and supplementation is required.
- **Bisphosphonates** are needed for osteoporosis. Despite raised serum lipid concentrations, PBC is not associated with an increased cardiovascular disease risk, and strategies for prevention of vascular events should be tailored to the individual.
- Pruritus is difficult to control; **colestyramine** is helpful, although unpalatable. Rifampicin, and naloxone and naltrexone (opioid antagonists) have been shown to be of benefit. Intractable pruritus can be relieved by plasmapheresis or a molecular absorbent recirculating system (MARS).
- The lack of effective medical therapy has made PBC a major indication for liver transplantation (see p. 1291).
- Fatigue is common and can be severely debilitating; there is no proven therapy and transplantation does not improve symptoms. Modafinil, used for narcolepsy, has shown promise but has yet to be evaluated in randomized studies; it may cause significant side-effects and has addictive potential.

Complications

Complications are those of cirrhosis. In addition, osteoporosis and, rarely, osteomalacia and a polyneuropathy occur.

Prognosis

Prognosis is very variable. Asymptomatic patients and those presenting with pruritus only will survive for more than 20 years. Symptomatic patients with jaundice have a more rapidly progressive course and may die of liver failure or bleeding varices within 5 years. Liver transplantation should therefore be offered when the serum bilirubin is persistently above 100 μmol/L.

Primary sclerosing cholangitis

Primary sclerosing cholangitis (PSC) is a chronic cholestatic liver disease characterized by fibrosing inflammatory destruction of both the intra- and extrahepatic bile ducts. In 75% of patients, PSC is associated with inflammatory bowel disease (usually ulcerative colitis); it is not unusual for PSC to predate the onset of inflammatory bowel disease. The causes are unknown but genetic susceptibility to PSC is associated with the HLA-A1-B8-DR3 haplotype. The auto-antibody pANCA (anti-neutrophil cytoplasmic antibody) is found in the serum of 60% of cases. Seventy per cent of patients are men and the average age of onset is approximately 40 years. Secondary PSC is seen in patients with HIV and cryptosporidium (see p. 1444), and may follow ketamine misuse.

Clinical features

With increasing screening of patients who have inflammatory bowel disease, PSC is detected at an asymptomatic phase with abnormal liver biochemistry, usually a raised serum ALP. Symptomatic presentation is usually with fluctuating pruritus, jaundice and cholangitis.

Diagnosis

The typical biliary changes associated with PSC may be identified by MRCP. The cholangiogram characteristically shows irregularity of calibre of both intra- and extrahepatic ducts, although either may be involved alone (Fig. 34.26).

Pathology

Histology can be contributory; it shows inflammation of the intrahepatic biliary radicles with associated scar tissue, classically described as having the appearance of ‘onion skin’. These changes range from minor inflammatory infiltrates to the level of established cirrhosis.

Management

PSC is a slowly progressive lesion (symptoms and biochemical tests may fluctuate), which ultimately leads to liver cirrhosis and associated decompensation. Recurrent cholangitis may be a feature before the onset of cirrhosis. Cholangiocarcinoma occurs in up to 15% of patients (see pp. 1308 and 1322).

The only proven treatment is liver transplantation. Ursodeoxycholic acid, a bile acid, has been evaluated extensively but there is no evidence of benefit. High-dose therapy (30 mg/kg) may be
Liver disease

**Fig. 34.28** Liver disease does not cause HH, although there is a history of HH in some patients. It is the most common single-gene disorder in Caucasians, with a frequency of 1 in 10. It is the most common single-gene disorder in Caucasians.

**Secondary biliary cirrhosis**

Cirrhosis can result from prolonged (for months) large-duct biliary obstruction. Causes include bile duct strictures, gallstones and sclerosing cholangitis. An ultrasound examination and MRCP, sometimes followed by ERC or percutaneous transhepatic cholangiography (where the ducts are cannulated under ultrasound guidance through the skin) if cannulation is difficult, are performed to outline the ducts, and any remedial cause is treated.

**Hereditary haemochromatosis**

Hereditary haemochromatosis (HH; see also p. 1269) is an inherited disease characterized by excess iron deposition in various organs, leading to eventual fibrosis and functional organ failure. There are four main types of inherited disorder:

- **type 1 HFE**: the *HFE* gene (mutation C282Y) is the most common and is on chromosome 6
- **type 2A**: the juvenile *HJV* gene (mutation G320V)
- **type 2B**: the juvenile *HAMP* gene (mutation 93delG)
- **type 4**: ferroportin: the *SLC40A1* gene (mutation V162del).

All are transmitted by an autosomal recessive gene, apart from the ferroportin iron overload, which is dominantly transmitted.

HH has a prevalence in Caucasians (homozygotes) of 1 in 400, but very variable phenotypic expression and a heterozygote (carrier) frequency of 1 in 10. It is the most common single-gene disorder in Caucasians.

**Pathology**

In symptomatic patients the total body iron content is 20–40 g, compared with 3–4 g in a normal person. The iron content is particularly increased in the liver (Fig. 34.28) and pancreas (50–100 times normal) but is also higher in other organs (e.g. endocrine glands, heart and skin).
In established cases the liver shows extensive iron deposition and fibrosis. Early in the disease, iron is deposited in the periportal hepatocytes (in pericanalicular lysosomes). Later, it is distributed widely throughout all acinar zones, biliary duct epithelium, Kupffer cells and connective tissue. Cirrhosis is a late feature.

**Clinical features**

The course of the disease depends on a number of factors, including gender, dietary iron intake, presence of associated hepatotoxins (especially alcohol) and genotypes. Overt clinical manifestations occur more frequently in men; the reduced incidence in women is probably explained by physiological blood loss and a smaller dietary intake of iron. Most affected individuals present in the fifth decade. The classic triad of bronze skin pigmentation (due to melanin deposition), hepatomegaly and diabetes mellitus is present only in cases of gross iron overload.

Hypogonadism secondary to pituitary dysfunction is the most common endocrine feature. Deficiency of other pituitary hormones is also found but symptomatic endocrine deficiencies, such as loss of libido, are very rare. Cardiac manifestations, particularly heart failure and arrhythmias, are common, especially in younger patients. Calcium pyrophosphate is deposited asymmetrically in both large and small joints (chondrocalcinosis), leading to an arthropathy. The exact relationship of chondrocalcinosis to iron deposition is uncertain.

**Complications**

Some 30% of people with cirrhosis will develop primary hepatocellular carcinoma (HCC). HCC has been described only very rarely in non-cirrhotic patients in whom the excess iron stores have been removed. Early diagnosis is vital.

**Investigations**

**Homoygotes**

- **Serum iron** is elevated (>30 μmol/L) in 90% with a reduction in the TIBC and a transferrin saturation of >45%.

- **Serum ferritin** is elevated (usually >500 μg/L or 240 nmol/L).

- **Liver biochemistry** is often normal, even with established cirrhosis.

**Heterozygotes**

Heterozygotes may have normal biochemical tests or modest increases in serum iron transferrin saturation (>45%) or serum ferritin (usually >400 μg/L).

**Genetic testing**

If iron studies are abnormal, genetic testing is performed.

**Liver biopsy**

This is not required for diagnosis but is useful to establish the extent of tissue damage, assess tissue iron and measure the hepatic iron concentration (>180 μmol/g dry weight of liver indicates haemochromatosis).

Mild degrees of parenchymal iron deposition in patients with other forms of cirrhosis, particularly if due to alcohol, can often cause confusion with true homozygous HH.

**Magnetic resonance imaging**

MRI shows a dramatic reduction in the signal intensity of the liver and pancreas owing to the paramagnetic effect of ferritin and haemosiderin. A highly T2-weighted, gradient recalled echo (GRE) technique detects all clinically relevant liver iron overload (>60 μmol/g of liver). In secondary iron overload (haemosiderosis), which involves the reticuloendothelial cells, the pancreas is spared, enabling distinction between these two conditions.

**Management**

**Venesection**

This prolongs life and may reverse tissue damage; the risk of malignancy still remains if cirrhosis is present. All patients should have excess iron removed as rapidly as possible. This is achieved using venesection of 500 mL performed twice weekly for up to 2 years: that is, 160 units with 250 mg of iron per unit, which equals 40 g removed. During venesection, serum iron and ferritin and the mean corpuscular volume (MCV) should be monitored. These fall only when available iron is depleted. Three or four venesections per year are required to prevent re-accumulation of iron. Serum ferritin should remain within the normal range.

Manifestations of the disease usually improve or disappear, except for diabetes, testicular atrophy and chondrocalcinosis. The requirements for insulin often diminish in diabetic patients. Testosterone replacement is frequently helpful.

In the rare patient who cannot tolerate venesection (because of severe cardiac disease or anaemia), chelation therapy with desferioxamine, either intermittently or continuously by infusion, has been successful in removing iron.

**Screening**

In all cases of HH, all first-degree family members must be screened to detect early and asymptomatic disease. HFE mutation analysis is performed with measurement of transferrin saturation and serum ferritin.

In the general population, serum iron and transferrin saturation are the best and cheapest tests available.

**Wilson’s disease (progressive hepatolenticular degeneration)**

Dietary copper is normally absorbed from the stomach and upper small intestine. Copper is transported to the liver loosely bound to albumin; in the liver, it is incorporated into apoceruloplasmin, forming caeruloplasmin, a glycoprotein synthesized in the liver, and secreted into the blood. The remaining copper is normally excreted in the bile and excreted in faeces.

Wilson’s disease is a very rare inborn error of copper metabolism that results in copper deposition in various organs, including the liver, the basal ganglia of the brain and the cornea. It is potentially
treatable and all young patients with liver disease must be screened for this condition.

**Aetiology**

Wilson’s disease is an autosomal recessive disorder with a molecular defect within a copper-transporting ATPase encoded by a gene (designated ATP7B) located on chromosome 13. It affects between 1 in 30,000 and 1 in 100,000 individuals. Over 300 mutations have been identified, the most frequent being His 1069 Gly (H1069Q), found in approximately 50% of Caucasian patients; compound heterozygotes are common. This mutation is rare in India and Asia. Wilson’s disease occurs worldwide, particularly in countries where consanguinity is common. There is a failure of both incorporation of copper into pro-caeruloplasmin, which leads to low serum caeruloplasmin, and biliary excretion of copper. There is a low serum caeruloplasmin in over 80% of patients but this is not the cause of the copper deposition. The precise mechanism for the failure of copper excretion is not known.

**Pathology**

The liver histology is not diagnostic and varies from that of chronic hepatitis to macronodular cirrhosis. Stains for copper show a periportal distribution but this can be unreliable (see later). The basal ganglia are damaged and show cavitation, the kidneys demonstrate tubular degeneration, and erosions are seen in bones.

**Clinical features**

Children usually present with hepatic problems, whereas young adults have more neurological problems, such as tremor, dysarthria, involuntary movements and eventually dementia. The liver disease varies from episodes of acute hepatitis, especially in children (which can go on to acute hepatic failure), to chronic hepatitis or cirrhosis.

Typical signs are those of chronic liver disease with neurological signs of basal ganglia involvement (see p. 862). A specific sign is the Kayser–Fleischer ring, caused by copper deposition in Descemet’s membrane in the cornea. It appears as a greenish-brown pigment at the corneoscleral junction and frequently requires slit-lamp examination for identification. It may be absent in young children.

**Investigations**

- **Serum copper and caeruloplasmin** are usually reduced but can be normal.
- **Urinary copper** is usually increased to 100–1000 μg in 24h (1.6–16 μmol); normal levels are <40 μg (0.6 μmol).
- **Liver biopsy** aids diagnosis, which depends on measurement of the amount of copper in the liver (>250 μg/g dry weight), although high levels of copper are also found in the liver in chronic cholestasis.
- **Haemolysis and anaemia** may be present.
- **Genetic analysis** is limited but selected exons are screened according to population groups.

**Management**

- Lifetime treatment with **penicillamine**, 1–1.5g daily, is effective in chelating copper. If treatment is started early, clinical and biochemical improvement can occur. Urinary copper levels should be monitored and the drug dose adjusted downwards after 2–3 years. Serious side-effects of the drug occur in 10% and include skin rashes, leucopenia, skin changes and renal damage.
- **Trientine** (1.2–1.8 g/day) and **zinc acetate** (150 mg/day) are used as maintenance therapy and for asymptomatic cases. All siblings and children of patients should be screened (ATP7B mutation analysis is useful) and treatment with zinc is given, even in the asymptomatic, if there is evidence of copper accumulation. A diet low in copper (i.e. excluding chocolate and peanuts) is advised.

**Prognosis**

Early diagnosis and effective treatment have improved the outlook. Neurological damage is, however, permanent. Acute hepatic failure or decompensated cirrhosis should be treated by liver transplantation.

**Alpha₁-antitrypsin deficiency**

A deficiency of α₁-antitrypsin (α₁-AT, see also p. 956) is sometimes associated with liver disease and pulmonary emphysema (particularly in smokers). Part of a family of serine protease inhibitors, or serpin superfamily, α₁-AT is a glycoprotein. Deficiency of α₁-AT is a genetic disorder and 1 in 10 northern Europeans carries an abnormal gene.

The protein is a 394-amino acid 52 kDa acute phase protein that is synthesized in the liver and constitutes 90% of the serum α₁-globulin seen on electrophoresis. Its main role is to inhibit the proteolytic enzyme, neutrophil elastase.

The gene is located on chromosome 14. The genetic variants of α₁-AT are characterized by their electrophoretic mobilities as medium (M), slow (S) or very slow (Z). The normal genotype is protease inhibitor MM (PIMM), the homozygote for Z is PiZZ, and the heterozygotes are PiMZ and PiSZ. S and Z variants are due to a single amino acid replacement of glutamic acid at positions 264 and 342 of the polypeptide, respectively. This results in decreased synthesis and secretion of the protein by the liver as protein–protein interactions occur between the reactive centre loop of one molecule and the β-pleated sheet of a second (loop sheet polymerization).

How this causes liver disease is uncertain. It is postulated that failure of secretion of the abnormal protein leads to an accumulation in the liver, leading to liver damage.

**Clinical features**

The majority of patients with clinical disease are homozygotes with a PiZZ phenotype. Some may present in childhood and a few require transplantation. Approximately 10–15% of adult patients will develop cirrhosis, usually over the age of 50 years, and 75% will have respiratory problems. Approximately 5% of patients die of their liver disease. Heterozygotes (e.g. PiSZ or PiMZ) may develop liver disease but the risk is small.

**Investigations**

- **Serum α₁-antitrypsin** is low, at 10% of the normal level in the PiZZ phenotypes, and 60% of normal in the S variant.

  **Histologically**, periodic acid–Schiff (PAS)-positive, diastase-resistant globules that contain α₁-AT are seen in periportal hepatocytes. Fibrosis and cirrhosis can be present.

**Management**

There is no treatment, apart from managing the complications of liver disease. Patients with hepatic decompensation should be assessed for liver transplantation and should stop smoking.

**Further reading**

This section describes the pathology and clinical features of alcoholic liver disease. The amounts needed to produce liver damage, alcohol metabolism and other clinical effects of alcohol are described on pages 1258–1259.

Ethanol is metabolized in the liver by two pathways, resulting in an increase in the NADH/NAD ratio. The altered redox potential causes increased hepatic fatty acid synthesis with decreased fatty acid oxidation; both events lead to hepatic accumulation of fatty acid, which is then esterified to glycerides.

The changes in oxidation-reduction also impair carbohydrate and protein metabolism and are the cause of the centrilobular necrosis of the hepatic acinus that is typical of alcohol damage. TNF-α release from Kupffer cells causes the release of reactive oxygen species, leading in turn to tissue injury and fibrosis.

Acetaldehyde is formed by the oxidation of ethanol, and its effect on hepatic proteins may well be a factor in producing liver cell damage. The exact mechanism of alcoholic hepatitis and cirrhosis is unknown, but since only 10–20% of people who drink heavily will develop cirrhosis, a genetic predisposition is recognized. Immunological mechanisms have also been proposed, with the release of cytokines, particularly IL-8, which is a neutrophil chemoattractant; infiltration with neutrophils is a feature of alcoholic hepatitis.

Alcohol can enhance the effects of the toxic metabolites of drugs (e.g. paracetamol) on the liver, as it induces microsomal metabolism via the microsomal ethanol oxidizing system (MEOS; see p. 1258).

Pathology
Alcohol can produce a wide spectrum of liver disease, from fatty change to hepatitis and cirrhosis.

Fatty liver
The metabolism of alcohol invariably produces fat in the liver (Fig. 34.29), mainly in zone 3. This is minimal with small amounts of alcohol, but with larger amounts the cells become swollen with fat (steatosis). There is no liver cell damage. The fat disappears on stopping alcohol. Steatosis is also seen in NAFLD (see p. 1287).

In some cases, collagen is laid down around the central hepatic veins (perivenular fibrosis) and this can sometimes progress to cirrhosis without a preceding hepatitis. Alcohol directly affects stellate cells, transforming them into collagen-producing myofibroblast cells (see p. 1264).

Alcoholic hepatitis
In addition to fatty change, there is infiltration by polymorphonuclear leucocytes and hepatocyte necrosis, mainly in zone 3. Dense cytoplasmic inclusions called Mallory bodies are sometimes seen in hepatocytes, and giant mitochondria are also a feature. Mallory bodies are suggestive of, but not specific for, alcoholic damage, as they can be found in other liver disease, such as Wilson’s disease and primary biliary cholangitis. If alcohol consumption continues, alcoholic hepatitis may progress to cirrhosis.

Alcoholic cirrhosis
This is classically of the micronodular type but a mixed pattern is also seen accompanying fatty change; evidence of pre-existing alcoholic hepatitis may be present.

Clinical features
Fatty liver
There are often no symptoms or signs. Vague abdominal symptoms of nausea, vomiting and diarrhoea are due to the more general effects of alcohol on the gastrointestinal tract. Hepatomegaly, sometimes huge, can occur, together with other features of chronic liver disease.

Alcoholic hepatitis
The clinical features vary in degree:
- The patient may be well, with few symptoms, the hepatitis being apparent only on the liver biopsy in addition to fatty change.
- Mild to moderate symptoms of ill-health, occasionally with mild jaundice, may occur. Signs include all the features of chronic liver disease. Liver biochemistry is deranged and the diagnosis is made on liver histology.
- In the severe case, often superimposed on alcoholic cirrhosis, the patient is ill, with jaundice and ascites. Abdominal pain is frequently present and a high fever is associated with the liver necrosis. On examination there is deep jaundice, hepatomegaly, sometimes splenomegaly, and ascites with ankle oedema. The signs of chronic liver disease are also present.

Alcoholic cirrhosis
This represents the final stage of liver disease from alcohol use. Nevertheless, patients can be very well with few symptoms. On examination, there are usually signs of chronic liver disease (p. 1263). The diagnosis is confirmed by liver biopsy.

The patient usually presents with one of the complications of cirrhosis. In many cases there are features of alcohol dependency (see p. 790), as well as evidence of involvement of other systems, such as polyneuropathy.

Investigations
Fatty liver
An elevated MCV often indicates heavy drinking. Liver biochemistry shows mild abnormalities with elevation of both serum amino-transferase enzymes. The γ-GT level is a useful test for determining whether the patient is taking alcohol. With severe fatty infiltration, marked changes in all liver biochemical parameters can occur.
Ultrasound or CT will demonstrate fatty infiltration, as will liver histology. Elastography (p. 1270) can be used to estimate the degree of fibrosis.

**Alcoholic hepatitis**

Investigations show a leucocytosis with markedly deranged liver biochemistry and elevated:
- serum bilirubin
- serum AST and ALT
- serum ALP
- PT.

A *low serum albumin* may also be found. Rarely, hyperlipidaemia with haemolysis (*Zieve syndrome*) may occur.

**Liver biopsy**, if required, is performed by the transjugular route because of the prolonged PT.

**Alcoholic cirrhosis**

Investigations are as for cirrhosis in general.

**Management and prognosis**

**General management**

All patients should stop drinking alcohol. Delirium tremens (a withdrawal symptom) is treated with diazepam. Intravenous thiamine should be given empirically to prevent Wernicke–Korsakoff encephalopathy. Bed rest is necessary, along with a diet high in protein and vitamin supplements. Parenteral nutrition is sometimes required. Patients must be advised to participate in alcohol cessation programmes. The likelihood of abstention is dependent on many factors, particularly social and family ones.

**Fatty liver**

The patient is advised to stop drinking alcohol; the fat will disappear subsequently, as long as patients are aware of the problems and can control their consumption.

**Alcoholic hepatitis**

In severe cases the alcoholic hepatitis leads to acute decompensation and the patient requires admission to hospital. Nutrition must be maintained with enteral feeding, if necessary, and vitamin supplementation given. Steroid therapy has been widely used in patients with a discriminant function score of more than 32 but a Lille score (p. 1270) suggests that there was no survival benefit.

**Discriminant function (DF)**

\[
\text{DF} = (4.6 \times \text{prothrombin time above control in seconds}) + \text{bilirubin (mg/dL)}
\]

\[
\text{Bilirubin mmol/L} + 17 \text{ to convert to mg/dL}.
\]

Severe = >32.

The response to steroid therapy can also be evaluated by the Lille score (>0.45 indicates poor response to steroids, which can therefore be stopped) and the Glasgow score (Boxes 34.23 and 34.24). A Glasgow score of more than 9 indicates that steroids are necessary because at above 9 the 28-day mortality is 75%, while at below 9 it is 50%. The MELD score (see Box 34.17) is also used but does not indicate which patients need steroid therapy.

Infection must be excluded or concomitantly treated. Treatment for encephalopathy and ascites is commenced. Antifungal prophylaxis should also be used.

**Further reading**

**BUDD–CHIARI SYNDROME**

In this condition there is obstruction to the venous outflow of the liver owing to occlusion of the hepatic vein. In one-third of patients the cause is unknown but specific causes include hypercoagulability states (e.g. paroxysmal nocturnal haemoglobinuria, polycythaemia...
vera) or thrombophilia (see p. 1011), the contraceptive pill and leukaemia. Other causes include occlusion of the hepatic vein owing to posterior abdominal wall sarcomas, renal or adrenal tumours, HCC, hepatic infections (e.g. hydatid cyst), congenital venous webs, radiotherapy or trauma to the liver.

**Clinical features**
The acute form presents with abdominal pain, nausea, vomiting, tender hepatomegaly and ascites (a fulminant form occurs particularly in pregnant women). In the chronic form there is enlargement of the liver (particularly the caudate lobe), mild jaundice, ascites, a negative hepatojugular reflex, and splenomegaly with portal hypertension.

**Investigations**
Investigations show a high protein content in the ascitic fluid and characteristic liver histology with centrilobular congestion, haemorrhage, fibrosis and cirrhosis. Ultrasound, CT or MRI will demonstrate hepatic vein occlusion with diffuse abnormal parenchyma on contrast enhancement. The caudate lobe is spared because of its independent blood supply and venous drainage. There may be compression of the inferior vena cava. Pulsed Doppler sonography or colour Doppler is useful, as it shows abnormalities of flow in the hepatic vein. Thrombophilia screening is mandatory. Multiple defects of coagulation occur. Thrombosis of the portal vein is present in 2% of patients.

**Differential diagnosis**
A similar clinical picture can be produced by inferior vena caval obstruction, right-sided cardiac failure or constrictive pericarditis, and appropriate investigations should be performed.

**Management**
In the acute situation, thrombolytic therapy can be given. Ascites should be treated, as should any underlying cause (e.g. polycythaemia). Congenital webs should be treated radiologically or resected surgically. A TIPS is the treatment of choice, as caval compression does not prejudice its efficacy. Surgical portocaval shunts are reserved for those who fail this treatment, providing there is no caval obstruction or severe caval compression when a caval stent can be inserted. Liver transplantation is the first-choice treatment for chronic Budd–Chiari syndrome and for the fulminant form. Life-long anticoagulation is mandatory following TIPS and transplantation.

**Prognosis**
The prognosis depends on the aetiology but the reported life expectancy is 3 years after the first symptoms. However, a step-wise approach to therapy, as described earlier, can lead to a 5-year survival rate of nearly 85%.

---

**FIBROPOLYCYSTIC DISEASES**

These diseases are usually inherited and lead to the presence of cysts or fibrosis in the liver, kidney and occasionally the pancreas, and other organs.

**Polycystic disease of the liver**
Multiple cysts can occur in the liver as part of autosomal dominant polycystic disease of the kidney (see p. 1405). These cysts are usually asymptomatic but occasionally cause abdominal pain and distension. Liver function is normal and complications such as oesophageal varices are very rare. The prognosis is excellent and depends on the kidney disease.

**Solitary cysts**
These are usually found by chance during imaging and are mainly asymptomatic.

**Congenital hepatic fibrosis**
In this rare condition the liver architecture is normal but there are broad collagenous fibrous bands extending from the portal tracts. Congenital hepatic fibrosis is often inherited as an autosomal recessive condition but can also occur sporadically. It usually presents in childhood with hepatosplenomegaly, and portal hypertension is common. It may present later in life and can be misdiagnosed as cirrhosis.

A wedge biopsy of the liver may be required to confirm the diagnosis. The outlook is good and the condition should be distinguished from cirrhosis. Patients who bleed do well after endoscopic therapy of varices (or a portocaval anastomosis) because of their good liver function.

**Congenital intrahepatic biliary dilation (Caroli’s disease)**
In this rare, non-familial disease there are saccular dilations of the intrahepatic or extrahepatic ducts. It can present at any age (although it usually does so in childhood) with fever, abdominal pain and recurrent attacks of cholangitis with Gram-negative septicemia. Jaundice and portal hypertension are absent. Diagnosis is by ultrasound, percutaneous transhepatic cholangiography and MRCP. There is an increased risk of biliary malignancy.

---

**LIVER ABSCESS**

**Pyogenic abscess**
Pyogenic abscesses are uncommon; they may be single or multiple. The most common used to be a portal pyaemia from intra-abdominal sepsis (e.g. appendicitis or perforations) but nowadays the aetiology is not known in many cases. In the elderly, biliary...
Liver disease

Sepsis is a common cause. Other causes include trauma, bacteremia and direct extension from, for example, a perinephric abscess.

The most common organism is *E. coli*, *Streptococcus milleri* and anaerobic organisms such as *Bacteroides* are often seen. Others include *Enterococcus faecalis*, *Proteus vulgaris* and *Staphylococcus aureus*. Often the infection is mixed.

Clinical features

Some patients present with malaise lasting several days or even months. Others can present with fever, rigors, anorexia, vomiting, weight loss and abdominal pain. In these patients, a Gram-negative septicaemia with shock can occur. On examination there may be little of note; alternatively, the patient may be toxic, febrile and jaundiced. In such patients the liver is tender and enlarged, and there may a pleural effusion or a pleural rub in the right lower chest.

Investigations

Patients are often investigated for ‘pyrexia of unknown origin’ and most investigations will be normal.

- **Serum bilirubin** is raised in 25% of cases.
- **Normochromic normocytic anaemia** may occur, usually accompanied by a polymorphonuclear leucocytosis.
- **Serum ALP, ESR and CRP** are often raised.
- **Serum vitamin B	extsubscript{12}** is very high, as it is stored in and subsequently released from the liver.
- **Blood cultures** are positive in only 30% of cases.

Imaging

Ultrasound is useful for detecting abscesses. A CT scan may be of value in complex and multiple lesions (Fig. 34.30). A chest X-ray will show elevation of the right hemidiaphragm, with a pleural effusion in the severe case. Depending on age, imaging of the colon may be necessary to find the source of infection.

Management

Aspiration of the abscess should be attempted under ultrasound control. Antibiotics should initially cover Gram-positive, Gram-negative and anaerobic organisms until the causative organism is identified.

Further drainage via a large-bore needle under ultrasound control or surgically may be necessary if resolution is difficult or slow. Any underlying cause must be treated.

Prognosis

The overall mortality depends on the nature of the underlying pathology but has been reduced to approximately 16% with needle aspiration and antibiotics. A unilocular abscess in the right lobe has the best prognosis. Scattered multiple abscesses have a very high mortality, with only 1 in 5 patients surviving.

Amoebic abscess

This occurs worldwide and must be considered in patients travelling from endemic areas. *Entamoeba histolytica* (see p. 571) can be carried from the bowel to the liver in the portal venous system, leading to portal inflammation with the development of multiple microabscesses and, eventually, single or multiple large abscesses.

Clinically, the onset is usually gradual but may be sudden. There is fever, anorexia, weight loss and malaise. There is often no history of dysentery. On examination the patient looks ill and has tender hepatomegaly and signs of an effusion or consolidation in the base of the right side of the chest. Jaundice is unusual.

Other infections of the liver

*Schistosomiasis*

*Schistosoma mansoni* and *S. japonicum* affect the liver but *S. haematobium* rarely does so (see also p. 578). During their life cycle the ova reach the liver via the venous system and obstruct the portal branches, producing granulomas, fibrosis and inflammation, but not cirrhosis.

Clinical features and investigations

Clinically, there is hepatosplenomegaly and portal hypertension, which is particularly severe with *S. mansoni*. In Egypt there is frequently concomitant chronic hepatitis C infection.

Investigations show a raised serum ALP, and ova can be found in the stools (centrifuged deposits) and in rectal and liver biopsies. Skin tests and other immunological tests often give false results and may also be positive because of past infection.
Other infections of the liver

Management

Treatment is with praziquantel, but fibrosis still remains with a potential risk of portal hypertension, characteristically pre-sinusoidal due to intense portal fibrosis.

Hydatid disease

Cysts caused by *Echinococcus granulosus* are single or multiple. They usually occur in the lower part of the right lobe. The cyst has three layers: an outside layer derived from the host, an intermediate laminated layer, and an inner germinal layer that buds off brood capsules to form daughter cysts (see also p. 581).

Clinical features and investigations

Clinically, there may be no symptoms or there may be a dull ache and swelling in the right hypochondrium.

Investigations show a peripheral eosinophilia in 30% of cases and usually a positive hydatid complement fixation test or haemagglutination (85%). Plain abdominal X-ray may show calcification of the outer coat of the cyst. Ultrasound and CT scan demonstrate cysts and may show diagnostic daughter cysts within the parent cyst (Fig. 34.31).

Management

Medical treatment (e.g. with albendazole 10 mg/kg, which penetrates into large cysts) results in cysts becoming smaller. Puncture, aspiration, injection, re-aspiration (PAIR) has been used since the 1980s. Fine-needle aspiration is undertaken under ultrasound control with chemotherapeutic cover. Surgery can be performed with removal of the cyst intact, if possible, after first sterilizing the cyst with alcohol, saline or cetrimide. Chronic calcified cysts can be left; there have been no well-designed clinical trials for any therapy.

Complications and prognosis

These include rupture into the biliary tree or other organs, or intraabdominelly, with spread of infection. The prognosis without any complications is good, although there is always a risk of rupture. Preventative measures include deworming pet dogs and preventing pets from eating infected carcasses, as well as veterinary control programmes.

*Echinococcus multilocularis* causes alveolar echinococcosis and is almost exclusively a hepatic disease, with a high mortality if not treated. Early diagnosis enables radical surgery and then continued chemosuppression.

Fig. 34.31 Multimodality imaging from the same patient demonstrating hydatid cysts containing multiple daughter cysts. (A) Ultrasound. (B) CT. (C) T2-weighted MRI. (D) T1-weighted MRI.
Acquired immunodeficiency syndrome

The liver is often involved in AIDS and is a significant cause of morbidity or mortality. HIV itself is not the cause of the liver abnormalities. Clinical hepatomegaly is common (60% of patients). The following are seen, although less frequently in areas where antiretroviral therapy (ART) is available:

- Pre-existing/coincidental viral hepatitis. The hepatitis (HBV, HCV, HDV) progresses more rapidly and is a leading cause of death.
- Neoplasia. Kaposi’s sarcoma and non-Hodgkin lymphoma may be seen, and there is an increased risk of HCC.
- Opportunistic infection (e.g. Mycobacterium tuberculosis, M. avium-intracellular, Cryptococcus, Candida albicans, toxoplasmosis).
- Drug hepatotoxicity.
- Secondary sclerosing cholangitis (see p. 1444).
- Non-cirrhotic portal hypertension. This is associated with ART and is more common in people who have had profound immunosuppression and received early nucleotides, such as didanosine (DDI). The incidence is believed to be declining with the introduction of early ART and less toxic drugs.

Further reading

Primary malignant tumours

Primary liver tumours may be benign or malignant, but the most common are malignant.

Hepatocellular carcinoma

Hepatocellular carcinoma (HCC) is the fifth most common cancer worldwide.

Aetiology

Carriers of HBV and HCV have an extremely high risk of developing HCC. In areas where HBV is prevalent, 90% of patients with this cancer are positive for HBV. Cirrhosis is present in approximately 80% of these people. The development of HCC is related to the integration of viral HBV DNA into the genome of the host hepatocyte (see p. 1278), and to the degree of viral replication (>10000 copies/mL). The risk of HCC in HCV is higher than in HBV (and even higher with both HBV and HCV), despite no viral integration. Unlike in HBV infection, cirrhosis is always present in HCV. Primary liver cancer is also associated with other forms of cirrhosis, such as alcoholic cirrhosis, NAFLD-associated cirrhosis and haemochromatosis. Males are affected more than females. Other aetiological factors are aflatoxin (a metabolite of a fungus found in groundnuts) and androgenic steroids, and there is a weak association with the contraceptive pill.

Pathology

The tumour either is single or occurs as multiple nodules throughout the liver. Histologically, it consists of cells resembling hepatocytes. It can metastasize via the hepatic or portal veins to the lymph nodes, bones and lungs.

Clinical features

The clinical features include weight loss, anorexia, fever, an ache in the right hypochondrium and ascites. The rapid development of these features in a cirrhotic patient is suggestive of HCC. On examination, an enlarged, irregular, tender liver may be felt. Increasingly, due to surveillance, HCC is found without symptoms in patients with cirrhosis.

Investigations

- Routine liver biochemistry, full blood count, serum creatinine and electrolytes.
- Serum α-fetoprotein may be raised but is normal in at least a third of patients.
- Ultrasound scans show filling defects in 90% of cases.
- Enhanced CT scans (Fig. 34.32) identify HCC but it is difficult to confirm the diagnosis in lesions smaller than 1 cm. An MRI scan can help to delineate lesions further.
- Tumour biopsy (Fig. 34.33), particularly under ultrasonic guidance, is now used less frequently for diagnosis, as imaging techniques show characteristic appearances (hypervascularity of the nodule and lack of portal vein washout) and because seeding along the biopsy tract can occur.

Management and prognosis

See page 126.

Prevention

Persistent HBV infection, usually acquired after perinatal infection, is a strong risk factor for HCC in many parts of the world, such as South-east Asia. Widespread vaccination against HBV is being used and this has reduced the annual incidence of HCC in Taiwan.
Fig. 34.32 Hepatocellular carcinoma (HCC). Two cases of HCC on (A–C) multiphasic contrast-enhanced CT and (D–F) MRI. HCC classically demonstrates enhancement on the arterial phase imaging (A, D) and washout on more delayed phases of imaging. In both cases there is subtle washout on the portal venous phase imaged (B, E) with more definite washout on the delayed phase imaging (C, F).
Cholangiocarcinomas are increasing in incidence and can be extrahepatic (see p. 1322) or intrahepatic (see p. 126). Intrahepatic adenocarcinomas arising from the bile ducts account for approximately 10% of primary tumours of the liver and biliary tract. They are not associated with cirrhosis or hepatitis B. In the Far East, they may be associated with infestation with *Clonorchis sinensis* or *Opisthorchis viverrini*. The clinical features are similar to those of primary HCC, except that jaundice is frequent with hilar tumours, and cholangitis is more common. There is an increased association with inflammatory bowel disease and primary sclerosing cholangitis (see p. 1299).

Surgical resection is rarely possible and patients usually die within 6 months. Transplantation is contraindicated, outside of specialized protocols.

**Benign tumours**

The most common benign tumour is a haemangioma. It is usually small and single but can be multiple and large. Haemangiomias are usually found incidentally on ultrasound, CT or MRI, and have characteristic appearances. They require no treatment.

**Hepatic adenomas** are associated with oral contraceptives. They can present with abdominal pain or intraperitoneal bleeding. Resection is required only for symptomatic patients, those with tumours of more than 5 cm in diameter, and those in whom discontinuation of oral contraception does not result in shrinkage of the tumour. Immunohistochemical characteristics are helpful for indicating malignant potential, which is far more common in men.

**Idiopathic adult ductopenia**

This unexplained condition is characterized by pruritus and cholestatic jaundice. Histology of the liver shows a decrease in intrahepatic bile ducts in at least 50% of the portal tracts, together with the features of cholestasis and marked fibrosis or cirrhosis. In most, the disease is progressive and the only treatment is liver transplantation.

**Indian childhood cirrhosis**

This condition of children is seen in the Indian subcontinent. The cause is unknown. Eventually, there is development of a micronodular cirrhosis with excess copper in the liver.

**Hepatic porphyrias**

These are dealt with on page 755.

**Cystic fibrosis**

Cystic fibrosis (see also p. 983) mainly affects the lung and pancreas, but patients can develop fatty liver, cholestasis and cirrhosis. The aetiology of the liver involvement is unclear.

**Coeliac disease**

Abnormal liver biochemical tests are common in coeliac disease (see also p. 1190) and return to normal with a gluten-free diet. A tissue transglutaminase test should be performed if hepatic causes are not found when investigating abnormal liver biochemistry.

**DRUGS AND THE LIVER**

**Drug metabolism**

The liver is the major site of drug metabolism. Drugs are converted from fat-soluble to water-soluble substances that can be excreted in the urine or bile. This metabolism of drugs is mediated by a group of mixed-function enzymes (see p. 253).

**Drug hepatotoxicity**

Many drugs impair liver function. When abnormal liver biochemical tests are found, drugs should always be considered as a cause, particularly when other causes have been excluded. Damage to the liver by drugs (drug-induced liver injury, DILI) is usually classified as being either predictable (or dose-related) or non-predictable (not dose-related) (see p. Box 12.9). However, there is considerable...
overlap and at least six mechanisms may be involved in the production of damage:
1. disruption of intracellular calcium homeostasis
2. disruption of bile canalicular transport mechanisms
3. formation of non-functioning adducts (enzyme–drug), which may then lead to
4. presentation on the surface of the hepatocyte as new immunogens (attacked by T cells)
5. induction of apoptosis
6. inhibition of mitochondrial function, which prevents fatty acid metabolism and accumulation of both lactate and reactive oxygen species.

The predominant mechanism or combination of mechanisms determines the type of liver injury: that is, hepatitic, cholestatic or immunological (skin rashes, fever and arthralgia, i.e. serum sickness syndrome). Eosinophilia and circulating immune complexes and antibodies are occasionally detected.

When a small amount of hepatotoxic drug whose effect is dose-dependent (e.g. paracetamol) is ingested, a large proportion of it undergoes conjugation with glucuronide and sulphate, while the remainder is metabolized by microsomal enzymes to produce toxic derivatives that are immediately detoxified by conjugation with glutathione. If larger doses are ingested, the former pathway becomes saturated and the toxic derivative is produced at a faster rate. Once the hepatic glutathione is depleted, large amounts of the toxic metabolite accumulate and produce damage (see p. 265).

The ‘predictability’ of drugs to produce damage can, however, be affected by metabolic events preceding their ingestion. For example, chronic alcohol users may become more susceptible to liver damage because of the enzyme-inducing effects of alcohol, or ill or starving patients may become susceptible because of the depletion of hepatic glutathione produced by starvation. Many other factors, such as environmental or genetic effects, may be involved in determining the ‘susceptibility’ of certain patients to certain drugs.

The incidence of drug hepatotoxicity is 14 per 100 000 population with a 6% mortality. It is the most common cause of acute liver failure in the USA. Liver transplantation is used.

### Hepatitic damage

The type of damage produced by various drugs is shown in Box 34.25. Most reactions occur within 3 months of starting the drug. Monitoring liver biochemistry in patients on long-term treatment, such as anti-tuberculosis therapy, is mandatory. If a drug is suspected of causing hepatic damage, it should be stopped immediately. Liver biopsy is of limited help in confirming the diagnosis, but occasionally, hepatic eosinophilia or granulomas may be seen. Diagnostic challenge with subtherapeutic doses of the drug is sometimes required after the liver biochemistry has returned to normal, to confirm the diagnosis.

### Individual drugs

**Paracetamol**

In high doses, paracetamol produces liver cell necrosis (see earlier). The toxic metabolite binds irreversibly to liver cell membranes. Overdosage is discussed on page 265.

**Steroid compounds**

Cholestasis is caused by natural and synthetic oestrogens, as well as methyltestosterone. These agents interfere with canicular

*NSAID, non-steroidal anti-inflammatory drug. Note: Anti-HIV drugs, e.g. maraviroc, cause hepatic dysfunction.*

**biliary flow** by blocking MRP2 and MDR3 (see Fig. 34.5) and cause a pure cholestasis.

Cholestasis is rare with the contraceptive pill because of the low dosage used. However, the contraceptive pill is associated with an increased incidence of gallstones, hepatic adenomas
Liver disease

(rarely, HCCs), the Budd–Chiari syndrome and peliosis hepatis. The latter condition, which also occurs with anabolic steroids, consists of dilation of the hepatic sinusoids to form blood-filled lakes.

Phenothiazines

Phenothiazines (e.g. chlorpromazine) can produce a cholestatic picture owing to a hypersensitivity reaction. This occurs in 1% of patients, usually within 4 weeks of starting the drug. Typically, it is associated with a fever and eosinophilia. Recovery occurs on stopping the drug.

Anti-tuberculous chemotherapy

Isoniazid produces elevated aminotransferases in 10–20% of patients. Hepatic necrosis with jaundice occurs in a smaller percentage. The hepatotoxicity of isoniazid is related to its metabolites and is dependent on acetylator status. Rifampicin produces hepatitis, usually within 3 weeks of starting the drug, particularly in patients on high doses. Pyrazinamide produces abnormal liver biochemical tests and, rarely, liver cell necrosis.

Amiodarone

This leads to a steatohepatitis histologically, and liver failure if the drug is not stopped in time.

Sodium valproate

This causes mitochondrial injury with microvesicular steatosis. Intravenous carnitine should be used as an antidote.

Drug prescribing for patients with liver disease

The metabolism of drugs is impaired in severe liver disease (with jaundice and ascites), as the removal of many drugs depends on liver blood flow and the integrity of the hepatocyte. In general, therefore, the effect of drugs is prolonged by liver disease and also by cholestasis. This is further accentuated by portosystemic shunting, which diminishes the first-pass extraction of drugs. With hypoprothrombinaemia, there is decreased protein binding of some drugs, and bilirubin competes with many drugs for the binding sites on serum albumin. In patients with portosystemic encephalopathy, care must be taken in prescribing drugs with a central depressant action, such as narcotics like codeine and anxiolytics. Other common drugs to be avoided in cirrhosis include angiotensin-converting enzyme (ACE) inhibitors (which cause hepatorenal failure) and NSAIDs (which cause bleeding).

INTRODUCTION

Biliary and pancreatic disease places a major burden on healthcare systems worldwide. In the West, acute pancreatitis and gallstone disease are the two most common gastrointestinal causes of urgent hospital admission. Pancreatic and biliary tree neoplasms carry a poor prognosis, pose significant diagnostic challenges and are increasing in incidence.

Patients with diseases of the biliary tract and pancreas may be cared for as inpatients and outpatients by either gastroenterologists or hepatologists, depending on local services, with complex disease being looked after in specialist centres where there is hepatobiliary surgical, radiological and endoscopic support. Endoscopic retrograde cholangiopancreatography (ERCP) and endoscopic ultrasound (EUS) are core procedures, allowing a range of interventions including stone extraction, stent placement and direct biopsy of lesions.

Key skills in this field include:

- managing emergency conditions, such as ascending cholangitis and acute pancreatitis
- being aware of the need for vigilance in the early diagnosis of pancreatic cancer and cholangiocarcinoma
- opportunities for learning about biliary tract and pancreatic disease include searching out, interviewing and examining inpatients with these conditions (who may be cared for on general surgical or gastrointestinal wards), observing ERCP and EUS procedures, and seeking to understand any treatment strategies employed. Attending an upper gastrointestinal surgical clinic and acute surgical on call, a surgical list to observe a laparoscopic cholecystectomy, and an upper gastrointestinal multidisciplinary team meeting may all prove useful.

**CORE SKILLS AND KNOWLEDGE**

In developed countries, up to 15% of the adult population have gallstones, which are the leading cause of hepatobiliary disease; although in many they do not cause symptoms, acute pancreatitis and ascending cholangitis are serious conditions with a significant mortality. Cancers of the pancreas and gallbladder are not uncommon, and often present late.

**INTRODUCTION**

Biliary and pancreatic disease places a major burden on healthcare systems worldwide. In the West, acute pancreatitis and gallstone disease are the two most common gastrointestinal causes of urgent hospital admission. Pancreatic and biliary tree neoplasms carry a poor prognosis, pose significant diagnostic challenges and are increasing in incidence.

Patients with upper abdominal pain (acute or chronic), cholestasis (painless or painful) or insidious onset of weight loss commonly present in primary and secondary care. Such presentations can represent major underlying pathology and should warrant prompt and appropriate investigation.

Key skills for managing pancreatobiliary disease include the ability to:

- recognize patterns of liver enzyme derangement, including cholestasis
- manage severe sepsis complicating biliary disease
- select a rational imaging modality for upper abdominal pain
- recognize and manage nutritional deficiency in patients with acute and chronic pancreatitis
- recognize and institute management of diabetes that is due to pancreatitis (see Box 23.4).

Management of pancreatobiliary disease may require the appropriate use of

- pancreatic enzyme supplements
- fat-soluble vitamin supplements (vitamins A, D and K)
- proton pump inhibitors to improve pancreatic enzyme function
- chemotherapy drugs in the management of pancreatic adenocarcinoma

Ultrasound, computed tomography (CT) and magnetic resonance imaging (MRI) technology enables the biliary tree and pancreas to be visualized with increasing resolution. Widespread use of such imaging has led to improved diagnosis but also to a burgeoning need to characterize and manage incidental, small, often asymptomatic lesions, particularly in the pancreas.

Endoscopic diagnosis of pancreatobiliary disease has been enhanced by improvements in EUS technology, and the re-emergence of direct cholangioscopy for visualization of the bile duct. Therapeutic endoscopy and laparoscopic surgery are now widely available and permit a minimally invasive approach to the management of almost all gallstone disease, and to the resection or palliation of pancreatobiliary cancer.
Biliary tract and pancreatic disease

BILIARY SYSTEM

Bile canaliculi form a network between the hepatocytes. These join to form thin bile ductules, which, in turn, enter the bile ducts in the portal tracts. These then combine to form the right and left hepatic ducts, which leave each liver lobe. The hepatic ducts join at the porta hepatis to form the common hepatic duct. The cystic duct connects the gall bladder to the lower end of the common hepatic duct. The gall bladder lies under the right lobe of the liver, and stores and concentrates hepatic bile; its capacity is approximately 50 mL. The common bile duct (CBD) is formed at the junction of the cystic and common hepatic ducts, and is 8 mm or less in diameter, passing through the head of the pancreas and narrowing at its lower end to pass into the duodenum. The CBD and pancreatic duct open into the second part of the duodenum, most often through a common channel at the ampulla of Vater, which contains the muscular sphincter of Oddi. This contracts rhythmically and prevents all of the bile from entering the duodenum, by maintaining a higher pressure than the gall bladder in the fasting state.

Gallstone disease represents a major cause of patient morbidity, particularly in the Western world, and has a major impact on healthcare economics. Gallstones may be present at any age but are unusual before the third decade. Their prevalence is strongly influenced by both age and gender. There is a progressive increase in the presence of gallstones with age and the prevalence is 2–3 times higher in women than in men, although this difference is less marked in the sixth and seventh decades. At this age the prevalence ranges between 20% and 30%. The increase in life expectancy is reflected in a greater burden of symptomatic gallstone disease. There are considerable racial differences, gallstones being more common in Scandinavians, South Americans and Native North Americans but less so in Asian and African groups. These racial differences may reflect both genetic and dietary factors. Some of these differences are being eroded by the adoption of Western diets containing high cholesterol in countries with emerging economies.

Pathogenesis

Types of gallstone

The large majority of gallstones are of two types: cholesterol stones (containing >50% of the sterol) and, less frequently, pigment stones, predominantly composed of calcium bilirubinate or polymer-like complexes with calcium, copper and some cholesterol.

Cholesterol gallstones

This type of stone accounts for 85% of gallstones in the Western world. The formation of cholesterol stones is the consequence of cholesterol crystallization from gall bladder bile. This is dependent on three factors:

- cholesterol supersaturation of bile
- crystallization-promoting factors within bile
- motility of the gall bladder.

The majority of cholesterol is derived from hepatic uptake from dietary sources. However, hepatic biosynthesis may account for up to 20%. The rate-limiting step in cholesterol synthesis is β-hydroxy-β-methyl glutaryl CoA (HMG-CoA) reductase, which catalyses the first step: that is, the conversion of acetate to mevalonate.

- The cholesterol formed is co-secreted with phospholipids into the biliary canaliculus as unilamellar vesicles.
- Cholesterol will crystallize into stones only when the bile is supersaturated with cholesterol relative to the bile salt and phospholipid content. This can occur as a consequence of excess cholesterol secretion into bile, which, in some instances, has been shown to be due to an increase in HMG-CoA reductase activity.
- Increased secretion of cholesterol into bile has also been associated with insulin resistance and the metabolic syndrome (see p. 1250).
- A high-cholesterol diet increases biliary cholesterol secretion and decreases bile salt synthesis and the bile salt pool in cholesterol gallstone subjects but not in controls.

These findings suggest that increased intestinal uptake of the sterol could play a role in gallstone pathogenesis. In support of this observation, pharmacological inhibition of cholesterol absorption prevents gallstone formation in a mouse model. Ezetimibe is a highly selective intestinal cholesterol absorption inhibitor, suppressing the uptake of dietary and biliary cholesterol across the brush border membrane of the enterocyte. This may offer a potential therapy for the management/prevention of gallstone formation in patients.

While cholesterol supersaturation of bile is essential for cholesterol stone formation, many individuals in whom such supersaturation occurs will never develop stones. It is the balance between cholesterol crystallizing and solubilizing factors that determines whether cholesterol will crystallize out of solution. A number of lipoproteins have been reported as putative crystallizing factors.

Statins are effective in the treatment of hypercholesterolaemia by competitively inhibiting HMG-CoA reductase. There is emerging evidence that statins reduce cholesterol secretion into bile and, by doing so, promote gallstone dissolution. The prevalence of gallstone disease in patient groups taking statins for the management of hypercholesterolaemia appears to be reduced.

Leptin (see p. 1247) has been shown to increase cholesterol secretion into bile. Elevated levels of leptin during rapid weight loss may account for the increased incidence of cholesterol gallstones.

An alternative mechanism of supersaturation is a decreased bile salt content, which may occur as a consequence of bile salt loss (e.g. terminal ileal resection or ileal involvement with Crohn’s disease).

The composition of the bile salt pool may also influence the ability to maintain cholesterol in solution. There is evidence that an increased proportion of deoxycholic acid (a hydrophobic bile acid) in the bile acid pool may predispose to cholesterol stone formation. This has been linked with slow colonic transit, during which cholic acid, the primary bile acid, may undergo microbial enzyme metabolism, yielding deoxycholic acid, which is then absorbed back into the bile salt pool (see Fig. 34.5).

Evidence from epidemiological, family and twin studies points to the role of genetic factors in gallstone formation. A number of lithogenic genes have been identified, which may interact with environmental factors. The process of bile formation is maintained by a network of adenosine triphosphate-binding cassette (ABC) transporters in the hepatocyte canalicular membrane, which enables biliary secretion of cholesterol, bile salts and phospholipids. This process is regulated by the nuclear receptors farnesoid X receptor (FXR) and liver X receptor (LXR). Loss-of-function mutations in specific ABC transporter genes have been associated with cholesterol gallstones secondary to bile salt and phospholipid deficiencies within the nascent bile (Fig. 35.1). However, monogenic susceptibility appears uncommon. There are rare cases in which a single
Biliary system

Missense mutation of the multidrug-resistant (MDR3) gene has been associated with extensive intra- and extrahepatic cholestasis at an early age (<40 years).

Gall bladder motility represents a further factor that may influence the cholesterol crystallization from supersaturated bile. There is evidence from animal models that gall bladder stasis leads to cholesterol crystallization mediated by hypersecretion of mucin. Abnormalities of gall bladder motility have been suggested as factors in such circumstances as pregnancy, multiparity and diabetes, as well as octreotide-related gall bladder stones (see p. 638). Recognized risk factors for cholesterol gallstones are shown in Box 35.1.

Bile pigment stones

The pathogenesis of pigment stones is entirely independent of cholesterol gallstones. There are two main types of pigment gallstone: black and brown.

Black pigment gallstones are composed of calcium bilirubinate and a network of mucus glycopolymers that interlace with salts, such as calcium carbonate and/or calcium phosphate. These stones range in colour from deep black to very dark brown and have a glass-like cross-sectional surface on fracturing. Because hyperbilirubinaemia is the critical risk factor, black stones are associated with all major haemolytic anaemias, such as spherocytosis, sickle cell disease and thalassaemia, and also with subclinical haemolysis from prosthetic valve replacements, malaria, hypersplenism from hepatic cirrhosis, and foot trauma in long-distance runners. An increased prevalence of black pigment gallstones is also seen in Gilbert’s syndrome (see p. 1272), which is associated with enhanced biliary secretion of monoglucuronosyl bilirubin.

There is evidence that bile salt loss into the colon (consequent on ileal resection or ileal disease) promotes solubilization and colonic reabsorption of bilirubin. This enhances the enterohepatic circulation and biliary secretion of bilirubin with the formation of gallstones. Pigment stones have also been linked with bacterial colonization of the biliary tree. Some pigment stones have been shown to contain bacteria, many of which produce glucuronidase and phospholipase, factors that are known to facilitate stone formation. It is speculated that this subclinical bacterial colonization of the bile duct is responsible for pigment stone formation.

Brown pigment stones are usually of a muddy hue and, on cross-section, seem to have alternating brown and tan layers. These stones are composed of calcium salts of fatty acids, as well as calcium bilirubinate. They are almost always found in the presence of bile stasis and/or biliary infection. Brown stones can form in any part of the biliary tree secondary to chronic stasis and the presence of anaerobic bacterial infection.

The Oriental hepatolithiasis syndrome (recurrent pyogenic cholangitis) is the most serious manifestation of pigment stone disease. Biliary strictures are formed, possibly due to nematode or fluke infestation within the extrahepatic and intrahepatic bile ducts. Ascaris lumbricoides, Clonorchis sinensis and Opisthorchis viverrini are the parasites most commonly recognized with this condition. Brown stones may also be the cause of recurrent bile duct stones following cholecystectomy, and are also found in the intrahepatic bile ducts in stenosing biliary disease such as Caroli’s syndrome and primary sclerosing cholangitis.

Clinical features

The majority of gallstones are asymptomatic and remain so during a person’s lifetime. Gallstones are increasingly detected as an incidental finding at the time of either abdominal radiography or ultrasound scanning (Fig. 35.2). Over a 10–15-year period, approximately 20% of these stones will be the cause of symptoms and 10% will involve severe complications. Once gallstones have become symptomatic, there is a strong trend towards recurrent complications, often of increasing severity. Gallstones do not cause dyspepsia, fat intolerance, flatulence or other vague upper abdominal symptoms.

The clinical syndromes associated with gallstones are shown in Fig. 35.3.
Biliary colic

Biliary colic is the term used for the pain associated with the temporary obstruction of the cystic or common bile duct by a stone usually migrating from the gall bladder. Despite the term ‘colic’, the pain of stone-induced ductular obstruction is of sudden onset, severe but constant (not like a ‘colic’), and has a crescendo characteristic. Some patients relate the symptoms to over-indulgence with food, particularly when this has a high fat content. The most common time of day for such an episode is in the mid-evening, lasting until the early hours of the morning.

Acute cholecystitis

The initial event in acute cholecystitis is the obstruction of gall bladder emptying. In 95% of cases a gall bladder stone can be identified as the cause (Fig. 35.4). Such obstruction results in an increase of gall bladder glandular secretion, leading to progressive distension that, in turn, may compromise the vascular supply to the gall bladder.

There is also an inflammatory response secondary to retained bile within the gall bladder. Infection is a secondary phenomenon following this sequence of obstructive, inflammatory and vascular events.

The initial clinical features of an episode of cholecystitis are similar to those of biliary colic described earlier. Over a number of hours, however, there is progression with severe localized right upper quadrant abdominal pain corresponding to parietal peritoneal involvement in the inflammatory process. The pain is associated with tenderness and muscle guarding or rigidity. This is frequently manifest by Murphy’s sign, consisting of pain on taking a deep breath when the examiner’s fingers are on the approximate location of the gall bladder. Occasionally, the gall bladder can become distended by pus (an empyema) and, rarely, an acute gangrenous cholecystitis develops, which can perforate, with generalized peritonitis.

Investigations

Biliary colic as a consequence of a stone in the neck of the gall bladder or cystic duct is unlikely to be associated with significant abnormality of laboratory tests. Abdominal ultrasound scan is the single most useful investigation for the diagnosis of gallstone-related disease (see Fig. 35.2).

Acute cholecystitis is usually associated with a moderate leucocytosis and raised inflammatory markers (e.g. C-reactive protein, CRP). Serum bilirubin, alkaline phosphatase and amiontransferase
levels may be marginally elevated in the presence of cholecystitis alone, even in the absence of bile duct obstruction. More significant elevation of the bilirubin and alkaline phosphatase is in keeping with bile duct obstruction. Abdominal ultrasound has a positive predictive value of 92% and a negative predictive value of 95% in patients with a clinical history of acute cholecystitis and Murphy’s sign. Look for:

- **gallstones** within the gall bladder, particularly when these are obstructing the gall bladder neck or cystic duct
- **focal tenderness** over the underlying gall bladder
- **thickening of the gall bladder wall**, which may also be seen with hypoalbuminaemia, portal hypertension and acute viral hepatitis.

Gallstones are a common finding in an ageing population, and in the absence of specific symptoms great care should be taken when determining whether the gallstones are responsible for any symptoms.

**Differential diagnosis**

Typical cases of biliary colic are usually suspected on the clinical history. The differential diagnosis includes irritable bowel syndrome (spasm of the hepatic flexure), carcinoma of the right side of the colon, atypical peptic ulcer disease, renal colic and pancreatitis.

The differential diagnosis of acute cholecystitis includes a number of other conditions marked by severe right upper quadrant pain and fever: for example, acute episodes of pancreatitis, perforated peptic ulceration or an intrahepatic abscess. Conditions above the right diaphragm, such as basal pneumonia, as well as myocardial infarction, may mimic the clinical picture on occasion.

**Management**

**Cholecystectomy**

Cholecystectomy is the treatment of choice for virtually all patients with symptomatic gall bladder stones. In patients admitted with specific gallstone-related complications (see later), cholecystectomy should be carried out during the period of that admission to prevent the risk of recurrence. For those presenting with pain alone, an elective procedure can be planned but the waiting time should be minimized to avoid the high risk of recurrent symptoms (approximately 30% over 4 months) and the need for another hospital admission.

Cholecystectomy should not be performed in the absence of typical symptoms just because stones are found on investigation. There is an ongoing debate as to whether prophylactic cholecystectomy is justified in young patients found to have small stones. Such patients have a long period over which they may develop symptomatic disease and small stones are an independent risk factor for the potentially serious complication of gallstone pancreatitis. The most recent guidance available does not recommend prophylactic surgery.

The laparotomy approach to cholecystectomy has now been replaced by the laparoscopic technique. Postoperative pain is minimized with only a short period of ileus and the early ability to mobilize the patient. Laparoscopic cholecystectomy can be safely carried out on a day-care basis in an elective setting in otherwise fit patients. This has considerable cost benefits over open cholecystectomy, which is now reserved for a small proportion of patients with contraindications, such as extensive previous upper abdominal surgery, ongoing bile duct obstruction or portal hypertension.

In approximately 5% of cases, a laparoscopic cholecystectomy is converted to an open operation because of technical difficulties: in particular, adhesions in the right upper quadrant or difficulty in identifying the biliary anatomy.

**Acute cholecystitis**

The initial management is conservative, consisting of keeping the patient nil by mouth, and administering intravenous fluids, opiates analgesia and intravenous antibiotics. Bacteria that are commonly associated with cholecystitis include *Escherichia coli, Bacteroides fragilis, Klebsiella, Enterococcus* and *Pseudomonas* species. Antibiotic selection is dictated by local policy and is guided by the severity of any associated sepsis and the result of any blood culture. Options include extended-spectrum cephalosporins (e.g. ceftriaxone) in combination with metronidazole, piperacillin/tazobactam or imipenem/meropenem.

Cholecystectomy is usually delayed for a few days to allow the symptoms to settle but can then be carried out quite safely in the majority of cases.

When the clinical situation fails to respond to this conservative management, particularly if there is increasing pain and fever, an empyema or gangrene of the gall bladder may have occurred. In this circumstance, urgent imaging (transabdominal ultrasound or CT scan) is required to define the pathology. Surgical intervention is usually needed, although a radiologically placed gall bladder drain can be used as a temporizing measure for the management of an empyema. The placement of a drain is the best option in patients who are considered unfit for early surgery (because of ongoing sepsis or significant co-morbidity).

**Specific complications of cholecystectomy**

These include a biliary leak, either from the cystic duct or the gall bladder bed. Injury to the bile duct itself occurs in up to 0.5% of laparoscopic operations and may have serious long-term sequelae in the form of a bile duct stricture and secondary biliary liver injury. Injuries to the extrahepatic biliary tree are more likely with variant duct anatomy, such as a low cystic duct insertion or draining of the cystic duct into the right posterior ducts rather than the CBD. There is an overall mortality of 0.2% associated with cholecystectomy.

**Stone dissolution and shock wave lithotripsy**

These non-surgical techniques for the management of gall bladder stones are used infrequently but still have a role in a few highly selected patients who may not be fit for cholecystectomy or have declined the surgical option.

**Stone dissolution**

Pure or near-pure cholesterol stones can be solubilized by increasing the bile salt content of bile. Most experience is with oral ursodeoxycholic acid. The approach requires long-term therapy and the recurrence rate of gallstones is high when therapy is stopped. Additional pharmacological tools for treating cholesterol gallstones include cholesterol-lowering agents that inhibit hepatic cholesterol synthesis (statins) or intestinal cholesterol absorption (ezetimibe), or drugs acting on specific nuclear receptors involved in cholesterol and bile acid homeostasis (see p. 1266).

**Extracorporeal shock wave lithotripsy**

A shock wave can be directed either radiologically or by ultrasound on to gall bladder stones. This technique was highly successful but only in a restricted patient population. The cystic duct requires patency for stone fragments to pass. Recurrence rates are high but may be reduced by the pharmacological approaches discussed earlier.

**Post-cholecystectomy syndrome**

This refers to right upper quadrant pain, often biliary in type, which occurs a few months after the cholecystectomy but may be delayed for a number of years. The patients often comment that the pain is
identical to that for which the original operation was carried out. In many cases, this syndrome is related to a functional large bowel disorder with colonic spasm at the hepatic flexure (hepatic flexure syndrome). It may be speculated that a functional gut disorder may have been responsible for the original pain that led to the cholecystectomy. In a small proportion of patients the pain is the result of a retained CBD stone; in a further subsection sphincter of Oddi dysfunction is a potential cause.

**Sphincter of Oddi dysfunction**

Sphincter of Oddi dysfunction (SOD) is a clinical syndrome of biliary or pancreatic pain and is caused by either:

- sphincter of Oddi stenosis, e.g. following prior instrumentation or passage of stones; or
- sphincter of Oddi hypertension.

A full history of the type of pain is performed, as well as an assessment of serum liver biochemistry and amylase during, and between, episodes of pain.

**Biliary SOD**

In **type I** disease, patients have biliary-type pain with both raised serum bilirubin, alkaline phosphatase or aminotransferases during episodes and a distended CBD on imaging.

In **type II** disease, patients have biliary-type pain and **either** abnormal liver biochemistry during episodes or a distended CBD.

In **type III** disease, there is recurrent biliary-type pain but no abnormality in the liver biochemistry and a normal-calibre CBD.

**Management** is as follows:

- Type I SOD usually responds to endoscopic sphincterotomy.
- Type II SOD sometimes responds to endoscopic sphincterotomy.
- Type III SOD does not respond to endoscopic sphincterotomy and therefore this should not be performed.

**Pancreatic SOD**

In **type I** disease, patients have recurrent pancreatic pain, a raised serum amylase and a dilated pancreatic duct.

In **type II** disease, patients have recurrent pancreatic pain with **either** transient hyperamylasaemia or a dilated pancreatic duct.

In **type III** disease, patients have pain but neither an elevated amylase nor a dilated pancreatic duct.

**Management** is as follows:

- Types I and II SOD may respond to endoscopic sphincterotomy.
- Type III SOD with pain only does not respond to endoscopic sphincterotomy.

**Common bile duct stones**

The classical features of CBD stones are biliary colic, fever and jaundice (acute cholangitis). This triad is present only in a minority of patients. Abdominal pain is the most common symptom and has the typical features of biliary colic (see earlier). Jaundice is a variable accompaniment and is almost always preceded by abdominal pain. A patient with bile duct stones may experience sequential episodes of pain, only some of which are accompanied by jaundice. In contrast to malignant bile duct obstruction, the level of jaundice associated with CBD stones characteristically tends to fluctuate. In the elderly or immunocompromised patient, cholangitis may present with very non-specific symptoms, and only associated abnormal liver biochemistry may point to the diagnosis.

Fever is present only in a minority of cases but indicates biliary sepsis and sometimes associated sepsicaemia. The presence of such biliary sepsis is a significant adverse prognostic factor.

A minority of patients with bile duct stones are discovered incidentally during imaging for gall bladder disease or other intra-abdominal pathology. Some 15% of patients undergoing cholecystectomy will have stones within the bile duct that are detected only at the time of operative cholangiography. The frequency of asymptomatic bile duct stones resulting in complications is not well documented. It is likely that many such stones will pass into the duodenum without causing symptoms. However, the potential for serious complication is well recognized; in most circumstances, incidentally identified bile duct stones are removed (see later).

**Examination**

If the patient is examined between episodes, there may be no abnormal physical finding. During a symptomatic episode the patient may be jaundiced with a fever and associated tachycardia. There is tenderness in the right upper quadrant, varying from mild to extremely severe.

More widespread abdominal tenderness extending from the epigastrium to the left upper quadrant, associated with distension, may indicate associated stone-related pancreatitis (see later).

**Investigations**

**Laboratory tests**

- **Full blood count** is usually normal in the presence of uncomplicated bile duct stones.
- **An elevated neutrophil count** and raised inflammatory markers (erythrocyte sedimentation rate (ESR) and CRP) are frequent accompaniments of cholangitis.
- **The raised serum bilirubin** tends to be mild and often transient. Very high concentrations of bilirubin (>200 μmol/L) almost always reflect complete bile duct obstruction.
- **Serum alkaline phosphatase and γ-glutamyl transpeptidase** are similarly elevated in proportion to the degree of hyperbilirubinaemia.
- **Aminotransferase levels** are usually mildly elevated, but with complete bile duct obstruction there may be very marked rises to 10–15 times the normal value. The alanine aminotransferase is characteristically higher than the aspartate aminotransferase. These high levels may lead to an initial misdiagnosis of a hepatic process.
- **Serum amylase levels** are often mildly elevated in the presence of bile duct obstruction but are markedly so if stone-related pancreatitis has occurred.
- **Prothrombin time** may be prolonged if bile duct obstruction has occurred and is sustained over several days; this reflects decreased absorption of vitamin K.

**Imaging**

- **Transabdominal ultrasound** is the initial imaging technique of choice. **Bile duct obstruction** is characterized by dilatation of intrahepatic biliary radicles, which are usually readily detected by the ultrasound scan. It may, however, not be possible to identify the cause of obstruction. Stones situated in the distal CBD are poorly visualized by transabdominal ultrasound and up to 50% are missed. The detection of stones within the gall bladder is poorly predictive of the cause of bile duct obstruction. Asymptomatic gallstones are common (up to 15%) in patients who are 65 years and older. Conversely, in 5–10% of patients with bile duct stones, no calculi can be seen within the gall bladder.
• **Magnetic resonance cholangiography (MRC)** delineates the fluid column within the biliary tree and is a sensitive technique for the detection of CBD stones in the presence of a dilated duct. The technique may be less accurate in the absence of duct dilation (see the role of EUS, later) (Fig. 35.5).

• **CT scanning** is an alternative way to detect bile duct dilation. Opaque stones are more readily identifiable within the bile duct than radiolucent cholesterol stones. CT scanning also provides a means of excluding other causes of bile duct obstruction, such as carcinoma of the head of the pancreas.

• **EUS (Fig. 35.6)** has enabled high-resolution imaging of the CBD, gall bladder and pancreas, although, unlike the preceding imaging techniques, it is an invasive procedure. The EUS probe in the duodenum is in close proximity to the distal CBD and hence can identify the majority of stones at this level. This technique is particularly useful for identifying small calculi (microcalculi) in a non-dilated CBD.

• **Endoscopic retrograde cholangiography (ERC).** In experienced hands, visualization of the CBD will be successful in 98% of cases, providing good documentation of bile duct stones (Fig. 35.7; see also Fig. 35.5). However, small stones can still be missed. ERC is an invasive procedure with recognized risks. In almost all circumstances, this is a therapeutic tool used to remove the stones that have been identified by the less invasive investigations described earlier.

### Differential diagnosis

Cholangitis may occur independently of gallstones in any condition associated with impaired biliary drainage. It is commonly linked with primary abnormalities of the biliary tree, such as sclerosing cholangitis and Caroli’s syndrome (a congenital disorder leading to ectasia/dilation of the intrahepatic bile ducts). Cholangitis may also complicate post-traumatic or surgery-associated bile duct strictures. It is unusual in malignant bile duct obstruction unless...

---

**Fig. 35.5** A patient presenting with abdominal pain and jaundice. (A) A magnetic resonance cholangiogram (MRC) shows evidence of a distal common bile duct stricture (bottom arrow) with a stone in the bile duct proximal to this (top arrow). (B) An endoscopic retrograde cholangiopancreatogram (ERCP) in the same patient confirms the details identified in the MRC scan. The stones (arrowed) were removed at the time of the ERCP after initial dilation of the stricture.

**Fig. 35.6** An endoscopic ultrasound scan with the probe in the first part of the duodenum. (A) The gall bladder (GB) and multiple small, echo-poor stones within (microlithiasis). The patient had presented with recurrent episodes of unexplained abdominal pain. (B) The common bile duct (CBD) and a stone (S) clearly identified within the lumen.
The cholangiogram shows a dilated common bile duct (between thick arrows) and multiple stones within (arrowed). These stones were removed at the time of ERCP by means of balloon and basket retrieval. Note the multiple clips to the left of the upper bile duct, which were placed at a prior laparoscopic cholecystectomy.

Management

Acute cholangitis has a high morbidity and mortality, particularly in the elderly or those with serious co-morbidity. Successful management depends on intravenous antibiotics (as for acute cholecystitis) and urgent bile duct drainage. In most circumstances the latter is achieved by the endoscopic retrograde approach (ERCP, see earlier). Access to the bile duct is achieved by sphincterotomy and thereafter the stones can be removed by either balloon or basket catheters. In the severely ill patient a plastic stent (a small tube prosthesis) can be inserted into the bile duct to maintain bile drainage without the need to remove the stones, hence minimizing the time required to complete the procedure. The residual stones can then be cleared and the stent removed endoscopically when the patient has recovered from the acute episode. If endoscopic drainage is not available or is prevented by an inability to access the second part of the duodenum, a radiologically placed percutaneous biliary drain represents an alternative management option. Surgical drainage during an acute cholangitic episode has been associated with a high mortality and has been replaced by the endoscopic or percutaneous approach.

Urgent endoscopic bile duct clearance is also indicated in some patients with acute gallstone pancreatitis but only when this coexists with persisting bile duct obstruction (see later). Patients who have retained CBD stones after a previous cholecystectomy are also optimally managed by endoscopic clearance.

Patients shown to have CBD stones as well as gall bladder stones may be treated using different approaches:

- **At the time of laparoscopic cholecystectomy**, which can also include exploration of the CBD via the cystic duct or via direct choledochotomy. By using these techniques the surgeon can extract stones from the CBD. The skills and time required for bile duct exploration are considerably greater than those for laparoscopic cholecystectomy alone. This single-procedure approach minimizes the length of hospital admission. Concerns around an increased risk of bile duct injury with bile duct exploration have not been confirmed in controlled studies.

- **An independently timed endoscopic approach**, either immediately before or after the cholecystectomy. Removal of CBD stones by this method is preferred in the UK. Large bile duct stones (>10 mm) may present a significant challenge to endoscopic removal. Mechanical lithotripsy facilitates stone fragmentation and removal into the duodenum. Extracorporeal shock wave stone fragmentation has been used but is not widely available. The recently increased availability of endoscopic cholangioscopy (direct visualization of the bile duct) has facilitated intraductal shock wave lithotripsy, utilizing electrohydraulic or laser probes.

- **A combined laparoscopic and endoscopic approach**, in which an ERC and duct clearance are carried out under the same anaesthetic used for the laparoscopic cholecystectomy. This approach leads to a shortened hospital stay and the use of only one anaesthetic.

Complications of gallstones

- Acute cholecystitis and acute cholangitis are discussed on page 1316.
- Gallstone-related pancreatitis is discussed on page 1329.
- Gallstones can occasionally erode through the wall of the gall bladder into the intestine, giving rise to a biliary enteric fistula. Passage of a gallstone through to the small bowel can give rise to an ileus or true obstruction.
- There is little evidence that gallstones are associated with an increased risk of adenocarcinoma of the gall bladder (see p. 1322).

**Gall bladder**

There are a number of non-calculous conditions of the gall bladder, some of which have been associated with symptoms.

**Acalculous cholecystitis**

Almost 10% of gall bladders removed for biliary symptoms are shown to have chronic inflammation within the wall but an absence of gallstones. Such cases are described as acalculous cholecystitis. In many instances the gall bladder inflammation is minor and of doubtful significance. In some cases, chemical inflammation of the gall bladder may occur from reflux of pancreatic enzymes back into the biliary tree, usually through the common channel at the ampulla of Vater. Bacterial and viral infections of the gall bladder have been recognized as a cause of acalculous cholecystitis. The decision to carry out cholecystectomy in the absence of defined gall bladder
stones should be guided by the specific features of the history and by evidence of a diseased gall bladder wall on ultrasound scanning.

A distinct subtype of acalculous cholecystitis is characterized by severe necroinflammation of the gall bladder and generally occurs in an elderly and already critically ill group of patients, usually after major trauma or surgery. Around 20% of these patients develop inflammatory masses with subsequent cholestasis and jaundice; gall bladder perforation is a frequent complication. Morbidity and mortality are very high, and aggressive management of sepsis with antibiotics and cholecystostomy (percutaneous gall bladder drainage) or urgent cholecystectomy is required.

**Cholesterosis of the gall bladder**

In cholesterosis, cholesterol and other lipids are deposited in macrophages within the lamina propria of the gall bladder wall. These may be diffusely situated, giving a granular appearance to the gall bladder wall, or on occasion may be more discrete, giving a polypoid appearance (see later). Cholesterosis of the gall bladder may coexist with gallstones but also occurs independently. Some degree of gall bladder cholesterolosis is found in up to 26% of laparoscopic cholecystectomy specimens, and as an incidental finding in up to 12% of autopsies in an elderly population. Interestingly, in contrast to cholelithiasis, rates are equal in men and women. It is doubtful whether isolated gall bladder cholesterolosis is a cause of symptoms.

**Adenomyomatosis of the gall bladder**

Adenomyomatosis is a gall bladder abnormality characterized by hyperplasia of the mucosa, thickening of the muscle wall and multiple intramural diverticula (the so-called ‘Rokitansky–Aschoff sinuses’).

The condition is usually detected as an incidental finding during investigation for possible gall bladder disease. It has been suggested that this condition is secondary to increased intraluminal gall bladder pressure but this is not proven. Gallstones frequently coexist, particularly when the adenomyomatosis is in a segmental distribution, but there is no evidence to support a direct relationship. It is unlikely that adenomyomatosis alone is a cause of biliary symptoms and it is not considered a pre-malignant state.

**Chronic cholecystitis**

There are no symptoms or signs that can conclusively be shown to be due to chronic cholecystitis. Symptoms attributed to this condition are vague, such as indigestion, upper abdominal discomfort or distension. There is no doubt that gall bladders studied histologically can show signs of chronic inflammation and, occasionally, a small, shrunken gall bladder is found either radiologically or on ultrasound examination. However, these findings can be seen in asymptomatic people and therefore this clinical diagnosis should not be made. Most patients with chronic right hypochondrial pain suffer from functional bowel disease (see p. 1159).

**Extrahepatic biliary tract**

**Primary sclerosing cholangitis**

In up to 40% of patients with primary sclerosing cholangitis (PSC; see also p. 1187) the clinical course is influenced by a dominant hilar or distal biliary stricture. This is relevant in those patients who do not have established advanced liver involvement, in whom maintenance of bile flow may protect the liver from secondary biliary injury. Drainage with a surgical hepatocojejunostomy has been beneficial in some cases, but outcomes of such restricted surgery in PSC are generally inferior to those of orthotopic liver transplantation. Repeated endoscopic balloon dilation of the dominant stricture, with or without temporary short-term stenting, has been associated with sustained improvement in jaundice and even prolonged transplant-free survival. A significant minority of dominant strictures in PSC, particularly those at the hilum, represent development of an associated cholangiocarcinoma (see later). Development of cholangiocarcinoma in this context carries a very poor prognosis and surgical resection is rarely feasible. A benign dominant stricture in a non-cirrhotic patient, with recurrent cholangitis, refractory jaundice and pruritus, may be an indication for orthotopic liver transplantation. Conversely, superadded cholangiocarcinoma is currently an absolute contraindication to liver transplantation in most healthcare systems.

**Autoimmune cholangitis**

Immunoglobulin (Ig) G4-associated cholangitis is the biliary manifestation of a multisystem fibro-inflammatory disorder in which affected organs have a characteristic lymphoplasmacytic infiltrate rich in IgG4-positive cells (see p. 65). The original description of this condition was in the context of autoimmune pancreatitis and around 70% of these patients have evidence of IgG4 cholangiopathy (see p. 1330). However, IgG4 cholangiopathy can exist in the absence of pancreatic involvement.

The large majority of cases are recognized in middle-aged or elderly men. Presentation is varied, depending on the systems involved, but may include abdominal pain and jaundice. Both intra- and extrahepatic biliary strictures may be seen and the findings may be misinterpreted as representing cholangiocarcinoma or PSC. The diagnosis relies on clinical suspicion, confirmation of an elevated serum IgG4 level, a typical lymphoplasmacytic infiltrate on histological examination of involved tissue, and clinical response to glucocorticosteroid treatment. The condition is almost always responsive to steroids but can lead to hepatic failure.

**Biliary cysts (choledochal malformation)**

Cystic malformations may occur anywhere in the biliary tree, although they are most commonly extrahepatic. The resulting dilation of the bile duct may be of saccular, diverticular or fusiform configuration. In many cases there is an associated abnormal pancreaticobiliary junction – a congenital malunion where the pancreatic duct drains directly into the CBD. The majority of symptomatic cases present in childhood with features of cholangitis, jaundice or a palpable mass. The formation of stones and sludge within the cystic segment may predispose to acute relapsing pancreatitis. In adult life, choledochal cysts may be a differential diagnosis in patients presenting with symptoms suggestive of bile duct stones. Extrahepatic bile duct cysts must be fully resected to avoid recurrent biliary sepsis, as well as reducing the risk (approximately 15%) of subsequent cholangiocarcinoma.

**Benign bile duct strictures**

Benign strictures are a recognized complication of biliary surgery. They may result from inadvertent direct stapling of the duct, or may be a secondary consequence of ischaemic injury (often in association with a bile duct leak). Strictures may also occur at the level of any bile duct anastomosis, either enteric or duct-to-duct. Biliary strictureing is also a rare complication of major trauma to the right upper quadrant. The inflammation and fibrosis of chronic pancreatitis commonly impinge on the intrapancreatic CBD (see later). This can result in cholestasis, jaundice and cholangitis.
In most cases, initial therapy includes endoscopic balloon dilation of the stricture and temporary bile duct stenting (see later). This may provide definitive management, but in some cases, surgical intervention with hepaticojejunostomy is required.

Haemobilia
Haemobilia describes blood in the biliary tree. This may be a consequence of liver trauma or a complication of liver surgery. Biopsy of the liver and erosion of a gallstone or hepatobiliary tumour into adjacent structures are also well-recognized causes. The end result is a fistula between a hepatic blood vessel and a bile duct. Haemobilia may be a cause of significant gastrointestinal blood loss and should be suspected when melaena is accompanied by right-sided upper abdominal pain and jaundice, particularly in the context of recent hepatobiliary intervention. However, the bleeding may occur without any overt biliary symptoms. If the diagnosis is suspected, bleeding may be managed by occlusion of the feeding blood vessel by radiological embolization. Some patients will require surgery to control the bleeding point.

Tumours of the biliary tract

Gall bladder polyps
Polyps of the gall bladder are a common finding, being seen in approximately 4% of all patients referred for hepatobiliary ultrasonography. The vast majority of these are small (<5mm) and non-neoplastic; they are inflammatory in origin or composed of cholesterol deposits (see earlier). Adenomas are the most common benign neoplasm of the gall bladder. Only a proportion of these have cancerous potential. The only reliable predictor of malignant risk is polyp size (>10mm). Cholecystectomy is recommended for any polyp of 10mm or larger in diameter.

Carcinoma of the gall bladder
Adenocarcinoma of the gall bladder represents 1% of all cancers. The mean age of occurrence is the early sixties, with a female-to-male ratio of 3:1. Gall bladder stones are often found in association with gall bladder cancer; gallstones have been suggested as an aetiopathological factor but this relationship remains unproven. Diffuse calcification of the gall bladder (porcelain gall bladder), considered to be the end-stage of chronic cholecystitis, has been associated with cancer of the gall bladder and is an indication for early cholecystectomy. Adenomatous polyps of the gall bladder in excess of 10mm in diameter are also recognized as pre-malignant lesions (see earlier).

Carcinoma of the gall bladder may be detected incidentally at the time of planned cholecystectomy for gallstones; in such circumstances, resection of an early lesion may be curative. Radical surgery with negative resection margins offers the only potential cure. However, early lymphatic spread to the liver and adjacent biliary tract precludes curative resection in more advanced lesions. Palliative chemotherapy treatment may be given, usually with either 5-fluorouracil (5-FU)-based regimes, or gemcitabine (a nucleoside analogue) and cisplatin (a platinum-containing anticancer drug), with some evidence of a modest improvement in survival. A small proportion of cases are sensitive to radiotherapy. However, the generally advanced stage of disease at presentation means that the overall 5-year survival is less than 5%.

Cholangiocarcinoma
Cancers of the biliary tree (see also p. 1310) are classified as intrahepatic (above the hilum of the liver) or extrahepatic (involving the hilum or bile duct distal to the hilum). The latter are classified either on the TMN classification or on the site of the lesion (Bismuth–Corlette classification of biliary strictures). These malignancies represent approximately 1% of all cancers. A number of associations have been identified, such as that with choledochal malformation (see earlier) and that with primary sclerosing cholangitis (see p. 1321). Chronic infection of the biliary tree with parasitic liver flukes, particularly Opisthorchis viverrini or Clonorchis sinensis, has also been strongly implicated in areas where they are endemic. Extrahepatic bile duct malignancy usually presents with jaundice and may be confirmed on imaging tests, initially ultrasound and thereafter CT and, in particular, magnetic resonance cholangiopancreatography (MRCP; Fig. 35.8). Typical findings are of a bile duct stricture with proximal biliary dilation, with or without a visible mass. Histopathological diagnosis often proves difficult because the malignant cells are few in number and contained within a dense stroma. Endoscopically obtained cytology specimens have only 30% sensitivity. This yield can be enhanced by using additional endoscopic sampling techniques, such as transpapillary biopsy, and analytical enhancements, such as fluorescent in situ hybridization and digital image analysis. The recent application of direct endoscopic cholangioscopy has enabled direct visualization of biliary lesions and targeted biopsy.

Cholangiocarcinoma is often detected at a late stage and is characterized by early perineural, vascular and lymphatic spread. In a minority of cases, complete surgical resection is feasible, offering the only chance of cure. Cholangiocarcinoma of the CBD may be amenable to a limited bile duct resection. Very distal lesions require a pancreaticoduodenectomy (Whipple procedure), and perihepatic lesions frequently require partial hepatic resection in addition to biliary resection. In some international centres, extensive neoadjuvant chemoradiation therapy, followed by liver transplantation, has been used to cure localized hilar cholangiocarcinoma. Results from

Fig. 35.8 Magnetic resonance cholangiopancreatography (MRCP) image of hilar cholangiocarcinoma extending into the left main duct. There is a normal-calibre distal bile duct (BD) and pancreatic duct (PD). The common hepatic duct and left main duct are strictured (arrowed). There is marked intrahepatic duct (IHD) dilation.
this emerging technique show promise, but cholangiocarcinoma remains an absolute contraindication to liver transplantation in most healthcare systems worldwide due to early disease recurrence.

The majority of patients with cholangiocarcinoma are treated palliatively with biliary decompression (see later) and gemcitabine- and cisplatin-based chemotherapy regimes.

Secondary malignant involvement of the biliary tree
Carcinoma of the head of the pancreas frequently presents with CBD obstruction and jaundice. Metastases to the bile duct from distant cancers are uncommon. Melanoma is the most frequent neoplasm to do so. Infiltration of the bile duct is not uncommon in disseminated lymphoma. Other carcinomas that may give rise to bile duct metastases, in order of frequency, are those arising in the lung, breast and colon, as well as those from the pancreas (metastatic as compared to direct infiltration).

Management
Palliation of malignant bile duct obstruction
All patients must be fully staged for operability using the imaging techniques described earlier. However, in the greater proportion of patients the treatment is palliative. Relief of bile duct obstruction has been shown to improve quality of life considerably and, with pain control, is the mainstay of effective palliation. Effective biliary decompression is also critical in jaundiced patients who wish to proceed with palliative chemotherapy. In recent years, endoscopic techniques have allowed the insertion of stents into the biliary tree to re-establish bile flow. The initial use of plastic stents has largely been replaced by self-expanding metal stents that have considerably longer periods of patency (Fig. 35.9). In the small proportion of patients in whom bile duct drainage is not possible endoscopically, the percutaneous route offers an alternative method of stent placement under radiological control.

PANCREAS
Anatomy and function
Structure
The pancreas extends retroperitoneally across the posterior abdominal wall from the second part of the duodenum to the spleen. Anatomically, it is divided into a head, which rests within the concavity of the duodenum; a body, lying behind the base of the stomach; and a tail, which ends abutting the spleen. The neck of the pancreas lies between the body and head, and is in front of the superior mesenteric artery and vein. The head of the pancreas surrounds these two vessels. An uncinate process emerges from the lower part of the head, lying behind the superior mesenteric artery. The pancreas consists of exocrine and endocrine cells. The exocrine pancreas comprises 98% of the parenchyma.

The functional unit of the exocrine pancreas is composed of an acinus and its draining ductule. A ductule from the acinus drains into interlobular (intercalated) ducts, which, in turn, drain into the main pancreatic ductal system. The main pancreatic duct itself joins the CBD to enter the duodenum as a short single duct at the ampulla of Vater.

Fig. 35.9 An endoscopic retrograde cholangiopancreatogram in a patient presenting with painless jaundice. (A) There is a tight stricture in the mid-common bile duct extending proximally over 4 cm (extent defined by arrows). The intrahepatic ducts (IHD) proximally are dilated. A guidewire (GW) has been placed endoscopically across the stricture. (B) A self-expanding metal stent has been placed across the stricture and released. The stent is compressed at the level of the stricture (arrowed) but will open fully over 24 h. The contrast in the intrahepatic ducts has largely drained through the stent. The distal margin of the stent is in the duodenum (D).
The endocrine component is scattered throughout the gland in the form of pancreatic islets (of Langerhans).

### Exocrine function

The pancreatic acinar cells are responsible for the production of digestive enzymes. These include amylase, lipase, collipase, phospholipase and the proteases (trypsin and chymotrypsin). These enzymes are stored within the acinar cells in secretory granules and are released by exocytosis (Fig. 35.10). The enzymes released by the acinar cells are transported into the duodenum by a high-volume pancreatic secretion, the majority of which is produced by the ductal cells. This fluid has a high concentration of bicarbonate, which neutralizes the gastric acid that has emptied into the duodenum. The neutralization of gastric acid is essential to facilitate pancreatic enzyme activity, which is pH-dependent (requiring a neutral pH).

After ingestion of a meal, pancreatic exocrine secretion is regulated by cephalic, gastric and intestinal stimuli. The cephalic phase is stimulated by behavioural cues related to the sight, smell and taste of food. The input from these sensory stimuli is integrated in the central nervous system at the dorsal vagal complex, and the output is transmitted to the exocrine pancreas via the vagus nerve.

The gastric phase of pancreatic secretion results from the effects of the meal in the stomach. The major stimulus of pancreatic secretion in the gastric phase is gastric distension, which causes secretion of an enzyme-rich fluid with little secretion of water and bicarbonate. This phase is also under vagal control. The intestinal phase of pancreatic secretion starts when protein, fat and gastric acid from the stomach enter the duodenum and continues for the duration of the digestive period. It is mediated by both hormones and enteropancreatic vagovagal reflexes. Feedback regulatory events eventually terminate pancreatic secretion.

- **Cholecystokinin (CCK)** plays a major role in meal-stimulated digestive enzyme secretion during the intestinal phase of pancreatic secretion. The hormone is produced in specialized gut endocrine cells (I cells) of the mucosa of the small intestine and is secreted in response to intraluminal food. There are no CCK receptors in human pancreatic cells, and CCK acts via receptors on vagal afferent fibres to stimulate pancreatic secretion.

- **Secretin** is also released from specialized enteroendocrine cells of the small intestine during a meal and, in particular, during duodenal acidification. Secretin has a direct effect on the pancreatic acinar cells, as well as the ductal cells. There is also a vagal-mediated secretory response. Secretin action is mediated via G-coupled receptors and calcium-mediated enzyme release. Secretin results in a bicarbonate-rich pancreatic secretion.

The efficiency of the digestive phase of pancreatic secretion requires a negative feedback mechanism to bring the process to a close. Completion of the postprandial secretory phase involves both neural and hormonal control.

- **Pancreatic polypeptide** is released from the islet cells of the pancreas in response to a meal and has an inhibitory effect on acinar enzyme secretion, via both a local effect and central receptors.

- **Somatostatin**, present within the pancreas, stomach and central nervous system, also has an inhibitory effect. It is released in response to food and its effect is mediated by both direct pancreatic acinar inhibition and a central nervous system inhibitory component.

- **Peptide YY (PYY)**, contained in endocrine cells of the distal small intestine is released by nutrients within the ileum and inhibits pancreatic secretion by acting on the acinar cells themselves, as well as centrally via the inhibitory regulation of vagal nerve.

There is also evidence that proteases within the duodenal lumen also have a negative feedback effect on acinar secretion. The gut-related peptides leptin and ghrelin, as well as influencing appetite behaviour, are also regulatory factors in the exocrine function of the pancreas. This effect is believed to occur via hypothalamic centres.

### Endocrine pancreas

This consists of hormone-producing cells arranged in nests or islets (islets of Langerhans). The hormones produced are secreted directly into the circulation and there is no access to the pancreatic ductular system. There are five main types of islet cell corresponding to different secretory components:

- Beta cells are the most common and are responsible for insulin production.
- Alpha cells produce glucagon.
- D cells produce somatostatin.
- PP cells produce pancreatic polypeptide.
- Enterochromaffin cells produce serotonin.

A number of other hormones have been identified within the endocrine pancreas, including gastrin-releasing peptide, neuropeptide Y and galanin. These are believed to be neurotransmitters active in the neuro-gastrointestinal axis.
Investigations

Assessment of exocrine function
Pancreatic exocrine function is assessed in the investigation of patients with possible chronic pancreatic disease. Clinically evident fat malabsorption does not occur until there has been an 85–90% reduction in pancreatic lipase and is therefore a very late manifestation of pancreatic disease.

Direct tests of pancreatic function
These tests rely on the analysis of a duodenal aspirate following pancreatic stimulation, using either naso-duodenal tube or endoscopic aspiration. The original test involved pancreatic stimulation with the oral administration of a specified meal (Lundh meal) then replaced with intravenous secretin and cholecystokinin. The aspirate was assessed for pancreatic enzymes and bicarbonate production. These procedures are invasive and require meticulous technique, and are now rarely used.

Non-invasive indirect tests of pancreatic function

Faecal tests
• Faecal elastase is an enzyme produced in the pancreas; as it is not degraded in the intestine, it has high concentrations within the faeces. Diminished levels are seen in moderate and severe pancreatic insufficiency. This assay has replaced the faecal chymotrypsin test. It is unaffected by the administration of oral pancreatic enzyme supplements. However, as it relies on the concentration of elastase within the stool sample, it can render false low results in the context of diarrhoea, or water contamination during sample collection.

• Faecal fat estimation. This is rarely performed.

Oral pancreatic function tests
• N-benzoyl-L-tyrosyl-p-aminobenzoic acid (basis of the PABA test) and fluorescein dilaurate are oral compounds utilized in pancreatic function tests. They are digested by pancreatic enzymes, releasing substrates that are excreted and measured in the urine. Both tests are commercially available and have good sensitivity in moderate to severe pancreatic exocrine failure.

Clinical application of pancreatic function tests
While the invasive duodenal aspiration tests represent the most sensitive and specific means of assessing pancreatic function, they are very rarely used outside specialized centres. The non-invasive tests are widely available but are highly sensitive only in the detection of severe pancreatic insufficiency. The faecal elastase test (in a commercially available form) provides similar sensitivity and specificity, and is the test of choice as a screening tool for pancreatic insufficiency.

Pancreatic imaging
Imaging (see p. 1270) has a pivotal role in the investigation and management of pancreatic disease, which covers the spectrum of acute, chronic and malignant conditions.

• A plain abdominal X-ray may show the calcification associated with chronic pancreatitis, particularly when alcohol is the aetiology.

• Transabdominal ultrasound of the pancreas usually offers reasonable views of the pancreas; it is a useful screening investigation for inflammation or neoplasia, and is reasonably sensitive for detection of gallstone disease in a patient with pancreatitis. Views may be limited by overlying bowel gas, and ultrasound should not be relied on in the exclusion of pancreatic neoplasia if clinical suspicion exists.

• CT scan with contrast enhancement and following a specific pancreatic protocol remains the ‘gold standard’ imaging technique for the investigation of pancreatic disease.

• MRI scanning represents an alternative to CT. MRCP gives clear definition of the pancreatic duct, as well as the biliary tree. Gallstones (including microlithiuria) may also be identified in the biliary tree using MRI/MRCP.

• Endoscopic ultrasonound (EUS) is very useful for identifying distal CBD stones, which may be the cause of an episode of acute pancreatitis. EUS can identify the early changes of chronic pancreatitis before these are evident with other imaging methods. There is also an increasing role for this technique to stage the operability of pancreatic adenocarcinoma, particularly with respect to vascular invasion. EUS is now considered the imaging technique of choice for investigating cystic lesions of the pancreas (see later). The technique allows fine-needle biopsy, as well as the therapeutic option of cyst drainage. EUS is a sensitive means of detecting small pancreatic tumours, particularly those of neuroendocrine origin.

• Endoscopic retrograde cholangiopancreatography (ERCP) is an invasive procedure and, while having a good safety profile, is associated with a small risk of serious adverse events: in particular, the precipitation of acute pancreatitis. The availability of MRCP and EUS has provided alternative means of defining pancreatic pathology. ERCP has an increasing therapeutic role in pancreatic disease (see later).

• 18F Fluorodeoxyglucose positron emission tomography (FDG-PET)/CT and 68 gallium-DOTATATE PET/CT are scintigraphic techniques with a high diagnostic accuracy in patients with suspected neuroendocrine tumours, including those of the pancreas. They are also useful in defining the location of a neuroendocrine tumour, identifying multifocal small lesions, evaluating treatment options and detecting metastatic disease.

In summary, an initial transabdominal ultrasound, supplemented by CT, provides sufficient diagnostic information for most inflammatory and neoplastic conditions of the pancreas. MRI and MRCP are now widely available and provide additional information, particularly with respect to pancreatic ductular and biliary anatomy. EUS is a useful, albeit more invasive, tool for the investigation of both benign and malignant disease of the pancreas, and facilitates fine-needle aspiration and biopsy of targetable lesions.

PANCREATITIS

Classification
Pancreatitis is divided into acute and chronic. By definition, acute pancreatitis is a process that occurs on the background of a previously normal pancreas and can return to normal after resolution of the episode. Nevertheless, acute alcoholic pancreatitis occurs only in chronic misuse of alcohol. In chronic pancreatitis there is continuing inflammation with irreversible structural changes. In practice, the differentiation between acute and chronic pancreatitis may be difficult. Any of the causes of acute pancreatitis, if untreated, may result in recurrent episodes, classified as acute relapsing pancreatitis and eventually bringing about permanent structural changes. In other cases, recurrent episodes of acute pancreatitis may represent exacerbations of an underlying chronic process.
**Acute pancreatitis**

Acute pancreatitis is a syndrome of inflammation of the pancreatic gland initiated by any acute injury. The causes of acute pancreatitis are listed in Box 35.2. In the Western world, gallstones and alcohol account for the vast majority of episodes. Alcohol also causes chronic pancreatitis (see later). The severity of the pancreatitis may range from mild and self-limiting to extremely severe, with extensive pancreatic and peripancreatic necrosis, as well as haemorrhage. In the most severe form (approximately 10% of cases) the mortality is between 40% and 80%.

**Pathogenesis**

This is still not completely understood. A precipitating event, such as gallstones or alcohol, is thought to induce the acute episode. Whatever the nature of the initiating insult, the pancreatic inflammatory response is secondary to the premature and exaggerated activation of digestive enzymes, principally trypsin, within the pancreas itself. In severe cases the subsequent cascade of autodigestion, microvascular injury, systemic inflammatory response and bacterial translocation can result in a devastating outcome.

**Gallstone pancreatitis**

The inducing effect is obstruction to pancreatic drainage at the ampulla by a stone or associated oedema. In this pathological situation, trypsinogen is cleaved (by cathepsin B) to trypsin, and trypsin degradation by chymotrypsin C is impaired and quickly overwhelmed. Intracellular calcium also increases and may also cause early activation of trypsinogen with upregulation of nuclear factor kappa B, leading to extensive acinar cell damage.

**Alcohol-induced pancreatitis**

There is evidence that alcohol interferes with calcium homeostasis in pancreatic acinar cells. In addition, activation of pancreatic stellate cells by acetaldehyde occurs, with production of collagen and then matrix proteins.

**Clinical features**

Acute pancreatitis is a differential diagnosis in any patient with upper abdominal pain. The pain usually begins in the epigastrium, accompanied by nausea and vomiting. As inflammation spreads throughout the peritoneal cavity, the pain becomes more intense. Involvement of the retroperitoneum frequently leads to back pain. The patient may give a history of previous similar episodes or be known to have gallstones. An attack may follow an alcoholic binge. However, in many cases, there are no obvious aetiological factors.

Physical examination at the time of presentation may show little more than a patient in pain with some upper abdominal tenderness but no systemic abnormalities. In severe disease the patient has a tachycardia and hypotension, and is oliguric. Abdominal examination may show widespread tenderness with guarding, as well as reduced or absent bowel sounds. Specific clinical signs that support a diagnosis of severe necrotizing pancreatitis include periumbilical (Cullen’s sign) and flank bruising (Grey Turner’s sign). In patients with gallstone aetiology the clinical picture may also include jaundice or cholangitis.

**Diagnosis**

**Blood tests**

- **Serum amylase** is an extremely sensitive test if it is three times the upper limit of normal when measured within 24 h of the onset of pain. A number of other conditions may occasionally cause a very elevated amylase (Box 35.3). Amylase levels gradually fall back towards normal over the next 3–5 days. With a late presentation the serum amylase level may give a false-negative result.
- **Urinary amylase** levels may be diagnostic, as they remain elevated over a longer period of time.
- **Serum lipase** levels are also raised in acute pancreatitis and remain elevated for a longer period of time than amylase levels. However, overall, the accuracy of serum lipase is not significantly greater than that of amylase and it is technically more difficult to measure.
- **CRP level** is useful in assessing disease severity and prognosis.

- **Other baseline investigations** include a full blood count, serum creatinine and electrolytes, blood glucose, liver biochemistry, plasma calcium and arterial blood gases. These are documented at presentation and then repeated at 24 and 48 h, providing a basis for assessing the severity of an attack (see later).

**Radiology**

- An erect chest X-ray is mandatory to exclude gastroduodenal perforation, which also raises the serum amylase (see Box 35.3). A supine abdominal film may show gallstones or pancreatic calcification.

- An abdominal ultrasound scan is used as a screening test to identify a possible biliary (gallstone) cause of pancreatitis. Gallstones are difficult to detect in the distal CBD but dilated intrahepatic ducts may occur in the presence of bile duct obstruction. Stones within the gall bladder are not sufficient to justify a diagnosis of gallstone-related pancreatitis. The ultrasound may also demonstrate pancreatic swelling and necrosis, as well as peripancreatic fluid collections if present. In severe pancreatitis the pancreas may be difficult to visualize because of gas-filled loops of bowel.

Assessment of disease severity

The majority of cases of acute pancreatitis are mild and run a short, self-limiting course. However, approximately 25% follow a more complicated course and in 10% this is life-threatening. The revised Atlanta criteria define mild, moderately severe or severe pancreatitis and are summarized in Box 35.4; they require assessment of organ failure using the Modified Marshall scoring system (Box 35.5). In practice, patients with moderately severe acute pancreatitis should be managed as having severe disease until sustained improvement is seen.

In severe cases, mortality may be as high as 80%. The initial clinical course is marked by a systemic inflammatory response syndrome (SIRS), haemodynamic instability and multiple organ failure. The consequences of SIRS, including respiratory and acute kidney injury, account for most of the mortality within the first 7 days of an episode of severe acute pancreatitis. After 7 days the majority of deaths are linked to delayed complications, such as sepsis due to infected collections or haemorrhage due to inflammatory effects on major vessels.

Accurate identification of patients likely to progress to severe pancreatitis permits appropriate monitoring and intensive care to be put in place. Early clinical assessment has shown to have poor sensitivity for predicting a severe attack. Similarly, individual laboratory tests have very limited value. Therefore, multiple factors have been used to develop clinical scoring systems. The Glasgow and Ranson scoring systems (Boxes 35.6 and 35.7) are based on such parameters and have been shown to have 80% sensitivity for predicting a severe attack, although only after 48 h from presentation. The Acute Physiology and Chronic Health Evaluation (APACHE) II score has been extensively adopted as a means of assessing the severity of a wide spectrum of illness. It is based on common physiological and laboratory values, patient age and the presence or absence of a number of other chronic health problems, including obesity (Box 35.8). This scoring system appears to have a high sensitivity and can be applied as early as 24 h after onset of symptoms. There is evidence that obesity affects the outcome of an episode of pancreatitis, perhaps because adipose tissue is a substrate for activated enzyme activity, worsening the inflammatory reaction. All scoring systems for predicting the severity of acute pancreatitis have proven to have modest utility in clinical practice. However, systematic classification tools can guide consistent clinical assessment and are certainly necessary in clinical studies and audit of outcomes.

Management

The initial management of acute pancreatitis is similar for all causes. A multiple factor scoring system (ideally, APACHE II with a modification for obesity) should be used at the end of the first 24 h after presentation to allow identification of patients with a predicted severe attack. This should be repeated at 48 h to identify a further subgroup who appear to be moving into the severe category. These patients should be managed on a high-dependency or intensive care unit and the case should be discussed with a specialist pancreatic unit at an early stage. Even patients outside the severe category may require considerable supportive care.
Early fluid losses in acute pancreatitis may be large, requiring well-maintained intravenous access and a urinary catheter to monitor circulating volume and renal function. Arterial and central venous catheterization may be necessary to facilitate close monitoring of haemodynamic status and permit repeat sampling of arterial blood gases.

- **Nasogastric suction.** This prevents abdominal distension and vomiting, and hence the risk of aspiration pneumonia.
- **Baseline arterial blood gases.** These are a key predictive factor for severity of an episode and determine the need for continuous oxygen administration.
- **Prophylactic antibiotics.** Controlled data for the use of antibiotics are available but the results are not uniform in showing benefit, particularly in demonstrating improved mortality. There is some evidence that the β-lactam imipenem reduces the incidence of infected pancreatic necrosis. Antibiotics should usually be reserved for cases where cholangitis or infected necrotic tissue is strongly suspected and, if possible, the choice should be guided by blood culture results.

- **Analgesia requirements.** Tramadol or another opiate is the drug of choice for immediate post-presentation pain control. Unless there is prompt resolution of pain, a patient-controlled system of administration is indicated to provide continuous and adequate pain relief. Fentanyl has been used widely for this application. There is a theoretical risk that morphine and diamorphine might exacerbate pancreatic ductular hypertension by causing sphincter of Oddi contraction. Although there are no clinical data to support this risk, some clinicians avoid these drugs in acute pancreatitis.

- **Feeding.** In a severe episode there is little likelihood of oral nutrition for a number of weeks. Total parenteral nutrition has been associated with a high risk of infection and has been replaced by enteral nutrition. In the absence of gastroparesis, most patients will tolerate nasogastric administration of feed without exacerbation of pain. In those with gastroparesis or poorly tolerated nasogastric feeding (exacerbation of pain or precipitation of nausea and vomiting), post-pyloric feeding should be instituted by the endoscopic placement of a nasojugal tube.

- **Anticoagulation.** Low-molecular-weight heparin should be given for prophylaxis of deep vein thrombosis.

In a small proportion of patients, multiorgan failure will develop for severity of an episode and determine the need for continuous oxygen administration.
Gallstone-related pancreatitis

In patients with gallstone-related pancreatitis and associated bile duct obstruction (particularly when complicated by cholangitis), endoscopic intervention with sphincterotomy and stone extraction is the treatment of choice. In the absence of bile duct obstruction, sphincterotomy and stone extraction are of proven benefit only when the episode of pancreatitis is predicted to be severe. In less severe cases of gallstone-related pancreatitis the presence of residual bile duct stones can be assessed electively by MRCP or EUS in the recovery phase of the acute episode; if stones are present, they can be removed by ERCP. To prevent a recurrent episode of gallstone pancreatitis, cholecystectomy should be carried out as soon as feasible after the acute episode has resolved.

Complications

These are listed Box 35.9. After the first 7 days, the prognosis of acute pancreatitis is most closely related to the extent of pancreatic necrosis. This can be most accurately assessed by contrast-enhanced CT, which should be carried out in all patients with severe disease after the first week. Extensive necrosis (>50% of the pancreas) is associated with a high risk of further complicated disease, frequently requiring surgical intervention.

In this minority of patients with extensive necrosis of the pancreatic and peripancreatic tissues, superimposed infection is associated with a greatly increased risk of mortality. A ‘step-up’, minimally invasive approach is now preferred, with open surgical debridement avoided if at all possible. Long courses of antibiotics are given, and percutaneous drainage and EUS-guided endoscopic necrosectomy are used to clear infected collections. The aims of such interventions are to control infection, evacuate devitalized tissues (the culture medium for invasive infection) and promote conditions for healing.

The best outcomes from intervention are achieved when debridement is delayed until at least 4 weeks after the onset of pancreatitis. When the damaged area has been walled off and liquefaction has begun, a pseudocyst develops. If necessary, acute sepsis may be controlled by percutaneous drainage of collections in the first instance.

Prognosis

The vast majority of patients with a mild to moderate episode of acute pancreatitis will make a full recovery with no long-term sequelae. Recurrent episodes of pancreatitis may occur, particularly if there has been any long-term pancreatic ductal damage. Patients with more severe acute pancreatitis may develop pancreatic insufficiency with respect to both exocrine (malabsorption) and endocrine function (diabetes); both of these carry their own significant, life-long morbidity.

Chronic pancreatitis

Aetiology

In developed countries, alcohol is reported to be the only aetiological factor in 60–80% of cases. There is a sizeable list of other reported aetiopathological factors, which can be categorized into toxic–metabolic, genetic, autoimmune, recurrent acute or severe acute pancreatitis, obstruction and idiopathic causes (Box 35.10).

Pathogenesis

There is increasing evidence that an increase in activated trypsin within the pancreas is a common pathway for the development of chronic pancreatitis. This may occur as a result of premature activation of trypsinogen to trypsin, or of impaired inactivation/clearance of the activated enzyme from the pancreas. It is believed that the increased or prolonged intrapancreatic enzyme activity leads to the precipitation of proteins within the duct lumen in the shape of plugs. These then form a nidus for calcification and cause ductal obstruction, leading to ductal hypertension and further pancreatic damage (Fig. 35.12).

In the case of alcohol-related chronic pancreatitis, ethanol increases intracellular calcium, promoting trypsinogen activation to trypsin, as well as diminishing the protective inactivation pathway. The observation that the vast majority of people drinking excess
alcohol do not develop pancreatitis suggests that the disease process is a complex interaction of different mechanisms. It is proposed that the alcohol is only one factor that interacts with other environmental and/or genetic influences (see later).

**Genetic aspects of chronic pancreatitis**

A number of genetic factors have been identified that influence the process of trypsin activation and inactivation. Cationic trypsinogen is the major form of trypsinogen produced in the pancreas and is encoded by the PRSS1 gene (Fig. 35.13). Gain-of-function mutations of this gene are recognized as the major factor in hereditary pancreatitis, an autosomal dominant condition with high penetrance.

Calcium levels within the pancreas have a role in the process of activation and inactivation of trypsinogen/trypsin and are, in part, modulated by the calcium-sensing receptor (CASR). Mutations coding for this receptor have been associated with pancreatic disease and are believed to facilitate the damaging effects of alcohol on the pancreas.

The serine protease inhibitor Kazal type 1 (SPINK-1) is a specific trypsin inhibitor and is co-secreted with trypsinogen by the acinar cells. Loss-of-function mutations of the SPINK-1 gene have been associated with the development of chronic pancreatitis and identified, in particular, as a factor in the development of tropical pancreatitis (almost certainly interacting with environmental triggers).

Chymotrypsin C is produced in trace amounts by the acinar cells and has also been shown to have a role in trypsin degradation. Loss-of-function mutations of the encoding gene have been identified in patients with chronic pancreatitis.

**Autoimmune chronic pancreatitis**

Two types of autoimmune chronic pancreatitis (ACP) have been identified. The most common variant (type 1) is seen predominantly in middle-aged men and is associated with raised serum and tissue levels of IgG4. Other autoantibodies, including those directed towards nuclear and smooth muscle antigens, are also observed. Extrapancreatic tissue involvement is common, including the biliary tree (autoimmune cholangitis; see earlier), as well as thyroid, salivary gland, and renal tissue (see p. 1378). In all these disorders there is a raised serum IgG4 level and, pathologically, there is a dense lymphoplasmacytic infiltrate with many IgG4-positive plasma cells, a mild to moderate eosinophil infiltrate and an obliterator phlebitis in some organs. ACP is one of the few settings in which the pathogenesis of the disease may be independent of the activated trypsin pathways.

The second variant (type 2) tends to occur in early midlife with an equal sex distribution and does not have the autoimmune markers or IgG4-positive cells. Some 30% of cases are associated with inflammatory bowel disease. Disease is much more likely to be restricted to the pancreas and lacks the associations with other organs/tissues seen with the type 1 variant. The hallmark of both types of autoimmune pancreatitis is evidence of responsiveness to steroids (see later).

The presentation of autoimmune pancreatitis is varied, particularly in type 1, in which extrapancreatic disease may predominate. Abdominal pain and weight loss are common features; jaundice may be an early symptom, both secondary to bile duct obstruction by the inflamed head of pancreas, and a manifestation of the cholangitis seen in type 1 cases.

**Clinical features**

Epigastric pain is the most common presentation of chronic pancreatitis, often radiating into the back. The pattern of pain may be episodic, with short periods of severe pain, or is chronic and unremitting. For those with an alcohol-related aetiology, exacerbations of the pain may follow further alcohol excess, although this is not a uniform relationship. Alcohol excess or meals with a high fat content may also lead to exacerbations of pain, independent of the aetiology.

During periods of abdominal pain, anorexia is common and weight loss may be severe. This is particularly so in those patients with chronic, unremitting symptoms. Exocrine insufficiency may develop at any time and occasionally malabsorption is the presenting feature in the absence of abdominal pain. Diabetes occurs in approximately 30% of cases and is usually a late event in the disease process, almost always following the development of exocrine insufficiency. Jaundice secondary to obstruction of the CBD during
its course through the fibrosed head of the pancreas may also occur and may be a presenting feature in a small proportion of patients.

Investigations
The extent to which investigations are required is dependent on the clinical setting.

- **Serum amylase and lipase** levels may be elevated, but in advanced disease there may not be sufficient residual acinar tissue to produce this elevation.
- **Serum IgG4 levels** should be measured in those cases with suspected autoimmune pancreatitis.
- **Faecal elastase** level will be abnormal in the majority of patients with moderate to severe pancreatic disease.
- **Gene mutation analysis** should be carried out in selected cases when the aetiology is uncertain. This is most relevant in patients presenting below the age of 40. Common mutations of the PRSS1, SPINK-1 and CFTR encoding genes are available via reference centres.
- **Transabdominal ultrasound scan** is frequently used for initial assessment.
- **Contrast-enhanced CT scanning** provides a more detailed assessment. In the presence of pancreatic calcification and a dilated pancreatic duct, the diagnosis of chronic pancreatitis can be readily established (Fig. 35.14). This may be much more difficult when these features are not present.
- **MRI with MRCP** is utilized to define more subtle abnormalities of the pancreatic duct, which may be seen in non-dilated chronic pancreatitis. Administration of intravenous secretin during an MRCP can afford dynamic images of pancreatic duct distension that offer an indirect measure of pancreatic exocrine function.
- **MRCP** has replaced diagnostic ERCP.
- **EUS** is used increasingly when doubt about the diagnosis remains after the imaging described, or specifically when complications of chronic pancreatitis, including pseudocyst formation and the possible development of malignancy, need assessment.

Differential diagnosis
The differential diagnosis is that of pancreatic malignancy. Carcinoma of the pancreas can reproduce many of the symptoms and imaging abnormalities that are commonly seen with chronic pancreatitis. The diagnosis of malignancy should be considered in patients with a short history when there is a localized pancreatic mass. Considerable difficulties may arise when a malignancy develops on the background of established chronic pancreatitis (the latter being a recognized pre-malignant lesion).

High-quality imaging is able to define malignant features with a localized mass lesion, local invasion and lymph node enlargement. EUS with fine-needle biopsy provides the most accurate assessment of a potential mass lesion.

Management
In patients with alcohol-related chronic pancreatitis, long-term abstinence is likely to be of benefit, although this has been difficult to prove. Tobacco smoking is also an independent risk factor for chronic pancreatitis and pancreatic cancer, and smoking cessation is strongly recommended. Autoimmune pancreatitis is steroid-responsive and failure to respond would put the diagnosis in question. Relapse is common when the steroids are withdrawn, and long-term immunomodulators (e.g. azathioprine) may be required.

Abdominal pain
For short-term flare-ups of pain, a combination of a non-steroidal anti-inflammatory drug (NSAID) and an opiate (tramadol) is usually sufficient for symptomatic relief. In patients with chronic unremitting pain, this may be inadequate and also risks opiate dependence.

Tricyclic antidepressants (e.g. amitriptyline) and membrane-stabilizing agents (e.g. pregabalin) are used for chronic pain and reduce the need for opiates. Coeliac axis nerve block may produce good pain relief but is unreliable in its efficacy and duration of action. In the majority of patients, some spontaneous improvement in pain control occurs with time. After a 6–10-year period, some 60% of patients will become pain-free. For recurrent severe or debilitating chronic pain, both endoscopic and surgical intervention has been used. Such intervention is indicated in patients with a dilated pancreatic duct upstream of a pancreatic duct stricture or stone. The endoscopic approach has centred on improving duct drainage by removing intraductal stones and duct stenting to maintain patency. Extracorporeal shock wave lithotripsy has been used to fragment stones within the head of the pancreas.

Surgical intervention usually involves a duct drainage procedure, which can be combined with partial resection of the diseased pancreas. Trials have reported improved pain control following surgical intervention, as compared with the endoscopic approach. However, many patients have a high level of debility (and often continued alcohol excess) and are unsuitable for major surgery due to co-morbidity or technical factors such as the presence of varices within the operative field. In such circumstances, endoscopic therapy is justified as a first measure and there is no evidence that this adversely influences subsequent surgery.

Malabsorption
The steatorrhoea associated with pancreatic insufficiency may be high, with up to 30 mmol of fat lost per 24 h. This will usually improve with pancreatic enzyme supplements. Current preparations are presented in the form of microspheres, which reduce the problems of acid degradation in the stomach. An acid suppressor (H₂-receptor antagonist or proton pump inhibitor) is also given. Despite this, a proportion of patients continue to malabsorb, usually reflecting the inadequate mixing of the pancreatic supplements with the food, as well as the low pH in the duodenum secondary to inadequate pancreatic bicarbonate production. There is no justification to reduce fat intake below the recommended levels of a normal diet, as this will contribute to the malnutrition seen in patients with chronic
Pancreatitis. Dietetic input is valuable for the management of malabsorption and also for monitoring and alleviating the malnutrition that is often seen secondary to abdominal pain and food aversion.

**Diabetes**
Diabetes associated with pancreatic endocrine failure may be difficult to control, with a rapid progression from oral hypoglycaemic agents to an insulin requirement. Labile blood sugar levels are a common problem secondary to inadequate glucagon production by the damaged pancreas.

**Autoimmune pancreatitis**
Most patients respond to glucocorticoid therapy, e.g. prednisolone 40mg daily for 4–6 weeks. Relapses are treated with azathioprine.

**Specific complications**
The most common structural complication of chronic pancreatitis is a [pancreatic pseudocyst](#), a fluid collection surrounded by granulation tissue (see p. 505). These usually occur in relationship to a period of enhanced inflammatory activity within the pancreas giving abdominal pain but may develop silently during what would appear to be a stable phase. Intra- or retroperitoneal rupture, bleeding or cyst infection may occur. The larger cysts may occlude nearby structures, including the duodenum and the bile duct. In pseudocysts less than 6cm in diameter, spontaneous resolution can be anticipated. In larger cysts that have been present for a period in excess of 6 weeks, resolution is less common and a long-term complication rate of approximately 30% can be anticipated. Many pseudocysts are closely opposed to the posterior wall of the stomach or duodenum, and can be successfully drained endoscopically using EUS to identify the optimum drainage site. A direct fistula is created between the pseudocyst lumen and the gastric or duodenal lumen, which is then kept patent by the insertion of removable stents. This approach will be successful in approximately 75% of cases. Surgical drainage is required for failures of endoscopic therapy or in circumstances where the pseudocyst anatomy does not allow endoscopic access.

**Ascites** and, occasionally, **pleural effusions** can be a direct consequence of chronic pancreatitis when there has been disruption of the main pancreatic duct. A high amylase level in the ascites or pleural fluid confirms the aetiology. Such disruptions of the main pancreatic duct require surgical intervention or ERCP and pancreatic duct stent placement.

There is an increased risk of [pancreatic cancer](#) in patients with chronic pancreatitis. The risk of malignancy is closely related to the duration of the inflammatory process. The highest incidence has been reported in hereditary pancreatitis, with a 50-fold increase and a lifetime risk as high as 40%. This reflects the early onset (in childhood) of the disease. Increases of 20–30-fold have been described in patients carrying other gene mutations and early onset of disease. The lifetime risk of malignancy in other causes of chronic pancreatitis, such as alcohol, which develop much later, is 10–15%. Cancer surveillance programmes have been proposed for the very high-risk groups (hereditary pancreatitis and other causes of early-onset disease), usually starting around the age of 40 years and relying on yearly imaging and tumour marker measurement.

**Cystic fibrosis**
Some 85% of people with cystic fibrosis (see p. 983) will have pancreatic exocrine failure, and in the majority of these this will develop in utero or the perinatal period. Malabsorption and failure to thrive are common presentations in the perinatal period and first year of life, and diabetes will develop subsequently in 30% of these patients during their lifetime.

In the remaining 15% of cases there is sufficient pancreatic exocrine secretion, which may persist throughout the patient’s lifetime. This reflects residual [CFTR](#) function and is associated with class IV and V mutations. The patients tend to present later in life and have less severe pulmonary involvement, although this is not uniform. Some of these cases will progress to pancreatic exocrine insufficiency at variable times in the course of their disease. A small proportion develop symptomatic pancreatitis as part of this process.

The [management](#) of pancreatic exocrine insufficiency in cystic fibrosis is necessary to optimize growth and overall nutrition. [Pancreatic enzyme supplements](#) are closely titrated against the level of steatorrhea. **Fat intake** should be maintained to avoid nutritional deficit. A daily **lipase intake** of up to 10,000 units/kg body weight is required. The efficacy of the supplements may be improved by the use of a [proton pump inhibitor](#). These drugs reduce the risk of acid denaturation of the enzymes and also prevent acidification of the duodenum, which also impairs the enzymes’ activity. Despite optimization of the use of enzyme supplements, a degree of fat malabsorption may persist. This reflects other luminal abnormalities of fat absorption in cystic fibrosis that are related to viscous mucus, small bowel bacterial colonization, and poor mixing of the food bolus with bile.

**Further reading**

**PANCREATIC CANCER**
The many types of pancreatic cancer can be divided into two main groupings. The vast majority of cases (about 99%) occur in the exocrine component of the pancreas. There are several subtypes of exocrine pancreatic cancer but their diagnosis and treatment have much in common. A small minority of pancreatic cancers arise in the endocrine tissue of the pancreas and have different clinical characteristics.

**Pancreatic adenocarcinoma**
The incidence of pancreatic cancer in the West has been estimated at approximately 10 cases per 100,000, with no increase over the last 20 years. The diagnosis is rarely made in persons younger than 40 years of age, and the median age at diagnosis is 71 years. Approximately 60% of patients with this condition are male. It is the eighth leading cause of death from cancer in men and the ninth leading cause of death from cancer in women throughout the world. Some 96% of pancreatic cancers are adenocarcinoma in type and the large majority are of ductal origin.

**Aetiology**
Smoking is associated with a twofold increase. Excessive intake of alcohol or coffee and excessive use of aspirin have also been implicated. There is an increased incidence of pancreatic cancer among patients with a history of diabetes and chronic pancreatitis. The risk of developing pancreatic cancer is most marked in those patients with a genetic mutation predisposing to chronic pancreatitis (there
is a 50 times increased risk in the presence of a PRSS-1 mutation; see Fig. 35.13). Although it is estimated that 5–10% of pancreatic cancers have an inherited component, the genetic basis for familial aggregation has not been identified in most cases. A subgroup of high-risk kindreds carry germ line mutations of DNA repair genes, such as BRCA2 and the partner and localizer of BRCA2. Among people with a known family history of pancreatic cancer in a first-degree relative, the relative risk of pancreatic cancer developing is increased by a factor of 2, 6 and 30 in people with one, two and three affected family members, respectively (Box 35.11).

Pathogenesis
Data suggest that pancreatic cancer results from the successive accumulation of gene mutations (Fig. 35.15). The cancer originates in the ductal epithelium and evolves from pre-malignant lesions to fully invasive cancer. The lesion called pancreatic intraepithelial neoplasia (PanIN) is the best-characterized histological precursor of pancreatic cancer. The progression from minimally dysplastic epithelium (PanIN grades 1A and 1B) to more severe dysplasia (grades 2 and 3) and finally to invasive carcinoma is paralleled by the successive accumulation of mutations. More than 90% of cases of PanIN of all grades have KRAS mutations. The mutational inactivation of the CDKN2A, p53 and SMAD family member (SMAD4) tumour suppressors is detected with increasing frequency in type 2 and type 3 lesions of PanIN, suggesting that they are rate-limiting events for tumour progression. Exome-sequencing studies have identified additional loss-of-function mutations encoding components of the SWI/SNF nucleosome remodelling complex, which are cumulatively detected in approximately 10–15% of pancreatic adenocarcinomas, as well as other, less frequent alterations.

A small percentage of pancreatic adenocarcinomas arise from cystic lesions, including intraductal papillary mucinous neoplasm (IPMN) and mucinous cystic neoplasia (see later). There is evidence that these cystic neoplasms demonstrate a similar multistep genetic and histological progression to invasive adenocarcinoma, although there are recognized differences in the mutational events that occur.

Clinical features
Approximately two-thirds of pancreatic cancers are located in the head of the pancreas, and the remainder in the body and tail (Fig. 35.16). Patients with pancreatic cancer most commonly present with abdominal pain, anorexia and weight loss. Many have experienced low-grade symptoms for a number of months before they present for investigation. New onset of depressive symptoms has also been identified as an early manifestation. In many cases the onset of these non-diagnostic symptoms is at a stage when there is already advanced local or metastatic disease. The pain associated with pancreatic cancer frequently radiates through into the back and, in some cases, is partially relieved by leaning forwards. Jaundice is a common, and maybe an early, manifestation of tumours of the ampulla and pancreatic head. This reflects the occlusion or compression of the distal CBD as it traverses the head of pancreas before entering the duodenum at the level of the ampulla. The patient may have noticed pale stools, dark urine and itching associated with bile duct obstruction in the absence (or prior to the onset) of detectable jaundice. Diabetes is present in at least 50% of patients with pancreatic cancer and may predate any other manifestation of disease. The obstruction of the pancreatic duct by the cancer may also lead to symptoms of malabsorption and overt steatorrhoea. An episode of symptomatic pancreatitis may, on occasion, be the presenting clinical picture. Other unusual presenting features can include thromboembolic phenomena, polyarthritis and skin nodules. These manifestations, distant to the tumour itself, have not been fully explained but may precede the development of a detectable pancreatic mass lesion by many months.

Signs
At the time of first presentation, there may be an absence of physical signs. Evidence of weight loss is common. Jaundice may be present, with associated scratch marks prompted by pruritus. In a proportion of cases the gall bladder will be palpable (Courvoisier’s sign).
secondary to an obstructed bile duct (or cystic duct). A palpable epigastric or central abdominal mass may be present as a reflection of advanced local disease. Liver metastases may be reflected in hepatomegaly.

**Diagnosis and investigations**

Patients with pancreatic adenocarcinoma frequently present for investigation at a late stage of tumour development, precluding curative surgery. In many cases, symptoms have been present for a number of months but have not led to investigation that is specifically aimed at confirming/excluding a pancreatic cancer. To improve outcome from this cancer there is increasing emphasis on earlier diagnosis. This is focused on targeted investigation in patients recognized as high-risk (see earlier). More emphasis is also placed on earlier referral for investigation in patients over the age of 40 who have low-grade symptoms that persist after initial assessment and empirical therapy. The upper gut symptoms frequently prompt referral for an upper gastrointestinal endoscopy. In most cases, this will not add diagnostic information and it is essential that a negative endoscopy does not delay further investigation – in particular, imaging.

- **Transabdominal ultrasound** is the initial imaging investigation in the majority of patients. In the presence of bile duct obstruction this will confirm dilated intrahepatic bile ducts, as well as a mass in the head of the pancreas. Ultrasound is less reliable when the cancer is found in the body and tail of the pancreas because of overlying bowel gas, and has a sensitivity of detection of 60%. A negative transabdominal ultrasound scan should not be considered as excluding the diagnosis.

- **Contrast-enhanced CT scan** should confirm the presence of a mass lesion in most cases of pancreatic adenocarcinoma (Fig. 35.17). Lymph node involvement and metastatic disease will also be identified. If there is a high index of suspicion, a dual-phase pancreatic protocol CT scan should be requested from the outset. A high-quality pancreatic protocol CT is required as a staging procedure prior to planned curative surgery. Extending the CT to the chest will exclude pulmonary metastases.

- **EUS** is the most sensitive (>85%) non-surgical procedure for the detection of pancreatic cancer (Fig. 35.18). In most cases, it does not add to the diagnostic and staging information provided by the CT scan. However, the procedure is valuable for the definition of small (<2 cm) lesions of the pancreas, which may be missed on CT. EUS is now the approach of choice for obtaining cytological confirmation of the underlying malignancy. A histological/cytological diagnosis is essential prior to planned chemotherapy. There are concerns that needle sampling of the tumour prior to a planned curative resection might lead to cancer cell seeding. This has been reported as a rare event (1–2%).

- **MRI and PET scanning** are useful techniques in a small proportion of patients when the local tumour or possibility of metastases has not been adequately defined.
Pancreatic cancer

Fig. 35.18 An endoscopic ultrasound scan with the probe in the distal stomach in a patient with pancreatic cancer. The patient presented with intractable periumbilical pain. A mass lesion of the pancreatic body is defined (tumour). There is invasion by the lesion into the splenic vein (SV, vasc invasion). The line of a transendoscopic needle is seen (needle tip), which has been placed under the guidance of the ultrasound probe to obtain a needle aspirate for cytological diagnosis.

• Several tumour markers have been evaluated for the diagnosis and monitoring of pancreatic cancer. The CA19–9 has reasonable sensitivity (80%) but a high false-positive rate. In individual patients, single values of these tumour markers may be of little help but a progressive elevation over time is often diagnostic; in such circumstances, tumour marker levels can be used to monitor response to treatment.

Differential diagnosis

The diagnosis should not be difficult in the presence of painless jaundice or epigastric pain radiating into the back with progressive weight loss. Unfortunately, many patients present with very minor symptoms, including pain, change in bowel habit and weight loss. Imaging, particularly abdominal CT, should be performed if pancreatic cancer is suspected. IgG4-related autoimmune pancreatitis is now recognized as a differential diagnosis in patients presenting with abdominal pain, jaundice and an abnormal pancreas on imaging (localized or diffuse enlargement; see earlier). Pancreatic cancer may rarely present with recurrent episodes of typical acute pancreatitis.

Management

The 5-year survival rate for carcinoma of the pancreas is approximately 3%. Some 90% of patients with a diagnosis of pancreatic adenocarcinoma will have a cause of death directly related to the disease. Surgical intervention represents the only chance of long-term survival. Approximately 20% of all cases have a localized tumour suitable for resection, but in an elderly population, many have co-morbid factors that preclude such major surgery. Assessment of the primary tumour and involvement of local vessels, including the coeliac artery, superior mesenteric artery and vein, portal vein and hepatic artery, is critical in determining resectability. Strategies for management are optimally defined as part of a multidisciplinary team approach.

When treatment is considered to be of curative intent, a pancreatoduodenectomy (Whipple procedure) is required to remove tumours of the head and neck of the pancreas. Tumours of the body and tail are resected as part of a distal pancreatectomy, which is increasingly carried out by the laparoscopic approach. Adjuvant and neo-adjuvant chemotherapy (fluorouracil or gemcitabine) has been used in those undergoing attempted curative resection, with some evidence of improved survival. There is early evidence that more intensive multidrug regimes (the addition of irinotecan and oxaliplatin) may further improve outcome but at the expense of increased drug toxicity. Radiotherapy has been evaluated as adjuvant treatment but does not have an established role.

In the large majority of cases, therapy is considered non-curative. Chemotherapy (see earlier) is widely used in this setting, with increasing emphasis on multidrug regimens (see p. 126). The mainstay of palliative therapy is attention to detail in managing the generalized and specific complications of pancreatic cancer.

• Pain is a debilitating feature in many cases. Management is best directed by dedicated pain teams. Opiates are a mainstay. There is some evidence that early intervention with coeliac axis block may have benefits.

• Nutritional deficit is a frequent feature at presentation and may be exacerbated by chemotheraphy. Early dietetic support may alleviate this. Malabsorption is common with pancreatic cancer and can be managed by the introduction of pancreatic enzyme supplementation. The adverse metabolic effects of diabetes can be avoided by early detection and management.

• Obstructive jaundice will occur at some stage in 70% of cases and is frequently associated with anorexia and nausea, as well as pruritus. Endoscopic placement of endoprosthesis (stents) offers excellent palliation (see p. 1323).

• Duodenal obstruction is seen in up to 20% of cases, particularly when the tumour is situated in the head or uncinate process of the pancreas. Endoscopic stenting is the treatment of choice with excellent palliation. Surgical bypass is an option in selected cases.

Pancreatic cystic neoplasms

Cystic lesions of the pancreas are common. Around 75% will be pseudocysts (see p. 1332) but, of the remainder, the majority are true cystic neoplasms. Careful characterization of lesions with CT and MRI, and discussion in a specialist pancreatic multidisciplinary team, are crucial. There is a high potential for the development of malignancy in true cystic neoplasms and therefore resection is generally recommended. The decision to operate may be difficult in patients with small (<3 cm) lesions of the head of the pancreas (in the absence of confirmed malignancy at presentation) and in those with significant co-morbidity. An initially conservative approach with follow-up imaging may be justified. Differentiation between pseudocysts and true cystic neoplasm may be difficult, even with multiple imaging techniques. EUS and fine-needle aspiration are frequently helpful in characterizing cystic lesions of the pancreas. EUS appearance (Fig. 35.19), cytology, and the measurement of cyst fluid carcinoembryonic antigen and amylase may help to categorize cystic lesions and identify malignant change.

Serous cystadenomas are composed of multiple small, cystic cavities lined by cuboidal, glycogen-rich, mucin-poor cells. These lesions tend to occur in an elderly age group and are often an asymptomatic finding. Malignant transformation in a serous cystadenoma is extremely rare and so surgical resection is rarely required. Larger serous cystadenomas may cause local compressive complications, including pain, which may warrant surgical resection.

Solid pseudopapillary neoplasms are rare lesions, usually found in women in their fourth decade; they may occur anywhere
Pancreatic neuroendocrine tumours

Pancreatic neuroendocrine tumours (NETs) are thought to arise from the cells of the islets of Langerhans and can secrete a variety of active hormones, most frequently insulin. Pancreatic NETs have increased in incidence over the last two decades, reaching an incidence of 4–5/1,000,000 population. They represent a heterogenous group of tumours with varying symptomology, tumour biology and prognosis. Between 25% and 50% of the patients present with symptoms related to hormones released from the tumour. The remainder have 'non-functioning' tumours that may be an incidental finding or present with symptoms related to tumour bulk, such as obstruction, jaundice, bleeding or abdominal mass. The increasing incidence of pancreatic NETs has been attributed to the widespread use of high-resolution cross-sectional imaging, leading to incidental detection of asymptomatic lesions.

In addition to insulin and glucagon, pancreatic NETs may synthesize ectopic hormones that are not usually found in the pancreas, such as gastrin, adrenocorticotropic, vasoactive intestinal peptide and growth hormone. While many pancreatic endocrine tumours are multihormonal, one peptide tends to predominate and is responsible for any clinical syndrome (see later). Non-functioning pancreatic NETs often contain peptide hormone on immunostaining but this remains functionally inactive. The majority of endocrine neoplasia pancreatic tumours are malignant in their behaviour. Between 10% and 15% of pancreatic NETs are linked to an inherited syndrome, such as the multiple endocrine neoplasia type 1 (MEN-1) or von Hippel–Lindau (VHL) syndrome (see p. 1407).

Clinical syndromes

Insulinoma is described on page 647.

A gastrinoma accounts for approximately 1 in 1000 cases of duodenal ulcer disease. The ulceration results from hypersecretion of gastric acid secondary in response to high serum gastrin concentrations, secreted by the pancreatic tumour (Zollinger–Ellison syndrome). Recurrent severe duodenal ulceration occurs, with only a partial response to acid suppression. The diagnosis is confirmed by an elevated gastrin level. High-dose proton pump inhibitors are used to suppress symptoms.

A VIPoma is an endocrine pancreatic tumour producing vasoactive intestinal polypeptide (VIP). This causes secretory diarrhoea secondary to the stimulation of adenyl cyclase within the entero-cyte (Verner–Morrison or watery diarrhoea syndrome). The clinical syndrome is one of profuse watery diarrhoea, hypokalaemia and a metabolic acidosis. To produce the syndrome, the tumours are usually in excess of 3 cm in diameter.

Glucagonomas are rare α-cell tumours that are responsible for a syndrome of migratory necrolytic dermatitis, weight loss, diabetes mellitus, deep vein thrombosis, anaemia and hypoalbuninaemia. The diagnosis is made by measuring pancreatic glucagon in the serum.

Somatostatinomas are rare malignant D-cell tumours of the pancreas. These tumours cause diabetes mellitus, gallstones and diarrhoea/steatorrhoea. They can be diagnosed by high serum somatostatin levels.

Investigations

Diagnosis is based on a combination of biochemical and histopathological markers. The biochemical diagnosis includes measurement of circulatory chromogranin A or specific hormones such as gastrin, insulin, glucagon and VIP. The histopathology includes features such as positive staining for chromogranin A and specific hormones such as gastrin, pro-insulin and glucagon.

Tumour localization depends on cross-sectional imaging, including CT and MRI scanning. The majority of NETs express somatostatin receptors, and a radiolabelled somatostatin analogue (such as octreotide) provides a means of tumour localization using scintigraphy. PET scanning with $^{18}$F-FDG-PET/CT or $^{68}$Ga-DOTATATE PET/CT is now widely used in the localization of primary disease and any metastases.
Identification of the primary and possibly metastatic lesions may be difficult despite multiple imaging techniques. EUS is the most sensitive means of detecting small primary NETs in the pancreas. It also offers the opportunity to undertake fine needle aspiration sampling of lesions, affording a cytopathological diagnosis (Fig. 35.20).

**Management**

Treatment of pancreatic NETs requires a multidisciplinary approach and depends on the presence or absence of metastatic (usually hepatic) disease. Where possible, surgical resection of the primary lesion is the optimal management of pancreatic endocrine tumours, as it offers the only possible cure. The propensity of many endocrine tumours to metastasise early precludes a cure in many cases. Debulking of the tumour, including liver metastases, is frequently carried out to facilitate systemic treatment.

**Somatostatin analogues**, such as octreotide and lanreotide, are used to control hormonal-related symptoms and also have a tumour-modulating effect. There is some evidence that somatostatin analogues combined with interferon-alfa also control tumour proliferation. Radionuclide therapy using somatostatin analogues has proven benefit in patients with tumours that express a high content of somatostatin receptors.

The **chemotherapeutic agents** streptozotocin, 5-fluorouracil and doxorubicin produce partial remission in approximately 40% of cases. Recent advances include the introduction of tyrosine kinase and the mammalian target of rapamycin (mTOR) inhibitors. Pancreatic NETs show a very high degree of vascularization, as well as abundant production and secretion of growth factors. There is preliminary evidence of benefit from anti-angiogenesis therapy utilizing vascular endothelial growth factor (VEGF) antagonists.

In patients with extensive liver metastasis, occlusion of the arterial blood flow by hepatic arterial embolization may control hormone-related symptoms. In most cases the tumours are slowly progressive and may allow a reasonable quality of life for many years.

## CORE SKILLS AND KNOWLEDGE

Renal disease is common: acute kidney injury (AKI) affects around 20% of hospitalized patients, and 10–15% of the general population meet the criteria for chronic kidney disease (CKD). The kidney is often involved in systemic conditions such as diabetes, hypertension, autoimmune disorders, haematological malignancies and infections, including human immunodeficiency virus (HIV) and viral hepatitis.

Renal physicians work in lifetime partnership with patients, their families and colleagues, including nurses, therapists, counsellors, nutritionists, technicians and pharmacists, in a multidisciplinary fashion. General nephrology is provided in secondary care, as patients with renal conditions such as CKD or nephrotic syndrome are managed in renal outpatients, and patients with AKI are investigated in general or renal-specific inpatient wards. Specialist services are offered in tertiary care. Renal physicians manage immunosuppression during and after kidney transplantation, and supervise peritoneal and haemodialysis to offer personalized, life-sustaining treatment that mixes physics with physiology. Nephrologists need to be general physicians, comfortable with complexity but able to understand and treat a wide variety of non-renal conditions in patients with CKD.

Key skills in renal medicine include:
- becoming comfortable with diagnosing the cause of AKI and managing its complications
- understanding CKD: its causes, complications and progression
- being familiar with the principles of dialysis and transplantation.

Opportunities for learning renal medicine include attending renal outpatient clinics, seeking out and assessing patients with AKI presenting to the hospital emergency department or acute admissions unit, and spending time with doctors or allied health professionals in specialist centres helping patients receiving renal replacement therapy (RRT).

## CLINICAL SKILLS FOR NEPHROLOGY

### History

In its early stages, renal disease is often asymptomatic and may be diagnosed incidentally. History-taking in renal medicine (Box 36.1) should be tailored to the individual patient, with the focus on either diagnostic or management questions as appropriate to the clinical context.

### A diagnostic approach to unexplained renal disease

The approach to thinking about the causes of unexplained renal dysfunction presented in Box 36.2 is especially relevant in AKI but is also relevant in CKD, especially when there is superimposed AKI or a rapid deterioration in kidney function.
Box 36.1 History-taking in kidney and urinary tract disease

Assessing the likely duration of renal dysfunction
- Duration of any symptoms present (see next section)
- Previous occasions on which urinalysis or measurement of urea and creatinine might have been performed, e.g. pre-employment or insurance medical examinations or patient checks in general practice
- Urine volume
- Oliguria is a powerful symptom of sudden kidney injury
- Slowly progressive kidney disease can see urine volume actually increase, as failing tubular function leads to a salt- and water-wasting state. As concentrating ability in the tubules fails, urine volume increases through the day and night, and so polyuria and nocturia are useful symptoms to suggest the length of time for which CKD has been present

Symptoms of uraemia
Symptoms are common when the serum urea concentration exceeds 40 mmol/L, but many patients develop uraemic symptoms at lower levels. Symptoms are generally non-specific but may include:
- Malaise, loss of energy
- Loss of appetite, loss of weight
- Insomnia
- Nocturia and polyuria
- Itching
- Nausea and vomiting

In more advanced uraemia, these symptoms become more severe and central nervous system symptoms are common, including mental slowing and clouding of consciousness, or in severe cases seizures and myoclonic twitching

Risk factors for renal disease
- Take a thorough past medical history, focusing particularly on diseases that commonly affect the kidney: diabetes, hypertension, systemic inflammatory diseases, blood-borne viruses, myeloma
- Ask about all medications the patient is using or has used in the past, remembering in particular known nephrotoxic agents (such as non-steroidal anti-inflammatory drugs, NSAIIDs), which the patient may have obtained over the counter and therefore may forget to disclose unless specifically asked, and traditional and herbal remedies, which are regularly implicated in renal disease
- Ask about a family history of renal disease or renal replacement therapy (RRT)
- Ask about recent ill health – conditions such as sepsis or dehydration can cause renal hyperperfusion and pre-renal AKI
- Ask about symptoms of urinary tract obstruction (see p. 1477)
- Ask about symptoms of systemic inflammatory or malignant conditions: fever, malaise, rashes, eye inflammation, hair thinning, nasal discharge, haemoptysis and others

Experience of RRT (where relevant):
Patients with advanced CKD
- What do they understand about their diagnosis?
- Would they wish to be considered for RRT or prefer a supportive/palliative approach to their disease?
- What is their lifestyle, and what form of RRT would offer them the best quality of life?

Patients receiving dialysis
- How are they coping with the treatment?
- Are there any symptoms relating to anaemia or CKD mineral and bone disease?
- Is transplantation feasible? (It is usually best to have considered the medical prospects of achieving transplantation before discussing the options with patients)

Kidney transplant recipients
- How is their general health?
- Any symptoms of opportunistic infections?
- How are they coping with their immunosuppressant medication? Any missed doses?
- Can their lifestyle be optimized to increase the likely survival of their graft?

Quantification of proteinuria

Quantifying the level of urinary protein is necessary in a number of renal conditions (see p. 1349). This is often done initially using a urine dipstick and then quantified using one of the three measures shown in Box 36.3. There is a rough equivalence between methods if proteinuria is non-selective (i.e. if protein is excreted in the urine in the same proportions as it is found in blood).

Box 36.2 Causes of unexplained renal dysfunction

Pre-renal causes
- Intercurrent illness, including systemic infection or sepsis in particular
- Vomiting, diarrhoea and dehydration
- Concurrent use of antihypertensives or diuretics, especially angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers

Intrarenal causes
- History of disease with associated renal manifestations, e.g. cast nephropathy in myeloma
- Nephrotoxic medications
- Symptoms suggestive of a systemic inflammatory disease
- Presence of proteinuria (see above)

Post-renal causes
- Symptoms of urinary tract obstruction
- Complete anuria
- History of a condition liable to progress to causing urinary tract obstruction: benign or malignant prostate disease, bladder or pelvic cancer
- Bladder distension or hydronephrosis on ultrasound

Box 36.3 Quantifying the level of urinary protein

<table>

</tr>
</tbody>
</table>

In healthy people there should be virtually no urinary albumin (uACR <2.5 mg/mmol for men, <3.5 mg/mmol for women); even very low levels above this threshold (not detectable by dipstick testing) indicate increased cardiovascular risk.

High levels of proteinuria (uPCR >200 mg/mmol) generally indicate glomerular disease, and uPCR >350 mg/mmol indicates nephrotic syndrome if other symptoms are present (hypoalbuminuria and fluid overload).
Examination

There are few physical signs specific to uraemia, although some of the features shown on the figure in grey boxes are often observed. The yellow boxes indicate signs related to RRT in patients with established end-stage renal disease, and may tell a story of treatment modalities previously received. Frequently, there are physical signs of peritoneal dialysis, haemodialysis and transplantation to be found (see also p. 170).

**General features**
- Short stature (childhood renal disease)
- Pallor (anaemia)
- Photosensitive pigmentation
- Yellowish complexion

**Fundoscopy**
- Signs of diabetic or hypertensive eye disease

**Mouth**
- Dry mouth suggests intravascular fluid depletion

**Neck**
- Observe jugular venous pressure to assess fluid status

**Chest**
- Basal crackles suggest fluid overload

**Heart**
- Pericardial friction rub

**Skin**
- Scratch marks due to uraemic prunus

**Abdomen**
- Grossly enlarged kidneys may be palpated in polycystic kidney disease

**Peripheral pulses**
- Reduced in widespread atherosclerotic disease

**Hands**
- Brown discoloration of the nails

**Legs**
- Signs of fluid overload (see p. 170)
- Purpuric rash suggests an underlying vasculitis with potential renal involvement

**Observation chart**
- Hypoxia and hypertension suggest fluid overload

**General features**
- Tremor may suggest toxicity from calcineurin inhibitor immunosuppression

**Mouth**
- Gingival hypertrophy with some immunosuppressant medications

**Neck**
- Scars from previous emergency venous dialysis catheters

**Chest**
- Tunneled dialysis catheters

**Forearms**
- Evidence of arteriovenous fistulae – check for a thrill to confirm patency

**Abdomen**
- Tenckhoff peritoneal dialysis catheter
- Kidney transplant: mass with overlying scar in the right (or left) iliac fossa

**Skin**
- Basal cell carcinomas and other malignant or pre-malignant change is common with chronic immunosuppressant use
INTRODUCTION

Nephrology has evolved over the last five decades from a peripheral to a major medical specialty, tasked with developing care strategies for over 10% of the world population who are believed to be living with kidney disease.

From pioneering experiments demonstrating the extraordinary role of the kidney in human physiology and blood pressure regulation to major advances in immunology and genomic medicine, the kidneys have been shown to maintain our internal environment, and to influence all systems when failing. The striking and oddly aesthetic pathology of the glomerulus, an array of local and systemic disease involved in injury to the kidney, and the complex consequences of fluid and electrolyte shifts and disorders (see Ch. 9) make the discipline a rewardingly broad and challenging one.

 Principally, however, the men, women and children living with kidney disease for decades, clustered in families and often presenting in extreme need, demand of all clinicians who come to the specialty our greatest skill, and where this is not enough, our most profound empathy. Caring for kidney disease is a humbling process for physicians, nurses and therapists, where we are asked to recognize the extraordinary courage of our patients literally every day or second day on dialysis. Our relationships with patients stretch for entire careers, always asking us to think beyond a single consultation or admission.

ANATOMY AND PHYSIOLOGY OF THE KIDNEY AND URINARY TRACT

Functional anatomy

The kidneys are paired organs, 11–14 cm in length in adults, 5–6 cm in width and 3–4 cm in depth. They lie in the retroperitoneum, on either side of the vertebral column at the level of T12–L3 (the right kidney lies lower than the left, pushed down by the liver). Each kidney is enclosed in a fibrous capsule, and has an outer cortex and an inner medulla (Fig. 36.1). There are about 1 million nephrons in each kidney. Each nephron contains a glomerulus, proximal tubule, loop of Henle, distal tubule and collecting duct. All glomeruli lie in the cortex, and tubules dip in and out of the medulla, where the collecting ducts merge to form the ducts of Bellini, emptying at a papilla at the apex of the renal pyramid into a calyx. Urine then flows through merging calyces into the renal pelvis, ureters and bladder.

The renal arteries branch off the abdominal aorta, dividing into smaller branches until arterial blood reaches the glomerulus. About 25% of people have dual or multiple renal arteries on one or both sides. Afferent glomerular arterioles arise from interlobular branch arteries to supply the glomerular capillary tuft, which drains into efferent glomerular arterioles. Efferent arterioles from (outer) cortical glomeruli drain into a peritubular
Anatomy and physiology of the kidney and urinary tract

A capillary network within the renal cortex and then into increasingly large and more proximal branches of the renal vein. By contrast, blood from the (inner) juxtamedullary glomeruli passes via vasa recta in the medulla and returns via the cortex to renal veins that drain into the inferior vena cava.

The renal capsule and ureters are innervated via T10–12 and L1 nerve roots, and renal pain is felt over the corresponding dermatomes.

**Nephron**

A ball of capillaries makes up the glomerular tuft, enclosed by Bowman's capsule, a chamber lined with specialized **parietal epithelial cells** that marks the origin of the tube (Fig. 36.2). The tuft, held together and regulated by **mesangial cells**, then serves as the filtration barrier, allowing filtrate from plasma to move into the urinary (Bowman's) space. The rate of glomerular filtration is influenced by changes in the contractile tone in either the afferent or the efferent arterioles; for example, efferent vasoconstriction will increase the transglomerular capillary pressure, and increase filtration.

Glomerular capillaries are lined with **endothelial cells**, fenestrated with 60–80 nm pores and covered with charged glycocalyx. The glomerular basement membrane (GBM), about 300 nm thick and made of type IV collagen, laminin and heparin sulphate, separates endothelium from podocytes (or visceral epithelial cells). Podocytes anchor on to the GBM by means of an extensive trabecular network of foot processes, and hang into Bowman's space. The interdigitating foot processes of podocytes then form the 40 nm filtration slit, a narrow potential space traversed by a protein ‘zipper’ that may prevent the passage of larger molecules (such as albumin) into the urinary space, and regulates the architecture and function of podocytes.

**Mesangial cells** (thought to be related to macrophages) sit within the tuft, able to contract and relax to control blood flow and the filtration surface area along the glomerular capillaries in response to a host of mediators. They also secrete the **mesangial matrix**, which provides the scaffolding for glomerular capillaries.

The **renal tubules** are lined by epithelial cells, which alter the composition of filtrate to form urine eventually. Proximal tubular cells have a luminal brush border to increase (by 30-fold) the surface composition of filtrate to form urine eventually. Proximal tubular matrix response to a host of mediators. They also secrete the proteins that form the slit diaphragm (SD) are essential for normal functioning of the filtration barrier. **Foot processes of podocytes** then form the 40 nm filtration slit, a narrow potential space traversed by a protein ‘zipper’ that may prevent the passage of larger molecules (such as albumin) into the urinary space, and regulates the architecture and function of podocytes.

**Juxtaglomerular apparatus**

The juxtaglomerular apparatus regulates flow and filtration in each individual nephron. Columnar epithelium in the macula densa (Fig. 36.3) senses the concentration of tubular fluid sodium (higher filtrate flow means more delivered sodium), triggering adenosine-mediated vasoconstriction of the afferent arteriole to drop glomerular filtration (so-called tubulo–glomerular feedback). Juxtaglomerular cells secrete renin, able to induce aldosterone release, allowing the apparatus to monitor flow, and respond when necessary to drop glomerular filtration rate (GFR) and retain salt to maintain fluid balance.

**Physiology**

A **hydrostatic pressure gradient** of approximately 10 mmHg (a capillary pressure of 45 mmHg minus 10 mmHg of pressure within Bowman's space and 25 mmHg of plasma oncotic pressure) provides the driving force for ultrafiltration of virtually protein-free and fat-free fluid across the glomerular filter into Bowman's space and so into the renal tubule (Fig. 36.4).

The **ultrafiltration rate** (GFR) varies with age and sex but is approximately 120–130 mL/min per 1.73 m² surface area in adults. This means that, each day, ultrafiltration of 170–180 L of water and unbound small-molecular-weight constituents of blood occurs. If these large volumes of ultrafiltrate were excreted unchanged as urine, it would be necessary to drink huge amounts of water and salts to stay in balance.
Absorption of solutes

Essential electrolytes and other blood constituents, such as glucose and amino acids, are absorbed from filtrate in transit along the long course of the nephron (see Fig. 36.3).

Sodium filters freely, and 60–80% of filtered sodium (and water) is reabsorbed in the late proximal tubule, where the apical membrane Na⁺/H⁺ exchanger (NHE3) trades hydrogen ions into the lumen for absorbed sodium, with anionic chloride (Cl⁻) accompanying sodium to maintain electric neutrality. Secreted H⁺ allows bicarbonate (HCO₃⁻), formed from water and CO₂ by cellular and luminal carbonic anhydrase, to exit the basolateral membrane with absorbed Na⁺. Recently, sodium–glucose co-transporters 1 and 2 (SGLT 1 and 2) have generated a lot of interest because of the use of their inhibitors in the treatment of diabetes. SGLT 2 is a predominant proximal
Absorption of water

Urine is concentrated by the countercurrent multiplier mechanism in the loop of Henle, the medullary interstitium, medullary blood vessels (vasa recta) and, finally, the collecting ducts (see p. 175). Sodium and urea in water flow as filtrate into the descending loop, permeable to water and impermeable to sodium. In the thick ascending limb (impermeable to water), active absorption of sodium by the Na+/K⁺/2Cl⁻ co-transporter into the interstitium increases the tissue osmolarity. Because of the hairpin nature of the loop, water from the permeable descending limb enters the interstitium by osmosis, where the vasa recta return fluid to the circulation. Constant active absorption of sodium in the ascending loop multiplies this process over time, and the solute concentration at the tip of the loop is four-fold that of extracellular fluid. By this mechanism, salt and water are returned to the circulation. Filterate entering the collecting duct is increasingly concentrated by the action of antidiuretic hormone (ADH, or vasopressin), leading to the release of intracellular aquaporin water channels, which insert themselves across the apical membrane. Water then enters the cell along an osmotic gradient. When the effect of ADH wears off, water channels return to the cell cytoplasm (see Fig. 9.8). The final urine volume is 1–2 L daily.

Glomerular filtration rate

In health the GFR remains constant owing to intrarenal regulatory mechanisms. In disease (e.g., a reduction in intrarenal blood flow, damage to or loss of glomeruli, or obstruction to the free flow of ultrafiltrate along the tubule) the GFR will fall. The ability to eliminate wastes and to regulate the volume and composition of body fluid will decline. This is measured as a rise in the plasma urea or creatinine, or as a reduction in measured GFR.

The concentration of urea or creatinine in plasma represents the dynamic equilibrium between production and elimination. In healthy subjects there is an enormous reserve of renal excretory function, and serum urea and creatinine do not rise above the normal range until there is a reduction of 50–60% in the GFR (Fig. 36.5). Thereafter, the level of urea depends on both the GFR and its production rate (Box 36.4). The latter is heavily influenced by protein intake and tissue catabolism. The level of creatinine is much less dependent on diet but is more related to age, sex and muscle mass. Once it is elevated, serum creatinine is a better guide to GFR than urea and is widely used to monitor further deterioration in the GFR.

Measuring or estimating the GFR

If a substance is filtered, and then unmodified by the tubules as it passes along the nephron, the concentration of that substance per mL will be the same in blood and urine. Accurate calculations of the GFR, particularly in cases where the urea and creatinine may be in the normal range or near normal, can be assessed by cystatin C and creatinine clearance. Cystatin C, a freely filtered low-molecular-weight protein, is a more accurate marker of kidney function than creatinine, though measurement has not widely entered clinical practice as yet.

Daily production of creatinine (principally from muscle cells) is fairly constant and little affected by protein intake. Serum creatinine and excreted (urinary) creatinine vary little throughout the day, allowing measurement of the creatinine clearance. Urine is collected over 24 hours for measurement of total urinary creatinine, paired with a single plasma creatinine measured during the 24-hour period. Creatinine clearance is calculated as $U \times V / P$, where $U$ = urine concentration of creatinine, $V$ = rate of urine flow in mL/
min, and $P =$ plasma concentration of creatinine. Normal ranges are 90–140 mL/min in men and 80–125 mL/min in women.

Alternatives for quantifying the true GFR include measuring iohexol or inulin clearance, or radio-isotope ($^{51}\text{Cr-EDTA}$) GFR. Neither is practical for daily clinical practice.

Estimated or calculated GFR – the eGFR

Measurement of GFR is cumbersome and time-consuming, and may be inaccurate if 24-hour urine collections are incomplete. Several formulae predict creatinine clearance or GFR from serum creatinine and patient characteristics, often derived from large trials. Variables include age, weight, gender and ethnicity. Commonly used equations are displayed in Box 36.5. All have their shortcomings, and are less accurate the closer a GFR is to normal (so patients with seemingly abnormal calculated GFRs may have normal kidney function). Of the equations, the CKD-EPI is more accurate than the modification of diet in renal disease (MDRD) study equation overall and is most reliable for predicting eGFR above 60 mL/min/1.73 m$^2$.

All these equations have not, however, been fully validated across all ranges of renal impairment, weights or body mass index (BMI), or in all ethnic groups. However, for monitoring patients with acute or chronic kidney disease, the convenience and ease of the eGFR has led to its widespread adoption.

### Box 36.5 Estimation of glomerular filtration rate (GFR)

To convert creatinine values in $\mu$mol/L to mg/dL, multiply by 0.0113.

**Cockcroft–Gault equation**

$$
\text{Creatinine clearance} = \frac{(140 - \text{age}) \times \text{weight (kg)} \times \text{constant}}{\text{Serum creatinine (µmol/L)}},
$$

Constant $= 1.23$ for males and 1.04 for women.

**Modification of diet in renal disease (MDRD) equation**

Calculation of estimated GFR by four variables:

$$
\text{Estimated GFR (mL/min/1.73m}^2) = 175 \times \frac{(\text{serum creatinine/κ, } 1) \times \text{max (serum creatinine/κ, 1})^{-1.209} \times 0.909249 \times 1.018 \times \text{constant (0.742 if female) \times 1.210 if black African)}}{\text{serum creatinine/κ, 1}}
$$

where $κ$ is 0.7 for females and 0.9 for males, $α$ is $0.329$ for females and $-0.411$ for males, min indicates the minimum or serum creatinine/κ or 1, and max indicates the maximum of serum creatinine/κ or 1.

(Adapted from MacGregor MS, Buag DE, Innes A. Chronic kidney disease. QJM. 2006; 99:365–375)

The kidney is also a major site for the catabolism (and so elimination) of many small-molecular-weight proteins and polypeptides, including many hormones such as insulin, parathyroid hormone (PTH) and calcitonin, by endocytosis carried out by the megalin–cubilin complex in the brush border of proximal tubular cells. In CKD the metabolic clearance of these substances is reduced and their half-life is prolonged. This accounts, for example, for the reduced insulin requirements of patients with diabetes as their renal function declines.

### Endocrine function

**Renin–angiotensin system**

(See Fig. 36.6.) The juxtaglomerular apparatus (JGA) regulates flow and filtration in each individual nephron. Columnar epithelium in the macula densa (see Fig. 36.3) senses the concentration of tubular fluid sodium (higher filtrate flow means more delivered sodium), triggering purinergic or adenosine-mediated vasoconstriction of the afferent arteriole to drop glomerular filtration (tubuloglomerular feedback).

Pro-renin, synthesized by specialized arteriolar smooth muscle cells in the JGA, is cleaved into the active proteolytic enzyme, renin.
• causes vasoconstriction of efferent (but also, to a lesser extent, afferent) renal arterioles, resulting in increase of glomerular capillary pressure to maintain GFR.

In diabetes mellitus, with absorption of excessively filtered glucose and sodium via SGLT-1 and SGLT-2 in the proximal tubules, sodium delivery is reduced at the JGA, which leads to activation of the renin–angiotensin axis and causes increased GFR; this is known as hyperfiltration of diabetes. The renin–angiotensin system can be blocked at several points with renin inhibitors, ACE inhibitors and angiotensin II receptor antagonists (AII-RAs). These are useful agents in the treatment of hypertension and heart failure (see pp. 1140 and 1073) but have differences in action: ACE inhibitors also block kinin production while AII-RAs are specific for AT₁ receptors.

**Erythropoietin**

Erythropoietin (EPO) (see also p. 325) is the major stimulus for erythropoiesis, the synthesis of red cells. It is a glycoprotein produced principally by fibroblast-like cells in the renal interstitium.

- Under *hypoxic* conditions, both the α and the β subunits of hypoxia inducible factor 2 (HIF-2) are expressed, forming a heterodimer and causing erythropoietin gene transcription. Once formed, erythropoietin binds to its receptors on erythroid precursor cells, to maintain normal red cell synthesis.
- Under *normal oxygen* conditions, only the HIF-2-β subunit is constitutively expressed. The α subunit undergoes proline hydroxylation in the presence of iron and oxygen. The hydroxylated HIF-2-α subunit binds to von Hippel–Lindau protein, with the activating ubiquitination and subsequent degradation of HIF-2-α via proteasomes, so that no erythropoietin is transcribed.

This and other hydroxylation steps have an absolute requirement for molecular oxygen; this forms the basis of oxygen sensing.

Loss of renal substance, with decreased erythropoietin production, results in a normochromic, normocytic anaemia. Conversely, erythropoietin secretion may be increased, with resultant polycythaemia, in people with polycystic renal disease, benign renal cysts or renal cell carcinoma.

Recombinant human erythropoietin is used routinely in clinical practice to treat the anaemia associated with chronic kidney disease. HIF stabilizers are compounds that are being used orally to promote endogenous erythropoietin production in the treatment of anaemia of CKD.

**Vitamin D metabolism**

Naturally occurring vitamin D (cholecalciferol, see also p. 474) requires hydroxylation in the liver at position 25 and again by a renal 1α-hydroxylase enzyme to produce the metabolically active 1,25-dihydroxycholecalciferol (1,25-(OH)₂D₃).

Activity of 1α-hydroxylase is decreased by fibroblast growth factor 23 (FGF23), produced by osteocytes in response to high phosphate to promote phosphaturia by downregulation of the sodium–phosphate co-transporter in the proximal tubule, and also to decrease intestinal phosphate absorption by inhibiting activation of vitamin D. FGF23 is increasingly recognized as a possible mediator of bone mineral disease in CKD.

Activity of 1α-hydroxylase is increased by:
- high plasma levels of PTH
- low serum phosphate
- low 1,25-(OH)₂D₃.

---

*Fig. 36.6* The renin–angiotensin–aldosterone system. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor antagonists can inhibit this system. BP, blood pressure.

Active renin is stored in the JGA, and released in response to a falling intravascular volume, pressure or increased fluid losses via the kidney. These are ‘sensed’ as:

- pressure changes in the afferent arteriole or changes in sympathetic tone
- chloride and osmotic concentration in the distal tubule via the macula densa (see *Fig. 36.3A*) – *tubuloglomerular feedback*
- local prostaglandin and nitric oxide release.

In the blood, renin converts angiotensinogen to inactive angiotensin I, which has two major actions (mediated by two types of receptor, AT₁ and AT₂). When AT₁ binds the AT₁ subtype (found in the heart, blood vessels, kidney, adrenal cortex, lung and brain), AT₁:
- causes rapid, powerful vasoconstriction
- stimulates the adrenal zona glomerulosa to increase aldosterone production (over hours or days), leading to sodium (and water) absorption in the collecting duct
Both 1,25-dihydroxycholecalciferol and 25-hydroxycholecalciferol are degraded in part by being hydroxylated at position 24 by 24-hydroxylase. The activity of this enzyme is reduced by PTH and increased by 1,25-(OH)_{2}D_{3} (which therefore promotes its own inactivation).

Reduced 1α-hydroxylase activity in diseased kidneys leads to relative deficiency of 1,25-(OH)_{2}D_{3}. As a result, gastrointestinal calcium and, to a lesser extent, phosphate absorption are reduced and bone mineralization is impaired. Reduced gut calcium absorption leads to hypocalcaemia, which is sensed by a specific calcium-sensing receptor (CaSR) on parathyroid glands, and in turn induces release of PTH. Receptors for 1,25-(OH)_{2}D_{3} are also found on parathyroid glands, and reduced receptor binding alters the set-point for release of PTH when plasma calcium falls. This combination contributes to the (common) secondary hyperparathyroidism seen in patients with CKD, even of modest degree.

### Autocrine function

#### Prostaglandins

Prostaglandins are unsaturated, oxygenated fatty acids, derived from the enzymatic metabolism of arachidonic acid, mainly by constitutively expressed cyclooxygenase-1 (COX-1) or inducible COX-2. COX-1 is highly expressed in the collecting duct, while COX-2 expression is restricted to the macula densa. Both COX isoforms finally convert arachidonic acid into PG{E_{2}} in the collecting duct (leading to a natriuresis/diuresis), prostacyclin (PGI_{2}) and thromboxane A_{2}, a vasoconstrictor, mainly synthesized in the glomerulus.

These all maintain renal blood flow and GFR in the face of vasoconstrictors such as angiotensin II, catecholamines and α-adrenergic stimulation. Inhibition of prostaglandin synthesis by NSAIDs results in a fall in GFR, sometimes sufficiently severe to cause AKI, particularly in the elderly, with volume depletion, or where ACE inhibitors or All-RAs are also being used.

#### Nitric oxide and the kidney

Nitric oxide (see Fig. 10.21), a molecular gas, is formed by the action of three isoforms of nitric oxide synthase (NOS), all of which are expressed in the kidney: eNOS is found in vessels, nNOS mainly in the macula densa and inner medullary collecting duct, and iNOS in several tubule segments. Nitric oxide binds soluble guanylate cyclase, enhancing the synthesis of cyclic guanosine monophosphate (cGMP) from guanosine triphosphate (GTP), and mediates the following physiological actions in the kidney:

- regulation of renal perfusion and glomerular pressure
- natriuresis, by inhibiting Na^{+}/K^{−}-ATPase and NHE3
- antagonism of ADH
- modulation of tubuloglomerular feedback (see p. 1343).

### Examination of the urine

#### Volume

In temperate climates, healthy adults will pass between 800 and 2500 mL per 24 hours (roughly 1 mL/kg per hour). Usually, the minimum urine output capable of maintaining solute excretion for health (without accumulation in the body) is around 650 mL per day. If the kidney loses concentrating capacity (as occurs in CKD or diabetes insipidus), higher urine volumes are needed for the same daily solute output, and urine outputs may rise well above 2500 mL. **Nocturia** is a symptom of kidney disease, as patients without the ability to concentrate solute into a small urine volume will wake needing to pass urine during the night. High daily volumes are also seen with glycosuria or increased protein catabolism following surgery, as the solute load requiring excretion is higher.

#### Dipsticks (chemical testing) and urine microscopy

Dipsticks are cheap and hugely helpful in investigating suspected kidney disease, using reagents fixed on pads that change colour on reacting with specific elements in urine.

#### Specific gravity and osmolality

Urine specific gravity (SG, where <1.008 is dilute and >1.020 is concentrated) is a measure of the weight of dissolved particles in urine, so urine osmolality reflects the number of such particles. Measurement of urine SG or osmolality can be helpful in confirming loss of concentrating ability (as might be seen when tubular function fails in acute tubular necrosis or CKD). It can also be helpful in oliguric patients, when a high SG might suggest pre-renal AKI, as opposed to established acute tubular necrosis (see p. 1389).

#### Urinary pH

Measurement of urinary pH (usually 5.5–6.5) is helpful only in the investigation and treatment of renal tubular acidosis (see p. 199).
Investigation of renal and urinary tract disease

Blood

Haematuria may originate from anywhere in the urinary tract. Once it is found on dipstick, a mid-stream sample may be spun at 2000 rpm and examined for red cells or casts on microscopy. Red cells (usually 1–2 per high-power field) are described as dysmorphic (altered in shape) if they originate from the early nephron (glomerular bleeding), and may be accompanied by red-cell casts. Casts are cylindrical bodies, moulded in the shape of the distal tubular lumen. Red-cell casts – even if only single – always indicate glomerular disease. A dipstick that is strongly positive for haematuria with no red cells seen on microscopy might suggest haemoglobinuria or myoglobinuria.

Bleeding may come from any site seen within the urinary tract (Fig. 36.7):

- **Overt bleeding from the urethra** is suggested when blood is seen at the start of voiding and then the urine becomes clear.
- **Blood diffusely present** throughout the urine comes from the bladder or above.
- **Blood only at the end of micturition** suggests bleeding from the prostate or bladder base.

Women will commonly have dipstick-positive haematuria during a period; it is usually worth repeating testing after menstruation.

Protein

Proteinuria is one of the most common signs of renal disease: normal individuals excrete less than 30 mg per day. Dipsticks will detect proteinuria from around 50–150 mg/L, and may be designed to test for either albuminuria or proteinuria. If two separate urine samples find proteinuria on dipstick testing, a random urine protein:creatinine ratio (uPCR) should be measured. This convenient test has largely replaced formal (timed) 24-hour urine collections for proteinuria; an alternative is the albumin:creatinine ratio (ACR). As albumin is usually the dominant protein lost in the urine, patients who have albuminuria always have proteinuria (and the urine PCR will be higher than the urine ACR). Confusingly, the terms are often used interchangeably. For people with diabetes the urine ACR has particular prognostic significance and is usually the preferred screening test (see p. 730) for the microalbuminuria found in early diabetic kidney disease.

Both tests are expressed as mg protein/mmol creatinine. Generally, an ACR of 2.5–20 mg/mmol corresponds to albuminuria of 30–300 mg daily (crudely, multiply the result by a factor of 15 – so an ACR of 50 mg/mmol = 750 mg/day albuminuria). Similarly, a uPCR of 3–30 mg/mmol corresponds to 30–300 mg daily (multiplying by a factor of 10 for this test – so a PCR of 50 mg/mmol = 500 mg proteinuria per day). The uPCR assay is relatively cheap and identifies patients whose proteinuria is of tubular and glomerular origin. ACR or PCR levels independently predict all-cause and cardiovascular mortality in the general population in addition to better risk stratifications of patients with CKD for future renal outcomes. Pyrexia, exercise and adoption of the upright posture (postural proteinuria) all increase urinary protein output but are benign. Proteinuria may associate with coarse granular casts seen on urine microscopy. Urine electrophoresis and immunofixation may detect light chains, which can be present in myeloma without a detectable serum paraprotein.

Electrolytes

Urinary electrolytes are unhelpful in CKD. The use of urinary sodium concentration in the distinction between pre-renal and intrinsic renal disease is discussed on page 1388.

Glucose

Renal glycosuria is uncommon, so that a positive test for glucose might prompt consideration of diabetes mellitus. Dipsticks for glucose are very sensitive, however.

Bacteria and pus cells

Dipstick tests for bacteriuria are based on the detection of nitrite produced from the reduction of urinary nitrate by bacteria, and also on the detection of leucocyte esterase, an enzyme specific for neutrophils. Both tests have limitations, particularly in the elderly. When positive, a mid-stream sample should be sent for microscopy, culture and sensitivities (MC&S).

Urine microscopy

(See p. 1348.) White blood cells (WBCs) may be seen on microscopy, as may bacteria. A measurement of 10 WBCs/mL or more in fresh mid-stream urine samples is abnormal and suggests urinary tract infection (UTI). Not all pyuria is UTI, though; pus cells are seen with renal stones, tubulointerstitial nephritis, papillary necrosis, tuberculosis and interstitial cystitis. White cell casts may be seen with (and are more characteristic of) acute pyelonephritis.

Granular casts are formed from abnormal cells within the tubular lumen and indicate active renal disease. Red-cell casts are highly suggestive of glomerulonephritis.

Blood and quantitative tests

The use of serum urea, creatinine and GFR as measures of renal function is discussed on page 1345. Other quantitative tests of disturbed renal function are described under the relevant disorders, as are specific diagnostic tests. Most assessments of kidney disease might include the tests described here.
Kidney and urinary tract disease

Serum biochemistry
- Urea, electrolytes, bicarbonate and creatinine, with a calculation of eGFR.
- Electrophoresis and immunofixation with serum free light chains for myeloma.
- Calcium, phosphate, alkaline phosphatase, with or without intact PTH, liver function, creatine kinase and lactate dehydrogenase.
- Blood glucose and HbA1c, which estimate chronic diabetic control.

Haematology
- Full blood count, blood film and ESR.
- Tests for sickle cell disease, when relevant.

Immunology
- Complement components may be low in active renal disease due to systemic lupus erythematosus (SLE), mesangiocapillary glomerulonephritis, post-streptococcal glomerulonephritis and cryoglobulinaemia.
- Autoantibody screening is useful in detection of SLE (see p. 457), scleroderma (p. 460), granulomatosis with polyangiitis and microscopic polyangiitis (p. 991), and Goodpasture’s syndrome (p. 992). Anti-phospholipase A2 receptor antibodies are positive in membranous nephropathy.
- Cryoglobulins are measured in unexplained glomerular disease, particularly mesangiocapillary glomerulonephritis.
- Antibodies to streptococcal antigens (antistreptolysin O titre (ASOT), anti-DNAse B) are sought if post-streptococcal glomerulonephritis is possible.
- Antibodies to hepatitis B and C may point to polyarteritis or membranous nephropathy (hepatitis B) or to cryoglobulinaemic renal disease (hepatitis C).
- Antibodies to HIV raise the possibility of HIV-associated renal disease.

Imaging techniques

Ultrasonography
Ultrasound of the kidneys and bladder is safe and non-invasive, avoiding ionizing radiation and intravascular contrast medium. In renal diagnosis, it is the imaging method of choice for:
- assessing renal size and symmetry (normal-sized kidneys with abnormal function suggest an acute cause, as kidneys scar as they fail, and may shrink in length and volume)
- ruling out obstruction, either of the bladder and ureters (with unilateral or bilateral hydronephrosis), or of the kidney itself (where pelvicalyceal dilatation may suggest high ureteric or pelvic disease)
- characterizing renal masses as cystic (either simple cysts or polycystic kidneys), or complex and solid (benign and malignant renal tumours, or infected collections)
- guiding interventions aimed at relieving obstruction (percutaneous nephrostomy)
- confirming renal vein patency, and suggesting (but not proving) renal artery disease, in the case of Doppler ultrasonography (duplex)
- looking for bladder tumours or stones; a scan obtained after voiding (post-micturition) allows bladder emptying to be assessed.

Computed tomography
Unenhanced computed tomography (CT) is the first-line investigation for cases of ureteric colic and suspected renal calculi. It has superseded excretion urography (also known as intravenous urography (IVU) or intravenous pyelography (IVP)).
- CT is also used to:
  - characterize renal masses that are indeterminate at ultrasonography
  - stage renal and bladder tumours
  - evaluate the retroperitoneum for tumours, retroperitoneal fibrosis (peri-aortitis) and other causes of ureteric obstruction
  - assess severe renal trauma
  - visualize the renal arteries and veins by CT angiography.

Disadvantages include radiation and contrast nephrotoxicity (see p. 1350).
- Positron emission tomography (PET), using 18F-fluorodeoxyglucose (FDG), is useful for detection of infection (e.g. in a cyst), inflammation or tumours, and is often used with CT (PET/CT).

Magnetic resonance imaging
Magnetic resonance imaging (MRI) is used as an alternative to CT with no irradiation:
- to stage prostate (and also renal and bladder) cancer
- to reconstruct the anatomy of the renal arteries using magnetic resonance angiography (MRA) with gadolinium as contrast medium; in experienced hands, its sensitivity and specificity approach those of renal angiography.

The Food and Drug Administration (FDA) advises not using gadolinium in patients with renal insufficiency because of the development of nephrogenic systemic fibrosis (see p. 681).

Plain X-ray
A plain radiograph of the abdomen may be useful to identify renal calcification or radiodense calculi in the kidney, renal pelvis and the line of the ureters or bladder (Fig. 36.8).

Fig. 36.8 Calcification in the renal tract. Calculi can occur at any site.
Antegrade pyelography
Antegrade pyelography (Fig. 36.9) involves percutaneous puncture of a pelvicalyceal system with a needle and the injection of contrast medium to outline the pelvicalyceal system and ureter to the level of obstruction. Drains can be sited and stents placed during the procedure.

Micturating cystourethrography
After bladder catheterization, contrast is instilled into the bladder. The catheter is then removed and the patient screened during voiding to check for vesico-ureteric reflux and to study the urethra and bladder emptying. Micturating cystourethrography (MCUG) is used in children with recurrent infection. It is rarely appropriate in adults, as with bladder wall hypertrophy in adulthood, vesico-ureteric reflux tends to disappear.

Aortography or renal arteriography
Conventional or digital subtraction angiography (DSA) is used diagnostically, and also in cases of suspected renal artery stenosis, to allow therapeutic renal artery balloon angioplasty and stenting. Complications include cholesterol embolization (see p. 1372) and contrast-induced kidney damage (contrast nephropathy).

Renal scintigraphy
Isotope studies are helpful for dynamic or static investigation of perfusion or excretion. Following venous injection of a bolus of tracer, emissions from the kidney can be recorded by gamma camera. Technetium-labelled diethyleneetriaminepenta-acetic acid (99mTc-DTPA) is excreted by glomerular filtration and can be used to confirm renal perfusion (e.g. in renal artery stenosis, see p. 1371). Dimercaptosuccinic acid labelled with technetium (99mTc-DMSA) is filtered by the glomerulus and then binds to proximal tubular cells.

Static studies are useful to assess the relative contribution in function of asymmetric kidneys, and to highlight ‘photon-deficient’ areas (where isotope is not seen), suggestive of scars or infarction, when compared to healthy tissue uptake. Mercapto-acetyltriglycine (MAG3) labelled with technetium (99mTc) is excreted by renal tubular secretion, so resistance to flow in the pelvis or ureter (with obstruction) prolongs the parenchymal transit of tracer with a delay in emptying the pelvis. On whole-kidney renograms, the time–activity curve fails to fall after an initial peak, or continues to rise (Fig. 36.10), confirming hold-up to flow. Furosemide may be given to exaggerate urine output and emphasize the delay, in order to aid diagnosis.

Transcutaneous renal biopsy
Renal biopsy (Box 36.6) is carried out under ultrasound control in specialized centres and requires interpretation by an experienced pathologist. It is helpful in the investigation of the nephritic and nephrotic syndromes, acute and chronic kidney disease, haematuria after urological investigations and renal graft dysfunction. Native renal biopsy material must be examined by conventional histochemical staining, by electron microscopy, and by immunoperoxidase or immunofluorescence. Techniques like in situ hybridization and polymerase chain reaction (PCR) analysis are also widely used in renal biopsy specimens.

The complications of transcutaneous renal biopsy are shown in Box 36.7.

Glomerular disease is usually described by kidney biopsy findings. Commonly used terms are shown in Box 36.8.

THE GLOMERULUS AND GLOMERULAR DISEASE
A glomerulus consists of a collection of capillaries seated within Bowman's capsule in the urinary space. Blood flows in via the afferent arteriole and exits via the efferent arteriole. Filtrate leaves Bowman's space and moves into the proximal tubule. The capillary tuft is supported by mesangial cells and mesangial matrix. Filtrate moves from...
Kidney and urinary tract disease

Box 36.6 Transcutaneous renal biopsy

Before biopsy
- Perform a coagulation screen; it must be normal.
- Group and save the serum for cross-matching.
- Give the patient a full explanation of what is involved and obtain consent.

During biopsy
- Ask the patient to lie prone with a hard pillow under the abdomen.
- Localize the kidney by ultrasound.
- Inject local anaesthetic along the biopsy track.
- Instruct the patient to hold a breath when the biopsy is performed.

After biopsy
- Apply pressure dressing to the biopsy site and ask the patient to rest in bed for 8–24 h.
- Maximize fluid intake to prevent clot colic.
- Check the pulse and blood pressure regularly.
- Advise the patient to avoid heavy lifting or gardening for 2 weeks.

Box 36.7 Complications of transcutaneous renal biopsy

- Macroscopic haematuria – up to 10%
- Pain in the flank, sometimes referred to the shoulder tip
- Perirenal haematoma
- Arteriovenous aneurysm formation – about 20%, almost always of no clinical significance

- Profuse haematuria demanding blood transfusion – 1–3%
- Profuse haematuria demanding occlusion of the bleeding vessel at angiography or nephrectomy – approximately 1 in 400
- Introduction of infection
- Mortality rate of about 0.1%

Box 36.8 Glomerular disease: commonly used terms

- Focal: some, but not all, glomeruli show the lesion
- Diffuse (global): most of the glomeruli (>75%) contain the lesion
- Segmental: only a part of the glomerulus is affected (most focal lesions are also segmental, e.g. focal segmental glomerulosclerosis)
- Global: all of the glomerulus is symmetrically involved
- Proliferative: an increase in cell numbers due to hyperplasia of one or more of the resident glomerular cells with or without inflammation
- Membrane alterations: capillary wall thickening due to deposition of immune deposits or alterations in basement membrane
- Crescent formation: epithelial cell proliferation with mononuclear cell infiltration in Bowman’s space

the capillary lumen into the urinary space across the glomerular filter (see p. 1343). Three elements are involved in allowing or preventing filtration: endothelium, the GBM and podocytes (Fig. 36.11).

Filtration barrier (slit diaphragm)
The glomerular filtration barrier (see Fig. 36.2) consists of the fenestrated endothelium, the GBM and the terminally differentiated visceral epithelial cells known as podocytes. Podocytes attach to the GBM by foot processes via adhesion molecules, such as αvβ3, and dystroglycans. Adjacent podocytes are joined laterally via their foot process by slit diaphragms, which bridge across the filtration slits. The various proteins comprising the slit diaphragm include nephrin, CD2-associated protein (CD2AP), canonical transient receptor potential channel 6 (TRPC6), podocin, P-cadherin, α- and β-catenin, and zonula occludens-1 (ZO-1). They co-localize within the subcellular domain to function as a molecular sieve. These proteins, in addition to providing structural support to the cytoskeletal proteins like filamentous actin, also have signalling functions in order to maintain the normal function of podocytes. Abnormalities in any of these proteins result in the breakdown of the filtration barrier with consequent torrential leak of macromolecules.

Podocyte changes
The podocyte structure (see earlier) is maintained by actin, which supports the cytoskeleton (see Fig. 36.2). A rearrangement of the fluid actin cytoskeleton leads to foot process effacement (flattening). As the architecture of the filtration slit is now disrupted, albumin leaks into the urine; recovery of the cytoskeleton reverses proteinuria. The cytoskeleton can be altered by:
- abnormalities of cytoskeletal proteins like α-actinin-4, which causes hereditary focal segmental glomerular sclerosis
- injury to or abnormalities of slit diaphragm proteins
- changes in the GBM itself
- direct injury to podocytes by viral infection, drugs, toxins or the local activation of the renin–angiotensin system.

Glomerular disease
Glomerular disease is the third most common cause (after diabetes and hypertension) of end-stage kidney disease (ESKD) in Europe and the USA, accounting for some 10–15% of such patients. These are diseases in which:
- there may be an immunologically mediated inflammatory injury to glomeruli, or structural or functional glomerular damage without inflammation
- renal interstitial damage is a regular accompaniment
- the kidneys are involved symmetrically
- secondary mechanisms of glomerular injury may come into play following an initial immune insult, such as fibrin deposition, platelet aggregation, neutrophil infiltration and free radical-induced damage
- haemodynamic consequences of a primary injury may further disturb glomerular function
- renal lesions may be part of a generalized disease (e.g. SLE).

Describing glomerular disease
The nomenclature relating to glomerular disease can be confusing, as descriptive terms (as seen on histology) overlap with clinical
syndromes and more recent molecular insights into the pathogenesis of disease. If there is predominant inflammation on histology, glomerular disease may be described as a glomerulonephritis. If inflammation is absent, glomerulopathy is more correct. There remains much overlap between the two, and the terms are often (wrongly) used interchangeably. It may be better to think about glomerular disease in terms of the predominant compartment involved, where the GBM separates podocytes from mesangial and endothelial cells.

- **Podocytes** (in the urinary compartment) are principally involved in glomerular diseases (usually glomerulopathies) that present as the nephrotic syndrome, where proteinuria is often heavy.

- **Endothelial and mesangial cells** (in the endocapillary compartment) are principally involved in glomerular disease presenting as nephritis (glomerulonephritis), where haematuria, proteinuria and often hypertension are equally evident.

- Podocytes, endothelial and mesangial cells may be equally involved where a glomerulonephritis presents with heavy proteinuria and the nephrotic syndrome as well.

Clinical classification of glomerular disease is also often used, although there is no complete correlation between histopathological types and clinical features. Four major glomerular syndromes are often described:

- **Nephrotic syndrome**: massive proteinuria (>3.5 g/day), hypalbuminaemia, oedema, lipiduria and hyperlipidaemia. Podocyte malfunction or injury is often causative.

- **Glomerulonephritis (nephritic syndrome)**:
  - **Acute glomerulonephritis**: abrupt onset of glomerular haematuria (red blood cell casts or dysmorphic red blood cells), non-nephrotic-range proteinuria, oedema, hypertension and transient renal impairment, or
  - **Rapidly progressive glomerulonephritis**: features of acute nephritis, focal necrosis with or without crescents, and rapidly progressive renal failure over weeks.

- **Mixed nephritic/nephrotic presentations**: where glomerulonephritis is part of a systemic disease (e.g., lupus nephritis, cryoglobulinaemia and Henoch–Schönlein purpura), a nephritic syndrome is often associated with the nephrotic syndrome.

- **Asymptomatic haematuria, proteinuria** or both.

Investigation of glomerular diseases is shown in Box 36.9.

### Nephrotic syndrome

Nephrotic syndrome is characterized by:

- hypoproteinaemia
- >3.5 g proteinuria/day
- dyslipidaemia
- salt and water retention, leading to oedema.

### Pathophysiology

#### Hypoalbuminaemia

Loss of urinary protein (largely albumin) of the order of 3.5 g or more daily in an adult may lead to hypoalbuminaemia. Normal dietary protein intake in the UK is around 70 g daily and the normal liver can synthesize albumin at a rate of 10–12 g daily. How, then, does a daily urinary protein loss of 3.5 g result in hypoalbuminaemia? This can be partly explained by increased catabolism of reabsorbed protein, largely albumin, in the proximal tubules, even though the rate of albumin synthesis is increased.

### Proteinuria

Proteinuria occurs partly because structural damage to the glomerular barrier (podocytes, basement membrane, fenestrated endothelium and endothelial charge) allows the passage of more and larger molecules. The filtration slit between podocytes and normal podocyte architecture, and interdigitating podocyte foot processes are critical to maintaining a barrier to protein loss into the urinary space, as is a functional GBM and healthy capillary endothelium (and its charge).

### Hyperlipidaemia

This is a consequence of increased synthesis of lipoproteins (such as apolipoprotein B, C-III lipoprotein (a)), as a direct consequence of a low plasma albumin. Low-density lipoprotein (LDL) increases, partly due to upregulation of a liver serine protease, pro-protein convertase subtilisin kexin-9 (PCSK9), which causes internalization of LDL receptors. Very-low-density lipoprotein (VLDL) and/ or intermediate-density lipoprotein (IDL) fractions increase, with no change (or a decrease) in high-density lipoprotein (HDL) (the LDL: HDL cholesterol ratio increases). There is also reduced clearance of the principal triglycerides bearing lipoprotein (chylomicrons and VLDL), as high plasma levels of free fatty acid (FFA) trigger release of appropriately sialylated angiopoietin-like 4 (ANGPTL4) protein from adipose tissue, heart and skeletal muscles, inhibiting lipoprotein lipase and resulting in hypertriglyceridaemia.

### Oedema in hypoalbuminaemia

See page 177.

### Management

#### General measures

- **Initial management** should be with dietary sodium restriction and a loop diuretic (e.g., furosemide or bumetanide). Unresponsive patients require furosemide 40–120 mg daily (or more) with the addition of amiloride (5 mg daily; monitor serum potassium concentration regularly). Nephrotic patients may malabsorb diu-
In minimal-change nephropathy (MCN; also called minimal-change disease) the glomerular lesions commonly associated with the nephrotic syndrome. Treat the underlying cause of any urinary protein leak. Specific measures

- **Normal protein intake** is advisable. A high-protein diet (80–90 g protein daily) increases proteinuria and can be harmful in the long term.
- **Hypercoagulable states** predispose to venous thrombosis. The hypercoagulable state is due to loss of clotting factors (e.g. antithrombin) in the urine and an increase in hepatic production of fibrinogen. Prolonged bed rest should be avoided, as thromboembolism is very common (particularly in membranous nephropathy). Long-term prophylactic anticoagulation may be indicated, and if renal vein thrombosis occurs, permanent anticoagulation is required.
- **Sepsis** is a major cause of death in nephrotic patients. The increased susceptibility to infection is partly due to loss of immunoglobulin in the urine. Pneumococcal infections are particularly common and pneumococcal vaccine should be given. Early detection and aggressive treatment of infections, rather than long-term antibiotic prophylaxis, constitute the best approach.
- **Lipid abnormalities** are responsible for an increase in the risk of cardiovascular disease in patients with proteinuria. Treatment of hypercholesterolaemia starts with an HMG-CoA reductase inhibitor (a statin).
- Lastly, **ACE inhibitors and/or angiotensin II receptor antagonists** (AII-RAs) are indicated for their antiproteinuric properties in all types of glomerulonephropathy, but most especially the nephrotic syndrome. These drugs reduce proteinuria by lowering glomerular capillary filtration pressure (a fall in efferent tone decreases the transglomerular capillary pressure, and so protein loss into the urinary space); blood pressure and renal function should be monitored regularly.

**Specific measures**

Treat the underlying cause of any urinary protein leak. **Box 36.10** shows the glomerular lesions commonly associated with the nephrotic syndrome.

**Causes of nephrotic syndrome**

**Minimal-change nephropathy (minimal-change disease)**

In minimal-change nephropathy (MCN; also called minimal-change disease, MCD), glomeruli appear normal on light microscopy (Fig. 36.12).

On electron microscopy, fusion of the foot processes of podocytes is seen, consistent with a disrupted podocyte actin cytoskeleton (see Fig. 36.2B). Neither immune complexes nor anti-GBM antibody can be demonstrated by immunofluorescence on glomerular staining for antibody.

Immature differentiating CD34 stem cells (rather than mature T lymphocytes) appear to be responsible for the pathogenesis of MCN. Podocyte function is also affected by interleukin 13 (IL-13), the production of vascular endothelial growth factor (VEGF), or the upregulation of vascular hyposialylated-angiopoietin-like 4 (ANGPTL4), secreted by the podocytes.

Many drugs have been implicated in MCN, including NSAIDs, lithium, antibiotics (cephalosporins, rifampicin, ampicillin), bispheosphonates and sulfasalazine. Atopy is present in 30% of cases of MCN, and allergic reactions can trigger the nephrotic syndrome. Infections, such as hepatitis C virus, HIV and tuberculosis, are rarer causes.

**Clinical features**

MCN is most common in children, particularly boys, and is responsible for the large majority of cases of nephrotic syndrome in childhood. Proteinuria is usually “highly selective”; where albumin, but not higher-molecular-weight proteins such as immunoglobulins, is lost in the urine. Oedema is usual and in children this may present predominantly around the face. The condition accounts for 20–25% of cases of adult nephrotic syndrome. It is often regarded as a condition that does not lead to CKD (but see focal segmental glomerulosclerosis below).

**Management**

- Manage symptoms with general measures (see earlier).
- High-dose corticosteroid therapy with prednisolone 60 mg/m² daily (up to a maximum of 80 mg/day) for a maximum of 4–6 weeks, followed by 40 mg/m² every other day for a further 4–6 weeks, reverses proteinuria in more than 95% of children. Response rates in adults are significantly lower and response may occur only after many months (12 weeks with daily steroid therapy and 12 weeks of maintenance with alternate-day therapy). Spontaneous remission also occurs and steroid therapy should, in general, be withheld if urinary protein loss is insufficient to cause hypoalbuminaemia or oedema. In both children and adults, if remission lasts for 4 years after steroid therapy, further relapse is very rare.
- Two-thirds of children relapse after steroid therapy and further courses of corticosteroids are required. One-third of these patients regularly relapse on steroid withdrawal, so that
a second-line agent should be added after repeat induction with steroids.

- Ciclosporin or tacrolimus may be effective (with or without steroids) but must be continued long-term to prevent relapse on stopping treatment. The antiproteinuric effect of these calcineurin inhibitors is normally attributed to its immunosuppressive action but may result from the stabilization of the actin cytoskeleton in kidney podocytes. Ciclosporin inhibits the calcineurin-mediated dephosphorylation of synaptotagmin (a regulator of actin cytoskeleton) and protects it from cathepsin L-mediated degradation. These results have shed new light on the role of calcineurin signalling in proteinuric kidney diseases. Excretory function and ciclosporin and tacrolimus trough blood levels must be monitored regularly, as both drugs are potentially nephrotoxic.

- Rituximab, a depleting monoclonal antibody directed against CD20 and present on B lymphocytes, is showing promise in reducing the number of recurrences in frequently relapsing disease, and also in minimizing the immunosuppressant burden in corticosteroid-dependent disease.

- Cyclophosphamide 1.5–2.0 mg/kg daily is given for 8–12 weeks with prednisolone 7.5–15 mg/day. This increases the likelihood of long-term remission. Steroid-unresponsive patients may also respond to cyclophosphamide. No more than two courses of cyclophosphamide should be prescribed in children because of the risk of side-effects, which include future infertility (azoospermia and premature ovarian failure).

- In corticosteroid-dependent children, the anthelmintic agent levamisole 2.5 mg/kg to a maximum of 150 mg on alternate days is also useful in maintenance of remission. Levamisole’s mode of action is attributable to its direct effects on podocytes by inducing expression of glucocorticoid receptor (GR) and activated GR signalling in podocytes.

### Congenital nephrotic syndrome

Congenital nephrotic syndrome (Finnish type) is an autosomal recessively inherited disorder due to mutations in the gene coding for a transmembrane protein, nephrin; it occurs at a frequency of 1 per 8200 live births in Finland. Nephrin is a critical element of the filtration slit, and its loss of function results in massive proteinuria shortly after birth. The disorder can be diagnosed in utero, as increased α-fetoprotein in amniotic fluid is a common feature. This condition is characterized by relentless progression to ESKD.

Other inherited nephrotic syndromes involve mutations in other genes that encode other podocyte proteins, such as podocin, α-actinin 4 and Wilms’ tumour suppressor gene. Congenital nephrotic syndrome patients are steroid-resistant. Mutation analysis in steroid-resistant nephrotic syndrome (SRNS) has identified more than 30 recessive or dominant genes, revealing that the encoded proteins are essential for glomerular function. Mutation analysis could be offered to all individuals who manifest with SRNS before the age of 25 years, for diagnosis and for exploration of possible therapies, as it may permit personalized treatment options based on genetic causation by way of ‘precision medicine’.

### Focal segmental glomerulosclerosis

Focal segmental glomerulosclerosis (FSGS) describes a sclerotic glomerular lesion that affects some (but not all) glomeruli, and some (but not all) segments of each tuft.

- **Primary FSGS** is an unusual primary cause of the nephrotic syndrome.

- **Secondary FSGS** looks similar on light microscopy. Although proteinuria may be heavy, hypoalbuminaemia is unusual.

### Primary focal segmental glomerulosclerosis

This disease of unknown aetiology usually presents as massive proteinuria (usually non-selective), haematuria, hypertension and renal impairment. The associated nephrotic syndrome is often resistant to steroid therapy. All age groups are affected. It usually recurs in transplanted kidneys, sometimes within days of transplantation, and particularly in patients with aggressive primary renal disease.

### Aetiology of primary FSGS

A circulating permeability factor causes the increased protein leak; plasma from patients increases membrane permeability in isolated glomeruli. Kidneys transplanted into murine models of FSGS develop the lesion, but kidneys from FSGS-prone mice transplanted to a normal strain are protected. Removal of this factor by plasmapheresis results in transient amelioration of proteinuria. The identity of the permeability factor remains unknown but recent findings suggest that cardiotoxin-like cytokine 1 is a likely candidate in FSGS. Soluble urokinase-like plasminogen activator receptor (SuPAR) was initially thought to be involved but now appears less likely to be causative, based on recent experimental and clinical evidence.

### Pathology

Segmental glomerulosclerosis is seen on light microscopy, which later progresses to global sclerosis. The deep glomeruli at the corticalmedullary junction are affected first. These may be missed on transcutaneous biopsy, leading to a mistaken diagnosis of MCN (see p. 1354). A pathogenetic link may exist between MCN and FSGS, as a proportion of cases classified as having the former condition develop progressive CKD, which is unusual. Electron microscopy demonstrates primarily foot process effacement, occasionally in a patchy distribution. The degree of podocyte foot process effacement on electron microscopy can help distinguish between ‘primary’ and ‘secondary’ FSGS. If severe foot process effacement is present in normal and sclerosed glomeruli on electron microscopy, primary FSGS is more likely (this is not the case if foot process effacement is largely localized to sclerosed glomeruli alone).

Five histological variants of FSGS exist:

- In **classic FSGS** (Fig. 36.13A) the involved glomeruli show sclerotic segments in any location of the glomerulus.

- The **glomerular tip lesion** is characterized by segmental sclerosis, at the tubular pole of all the affected glomeruli at a very early stage (tip FSGS, Fig. 36.13B). These patients have a more favourable response to steroids and disease runs a more benign course.

- In **collapsing FSGS** (Fig. 36.13C), podocytes are usually enlarged and coarsely vacuolated with wrinkled and collapsed capillary walls. Collapsing FSGS is commonly seen in young black people with HIV infection, and is known as HIV-associated nephropathy (HIVAN; see later).

- The **perihilar variant** (Fig. 36.13D) consists of perihilar sclerosis and hyalinosis in more than 50% of segmentally sclerotic glomeruli. It is frequently observed with secondary FSGS.

- The **cellular variant** (Fig. 36.13E) is characterized by at least one glomerulus with segmental hypercellularity (proliferation) that occludes the capillary lumen.
Kidney and urinary tract disease

**Management**

- **Prednisolone** 0.5–2 mg/kg per day is used in most patients and continued for 6 months before the patient is considered resistant to therapy, which is common.
- **Ciclosporin or tacrolimus** may be effective in reducing or stopping urinary protein excretion. Relapse after reducing or stopping drug is very common, so that long-term use is required.
- **Cyclophosphamide, chlorambucil or azathioprine** is used as second-line therapy in adults. In patients with FSGS with mesangial hypercellularity and tip lesion, cyclophosphamide 1–1.5 mg/kg per day with 60 mg of prednisolone for 3–6 months, followed by prednisolone and azathioprine, can be used as maintenance therapy.

About 50% of patients progress to ESKD within 10 years of diagnosis, particularly those who are resistant to therapy. The recurrence of this renal lesion following renal transplantation is very high, with the secondary changes of FSGS. It is also described as remnant nephropathy (see p. 1393). Associations include:

- **reduced nephron number** (e.g. nephrectomy, hypertension, gross obesity, ischaemia, sickle nephropathy, reflux nephropathy, chronic allograft nephropathy, IgA nephropathy, and scarring following renal vasculitis)
- **mutations** in specific podocyte genes
- **viruses**, e.g. HIV type 1, erythrovirus B19, cytomegalovirus, Epstein–Barr virus and simian virus 40
- **drugs** such as heroin, all interferons, anabolic steroids, lithium, sirolimus, pamidronate and calcineurin inhibitors, e.g. ciclosporin, which can also cause FSGS
- **APOL1 gene mutations** on chromosome 22 as G1/G2 renal disease variant (acquired to give protection against African trypanosomiasis) in patients of African ancestry, which makes them susceptible to FSGS in response to insults such as hypertension, SLE and HIV.

**Secondary FSGS**

Secondary FSGS with similar glomerular changes is seen as a secondary phenomenon when the number of functioning nephrons is reduced for any reason. Here, FSGS represents the common final glomerular lesion seen in response to subsequent haemodynamic glomerular strain. As nephrons fail, increased flow through the remaining nephrons leads to glomerular hypertrophy and hyperfiltration, and hydraulic injury, with the secondary changes of FSGS. It is also described as remnant nephropathy (see p. 1393). Associations include:

- **reduced nephron number** (e.g. nephrectomy, hypertension, gross obesity, ischaemia, sickle nephropathy, reflux nephropathy, chronic allograft nephropathy, IgA nephropathy, and scarring following renal vasculitis)
- **mutations** in specific podocyte genes
- **viruses**, e.g. HIV type 1, erythrovirus B19, cytomegalovirus, Epstein–Barr virus and simian virus 40
- **drugs** such as heroin, all interferons, anabolic steroids, lithium, sirolimus, pamidronate and calcineurin inhibitors, e.g. ciclosporin, which can also cause FSGS
- **APOL1 gene mutations** on chromosome 22 as G1/G2 renal disease variant (acquired to give protection against African trypanosomiasis) in patients of African ancestry, which makes them susceptible to FSGS in response to insults such as hypertension, SLE and HIV.

**HIV-associated nephropathy**

In HIV-associated nephropathy (HIVAN), glomeruli are characteristically ‘collapsed’ on light microscopy (see Fig. 36.13C); podocytes are enlarged, hyperplastic and coarsely vacuolated, containing protein absorption droplets and overlying capillaries with varying degrees of wrinkling and collapse of the walls. Direct podocyte HIV-1 infection is associated with loss of podocyte-specific markers such as Wilms’ tumour factor and synaptopodin in HIVAN. HIVAN presents with nephrotic-range proteinuria, oedema and CKD, which can be rapid in progression. Anti-retroviral therapy
(ART) may reverse the renal lesions, and restores renal function if treatment is commenced early.

**Membranous glomerulopathy**

Autoimmune membranous glomerulopathy occurs mainly in adults and predominantly in men. It presents with asymptomatic proteinuria or frank nephrotic syndrome. Microscopic haematuria, hypertension and/or renal impairment may accompany the nephrotic syndrome. As in other glomerular disease, hypertension and a greater degree of renal impairment are poor prognostic signs. In membranous glomerulopathy, one-third of patients undergo spontaneous or therapy-related remission. About 40% develop CKD, usually in association with persistent nephrotic-range proteinuria. Younger people, females and those with asymptomatic proteinuria of modest degree at the time of presentation do best.

**Pathogenesis**

A majority of patients (75%) with idiopathic or autoimmune membranous nephropathy have been found to have immunoglobulin G4 (IgG4)-type autoantibodies against M type phospholipase A2 receptor (PLA2R), a glycoprotein constituent of normal glomeruli. PLA2R is present in normal human podocytes and in immune deposits in patients with idiopathic membranous nephropathy, indicating that it could be a major autoantigen in this disease; it is linked to human leucocyte antigen (HLA)-DQA1. Antibodies against a novel podocyte antigen, thrombospondin type 1 domain-containing 7A (THSD7A), have been identified in 3% of PLA2R-negative patients with membranous nephropathy, associated in membranous glomerulopathy with underlying malignancy.

In secondary membranous nephropathy, where no detectable anti-PLA2R or anti-THSD7A antibodies (or glomerular antigen staining) can be found, glomerular histology is identical to that seen in autoimmune disease. Causes include:

- drugs (e.g. penicillamine, gold, NSAIDs, probenecid, mercury, captopril)
- other autoimmune disease (e.g. SLE, thyroiditis)
- infections (e.g. hepatitis B, hepatitis C, schistosomiasis, Plasmodium malariae)
- cancers (e.g. carcinoma of the lung, colon, stomach, breast and lymphoma)
- other causes (e.g. sarcoidosis, sickle cell disease).

On light microscopy, capillary loops appear thick. Using a periodic acid–Schiff or silver stain (which highlights basement membrane), ‘spikes’ of basement membrane are visible. On electron microscopy, small, electron-dense deposits in the subepithelial aspects of the capillary walls are seen, encircled by perpendicular basement membrane spikes. Uniform granular capillary wall deposits of PLA2R antigen and IgG subclasses (IgG4 is predominant in idiopathic membranous nephropathy), as well as complement C3, are seen on immunofluorescence. Late in the disease, deposits are completely surrounded by basement membrane and are undergoing resorption, which appears as uniform thickening of the capillary basement membrane on light microscopy (Fig. 36.14).

**Management**

As many as one-third or more of patients will undergo spontaneous remission if watched for at least 6–12 months, particularly if kidney function is normal, anti-PLA2R antibodies are low in titre and proteinuria is modest. In general, patients with heavier proteinuria, progressive renal dysfunction and a high titre of anti-PLA2R antibodies are considered for early treatment.

- All patients should receive ACE inhibition at the maximum tolerated dose, anticoagulation, diuretics and a statin if indicated.
- Rituximab, an anti-CD20 antibody (which ablates B lymphocytes), is effective in inducing remission, maintaining or improving renal function, and reducing proteinuria; few significant adverse affects have been shown in the short term.
- The alkylating agents cyclophosphamide (1.5–2.5 mg/kg per day for 6–12 months with 1 mg/kg per day of oral prednisolone on alternate days for the first 2 months) and chlorambucil (0.2 mg/kg per day in months 2, 4 and 6, alternating with oral prednisolone 0.4 mg/kg per day in months 1, 3 and 5) are both effective.
- Ciclosporin or tacrolimus is of use, though relapse is common and treatment courses are longer.
- Oral corticosteroids are of no benefit alone but may be additive.

**Amyloidosis**

Amyloidosis is a systemic disorder of protein folding, in which normally soluble proteins or fragments are deposited extracellularly as abnormal insoluble fibrils (usually β-pleated sheets that are resistant to proteolysis), causing progressive organ dysfunction and death.

The disease may be acquired or inherited. Classification is based on the nature of the precursor plasma proteins (at least 20) that form the fibrillar deposits. The most common forms are AL amyloidosis (where abnormal protein may be derived from light chains or immunoglobulin) and AA amyloidosis (where deposits form from serum amyloid A protein). The renal consequences are similar, even if systemic features differ.
Pathophysiology

AL amyloidosis (immunoglobulin light chain-associated)

This is a plasma cell dyscrasia, related to multiple myeloma, in which clonal plasma cells in the bone marrow produce immunoglobulins that are amyloidogenic. This may be the outcome of destabilization of light chains owing to substitution of particular amino acids into the light chain variable region. There is a clonal dominance of amyloid light (AL) chains – either the dominant κ or γ isotype – which are excreted in the urine (as Bence Jones protein). This type of amyloid may be seen in association with other lymphoproliferative disorders, such as myeloma, Waldenström’s macroglobulinaemia or non-Hodgkin lymphoma. It rarely occurs before the age of 40 years.

The clinical features are related to the organs involved. As well as nephrotic syndrome, the heart may be affected (presenting with heart failure), and autonomic and sensory neuropathies are relatively common. Carpal tunnel syndrome with weakness and paraesthesia of the hands may be an early feature.

On examination, hepatomegaly and, rarely, splenomegaly, cardiomyopathy, polynuropathy and bruising may be seen. MacroGLOSSIA occurs in about 10% of cases and periorbital purpura in 15%.

Reactive systemic (secondary AA) amyloidosis

This is due to amyloid formed from serum amyloid A (SAA), an acute-phase protein that rises in response to inflammatory stimuli in a similar way to C-reactive protein (CRP). It is, therefore, related to chronic inflammatory disorders and chronic infection.

Clinical features depend on the nature of the underlying disorder. Chronic inflammatory disorders include rheumatoid arthritis, inflammatory bowel disease and untreated familial Mediterranean fever. In developing countries, it is still associated with infectious diseases such as tuberculosis, bronchiectasis and osteomyelitis. In higher-income countries, it is often seen in injecting drug users, who may have chronic skin abscesses and sinus formation related to injection sites. AA amyloidosis often presents with nephrotic syndrome, CKD, hepatomegaly and splenomegaly. MacroGLOSSIA is not a feature and cardiac involvement is rare.

Familial amyloidoses

These are autosomally dominant transmitted diseases where the mutant protein forms amyloid fibrils, starting usually in middle age. The most common form is due to a mutant transthyretin, leading to transthyretin-associated amyloidosis (ATTR). Transthyretin is a tetrameric protein with four identical subunits, which functions as a transport protein for thyroxine and retinol-binding protein, and is mainly synthesized in the liver. Over 80 amino acid substitutions have been described; for example, a common substitution is that of methionine for valine at position 30 (Met 30) in all racial groups, and alanine for threonine (Ala 60) in the English and Irish. These substitutions destabilize the protein, which precipitates following stimulation, and can cause nephrotic syndrome, although more commonly other problems, including polynuropathy or cardiomyopathy, predominate.

Clinically, peripheral sensorimotor and autonomic neuropathy is common, with symptoms of autonomic dysfuction, diarrhoea and weight loss. Renal disease is less prevalent than with AL amyloidosis. MacroGLOSSIA does not occur. Cardiac problems are usually those of conduction. There may be a family history of unidentified neurological disease.

Other hereditary systemic amyloidoses include various familial amyloid polyneuropathies (e.g. Portuguese, Icelandic, Dutch). The brain is a common site of amyloid deposition (see p. 881), although it is not directly affected in any form of acquired systemic amyloidosis. Intracerebral and cerebrovascular amyloid deposits are seen in Alzheimer’s disease.

Diagnosis

The diagnosis can often be made clinically when features of amyloidosis are present elsewhere. On imaging, the kidneys are often large. Scintigraphy with radiolabelled serum amyloid P (SAP), a technique for quantitatively imaging amyloid deposits in vivo, is used to detect the rate of regression or progression of amyloidosis over a period of time.

Renal biopsy is necessary in all suspected cases of renal involvement. Widespread eosinophilic deposits are seen in the mesangium, capillary loops and arteriolar walls. Deposits stain pink, with green bi-refringence under polarized light with Congo red (Fig. 36.15). On electron microscopy the characteristic fibrils of amyloid can be seen. Amyloid consisting of immunoglobulin light chains (AL amyloid) can be identified by immunohistochemistry in only 40% of cases, as compared to almost 100% of patients with protein found in secondary amyloid (AA amyloid). If the primary presentation of amyloidosis is with non-renal disease, or if renal histology cannot be obtained, amyloid deposits can be seen in tissues obtained from the rectum, gums, abdominal fat or myocardium.

A paraproteinaemia and light chains in the urine may be seen in AL amyloidosis, along with a possible increase in plasma cells on bone marrow biopsy. In secondary or reactive amyloidosis, there will be an underlying inflammatory disorder. Genetic testing for inherited amyloidosis should be undertaken where there is a relevant family history.

Management

Treatments that reduce production of the amyloidogenic protein can improve organ function and survival:

- Myeloma-directed therapy (such as bortezemib or rituximab) is used to treat AL amyloidosis, with or without stem cell transplantation.
- In AA amyloidosis, production of serum amyloid A can sometimes be decreased by treatment of the underlying inflammatory condition but cannot be completely suppressed. Colchicine may help in familial Mediterranean fever.
- In ATTR amyloidosis, where transthyretin is predominantly synthesized in the liver, liver transplantation (causing a complete disappearance of the mutant protein from the blood) is considered as the definitive therapy.

Renoprotective measures should be started (see Box 36.12), as should relevant treatment started for nephrotic syndrome and heart failure. As renal failure progresses, the success of dialysis and
Diabetic nephropathy

Diabetic renal disease is the leading cause of ESKD in the Western world, arising largely as a complication of type 2 diabetes mellitus. Diabetic kidney disease occurs in about 20–30% of both type 1 and type 2 diabetics (see p. 729); the natural history is similar from the onset of proteinuria, and the histological lesion is the same. Risk factors for nephropathy include poor glycaemic control, hypertension, male gender, ethnicity and social deprivation.

Pathology

Pathophysiology is fully discussed on page 730. Glomerular hyperfiltration (the GFR increases to >150 mL/min per m²) and initial enlargement of kidney volume occur as local vasoactive factors increase flow. The GBM thickens and the mesangium expands. Progressive depletion of podocytes (see p. 1352) from the filtration barrier (through apoptosis or detachment) results in podocytyria early in the disease. Proteinuria evolves as filtration pressures rise and the filter is compromised. Later, glomerulosclerosis develops with nodules (Kimmelstiel–Wilson lesion) and hyaline deposits in the glomerular arterioles (Fig. 36.16). Mesangial expansion and hyalinosis are partly due to amyloid (β-islet-specific amyloid protein) deposits, with increasing proteinuria.

The Renal Pathology Society has developed a consensus classification combining type 1 and type 2 diabetic nephropathies (Box 36.11). This discriminates lesions by various degrees of severity for use in international clinical practice.

Management

Lifestyle changes (cessation of smoking, attention to salt intake, weight loss and increased exercise) are necessary to prevent progression of any diabetic complication.

- **Aim for good (intensive) glycaemic control.** If achieved for even a limited period, this reduces the incidence of ESKD and other microvascular complications in the long term (the so-called ‘legacy effect’ in both type 1 and type 2 diabetes mellitus). SGLT2 inhibitors (dapagliflozin, canagliflozin and empagliflozin) and glucagon-like peptide-1 (GLP-1) agonists such as liraglutide, semaglutide and dulaglutide (safe in renal impairment) have been shown to have specific cardiac (particularly heart failure) and renoprotective effects, in addition to controlling blood glucose.

- **Control dyslipidaemia.**

- **Control blood pressure** to <130/80 mmHg with ACE inhibitors or ARBs; these should be used once microalbuminuria develops, even if blood pressure control is good.

As in other kidney diseases, however, nearly the entire course of renal injury in diabetes is clinically silent. The aim of medical intervention during this silent phase is to slow GFR decline over time (Box 36.12). Despite intensified metabolic and blood pressure control, many still go on to develop ESKD. Other interventions with a less robust evidence base include:

- **Pentoxiphylline** (previously used for peripheral vascular disease) slows the rate of GFR decline and proteinuria (by putatively reducing the production of tumour necrosis factor-alpha, TNF-α). This interesting observation requires external validation.

- **Atrasentan** (a selective endothelin A receptor (ETaR) antagonist combined with renin–angiotensin system inhibitors) is similarly generally safe and effective in reducing residual albuminuria. This could ultimately translate into improved renal outcomes in patients with type 2 diabetic nephropathy but this needs confirmation in long-term follow-up studies.

Isolated proteinuria without haematuria

In asymptomatic patients this is often an incidental finding. It is usually found below 1 g/day with normal renal function. Over 50% of these patients have (benign) postural proteinuria, although it may be an early sign of a serious glomerular lesion such as membranous

**Box 36.12 Renoprotection**

**Goals of treatment**

- Blood pressure <130/80 mmHg
- Proteinuria <0.3 g/24 h

**Treatment measures**

Patients with chronic kidney disease and proteinuria >1 g/24 h:

- Angiotensin-converting enzyme inhibitor increasing to maximum dose
  - Angiotensin receptor antagonist if goals are not achieved
- Addition of diuretic to prevent hyperkalaemia and help to control blood pressure
- Addition of calcium-channel blocker (verapamil or diltiazem) if goals are not achieved

**Additional management**

- Statins to lower cholesterol to <4.5 mmol/L
- Smoking cessation (threefold higher rate of deterioration in chronic kidney disease)
- Treatment of diabetes (HbA1c <7%, 53 mmol/mol)
- Normal protein diet (0.8–1 g/kg body weight)

*In type 2 diabetes start with angiotensin receptor antagonist.*
Glomerulonephritis (asymptomatic, acute and rapidly progressive)

Glomerulonephritis (GN) is immunologically mediated, with involvement of cellular immunity (T lymphocytes, macrophages/dendritic cells), humoral immunity (antibodies, immune complexes, complement) and other inflammatory mediators (including cytokines, chemokines and the coagulation cascade). The immune response can be directed against known target antigens, particularly when GN complicates infections, cancers or drugs. The underlying antigenic target is more often unknown. Primary GN may occur in genetically susceptible individuals (usually determined by major histocompatibility complex (MHC) genes like HLA-A1, B8, DR2 and DR3), following environmental insults. Circulating autoantibodies and/or abnormalities in serum complement, and glomerular deposition of antibodies, immune complexes, complement and fibrin characterize the condition. GN may present as:

- asymptomatic urinary abnormalities
- acute nephritis (nephritic syndrome)
- rapidly progressive glomerulonephritis.

The same underlying histology may often present in any of these ways, and these should be seen as clinical syndromes on a spectrum rather than as distinct diseases.

Asymptomatic urinary abnormalities

Haematuria with or without sub-nephrotic-range proteinuria in an asymptomatic patient may lead to the early discovery of potentially serious glomerular disease such as SLE, Henoch–Schönlein purpura, post-infectious GN or idiopathic hypercalciuria in children. Asymptomatic haematuria is also the primary presenting manifestation of a number of specific glomerular diseases discussed below.

Acute nephritis (nephritic syndrome)

This classically presents as:

- haematuria (macroscopic or microscopic) – with red-cell casts on urine microscopy
- proteinuria
- hypertension
- oedema (periorbital, leg or sacral)
- temporary oliguria and uraemia.

Nephritis can present indolently or incidentally, and is usually distinguished from rapidly progressive glomerulonephritis by the lack of cellular necrosis (and crescent formation) in the glomeruli seen on biopsy, and the rate at which renal decline evolves. These syndromes should be seen as a continuum.

Rapidly progressive glomerulonephritis

Rapidly progressive glomerulonephritis (RPGN) is a syndrome with glomerular haematuria (red blood cell casts or dysmorphic red blood cells), rapidly developing acute kidney failure over weeks to months and focal glomerular necrosis (Fig. 36.17) with or without glomerular crescent development on renal biopsy. The ‘crescent’ is an aggregate of macrophages and epithelial cells in Bowman’s space. RPGN can develop with immune deposits (anti-GBM or immune complex type, e.g. SLE) or without immune deposits (pauci-immune, e.g. anti-proteinase 3 (PR3) and or anti-myeloperoxidase–antineutrophil cytoplasmic antibodies (MPO-ANCA)-positive vasculitides). It can also develop as an idiopathic primary glomerular disease, or can be superimposed on secondary glomerular diseases such as IgA nephropathy, membranous GN and post-infective GN. It can be classified based on the pattern of immune complex deposition in glomeruli (seen on immunofluorescence); that is, linear, granular and negative immunofluorescent patterns (Box 36.13).

Post-streptococcal glomerulonephritis

Post-streptococcal glomerulonephritis (PSGN) occurs in childhood. An acute nephritis follows 1–3 weeks after a streptococcal infection. Streptococcal throat infection, otitis media or cellulitis can all be responsible. The infecting organism is a Lancefield group A β-haemolytic streptococcus of a nephritogenic type. The latent interval between infection and the development of symptoms and signs of renal involvement reflects the time taken for immune complex formation and deposition and glomerular injury to occur. PSGN is now rare in developed countries. Renal biopsy shows diffuse, florid, acute inflammation in the glomerulus (without necrosis but occasionally with cellular crescents), with neutrophils and deposition of IgG and complement (Fig. 36.18). Similar biopsy findings may be seen in non-streptococcal post-infectious glomerulonephritis (Box 36.14).
Management

Aim for good blood pressure control, diuretics and salt restriction for oedema, and dialysis as necessary. If recovery is slow, corticosteroids may be helpful. The prognosis is usually good in children. A small number of adults develop hypertension and/or CKD later in life. Therefore, in older patients, an annual blood pressure check and measurement of serum creatinine are required. Evidence in support of long-term penicillin prophylaxis after the development of GN is lacking. In non-streptococcal post-infectious GN, prognosis is equally good if the underlying infection is eradicated.

Glomerulonephritis with infective endocarditis

GN occurs rarely in patients with infective endocarditis or infected ventriculoperitoneal shunts (shunt nephritis). Histological appearances resemble those of post-infectious GN but lesions are usually focal and segmental. Crescentic GN with AKI has been described, particularly with *Staphylococcus aureus* infection. Appropriate antibiotic therapy or surgical eradication of infection in fulminant cases usually results in a return of normal renal function. In non-streptococcal post-infectious GN, prognosis is equally good if the underlying infection is eradicated.

IgA nephropathy

IgA nephropathy (Fig. 36.19) has replaced PSGN as the most common form of GN worldwide. Demographic and family studies support the existence of a genetic contribution to the pathogenesis of IgA nephropathy but results from genetic association studies of candidate genes are inconsistent. A genome-wide analysis study conducted in European patients showed a strong association on chromosome 6p in the region of the MHC/DQ and HLA-B loci.

Histology

There is a focal and segmental proliferative GN with mesangial deposits of polymeric IgA1. In some cases, IgG, IgM and C3 are also seen in the glomerular mesangium. Superimposed crescent formation is frequent, particularly following macroscopic haematuria associated with upper respiratory tract infection.

An Oxford histological classification for IgA nephropathy is shown in Box 36.15. The features have prognostic significance and should be taken into account for predicting outcome independent of the clinical features, both at the time of presentation and during follow-up.

Pathogenesis

The disease may be a result of a number of events, including:

- exaggerated bone marrow and tonsillar IgA1 immune response to viral or other antigens
- an abnormality in O-linked galactosylation in the hinge region of the IgA1 molecule
- functional abnormalities of two IgA receptors: CD89 expressed on blood myeloid cells and the transferring receptor (CD71) on mesangial cells
- circulating immune complexes composed of a glycan-specific IgA and a galactose-deficient IgA1 antibody.
- IgA-rich immune complexes deposited in the glomerular mesangium induce mesangial cell activation and proliferation, and matrix synthesis and deposition. Removal of these complexes by bacterial proteases attenuates injury, and it is thought that glycan-specific...
autoantibodies, rather than IgA1 itself, play a key role in the pathogenesis. Up to 50% of patients exhibit elevated serum IgA (polyclonal). Several diseases are associated with IgA deposits, including Henoch–Schönlein purpura, chronic liver disease, malignancies (especially carcinoma of bronchus), seronegative spondyloarthritides, coeliac disease, mycosis fungoides and psoriasis.

**Clinical features**

IgA nephropathy tends to occur in children and young males, presenting with asymptomatic microscopic haematuria or recurrent macroscopic haematuria following an upper respiratory or gastrointestinal viral infection. Proteinuria occurs and 5% of cases can be nephrotic. The prognosis is usually good, especially in those with normal blood pressure, normal renal function and absence of proteinuria at presentation. Surprisingly, recurrent macroscopic haematuria is a good prognostic sign, although this may be due to ‘lead-time bias’ (see p. 102), as patients with overt haematuria come to medical attention at an earlier stage of their illness. The risk of eventual development of ESKD is about 25% in those with proteinuria of more than 1 g per day, elevated serum creatinine, hypertension, ACE gene polymorphism (DD isoform) and tubulointerstitial fibrosis on renal biopsy.

**Management**

All patients, with or without hypertension and proteinuria, should receive an ACE inhibitor or an AI-RA, to reduce proteinuria and preserve renal function.

- Patients with proteinuria of >1–3 g/day, mild glomerular changes and normal renal function may be treated with steroids, aiming to reduce proteinuria and stabilize function.
- In patients with higher-risk progressive disease with proteinuria of >750 mg/day and eGFR falling to <60 mL/min, prednisolone alone or with cyclophosphamide for 3 months, followed by maintenance with prednisolone, has failed to demonstrate any benefit.
- Tonsillectomy can reduce proteinuria and haematuria in those with recurrent tonsillitis.

*Mesangial hypercellularity is scored 0 for glomeruli with <4 mesangial cells per mesangial area; 1 for those with 4–5 cells; 2 for 6–7 cells; and 3 for 8 cells. Scores obtained for all glomeruli are then averaged.

---

**Alport’s syndrome**

Alport’s syndrome is a rare hereditary nephritis with haematuria, proteinuria (<1–2 g/day), progressive kidney disease and high-frequency nerve deafness. Approximately 15% of cases may have ocular abnormalities, such as bilateral anterior lenticonus, and macular and perimacular retinal flecks. In about 85% of patients with Alport’s syndrome there is an X-linked inherited mutation in the COL4α5 gene encoding the COL4α5 collagen chain, a critical component of the GBM. In female carriers, penetrance is variable and depends on the type of mutation or degree of mosaicism following hybridization of the X chromosome.

These mutations present as post-translational defects in α3, α4 and α5 chains, and result in incorrect assembly or folding of monomers; defective monomers are rapidly degraded. Over time the basement membrane undergoes selective proteolysis, and glomerular membranes thicken unevenly, split and ultimately detiorate. Although the basement membrane is abnormal, podocyte function and the slit diaphragm are unaffected, and so proteinuria in Alport’s syndrome is often mild and is the result of glomerular sclerosis, rather than primary loss of slits pores. In some patients with Alport’s syndrome and carriers, a thin basement membrane, as seen in benign familial haematuria, is the only abnormality detected on histology. For this reason the boundary between Alport’s and benign familial haematuria has become increasingly vague.

**Management**

The disease is progressive and accounts for some 5% of cases of ESKD in childhood or adolescence. Patients with mild CKD can be treated with ACE inhibitors to attenuate proteinuria. Exciting experimental evidence suggests that mesenchymal stem cells can transdifferentiate into podocytes, repair basement abnormalities and slow the rate of progression.

**Thin GBM disease**

This condition is inherited in autosomal dominant fashion and typically presents with persistent microscopic glomerular haematuria (red blood cell casts or dysmorphic red blood cells). The diagnosis is made on renal biopsy, which shows thinning of the glomerular capillary basement membrane on electron microscopy. The condition was under-diagnosed and is much more common than previously believed. The prognosis for renal function is usually very good but some patients develop renal insufficiency over decades. No treatment is of known benefit.

**Anti-GBM glomerulonephritis**

Anti-GBM glomerulonephritis (Fig. 36.20A), characterized by linear capillary loop staining with IgG and C3 and extensive crescent formation, accounts for 15–20% of all cases of RPGN, although overall represents less than 5% of all forms of GN. This condition is rare, with an incidence of 1 per 2 million in the general population. About two-thirds of these patients have Goodpasture’s syndrome with associated lung haemorrhage (see p. 992). The remainder have a renal restricted anti-GBM RPGN, which is seen in patients over 50 years and affects both genders equally.

Anti-GBM antibodies (detected by enzyme-linked immunosorbent assay, or ELISA) are present in serum and are directed against the non-collagenous (NCI) component of α3 (IV) collagen of the basement membrane. Anti-GBM GN never occurs in patients with Alport’s syndrome; although it can develop after patients with Alport’s receive a kidney transplant, anti-GBM alloantibodies evolve in response to the ‘foreign’ α3, α4, α5 (IV) collagen network absent in a patient’s own kidneys.
The thymus expresses \( \alpha_3 \) (IV) NCl peptides that eliminate autoreactive CD4\(^+\) helper T cells, but a few such cells escape deletion and are kept in check by circulating regulatory (Treg) cells. Breakdown of this peripheral tolerance (the mechanism of which is unknown) results in autoreactive CD4\(^+\) cells producing anti-GBM antibodies. These antibodies are very specific: antibodies against \( \alpha_1 \), \( \alpha_2 \) and \( \alpha_3 \) NCI domains do not cause RPGN. Since the \( \alpha_3 \) (IV) NCI epitope is hidden within the \( \alpha_3 \), \( \alpha_4 \) and \( \alpha_5 \) (IV) promoter, it is presumed that an environmental factor, such as exposure to hydrocarbons or tobacco smoke, is required in order to reveal cryptic epitopes to the immune system.

The mechanism of renal injury is complex. When anti-GBM antibody binds basement membrane, it activates complement and proteases, and results in disruption of the filtration barrier and Bowman’s capsule, causing proteinuria and the formation of crescents. Crescent formation is facilitated by IL-12 and interferon-gamma, which are produced by resident and infiltrating inflammatory cells.

Management involves:

- **plasma exchange** to remove circulating anti-GBM antibodies
- **steroids** to suppress inflammation from antibody already deposited in the tissue
- **cyclophosphamide** to suppress further antibody synthesis.

The prognosis is directly related to the extent of glomerular damage (measured by percentage of glomeruli containing crescents, serum creatinine and need for dialysis) at the initiation of treatment. When oliguria occurs or serum creatinine rises above 600–700 \( \text{mol/L} \), renal failure is usually irreversible. Once the active disease is treated, this condition, unlike other autoimmune diseases, does not follow a remitting/remitting course. If left untreated, autoantibodies diminish spontaneously within 3 years and autoreactive T cells cannot be detected in convalescent patients. This is suggestive of re-establishment of peripheral tolerance, which coincides with re-emergence of regulatory CD25\(^+\) cells in the peripheral blood; these play a key role in inhibiting the autoimmune response. The emergence and persistence of these regulatory cells may underlie the ‘single hit’ nature of this condition.

**ANCA-positive small-vessel vasculitis**

(See also p. 464.) Inflammation and necrosis of the blood vessel wall occurs in many primary vasculitic disorders. The small-vessel vasculitides affecting the kidney include:

- granulomatosis with polyangiitis (GPA)
- microscopic polyangiitis (MPA)
- renal-limited vasculitis (without systemic features)
- eosinophilic granulomatosis with polyangiitis (which is frequently ANCA-negative).

The ANCA-associated small-vessel vasculitides are GPA, MPA and renal-limited vasculitis. GPA and MPA share a common pathology with focal necrotizing lesions, which affect many different vessels and organs:

- in the lungs, a capillaritis may cause lung haemorrhage
- within the glomerulus of the kidney, crescentic GN and/or focal necrotizing lesions may cause AKI (see Fig. 36.17)
- in the dermis, there may be a purpuric rash or vasculitic (Fig. 36.21) ulceration.

Renal histology is regarded as a ‘gold standard’ for diagnosis and prognostication of ANCA-associated GN. A consensus group proposed a new classification around four general categories of lesions:

- **focal** (\( \geq 50\% \) normal glomeruli not affected by the disease process)
- **crescentic** (\( \geq 50\% \) of glomeruli with cellular crescents)
- **mixed** (a heterogeneous glomerular phenotype in which no glomerular feature predominates)
- **sclerotic** (\( \geq 50\% \) of glomeruli with global sclerosis).

This system has been shown to have a prognostic value for 1- and 5-year renal outcomes and may guide therapy.
Pathogenesis

There are two forms of ANCA (see p. 416; Fig. 36.22): PR3-ANCA (cANCA) and MPO-ANCA (pANCA). If ELISA and indirect immunofluorescence techniques are combined, diagnostic specificity is 99%. ANCA and anti-GBM antibodies do occur together; such patients tend to follow the natural history of Goodpasture’s syndrome.

- **PR3-ANCA positivity** is found in the large majority (>90%) of patients with active GPA and in up to 50% of patients with MPA.
- **Anti-MPO positivity** is present in the majority of patients with renal-limited vasculitis and in a variable number of cases of MPA. There is some evidence to suggest that ANCA is pathogenic and not just markers of disease; for example, development of drug-induced ANCA is associated with vasculitic lesions in humans. Eosinophilic GPA may have either anti-MPO or anti-PR3 ANCA.
- **Positivity for both types of ANCA** antibodies occurs in up to 10% of patients, who have a variable clinical course but a worse renal outcome.
- **Drugs** (e.g. propylthiouracil, hydralazine, minocycline, penicillamine) may induce vasculitis associated (most commonly) with MPO-ANCA, often in very high titres. Cases of drug-induced ANCA-associated vasculitis present with constitutional symptoms, arthralgia and cutaneous vasculitis. Crescentic GN and lung haemorrhage also occur.

Both ANCA autoantigens are present in immature neutrophil granules. In contrast to the normally silenced state of these two genes in mature neutrophils of healthy subjects, PR3 and MPO are aberrantly expressed in mature neutrophils of patients with ANCA vasculitis due to unsilencing of both antigens because of epigenetic modifications.

- It is unclear how and why **autoimmunity** causes the formation of ANCA antibodies. Patients with anti-PR3 have autoantibodies to a peptide translated from the antisense DNA strand of PR3 (complementary PR3; cPR3). This suggests that autoimmunity is initiated via a response against a peptide that is antisense or complementary to the autoantigen, which then induces anti-idiotypic antibodies (autoantibodies) that cross-react with the autoantigen.
- Infection by fimbriated bacteria (Gram-negative pathogens such as *Escherichia coli*, *Klebsiella pneumoniae* and * Proteus mirabilis*) can, through molecular mimicry, trigger cross-reactive autoimmunity to lysosomal membrane protein 2 (LAMP-2), a membrane protein co-localized with PR3 and MPO in the intracellular vesicles of neutrophils.

Management

The sooner treatment is instituted, the greater chance there is of recovery of renal function.

- **High-dose oral corticosteroids** and **intravenous pulsed cyclophosphamide** are of benefit in inducing remission. The best indicators of adverse prognosis are pulmonary haemorrhage and severity of renal failure at presentation.
- **Rituximab** is equally effective in inducing remission in ANCA- associated vasculitides in the short term (6–12 months), with similar adverse event rates. Rituximab may be a therapeutic option in patients who cannot tolerate cyclophosphamide, and in those whose disease is poorly controlled and who relapse while on cyclophosphamide.

**Fulminant disease** requires intensification of immunosuppression with adjuvant plasma exchange or intravenous pulsed methylprednisolone (1 g/day for 3 consecutive days). In the PEXIVAS study of more than 700 patients with severe ANCA-positive RPGN, with or without lung haemorrhage, the addition of plasma exchange neither saved lives nor avoided ESKD. This study also demonstrated that lower-dose oral glucocorticoids than conventionally used significantly reduced serious infection rates without less effective disease control.

- Once remission has been achieved, azathioprine can be substituted for cyclophosphamide, which was more effective than mycophenolate in a head-to-head comparison trial. Use of rituximab every 3 months in fixed dose has been shown to be superior to azathioprine in the maintenance of remission.
- Colonization of the upper respiratory tract with *Staph. aureus* increases the risk of relapse, and treatment with sulfamethoxazole/trimethoprim reduces the relapse rate.
- Relapse after complete withdrawal of immunosuppression occurs relatively frequently, and long-term, relatively low-dose immunosuppression may be necessary.
- Up to 25% of patients with PR3-ANCA harbour antibodies against human plasminogen and/or tissue plasminogen activator. Their presence has been correlated with venous thromboembolic events and fibrinoid necrotic glomerular lesions, suggesting functional interference with fibrinolysis. However, a formal role for anticoagulation in patients with ANCA-associated GN remains uncertain.

**Mixed nephritic and nephrotic syndrome**

Injury involves mesangial cells, endothelium, the basement membrane and podocytes in this heterogeneous group of conditions.

**Mesangiocapillary (membranoproliferative) glomerulonephritis**

Mesangiocapillary (membranoproliferative) glomerulonephritis (MCGN) is an uncommon descriptive lesion that has three subtypes with similar clinical presentations: nephrotic syndrome, haematuria, hypertension and renal impairment. They also produce similar
Microscopic findings, although the pathogenesis may be different. Electron microscopy defines:

- **Type 1 MCGN:** involves mesangial cell proliferation, with mainly subendothelial immune deposition and apparent splitting of the capillary basement membrane, giving a ‘tramline’ effect. It can be associated with persistently reduced plasma levels of C3 and normal levels of C4, and activation of the classical complement cascade. It is often idiopathic but occurs with chronic infection (abscesses, infective endocarditis, infected ventriculo-peritoneal shunt) or cryoglobulinaemia secondary to hepatitis C infections (Fig. 36.23A).

- **Type 2 MCGN, or C3 nephropathy:** demonstrates mesangial cell proliferation with electron-dense, linear (ribbon-like) intramembranous deposits that usually stain for C3 only (Fig. 36.23B). This dense deposit disease may be idiopathic, or associated with factor H deficiency and partial lipodystrophy (loss of subcutaneous fat on the face and upper trunk). Alternatively, C3 nephropathy presents with low C3 levels (as in type 1 MCGN), due in this case to activation of the alternative pathway of the complement cascade, where loss-of-function mutations in complement factor H or other such factors allow uncontrolled alternative pathway activation. Autoantibodies to the C3 convertase enzyme (C3 nephritic factor) are present. In patients of Cypriot origin, an autosomal dominant inherited heterozygous duplication in the CFHR5 gene (CFHR5 nephropathy) leads to a similar presentation.

- **Type 3 MCGN** has features of both type 1 and type 2 disease. Complement activation appears to be via the final common pathway of the cascade.

  Most patients eventually go on to develop ESKD over several years. C3 nephropathy, particularly with an underlying genetic cause, recurs in a high proportion of renal transplant patients, usually within the first year but is less common in type 1 disease (25%).

### Management

In idiopathic MCGN (all age groups) with normal renal function and non-nephrotic-range proteinuria, no specific therapy is required. Good blood pressure control, ideally with an ACE inhibitor, is of benefit.

In children with the nephritic syndrome and/or impaired renal function, a trial of steroids may be warranted (alternate-day prednisolone 40 mg/m² for a period of 6–12 months). If no benefit is seen, this treatment is discontinued. Regular follow-up, with control of blood pressure, use of agents to reduce proteinuria and correction of lipid abnormalities, is necessary.

In adults with the nephritic syndrome and/or renal impairment, aspirin (325 mg) or dipyridamole (75–100 mg) daily, or a combination of the two, may be given for 6–12 months. Again, if no benefits are seen, the treatment should be stopped. Treatment to slow the rate of progression of CKD is instituted (see p. 1398). In C3 nephropathy due to loss-of-function mutation in complement factor H, anti-C5 antibody (eculizumab) has been used successfully in several patients and in recurrence following transplantation.

### IgM nephropathy

This disorder is characterized by increased mesangial cellularity in most of the glomeruli, associated with granular immune deposits of IgM and complement. People present with episodic or persistent haematuria and the nephrotic syndrome. Unlike in minimal-change disease, the prognosis is not uniformly good, as steroid response is only 50%. Between 10% and 30% develop progressive renal insufficiency with evidence of secondary FSGS (see p. 1355) on repeat biopsy.

### C1q nephropathy

C1q nephropathy is very similar to IgM nephropathy in terms of presenting features and microscopic appearance, with the exception of C1q deposits in the mesangium. Sometimes it is misdiagnosed as lupus nephritis, particularly in people with negative serology (so-called ‘seronegative lupus’). The distinguishing features are intense C1q staining and absence of tubuloreticular inclinations (attributable to high circulating interferon-alfa) on electron microscopy.

### Monoclonal gammopathy of renal significance

A monoclonal gammopathy of undetermined significance (MGUS, see p. 408) occurs in asymptomatic people with a paraprotein or M-band (often incidentally) detected in blood. Renal (usually glomerular) disease is increasingly recognized in association, related to deposition or precipitation of monotypic whole immunoglobulin or light chains in the kidney. Renal injury is driven by a clonal B-cell or plasma cell population.
Kidney and urinary tract disease

The following are included under the term monoclonal gammopathy of renal significance (MGRS):

- deposition diseases: AL amyloid (see p. 1357), immunotactoid and fibrillary GN, monoclonal immunoglobulin deposition diseases (MIDDs, including light chain and heavy chain DD), proliferative GN with monoclonal immunoglobulin deposition and light chain tubulopathy
- precipitation diseases: cryoglobulinaemic GN
- complement activation diseases: paraprotein-associated C3 nephropathy and atypical haemolytic uraemic syndrome (HUS, see p. 1368).

Diagnosis is usually made in the context of a detectable paraprotein and characteristic renal biopsy findings, and progression to ESKD is common unless treatment is given. Conventional immunosuppression is of no benefit, but clone-directed therapy with bortezomib, rituximab or potentially daratumumab offers better outcomes.

Idiopathic fibrillary glomerulopathy

In this rare condition, microfibrillary structures are seen in the mesangium and glomerular capillary wall, visible on electron microscopy, and staining is positive for a specific marker, DNAJB9. Fibrils are larger than in amyloidosis (20–30 nm as opposed to 10 nm in diameter) and do not stain with Congo red. Patients present with proteinuria, mostly in the nephrotic range (60%), and microscopic haematuria (70%), hypertension and CKD (50%) that may progress rapidly; 40–50% develop ESKD within 2–6 years. No treatment is known to be of benefit.

Immunotactoid glomerulopathy

In this disorder, microtubules that are much larger (30–40 nm in diameter) than the fibrils in fibrillary glomerulopathy are seen on electron microscopy. The majority of patients have circulating paraproteins, or monoclonal immunoglobulin deposition is seen in the glomeruli on immunofluorescence microscopy. A lymphoproliferative disease is the underlying cause in over 50% of cases. The clinical presentation and course are similar to those of fibrillary glomerulopathy. Complete or partial remission of the nephrotic syndrome can be achieved with chemotherapy in 80% of patients.

Fibronectin glomerulopathy

This is also a form of glomerulonephritis due to fibrillar deposits, which, unlike amyloidosis but like fibrillary glomerulonephritis and immunotactoid glomerulopathy, is negative for Congo red staining. It is inherited as an autosomal dominant disorder and is associated with the massive deposition of fibronectin, a large dimeric glycoprotein consisting of two similar subunits (approximately 250 kDa in weight). The possible genetic abnormality in this disorder is a loss-of-function mutation in uteroglobin.

It presents with varying degrees of proteinuria seen first between the ages of 20 and 40, followed by hypertension, microscopic haematuria, and slow progression to ESKD in most patients.

Systemic lupus erythematosus (lupus nephritis)

Overt renal disease occurs in at least one-third of systemic lupus erythematosus (SLE) patients and, of these, 25% reach ESKD within 10 years (see also p. 458). Histologically, almost all patients will have changes. Box 36.16 shows the progression of the histological findings and the clinical picture from classes I to VI.

Serial renal biopsies show that in approximately 25% of patients, histological appearances change from one class to another during the inter-biopsy interval. Immune deposits in the glomeruli and mesangium are characteristic of SLE (tubuloreticular structure in glomerular endothelial cells) and stain positive for IgG, IgM, IgA and the complement components C3, C1q and C4 on immunofluorescence.

Pathophysiology

SLE is known to be a multifactorial autoantigen-driven, T-cell-dependent and B-cell-mediated autoimmune disorder.

- Lupus nephritis typically associates with multiple circulating autoantibodies to cellular antigens (particularly anti-dsDNA, anti-Ro) and with complement activation, which leads to reduced serum levels of C3, C4 and (particularly) C1q.
- C1q is the first component of the classical pathway of the complement cascade (see p. 44) and is involved in the activation of complement and clearance of self-antigens generated during apoptosis.
- Although self DNA was thought to be the inciting autoantigen, nucleosomes (structures comprising DNA and histone, generated during apoptosis) are more likely to be antigenic.
- Nucleosome-specific T cells, antinucleosome antibodies and nephritogenic immune complexes are generated.
- T-helper 2 (Th2) cells, with basophils and B-cell survival factors (such as BLYS), enhance B-cell differentiation and survival, and stimulated nucleic acid-binding receptors promote the production of autoreactive antibodies.
• Positively charged histone components of the nucleosome bind to the negatively charged heparan sulphate of the GBM, targeting an inflammatory reaction to the kidney.
• Inflammation stimulates complement activation, mesangial cell proliferation, mesangial matrix expansion and recruitment of inflammatory leucocytes.

The extraglomerular renal features of lupus nephritis include tubulointerstitial nephritis (75% of patients), renal vein thrombosis and renal artery stenosis. Thrombotic manifestations are associated with autoantibodies to phospholipids (antiphospholipid or lupus anticoagulant, see p. 459), and may present as infarction of glomerular segments, thrombotic microangiopathy or vasculitis.

Management

Initial management depends on the clinical presentation but hypertension and oedema should always be treated. Disease activity, kidney biopsy and histology, as well as the presence or absence of extrarenal manifestations of lupus, guide therapy. **Type I lupus nephritis** requires no specific treatment. **Type II** usually runs a benign course but some patients are treated with hydroxychloroquine and/or steroids alone.
• There have been a number of clinical trials with immunosuppressive agents in types III, IV and V lupus nephritis. Outcomes are affected by ethnicity, clinical characteristics, irreversible damage (on renal biopsy), initial response to treatment and the future frequency of renal flares.
• Steroids and high-dose intravenous cyclophosphamide or mycophenolate mofetil (MMF) may be used as induction therapy. In white populations, low-dose cyclophosphamide is a good alternative to high-dose cyclophosphamide, as it is similarly effective and associated with less toxicity.
• MMF is as effective as high-dose intravenous cyclophosphamide in the induction phase with a similar safety profile, but cyclophosphamide may be inferior to MMF in black and Hispanic people, possibly because of poor tolerance.
• Most patients respond to induction therapy. Remission is maintained with MMF (superior to azathioprine) or azathioprine, which is similar in effectiveness to ciclosporin in reducing the risk of relapse.
• B-cell depletion with rituximab (anti-CD20) has been used in some patients, with favourable results over the short term. However, controlled trials have not shown consistent results. It might be useful in severe, refractory lupus nephritis.

Prognosis

Treatment leading to the normalization of proteinuria, hypertension and renal dysfunction indicates a good prognosis. The prognosis is better in patients with types I, II and V disease. Glomerulosclerosis (type VI) usually predicts ESKD.

**Cryoglobulinaemic renal disease**

Cryoglobulins (CGs) are individual or mixed immunoglobulins and complement components, which precipitate reversibly in the cold. Three types are recognized:
- **Type I** is characterized by a cryoprecipitable immunoglobulin of a single monoclonal type, as is found in multiple myeloma and lymphoproliferative disorders.
- **Types II and III** cryoglobulinaemias are mixed types. In each, an antiglobulin is bound to the Fc portion of polyclonal IgG. In type II the antiglobulin is usually monoclonal IgM with rheumatoid factor activity, often associated with hepatitis C virus infection but also with other causes listed later. In type III the antiglobulin is polyclonal IgM. Type II cryoglobulinaemias account for 40–60% cases, while 40–50% of all CG cases are of type III.

Glomerular disease is more common in type II than in type III cryoglobulinaemia. In approximately 30% of these “mixed” cryoglobulinaemias, no underlying or associated disease is found (essential cryoglobulinaemia). Recognized associations include viral infections (hepatitis B and C, HIV, cytomegalovirus, Epstein–Barr infection), fungal and spirochaetal infections, malaria and infective endocarditis, and autoimmune rheumatic diseases (SLE, rheumatoid arthritis and Sjögren’s syndrome). Glomerular pathological changes resemble those of MCGN (see Fig. 36.23).

**Presentation** is usually in the fourth or fifth decade of life, and women are more frequently affected than men. Systemic features include purpura, arthralgia, leg ulcers, Raynaud’s phenomenon, evidence of systemic vasculitis, a polynuropathy and hepatic involvement. The glomerular disease typically presents as asymptomatic proteinuria, microscopic haematuria or both, but presentation with an acute nephritic and nephrotic syndrome (most commonly) or features of CKD also occurs.

Complement is consumed, cryoglobulins can be detected, and protein electrophoresis, rheumatoid factor, autoantibodies and antiviral antibodies or mRNA of hepatitis C, depending on the associated disorder, should be sought.

The underlying cause should be treated; as hepatitis C virus infection is the most common cause, antivirals, such as directly acting antiviral agents, are highly efficacious. Intensive plasma exchange or cryofiltration has been used in selected cases where vasculitis is limb-, organ- or life-threatening to achieve rapid removal of cryoglobulins.

Uncontrolled studies of the anti-CD20 chimeric monoclonal antibody rituximab, which depletes B cells, appear promising.

**Immunoglobulin A vasculitis (Henoch-Schönlein syndrome)**

This clinical syndrome comprises a characteristic skin rash, abdominal colic, joint pain and GN. Approximately 30–70% have clinical evidence of renal disease with haematuria and/or proteinuria. The renal disease is usually mild but the nephrotic syndrome and AKI can occur.

The renal lesion is a focal segmental proliferative glomerulonephritis, sometimes with mesangial hypercellularity. In more severe cases, epithelial crescents may be present. Immunoglobulin deposition is mainly IgA in the glomerular mesangium distribution, similar to IgA nephropathy. There is no treatment of proven benefit; steroid therapy is ineffective and management is usually supportive. In crescentic GN, aggressive immunosuppression has been tried but with variable outcome.

Other glomerular disorders

**Fabry’s disease**

This X-linked lysosomal storage disease results from a deficiency of the enzyme α-galactosidase. Glycosphingolipids (globotriaosylceramide) accumulate in many cells; in the kidney, podocytes are affected. Systemic features include angiokeratomas in the skin, cardiovascular disease, neuropathies and proteinuric progressive CKD. Enzyme replacement with agalsidase (α-galactosidase) slows progression and injury to the heart, kidney and skin. In certain cases migalastat, an oral molecular chaperone, is effective.

**Sickle nephropathy**

Sickle disease or trait is complicated relatively commonly by papillary sclerosis or necrosis, nephrogenic diabetes insipidus and
1368 Kidney and urinary tract disease

incomplete renal tubular acidosis. Glomerular lesions are rare and can sometimes be traced to hepatitis B or C infection acquired through repeated blood transfusions. Occasionally, proteinuria or nephrotic syndrome with progressive renal insufficiency is seen without prior infection, particularly in APOL1 G1/G2 gene variant. Rarely, membranous GN or mesangiocapillary GN with IgG deposits occurs in association. No form of effective therapy is known.

Glomerulopathy associated with pre-eclampsia

Patients with pre-eclampsia present with hypertension and proteinuria, often of rapid onset, which usually disappears after delivery. The glomerular lesion is characterized by marked endothelial swelling and obliteration of capillary lumina. The renal lesion may not be reversible and 30% of patients have changes for 6 months or more. In severe cases, associated with cortical necrosis, there may be a microangiopathic haemolytic anaemia. Normal placental development, regulated by angiogenic factors like vascular endothelial growth factor (VEGF) and by placental growth factors, does not occur in pre-eclampsia. Implantation is abnormal, in part due to a soluble fms-like tyrosine kinase (sFlt1) receptor, an antagonist of placental growth factor and specifically of VEGF, which is upregulated in the placenta of patients with pre-eclampsia. High circulating levels of these receptors antagonize angiopoietic factors and cause endothelial dysfunction. Excessive free radical generation in the placenta of pre-eclamptic patients is due to upregulation of NADPH oxidase activity, caused by generation of an angiotensin II receptor agonist antibody in some patients.

Paraneoplastic glomerulonephritis

A rare complication of malignancy, paraneoplastic GN is usually misdiagnosed as idiopathic GN. A number of cancers involve the kidney:

- **Thymoma or Hodgkin lymphoma**: polarization of the immune response towards a Th2 profile and possibly excessive production of IL-13 leads to the development of minimal change disease, mesangiocapillary GN or membranous nephropathy.
- **B-cell lymphoma and leukaemia**: these may induce injury through the presence of monoclonal immunoglobulin, cryoglobulin, and possibly hepatitis C virus infection.
- **Polycythaemia vera, essential thrombocythaemia or primary myelofibrosis**: severe thrombocytosis may induce FSGS, possibly due to elevated levels of platelet-derived growth factor.
- **Myelodysplastic syndromes**: autoimmunity causes a variety of glomerulonephritides.
- **Epithelial carcinoma**: glomerular inflammatory cells and subepithelial immune IgG1- and IgG2-containing complexes are usually present and may aid in the diagnosis of paraneoplastic membranous nephropathy.

KIDNEY INVOLVEMENT IN OTHER DISEASES

**Polyarteritis nodosa**

Classical polyarteritis nodosa (PAN) is a multisystem disorder (see also p. 465). Aneurysmal dilation of medium-sized arteries presents as hypertension, polyneuropathy and ischaemic infarction of a number of organs (including skin, gut, heart and brain). Aneurysms may be seen on renal arteriography. The condition is more common in men and in the elderly; typically, patients are ANCA-negative. PAN may be associated with drug use and hepatitis B infection. This form of polyangitis is linked with slowly progressive CKD, often accompanied by severe hypertension. Rapidly progressive kidney failure is rare. Treatment with immunosuppression is less effective than it is for microscopic polyangitis.

**Systemic sclerosis (scleroderma)**

Systemic sclerosis (scleroderma, SSc; see p. 460) is a chronic multisystem disease characterized by fibrosis and vasculopathy of the skin and visceral organs. Plasmacytoid dendritic cells appear to produce high plasma levels of CXCL4, which associated with both skin and lung fibrosis, as well as with pulmonary arterial hypertension in patients with SSc.

Some 10% of SSc patients develop scleroderma renal crisis, characterized by accelerated hypertension, rapidly progressive kidney failure and proteinuria. On kidney biopsy, ‘onion skinning’ in arcuate and interlobular arteries is seen and results from vessel intimal proliferation, fibrin thrombi and fibrinoid necrosis. The treatment of choice is ACE inhibitors, which have led to a remarkable improvement in outcomes in scleroderma renal crisis. Death is now rarely due to renal failure, though fewer than 30% of patients progress to ESKD.

**Haemolytic uraemic syndrome**

Haemolytic uraemic syndrome (HUS) is characterized by intravascular haemolysis with red cell fragmentation (microangiopathic haemolysis), thrombocytopenia and AKI due to thrombosis in small arteries and arterioles (Fig. 36.25). These features are also seen in disseminated intravascular coagulation but coagulation tests are typically normal in HUS.

**Diarrhoea-associated HUS**

Diarrhoea-associated HUS (D+ HUS) often follows a febrile illness, particularly gastroenteritis associated with E. coli, notably strain O157. The latter produces verocytotoxin (or shiga toxin), with a pathogenic A unit that inhibits protein synthesis and initiates
endothelial damage. B units facilitate entry of the A unit into the endothelial cells by binding to a receptor (Gb3) on the endothelial cell. Toxins are transported to and into endothelial cells from the gut on neutrophils. Most patients with D+ HUS recover renal function but commonly require supportive care, including fluid and electrolyte balance, antihypertensives, nutritional support and dialysis. Plasmapheresis is not beneficial. About 5% die during the acute episode, 5% develop ESKD and 30% exhibit evidence of long-term damage with persistent proteinuria. Antibiotic and antimotility agents for diarrhoea increase the risk of HUS and its complications.

Atypical HUS
Atypical HUS (aHUS) is a complement-driven illness, often related to a deficiency of complement factor H (CFH) or complement factor I (CFI). Factor H is a soluble protein produced by the liver, which regulates the activity of the alternative complement activation pathway; in particular, it protects host cell surfaces from complement-mediated damage. In some families with aHUS a mutation has been traced to another complement regulatory protein, CD46 (previously known as membrane co-factor protein, MCP). This protein is highly expressed in the kidney and normally prevents glomerular C3 activation. A loss-of-function mutation in CD46 results in unopposed complement activation and development of HUS. Functional deficiency of these factors can be acquired due to autoantibody formation, either as an isolated phenomenon or as part of an autoimmune disease such as SLE. A loss-of-function mutation in thrombomodulin (a membrane-bound anticoagulant glycoprotein) has been identified as an alternative complement pathway. Rarely, gain-of-function mutations can affect genes encoding the alternative pathway C3 convertase components, CFB and C3.

Management of aHUS
Treatment is often difficult, and severe hypertension and recurrence are frequent. The course of the disease is often indolent and progressive.

- Plasmapheresis or plasma infusion is used at initiation of therapy in the majority of patients, often until diagnosis is clear.
- C5 activation is one of the critical steps in the activation of complement cascade. Eculizumab, a monoclonal humanized anti-C5 antibody, has transformed outcomes, both at acute presentation and in prevention of recurrence (in native kidneys and in transplants).
- Liver transplantation is a potentially curative treatment in patients harbouring CFH and CFI mutations.

Sporadic cases of aHUS
These can be associated with pregnancy, SLE, scleroderma, malignant hypertension, metastatic cancer, HIV infection and various drugs, including oral contraceptives, cyclosporin, tacrolimus, chemotherapy agents (e.g. cisplatin, mitomycin C, bleomycin) and heparin. Management is supportive, with removal of the offending agent or specific treatment of the underlying cause. There is no evidence in favour of plasma infusion or plasmapheresis in these sporadic cases but it is tried, usually as a last resort.

Streptococcus pneumoniae produces an enzyme (possibly neuroaminidase) that can expose an antigen (Thomsen antigen) present on red blood cells, platelets and glomeruli. Antibodies to the antigen result in an antigen–antibody reaction and can lead to HUS and anaemia. The improved outcome is due to increasing awareness of this complication, judicious use of (washed) blood products and avoidance of plasma infusion or plasmapheresis.

Metabolism-associated HUS
Cobalamin C disease is a hereditary disorder of vitamin B₁₂ metabolism that may cause HUS and multiple organ damage in infants and, rarely, adults. It is caused by mutations in a gene encoding the methylmalonic aciduria and homocystinuria type C protein (MMACHC). The resulting deficiency in methylcobalamin causes hyperhomocysteinaemia, decreased plasma methionine levels and methylmalonic aciduria.

Abnormal cobalamin C metabolism is associated with platelet activation, generation of reactive oxygen species, endothelial dysfunction, increased tissue factor expression, coagulopathy and HUS.

Parenteral hydroxocobalamin is the principal treatment for infants.

Thrombotic thrombocytopenic purpura
Thrombotic thrombocytopenic purpura (TTP; see p. 374) is characterized by microangiopathic haemolysis, renal failure and evidence of neurological disturbance. Young adults are most commonly affected. Wherever TTP or HUS is suspected, the serum activity of ADAMTS13 should be measured. ADAMTS13 activity is reduced in TTP, but normal in HUS and other conditions that cause thrombotic microangiopathy.

Antiphospholipid syndrome
In the antiphospholipid syndrome (APS; see p. 459) the binding of antiphospholipid antibodies (aPL) to beta 2 glycoprotein I (β2GPI) induces endothelial cell–leucocyte adhesion and thrombus formation through the inhibition of endothelial nitric oxide synthase (eNOS).

The central feature of APS is recurrent thrombosis (both venous and arterial) and early pregnancy loss in the presence of antiphospholipid antibodies. Antibodies may be primary, or secondary to infection (HIV, hepatitis C) or autoimmune disease (SLE). Some 50% have renal involvement with proteinuria. Thrombotic microangiopathy is a rare but well-recognized presentation. In some cases a lupus nephritis-like lesion (usually mesangiocapillary GN) is seen. The only proven treatment for APS is systemic anticoagulation. Use of steroids or plasmapheresis is reserved for patients with APS and life-threatening renal involvement with thrombotic microangiopathy. Treatment is variably successful (30–70%).

Multiple myeloma
AKI is relatively common in myeloma, occurring in 20–30% of affected individuals at the time of diagnosis, and is mainly due to the nephrotoxic effects of the abnormal immunoglobulins. It is often irreversible and may present as:

- **light chain cast nephropathy** – intratubular deposition of light chains, particularly kappa chains, which characteristically appear on renal histology as fractured casts with a giant cell reaction (Fig. 36.26)
- **AL amyloidosis** – deposition of amyloid fibrils of light chains (Congo red-positive)
- **light chain deposition disease** – nodular glomerulosclerosis with granular deposits of usually lambda light chains (Congo red-negative)
- **plasma cell infiltration** – often an incidental finding at postmortem
- **Fanconi’s syndrome** – tubular toxicity due to light chains
- **hypercalcaemic nephropathy** – bone resorption causing hypercalcaemia
Kidney and urinary tract disease

- hyperuricaemic nephropathy – tumour lysis causing tubular crystallization of uric acid
- radiocontrast nephropathy – interaction between light chains and radiocontrast.

Treatment of the underlying myeloma is key to recovery (see p. 409). If a patient with cast nephropathy and severe AKI remains dialysis-dependent, the prognosis is poor. Commencement of effective bortezomib-based chemotherapy, which decreases light chain production, and a high-cut-off haemodialysis have shown some promise in relapsed myeloma.

Hypertension and the Kidney

Hypertension can be the cause or the result of renal disease. It is often difficult to differentiate between the two on clinical grounds. Routine tests (see p. 1134) should be performed on all hypertensive patients, though renal imaging is usually unnecessary.

The mechanisms responsible for normal regulation of arterial blood pressure and the development of essential primary hypertension are unclear (see p. 1137). One basic concept is that long-term regulation of arterial pressure is closely linked to the ability of the kidneys to excrete sufficient salt to maintain normal sodium balance, extracellular fluid volume and normal blood volume at normotensive arterial pressures. Cross-transplantation experiments suggest that hypertension travels with the kidney, as hypertension develops in the normotensive recipient of a kidney genetically programmed for hypertension. Similarly, patients with ESKD due to hypertension become normotensive after receiving a kidney transplant from normotensive donors, provided the new kidney functions well.

One renal factor contributing to future hypertension is the total number of nephrons per kidney (“nephron dose”). People with hypertension and normal renal function have a significantly reduced number of nephrons in each kidney, and individual nephrons are enlarged as a result of glomerular hyperfiltration (see p. 1359). Where hypertension is more common (as it is in black or Hispanic men and women), increased glomerular volume is found (a surrogate marker for reduced nephron number).

Whether reduced nephron number is genetic or environmental in origin is unclear. Changes in the intrauterine environment may lead to poor renal growth (and reduced renal volume, suggesting lower nephron number) before birth, low birth weight and hypertension in adult life.

Excess renal sympathetic activity may also contribute. Strategies to achieve bilateral renal sympathetic denervation were hugely effective in patients with refractory hypertension in uncontrolled studies; to date, this benefit has not been borne out by a well-controlled trial.

Essential hypertension

In essential hypertension, arteriosclerosis of major renal arteries and changes in the intrarenal vasculature (nephrosclerosis) occur. Arterial pressure is a product of cardiac output and systemic vascular resistance (SVR). The compliance of systemic arteries is, then, a critical component; ‘stiff’ (sclerotic) arteries cannot modulate pressure surges in systole, and systolic pressures rise. Over time, vessels (and the kidney) remodel:

- In small vessels and arterioles, intimal thickening with reduplication of the internal elastic lamina occurs and the vessel wall becomes hyalinized.
- In large vessels, concentric reduplication of the internal elastic lamina and endothelial proliferation produce an ‘onion skin’ appearance.
- Reduction in size of both kidneys occurs; this may be asymmetrical if one major renal artery is more affected than the other.

The proportion of sclerotic (scarred) glomeruli is increased, compared with that in age-matched controls.

Renal function does deteriorate with these changes but severe CKD is unusual in white people (1 in 10 000). In people of black African descent, by contrast, hypertension much more often results in the development of CKD, with a fourfold higher incidence of ESKD compared to that in white people. This difference in incidence of hypertensive renal disease may be due to overestimation of the diagnosis on clinical grounds, a higher incidence of hypertension (usually salt-sensitive), reduced nephron number and a higher frequency of susceptibility alleles for ESKD in the (West) African than the European gene pool.

A genome-wide study found statistically stronger associations between two independent sequence variants in the apolipoprotein L1 gene (APOL1) and non-diabetic nephropathy in African–Americans, in hypertension-attributed ESKD. These kidney disease risk variants most likely arose due to the positive selection for evolutionary advantage that these variants in APOL1 conferred against trypanosomal infection and protection from African sleeping sickness. These observations provide some evidence, similar to findings in sickle cell anaemia, that natural selection might protect from one disease but allow another one to develop.

In accelerated or malignant-phase hypertension:
- Arteriolar fibrinoid necrosis occurs, probably as a result of plasma entering the media of the vessel through splits in the intima.
- It is prominent in afferent glomerular arterioles.
- Fibrin deposition within small vessels is often associated with thrombocytopenia and red cell fragmentation seen on the peripheral blood film (microangiopathic haemolytic anaemia).

Microscopic haematuria, proteinuria (usually of modest degree – 1–3 g daily) and progressive CKD occur. If disease is untreated, fewer than 10% of patients survive 2 years.
Renal hypertension

Hypertension commonly complicates bilateral renal disease such as chronic GN, bilateral reflex nephropathy, polycystic disease and analgesic nephropathy. Two main mechanisms are responsible:

- Activation of the renin–angiotensin–aldosterone system
- Retention of salt and water as excretory function declines, leading to an increase in blood volume and blood pressure.

As CKD progresses, salt and water overload becomes ever more involved in driving high blood pressure.

Hypertension occurs earlier, is more common and tends to be more severe in patients with glomerular disease (GN) than in those with tubulointerstitial diseases such as reflux or analgesic nephropathy.

Management is described on page 1140. Meticulous control of blood pressure may prevent ongoing or new vascular or parenchymal changes, and further deterioration of renal function. There is good evidence that ACE inhibitors offer additional renoprotective benefits for the same degree of blood pressure control than other agents. In a study of African-Americans with hypertension, intensive blood pressure control (130/78 mmHg) was not superior to standard control (141/86 mmHg) in the prevention of ESKD. However, in the same study, patients with proteinuria benefited more from intensive blood pressure control. The presence of the APOL1 risk allele was associated with rapid decline of GFR, irrespective of achieved blood pressure or baseline proteinuria.

Renovascular disease

Renal ischaemia, or a fall in perfusion pressures in the afferent glomerular arterioles, leads to increased production and release of renin from the juxtaglomerular apparatus (see p. 1343). This, in turn, causes a consequent increase in angiotensin II, a potent vasoconstrictor, which also triggers aldosterone secretion, stimulates thirst and leads to vascular smooth muscle hypertrophy and fibrosis in the kidney.

In renal artery stenosis, narrowing of the renal artery or arteries causes a fall in renal perfusion pressure on the distal side of the stenosis; in each affected kidney, angiotensin release occurs and local salt and water reabsorption is increased. Urine from the ischaemic kidney is more concentrated, with a lower sodium concentration than urine from an unaffected kidney. GFR is decreased on the ischaemic side as well.

Narrowing of the renal arteries (renal artery stenosis) is caused by one of two pathologies: atherosclerotic renovascular disease or fibromuscular dysplasia.

Atherosclerotic renovascular disease

Atherosclerotic renovascular disease (ARVD) is a common cause of hypertension and CKD due to ischaemic nephropathy. Its incidence increases with age:

- 5% in those under 60 years of age
- 16% in those over 60 years of age.

In most patients the atherosclerotic lesion is ostial (within 1 cm of the origin of the renal artery) and usually associated with symptomatic atherosclerotic vascular disease elsewhere. Patients with peripheral vascular disease (39%), coronary artery disease (10–29%), congestive cardiac failure (34%) and aortic aneurysm (38%) are at high risk of developing significant renal artery stenosis.

Many patients are asymptomatic and are discovered incidentally during investigation for other conditions. Aortography experience from the USA shows that 11% of asymptomatic patients have significant unilateral stenosis and 4% have bilateral disease. ARVD results in hypertension (present in 50%), sodium retention (ankle and flash pulmonary oedema), proteinuria (usually in the subnephrotic range) and decreased GFR. Beyond the stenosis, affected kidneys demonstrate changes histologically, with vascular sclerosis, tubular atrophy, interstitial fibrosis with inflammatory cellular infiltrate, atubular glomeruli, cholesterol emboli and secondary FSGS changes. These changes are often described as ‘ischaemic nephropathy’. The affected kidney loses volume (as fibrosis replaces normal tissue) and becomes smaller on ultrasound measurement. These morphological changes are responsible for the associated fall in GFR; the arterial stenosis itself drives hypertension.

Renovascular disease should be considered in:

- Patients with hypertension and/or CKD with abdominal or other audible bruits
- Patients with renal asymmetry, particularly where ultrasound suggests >1.5 cm difference in length
- Recurrent flash pulmonary oedema without cardiopulmonary disease
- Progressive CKD in patients with evidence of generalized atherosclerosis.

Management

The aims of treatment are to prevent decline in renal function and to reverse salt and water overload. Most patients with ARVD will die a cardiovascular death and modifiable risk factors should be addressed. All patients with ARVD should be managed with a combination of aspirin, statins and optimal control of blood pressure as prophylaxis against progression of atherosclerosis. Hypertension should be controlled, ideally with an ACE inhibitor. This is the paradox of ARVD: angiotensin drives the renal and cardiac events, so ACE inhibition is ideal medical therapy. However, because ACE inhibitors will cause a fall (often significant) in renal perfusion beyond the stenosis, ACE inhibitors can cause AKI in patients with bilateral, haemodynamically significant ARVD.

Renal artery stenosis can also progress to occlusion, particularly in patients with stenosis of more than 75%, as shown by serial angiography. Revascularization offers definitive treatment of stenotic lesions in ARVD:

- Options in renal artery stenosis include transluminal angioplasty to dilate the stenotic region, insertion of stents across the stenosis (sometimes the only endoscopic option when the stenosis occurs close to the origin of the renal artery from the aorta, making angioplasty technically difficult or impossible), reconstructive vascular surgery and nephrectomy.
- Indications for revascularization are vessels with stenosis of >75% and recurrent flash pulmonary oedema, drug-resistant severe hypertension, ARVD affecting a solitary functioning kidney, patients with cardiac failure needing ACE inhibitors, unexplained progressive CKD and dialysis-dependent renal failure.

In a number of trials, renal artery stenting did not confer a significant benefit with respect to the prevention of clinical events (cardiovascular events, progressive renal insufficiency or the need for
RRT) when added to comprehensive, multifactorial medical therapy in people with atherosclerotic renal artery stenosis and hypertension or CKD. Up to 30% of renal artery interventions will be complicated by atheroembolism, which may lead to further functional deterioration.

**Prognosis**
Mortality is high because of other associated co-morbidities, and ARVD patients have generalized endothelial dysfunction. ARVD patients with ESKD have higher death rates than those with other causes of ESKD. Five-year survival is only 18% in patients with ESKD due to ARVD.

**Fibromuscular dysplasia of the renal arteries**
Fibromuscular dysplasia (FMD) is often asymptomatic, occurring in younger women with hypertension. It is far less common than ARVD. FMD affects many arterial beds, including the carotid and coronary arteries. Renal function is often normal.

MRA (gadolinium-enhanced) reveals a characteristic string of beads appearance in the mid-renal artery (rather than affecting the ostium, as seen in ARVD).

Angioplasty (occasionally with stent insertion) or, rarely, surgery was offered to affected individuals. Cure rates were only 36% and 54%, respectively, in a study of over 2000 patients (defining cure as blood pressure <140/90 mmHg without treatment), and the blood pressure outcome was strongly age-related. Procedural complications were common: 12% after angioplasty and 17% after surgery. Current medical antihypertensive therapy is very effective in this group and angioplasty is now not usually performed.

**Screening for renovascular disease**

- **Radionuclide studies** (see p. 1351) can demonstrate decreased renal perfusion on the affected side. In unilateral renal artery stenosis a disproportionate fall in isotope uptake occurs on the affected side after administration of captopril. A completely normal result makes renovascular disease unlikely.

- **Doppler ultrasound** is sensitive but highly operator-dependent and time-consuming. Higher renal artery velocity on Doppler may mean a higher pressure differential across a stenosis. Doppler also describes the intrarenal vascular resistance, which can be valuable in predicting the success of revascularization procedures. A resistive index of >0.8 is a predictor of poor response following intervention.

- **MRA** can be used to visualize the renal arteries and there is a good – though not perfect – correlation between MRA findings and those of renal arteriography.

- **CT scanning** permits non-invasive imaging of the renal arteries. It is much less expensive than MRA but does expose the patient to ionizing radiation and to contrast injection, and is less reliable than MRA.

- **Renal arteriography** (see p. 1351) is used to confirm the diagnosis of renal arterial disease. It also allows therapeutic intervention if needed at diagnosis.

**Further reading**

**Renal artery occlusion**
This occurs from thrombosis in situ, usually in a severely damaged atherosclerotic vessel, or more commonly from embolization, such as in atrial fibrillation. Both lead to renal infarction, either of a wedge of kidney or of the whole kidney. Occlusion of a small branch artery may produce no effect but occlusion of larger vessels results in dull flank pain, macroscopic haematuria and varying degrees of CKD. Intra-arterial thrombolytic therapy has been tried with mixed results.

**Cholesterol embolization (atheroembolic renal disease)**
Showers of cholesterol-rich atheromatous material from ulcerated plaques reach the kidney from the aorta and/or renal arteries, particularly after catheterization of the abdominal aorta or attempts at renal artery angioplasty. Anticoagulants and thrombolytic agents also precipitate non-traumatic cholesterol embolization. Renal failure from cholesterol emboli may be acute or slowly progressive. Clinical features include fever, eosinophilia, back and abdominal pain, and evidence of embolization elsewhere, such as to the retina or digits. The diagnosis can be confirmed by renal biopsy (Fig. 36.27). It is more common in males, the elderly (>70 years) and patients with cardiovascular disease. Over 80% have abnormal renal function at baseline. Atheroembolic renal disease occurs spontaneously in 25% of cases. The 2-year mortality is 30% and a similar percentage of patients develop CKD. Baseline co-morbidities – that is, reduced renal function, presence of diabetes, history of heart failure, acute/subacute presentation and gastrointestinal tract involvement – are significant predictors of event occurrence. The risk of dialysis and death is 50% lower among those receiving statins.

**Renal vein thrombosis**
This is usually of insidious onset, occurring in patients with the nephrotic syndrome, with a renal cell carcinoma, and in thrombophilia (see p. 1011) with an increased risk of venous thrombosis. Anticoagulation is indicated.
Renal calculi and nephrocalcinosis

Renal and vesical calculi

Nephrolithiasis, or renal stones, usually occurs in the upper urinary tract. It is very common worldwide, with a lifetime risk of about 10%.

Most stones are composed of calcium oxalate and phosphate; these are more common in men (Box 36.17). Mixed infective stones, which account for about 15% of all calculi, are twice as common in women as in men. The overall male to female ratio of stone disease is 2:1.

Stone disease is frequently recurrent and more than 50% of patients will experience a second stone within 10 years of their first. The risk of recurrence increases if a metabolic or structural abnormality predisposing to stone formation is present and is not modified by treatment. Nephrolithiasis is not a benign condition; observational studies show an association with an increased risk of ESKD, bone diseases, hypertension and myocardial infarction.

Aetiology

Stones form because solute concentrations exceed saturation, often in the context of a trigger or nidus to crystallize around. Inhibitors of crystal formation prevent stone formation in normal urine, despite the concentrations of stone-forming substances exceeding maximum solubility in water. Factors predisposing to stone formation in these so-called ‘idiopathic stone-formers’ are:

- Chemical composition of urine that favours stone crystallization.
- A concentrated urine resulting from dehydration (particularly in those who are living or working in a hot climate or environment).
- Impairment of inhibitors that prevent crystallization in normal urine. These inhibitors include inorganic magnesium, pyrophosphate and citrate. Organic inhibitors include glycosaminoglycans and nephrocalcin (an acidic protein of tubular origin). Tamm–Horsfall protein may have a dual role in both inhibiting and promoting stone formation; it usually inhibits crystallization of urinary oxalate but in an undersialylated form promotes stone formation.

Recognized risk factors for stone formation are listed in Box 36.18.

Stones may be single or multiple, and vary enormously in size from minute, sand-like particles to staghorn calculi or large stone concretions in the bladder. They may be located within the renal parenchyma or within the collecting system. Stones regularly cause obstruction, leading to hydroureteronephrosis; a combination of obstruction and infection often causes lasting damage to the kidney.

- Drugs (see text)

Hypercalcaemia

If the GFR is normal, hypercalcaemia almost invariably leads to hypercalciuria. Common causes of systemic hypercalcaemia leading to stone formation are:

- primary hyperparathyroidism (see p. 644)
- vitamin D ingestion
- sarcoidosis.

Hypercalciuria

This is by far the most common metabolic abnormality detected in calcium stone-formers. Approximately 8% of men excrete more than 7.5 mmol of calcium per day. Calcium stone formation is more common in this group, although the cut-off is entirely arbitrary. In women, a 24-hour calcium excretion of more than 6.25 mmol tends to make stone formation more likely.

About 90% of ionized calcium filtered by the kidney is reabsorbed in the tubule, controlled largely by PTH. Causes of hypercalciuria include:

- hypercalciemia
- high dietary intake of calcium
- excessive resorption of calcium from the skeleton, such as occurs with prolonged immobilization or weightlessness
- idiopathic hypercalciuria.

Idiopathic hypercalciuria is a common risk factor for the formation of stones, and can be thought of as accelerated calcium transport, with enhanced gut uptake, and increased urine excretion of calcium.

Hyperoxaluria

There are two inborn errors of glyoxylate metabolism that cause increased endogenous oxalate biosynthesis and are inherited in an autosomal recessive manner:

- type 1: alanine-glyoxylate aminotransferase deficiency
- type 2: glyoxylate reductase hydroxypyruvate reductase deficiency.

In both types, calcium oxalate stone formation occurs. The prognosis is poor, as widespread calcium oxalate crystal deposition in the kidneys leads to CKD in the late teens or early twenties. Successful liver transplantation has been shown to cure the metabolic defect.

Much more common causes of mild hyperoxaluria are:

- excess ingestion of foodstuffs high in oxalate, such as spinach, rhubarb and tea
- dietary calcium restriction, with compensatory increased absorption of oxalate
- gastrointestinal disease (e.g. Crohn’s), usually with an intestinal resection, associated with increased absorption of oxalate from the colon.

Dehydration secondary to fluid loss from the gut also plays a part in stone formation.

Hyperuricaemia and hyperuricosuria

Uric acid stones account for 3–5% of all stones in the UK but in Israel the proportion is as high as 40%. Uric acid is the endpoint of purine
metabolism. Hyperuricaemia (see p. 452) can occur as a primary defect in idiopathic gout and as a secondary consequence of increased cell turnover: for example, in myeloproliferative disorders. Increased uric acid excretion occurs in these conditions and stones will develop in some patients. Some uric acid stone-formers have hyperuricosuria (>4 mmol/24 h on a low-purine diet), without hyperuricaemia.

Dehydration alone may also cause uric acid stones to form. Patients with ileostomies are at particular risk, both from dehydration and from the fact that loss of bicarbonate from gastrointestinal secretions results in the production of an acid urine (uric acid is more soluble in an alkaline medium than in an acid one).

Some patients with calcium stones also have hyperuricaemia and/or hyperuricosuria; it is believed that the calcium salts precipitate on an initial nidus of uric acid in such patients.

**Urinary tract infection**

Mixed infective stones are composed of magnesium ammonium phosphate together with variable amounts of calcium. Such struvite stones are often large, forming a cast of the collecting system (stag-horn calculus). These stones are usually due to urinary tract infection with organisms such as *Proteus mirabilis* that hydrolyse urea, with formation of the strong base ammonium hydroxide. The availability of ammonium ions and the alkalinity of the urine favour stone formation. An increased production of mucoprotein from infection also creates an organic matrix on which stone formation can occur.

**Cystinuria**

Cystinuria results in the formation of cystine stones (about 1–2% of all stones).

**Primary renal disease**

- **Polycystic renal disease** (see p. 1405) shows a high prevalence of stone disease.
- **Medullary sponge kidney** involves dilation of the collecting ducts that leads to urinary stasis and calcification (Fig. 36.28). Approximately 20% of these patients have hypercalciuria and a similar proportion have a renal tubular acidification defect.
- **Renal tubular acidosis**, either inherited and acquired, is associated with nephrocalcinosis and stone formation. Persistently alkaline urine and reduced urinary citrate excretion lead to stone formation, as calcium and citrate form a soluble complex in urine.

**Drugs**

Some drugs promote calcium stone formation (e.g. loop diuretics, antacids, glucocorticoids, theophylline, vitamins D and C, acetazolamide); some promote uric acid stones (e.g. thiazides, salicylates); and some precipitate into stones (e.g. indinavir, triamterene, sulfadiazine).

**Clinical features**

Most people with urinary tract calculi are asymptomatic.

- Pain is the most common symptom and may be sharp or dull, constant, intermittent or colicky (Box 36.19).
- If the urinary tract is obstructed, fluids or diuretics (including alcohol) make the pain worse as peristaltic flow increases.
- Exertion may cause mobile calculi to move, precipitating pain and, occasionally, haematuria.
- Ureteric colic occurs when a stone enters the ureter and either obstructs it or causes spasm during its passage down the ureter. Classically, pain radiates from the flank to the iliac fossa, testis or labia (in the distribution of the first lumbar nerve root). Pallor, sweating and vomiting often occur and the patient is restless, trying to obtain relief from the pain. Haematuria often occurs. Untreated, the pain of ureteric colic typically subsides after a few hours.

When urinary tract obstruction and infection are present, the features of acute pyelonephritis or of a Gram-negative septicaemia may dominate the clinical picture.

Calciﬁed papillae may mimic ordinary calculi, so that causes of papillary necrosis such as analgesic abuse should be considered (see p. 1386).

**Bladder stones**

Bladder stones (Box 36.20) are usually associated with bacteriuria and present with frequency, dysuria and haematuria; severe introital or perineal pain may occur if trigonitis is present.
A calculus at the bladder neck or an obstruction in the urethra may cause bladder outflow obstruction, resulting in anuria and painful bladder distension.

**Investigations**
- *Dipsticks* are used to test for red cells, protein and glucose.
- *Chemical analysis* should be employed for passed stones.
- A mid-stream specimen of urine should be taken for microscopy (crystals) and culture.
- Serum urea, electrolyte, creatinine (eGFR) and calcium levels should be measured.
- *Ultrasonography* shows kidney stones and renal pelvis dilation well but ureteric stones can be missed.
- Computed tomography of kidneys, ureters and bladder (CT-KUB) is the best diagnostic test available and has a sensitivity of >95%. It involves radiation and in young patients many physicians perform ultrasonographs as the first investigation.

A normal CT excludes the diagnosis of pain due to calculous disease. The CT-KUB appearances in a patient with acute left ureteric obstruction are shown in Fig. 36.29.

Pure uric acid stones are radiolucent and show as a filling defect after injection of contrast medium if excretion urography is performed. Uric acid stones are readily seen on CT scanning (Fig. 36.30). Mixed infective stones in which organic matrix predominates are barely radio-opaque.

**Management**
Renal colic is painful. Analgesia with an NSAID, such as diclofenac 75 mg i.m., compares favourably with opiates such as diamorphine or pethidine. Stones of less than 0.5 cm diameter usually pass spontaneously, particularly if hydration is maintained (patients that can drink should aim for over 2.5 L intake). Alpha-blockers (e.g. tamsulosin) were thought to help expulsion of distal ureteral stones of less than 6 mm in size (alpha receptors are predominantly present in the distal ureter and detrusor) but a randomized controlled trial has shown no benefit.

Stones of more than 1 cm diameter usually need urological or radiological intervention. Extracorporeal shock-wave lithotripsy (ESWL) will fragment most stones, which then pass spontaneously. Ureteroscopy with a YAG laser can be used for larger stones. Percutaneous nephrolithotomy is also used. Open surgery is rarely needed.

**Investigation of the cause of stone formation**
Investigation of the cause of stone formation
In an elderly patient who has had a single episode with one stone, only limited investigation is required. Younger patients and those with recurrent stone formation need detailed investigation.
- Renal imaging excludes structural abnormalities of the urinary tract.
- Urine culture excludes significant bacteriuria.
- Chemical analysis is performed on any stone passed (required in the diagnosis of cystinuria or uric acid stone formation).
- Serum calcium is investigated if hypercalcaemia is present (see p. 1375).
- Serum urate concentration is often, but not invariably, elevated in uric acid stone-formers.
- A screening test for cystinuria should be carried out by adding sodium nitroprusside to a random unacidified urine sample; a purple colour indicates that cystinuria may be present. Urine chromatography is required to define the diagnosis precisely.
- Urinary calcium, oxalate and uric acid output should be measured in two consecutive, carefully collected 24 hour urine samples. After aliquots are withdrawn for estimation of uric acid, the urine is acidified to prevent crystallization of calcium salts on the walls of the container, which would give falsely low results for urinary calcium and oxalate.
- Plasma bicarbonate is low in renal tubular acidosis. The finding of a urine pH that does not fall below 5.5 in the face of metabolic acidosis is diagnostic of this condition (see p. 199).

**Prevention of recurrent stones**
- All idiopathic stone-formers, where no metabolic abnormality is present, should maintain a high intake of fluid throughout the day and night to ensure a daily urine volume of 2–2.5 L. This reduces saturation of solute.

---

**Box 36.20 Bladder stones**
Occur where stasis, infection and a nidus for stone formation come together:
- Bladder outflow obstruction (e.g. urethral stricture, neuropathic bladder, prostatic obstruction)
- Presence of a foreign body (e.g. catheters, non-absorbable sutures)
With idiopathic hypercalciuria, dietary calcium restriction is inappropriate, as restriction results in hyperabsorption of oxalate. Foods rich in oxalate should be avoided (nuts, spinach, chocolate, rhubarb). Patients who live in a hard-water area may benefit from drinking softened water.

Salt intake should be limited to 50 mmol/day (calcium excretion increases by 0.6 mmol/day for every 100 mmol Na+ in the urine).

If hypercalciuria stone formation persists, a thiazide diuretic (e.g. bendroflumethiazide 2.5 or 5 mg each morning) reduces urinary calcium excretion. This indirect effect is due to mild volume contraction resulting in increased calcium absorption in the proximal renal tubule.

Reduction of animal proteins to 50 g/day is also advisable.

Where mixed infective stones recur, long-term, low-dose prophylactic antibiotics may prevent bacteriuria.

Urinary acid stones can be prevented by the long-term use of allopurinol or febuxostat to maintain the serum urate and urinary uric acid excretion in the normal range. Alkalization to a pH of 7 requires high doses of potassium citrate or bicarbonate. An alternative option is long-term use of the chelating agent penicillamine; this causes cystine to be converted to the more soluble penicillamine–cysteine complex. Side-effects include drug rashes, blood dyscrasias and immune complex-mediated glomerulonephritis. However, it is especially effective in promoting dissolution of cystine stones already present. Other cystine-binding drugs include captopril and tiopronin.

Monogenic hyperoxaluria can be managed with oral high-dose pyridoxine if type 1 (though no response will occur with type 2). Unfortunately, there is currently no proven pharmacotherapy for effective treatment of the more common form of ‘idiopathic’ hyperoxaluria present in up to 40% of stone-formers. Probiotic Oxalobacter formigenes has shown some promise.

Nephrocalcinosis

The term ‘nephrocalcinosis’ means diffuse renal parenchymal calcification that is detectable radiologically (Fig. 36.31). The condition is typically painless. Hypertension and CKD commonly occur. The main causes of nephrocalcinosis are listed in Box 36.21.

Dystrophic calcification occurs following renal cortical necrosis. In hypercalcaemia and hyperoxaluria, deposition of calcium oxalate results from the high concentration of calcium and oxalate within the kidney.

In renal tubular acidosis (see p. 199), failure of urinary acidification and a reduction in urinary citrate excretion both favour calcium phosphate and oxalate precipitation, since precipitation occurs more readily in an alkaline medium and the calcium-chelating action of urinary citrate is reduced.

Management and prevention of nephrocalcinosis consist of treating the cause.

URINARY TRACT OBSTRUCTION

Urinary tract obstruction can occur at any point between the kidney and the urethral meatus. Obstruction can be partial or complete, and
Urinary tract obstruction

Box 36.22 Causes of urinary tract obstruction

**Within the lumen**
- Calculus
- Blood clot
- Sloughed papilla (diabetes; analgesia misuse; sickle cell disease or trait)
- Tumour of renal pelvis, ureter or bladder

**Within the wall**
- Pelviureteric neuromuscular dysfunction (congenital, 10% bilateral)
- Ureteric stricture (tuberculosis, especially after treatment; calculus; after surgery)
- Ureterovesical stricture (congenital; ureteroceles; calculus; schistosomiasis)
- Congenital megaureter
- Congenital bladder neck obstruction
- Neuropathic bladder
- Urethral stricture (calculus; gonococcal; after instrumentation)
- Congenital urethral valve
- Pin-hole meatus

**Pressure from outside**
- Pelviureteric compression (bands; aberrant vessels)
- Tumours (e.g. retroperitoneal tumour or glands; carcinoma of colon; tumours in pelvis, e.g. carcinoma of cervix)
- Diverticulitis
- Aortic aneurysm
- Retroperitoneal fibrosis (peri-aortitis, e.g. IgG4 disease)
- Accidental ligation of ureter
- Retrocaval ureter (right-sided obstruction)
- Prostatic obstruction
- Phimosis

leads to delayed transit of urine, rising urinary tract (and intrarenal) pressure, and – if obstructing both kidneys – eventual renal impairment.

**Aetiology**

Obstructing lesions may lie within the lumen, in the wall of the urinary tract or outside the wall, causing obstruction by external pressure. Obstruction causing dilation of the renal pelvis and/or ureter is known as hydronephrosis. The major causes of obstruction are shown in Box 36.22. In children, obstruction usually results from congenital abnormalities or urethral valves. In young women, pelvic tumours, pregnancy or stones cause obstruction. In younger men, stones are the dominant cause, but bladder outflow obstruction (prostatic disease) dominates later in life.

**Pathophysiology**

Urine continues to be formed despite obstruction to flow. This leads to:
- progressive rise in intraluminal pressure
- dilation proximal to the site of obstruction
- compression and thinning of the renal parenchyma, eventually reducing it to a thin rim and resulting in a decrease in the size of the kidney.

Acute obstruction is followed by transient renal arterial vasodilation succeeded by vasoconstriction, probably mediated mainly by angiotensin II and thromboxane A₂. Ischaemic interstitial damage mediated by free oxygen radicals and inflammatory cytokines compounds the damage induced by compression of the renal substance.

**Clinical features**

**Symptoms**

Loin pain occurs, which can be dull or sharp, and constant or intermittent. Pain is made worse if urine flow and volume increase, as the collecting system distends. A high fluid intake or diuretics, including alcohol and coffee, may provoke pain.

Complete anuria is strongly suggestive of complete bilateral obstruction or complete obstruction of a single kidney.

Polyuria may occur in partial obstruction, as rising pressures impair renal tubular concentrating capacity; intermittent anuria and polyuria indicate intermittent complete obstruction.

Infection is a major complication and may give rise to malaise, fever and sepsicaemia.

Bladder outflow obstruction may occur with few symptoms. Hesitancy, narrowing and diminished force of the urinary stream, terminal dribbling (lower urinary tract symptoms, or LUTS) and a sense of incomplete bladder emptying are typical features (see p. 1480). Infection is common (and may precipitate acute retention) with frequency, urgency, urge incontinence, dysuria and the passage of cloudy, smelly urine. Acute bladder retention causes significant discomfort and distress, though in the elderly may present as confusion and agitation alone.

**Signs**

On abdominal palpation, loin tenderness may be present, and occasionally an enlarged hydronephrotic kidney is palpable. In acute or chronic retention the enlarged bladder can be felt or percussed. Examination of the genitalia, rectum and vagina is performed, since prostatic obstruction and pelvic malignancy are common causes of urinary tract obstruction. However, the apparent size of the prostate on digital examination is a poor guide to the presence of prostatic obstruction.

**Investigations**

- **Urinalysis** is performed for haematuria.
- A mid-stream sample of urine for MC&S is assessed to exclude infection.
- **Routine biochemical investigations** may show a raised serum urea or creatinine (or a reduced eGFR), hyperkalaemia, or anaemia of chronic disease. Prostate-specific antigen may be abnormal (see p. 1480).
- **Ultrasonography** (see p. 1350) is the investigation of choice to confirm or rule out upper urinary tract dilation. Ultrasound cannot distinguish a baggy, low-pressure, unobstructed system from a tense, high-pressure, obstructed one, so that false-positive scans are seen. Stones in the ureter can be missed.
- **Plain abdominal X-ray** may detect radiolucent stones/calcification but can miss stones lying over the bone.
- **CT scanning** has a high sensitivity and can visualize uric acid (radiolucent) stones as small as 1 mm, as well as details of the obstruction. CT also allows detection of local mass lesions or lymphadenopathy.
- **Excretion urography** is now seldom used. A characteristic delayed nephrogram is seen on the obstructed side (owing to a reduction in the GFR). With time, the nephrogram on the affected side becomes denser than normal, owing to the prolonged nephron transit time, and the site of obstruction with proximal dilation is seen (Fig. 36.32).
- **Radionuclide studies** (see p. 1351) have a role in longstanding obstruction to differentiate true obstructive nephropathy from retention of tracer in a baggy, low-pressure, unobstructed pelvicalyeal system.
- **Antegrade pyelography and ureterography** (see p. 1351) define the site and cause of obstruction. This technique can be combined with drainage of the collecting system by percutaneous needle nephrostomy.
Kidney and urinary tract disease

• **Retrograde ureterography** (see p. 1350) offers the option of relieving ureteric obstruction from below at the time of examination. In obstruction due to neuromuscular dysfunction at the pelviureteric junction or retroperitoneal fibrosis, the collecting system may fill normally from below.

• **Cystoscopy, urethroscopy and urethrography** can visualize obstructing lesions within the bladder and urethra directly. Urethrography involves introducing contrast medium into the bladder by catheterization or suprapubic bladder puncture, and taking X-ray films during voiding to show obstructing lesions in the urethra. It is of particular value in the diagnosis of urethral valves and strictures.

**Management**

Treatment aims to:

- relieve the obstruction
- treat the underlying cause
- prevent and treat infection
- preserve renal function.

An obstructed and infected urinary tract is a medical emergency; delay can lead to sepsicaemia.

- Bladder catheterization offers rapid relief of outflow tract obstruction. If a urinary catheter cannot be passed urethrally, a suprapubic catheter should be placed.
- Obstructed and hydroureteric kidneys can be relieved by placing a percutaneous nephrostomy under ultrasound guidance.
- It is also possible to relieve obstructed ureters by cystoscopic (retrograde) stenting.

**Post-obstructive diuresis**

This occurs after relief of the obstruction at any site in the urinary tract. Massive diuresis may occur following relief of bilateral obstruction, as prior sodium and water retention, the osmotic effect of retained solutes and defective renal tubular reabsorptive capacity correct. This diuresis is associated with increased blood volume and high levels of atrial natriuretic peptide (ANP). The diuresis is usually self-limiting, but a minority of patients develop severe sodium, water and potassium depletion needing intravenous replacement. In milder cases, oral salt and potassium supplements, together with a high water intake, are sufficient.

**Specific causes of obstruction**

**Calculi**

These are discussed on page 1373.

**Pelviureteric junction obstruction**

A functional disturbance in peristalsis of the collecting system, without any mechanical obstruction, causes pelvic hydronephrosis (Fig. 36.33). In patients with recurrent loin pain or progressive kidney damage, surgical correction by open or percutaneous pyeloplasty is indicated.

**Obstructive megaureter**

This childhood condition may become evident only in adult life. It results from the presence of a region of defective peristalsis at the lower end of the ureter adjacent to the ureterovesical junction. The condition is more common in males. It presents with urinary tract infection, flank pain or haematuria. The diagnosis is made on imaging with ultrasound, CT or, if necessary, ascending ureterography.
Excision of the abnormal portion of ureter with re-implantation into the bladder is always indicated in children and in adults when the condition is associated with evidence of progressive deterioration in renal function, bacteriuria that cannot be controlled by medical means, or recurrent stone formation.

**Retroperitoneal fibrosis (chronic peri-aortitis)**

Retroperitoneal fibrosis (RPF) is a descriptive term used when inflammatory fibrotic tissue encases the aorta and ureters; it has a number of underlying causes. RPF is three times more common in men than in women and is an IgG4-related disease (see p. 65).

Extraluminal ureteric obstruction leads to unilateral or bilateral obstruction. The condition may extend from the level of the second lumbar vertebra to the pelvic brim. In up to 15% of patients the fibrotic process can extend outside the retroperitoneum, consistent with it being a systemic condition. Mediastinal fibrosis, Riedel fibrosis, thyroiditis, sclerosing cholangitis, fibrotic orbital pseudotumour, fibrotic arthropathy, and pleural, pericardial and lung fibrosis have been reported with increasing frequency in IgG4-related disease.

RPF is thought to be either an autoallergic response to leakage of material, probably ceroid, from atheromatous plaques, producing an inflammatory reaction, or a systemic autoimmune disease. There is an association with HLA-DRB1*03, an allele linked to various autoimmune diseases. RPF is possibly initiated as a vasa vasmorum vasculitis in the aortic wall, which is often seen in chronic peri-aortitis. This inflammatory process can cause medial wall thinning and promote atherosclerosis, and also extends into the surrounding retroperitoneum with a fibro-inflammatory reaction typical of chronic peri-aortitis. The autoimmune reaction to plaque antigens could be an epithenomenon of this immune-mediated process. Activating antibodies against fibroblasts (detectable in one-third of patients) have also been implicated in the pathogenesis, as has the presence of IgG4-bearing plasma cells; the latter is a common finding in autoimmune chronic pancreatitis, a disorder sometimes associated with idiopathic retroperitoneal fibrosis. In addition, several infiltrating B cells show clonal or oligoclonal immunoglobulin heavy chain rearrangement. These findings raise the possibility of RPF being a primary B-cell disorder.

**Aetiology of RPF**

Causes are many:
- **Idiopathic** (in 60–70%).
- **Secondary** causes include:
  - drugs (methysergide, lysergic acid, ergot-derived dopamine receptor agonists (cabergoline, bromocriptine, pergolide), ergotamine, methyldopa, hydralazine, beta-blockers)
  - malignancy (carcinomas of the colon, prostate, breast, stomach, carcinoma, Hodgkin and non-Hodgkin lymphomas, sarcomas)
  - infection (tuberculosis, syphilis, histoplasmosis, actinomycosis, fungal infections)
  - surgery/radiotherapy (lymph node resection, colectomy, hysterectomy, aortic aneurysm repair).

Recognized associations include untreated abdominal aortic aneurysm, smoking and asbestososis.

**Clinical features and investigation of RPF**

RPF may present with malaise, low back pain, weight loss, testicular pain, claudication and haematuria.

**Laboratory tests** show normochromic anaemia, CKD, raised ESR and CRP, and increased serum IgG4 levels. **Imaging** with ultrasound will show a poorly circumscribed peri-aortic mass. The test of choice is contrast-enhanced CT, which will show the mass, lymph nodes and tumour (Fig. 36.34). MRI will demonstrate similar findings but does not require contrast. FDG-PET, a functional imaging modality, assesses the metabolic activity of the retroperitoneal mass; it also allows whole-body imaging and can detect occult malignant or infectious foci, particularly in secondary RPF.

**Management of RPF**

A biopsy is performed to exclude an underlying infection, lymphoma or carcinoma. Initial management may involve decompressing obstructed ureters by stenting (anterograde or retrograde). Corticosteroids may reverse the obstructing inflammatory tissue, if only as a holding measure before definitive treatment of the underlying cause. Rituximab is effective in cases of proven IgG4-related disease. Response to treatment and disease activity are assessed by serial measurements of ESR and eGFR, and repeat FDG-PET scans can also monitor disease.

Obstruction is relieved surgically by ureterolysis. A long-term ureteric stent or stents can be used with chronic corticosteroid therapy, but regular (usually 6-monthly) changes of the stent(s) are required if the peri-aortic mass does not regress.

Relapse after withdrawal of steroid therapy may occur and treatment may need to be continued for years. Mycophenolate or tamoxifen is also effective. Long-term follow-up is mandatory.

**Benign prostatic hypertrophy**

Benign prostatic hypertrophy (see p. 1480) is a common cause of urinary tract obstruction.

**Prognosis of urinary tract obstruction**

The prognosis depends on the cause and the stage at which obstruction is relieved. Four factors influence the rate at which kidney damage occurs, its extent, and the degree and rapidity of recovery of renal function after relief of obstruction:
- whether obstruction is partial or complete
- the duration of obstruction
- the presence or absence of infection
- the site of obstruction.

Complete obstruction for several weeks will lead to irreversible or only partially reversible kidney damage. If complete obstruction lasts several months, irreversible destruction of the affected kidney occurs. Partial obstruction carries a better prognosis, depending on its severity. Bacterial infection with obstruction rapidly increases kidney damage. Obstruction at or below the bladder neck leads to hypertrophy and trabeculation of the bladder without a rise in...
Kidney and urinary tract disease

Pressure within the upper urinary tract, in which case the kidneys are protected from the effects of back-pressure.

DRUGS AND THE KIDNEY

The kidney eliminates many drugs, as well as the (often active) products of drug metabolism in the liver. Dosing requires some thought with CKD, particularly in the elderly. Many drugs can further impair renal function, either over time, or acutely if hypovolaemia occurs (with vomiting or diarrhoea, for example), where a prescribed drug (such as an ACE inhibitor) prevents an appropriate response.

Drug-induced impairment of renal function

Renal perfusion falls with drugs that cause:
- hypovolaemia, e.g.:
  - loop diuretics such as furosemide, especially in elderly patients
  - renal salt and water loss, such as from hypercalcaemia induced by vitamin D therapy (since hypercalcaemia adversely affects renal tubular salt and water conservation)
- decrease in cardiac output, which impairs renal perfusion (e.g. beta-blockers)
- decrease in renal blood flow (e.g. ACE inhibitors, particularly in the presence of renovascular disease).
Drugs may directly damage the kidney:
- Acute tubular necrosis produced by direct nephrotoxicity from prolonged or high-dose treatment with aminoglycosides (e.g. gentamicin, amikacin), amphotericin B, tenofovir, cisplatin or calcineurin inhibitors. The combination of aminoglycosides with loop diuretics is particularly nephrotoxic.
- Crystal nephropathies caused by antivirals such as aciclovir and indinavir.
- Acute tubulointerstitial nephritis (see p. 1385), a cell-mediated hypersensitivity nephritis occurring with many drugs, including penicillins, cephalosporins, proton pump inhibitors, diuretics, sulphonamides and NSAIDs (which have many other effects on the kidney; Box 36.23).
- Chronic tubulointerstitial nephritis due to drugs (see p. 1386).
- Membranous glomerulonephritis, e.g. penicillamine, gold, anti-TNF (see p. 1337).
- Retroperitoneal fibrosis with urinary tract obstruction – can result from the use of drugs (see p. 1379).

Using drugs in patients with impaired renal function

See Box 36.24.

Absorption

Absorption can be unpredictable in uraemia, as gastric emptying may be delayed, and nausea and vomiting are frequent.

Box 36.24 Safe prescribing in kidney disease

Safe prescribing in CKD demands knowledge of the clinical pharmacology of the drug and its metabolites in normal individuals and in uraemia. The clinician should ask the following questions when prescribing, and discuss them with the patient:
1. Is treatment mandatory? Unless it is, it should be withheld.
2. Can the drug reach its site of action? For example, there is little point in prescribing the urinary antiseptic nitrofurantoin in severe CKD since bacteriostatic concentrations will not be attained in the urine.
3. Is the drug’s metabolism altered in uraemia?
4. Will accumulation of the drug or metabolites occur? Even if accumulation is a potential problem, owing to the drug or its metabolites being excreted by the kidneys, it is not necessarily an indication to change the drug given. The size of the loading dose will depend on the size of the patient and is unrelated to renal function. Avoidance of toxic levels of drug in blood and tissues subsequently requires the administration of normal doses of the drug at longer time intervals than usual, or in smaller doses at the usual time intervals.
5. Is the drug toxic to the kidney?
6. Are the effective concentrations of the drug in biological tissues similar to the toxic concentrations? Should blood levels of the drug be measured?
7. Will the drug worsen the uraemic state by means other than nephrotoxicity, e.g. steroids, tetracycline?
8. Is the drug a sodium or potassium salt? These are potentially hazardous in uraemia.

- Not surprisingly, adverse drug reactions are more than twice as common in patients with CKD as in normal individuals. Elderly patients, in whom unsuspected CKD is common, are particularly at risk. Attention to the above and titration of the dose of drugs employed should reduce the problem.
- The dose may be titrated by:
  - observation of its clinical effect, e.g. hypotensive agents
  - early detection of toxic effects
  - measurement of drug levels in the blood, e.g. gentamicin levels.

Metabolism

The rate of drug metabolism by the kidney is reduced as a result of:
- Reduced drug catalysis. Insulin, for example, is in part catalyzed by the normal kidney. In renal disease, insulin catalysis is reduced. For this reason, the insulin requirements of diabetics decline as renal function deteriorates.
- Reduced conversion of a precursor to a more active metabolite. An example is the conversion of 25-hydroxycholecalciferol to the more active 1,25-(OH)₂D₃. The 1α-hydroxylase enzyme responsible for this conversion is located in the kidney. In renal disease, production of the enzyme declines and deficiency of 1,25-(OH)₂D₃ results.
Protein binding
Reduced protein binding of a drug potentiates its activity and increases the potential for toxic side-effects. Hypoaalbuminaemia (in the nephrotic syndrome) leads to increased free drug, as do uremic toxins binding to albumin (occupying drug-binding sites). Measurement of total plasma concentration (albumin-bound and free drug) of such drugs can give misleading results. For example, more free phenytoin than albumin-bound phenytoin is present in CKD, for the same total plasma concentration seen in healthy individuals – and lower levels will control seizures in patients with CKD.

Volume of distribution
Salt and water overload or depletion may occur in patients with renal disease. This affects the concentration of drug obtained from a given dose.

End-organ sensitivity
The renal response to drug treatment may be reduced in renal disease. For example, mild thiazide diuretics have little diuretic effect in patients with severe CKD.

Renal elimination
In CKD, drugs eliminated by the kidneys are no longer excreted normally. Water-soluble drugs, such as gentamicin, which are poorly absorbed from the gut, typically given by injection and not metabolized by the liver, give rise to far more problems than lipid-soluble drugs such as propranolol, which are well absorbed and principally metabolized by the liver.

Drugs affecting protein anabolism and catabolism
Tetracyclines, with the exception of doxycycline, have a catabolic effect. Increased nitrogenous waste products are not well cleared and ureaemia may be more marked. Corticosteroids also have a catabolic effect and may lead to a disproportionate increase in urea compared to creatinine when used in high doses in CKD.

Problem patients
Particular problems are presented by patients with rapidly changing renal function, such as those with evolving AKI or recovering acute tubular necrosis. In addition, drugs may be removed by dialysis and haemofiltration, which will affect the dosage required.

**URINARY TRACT INFECTION**

Urinary tract infection (UTI) is common, particularly in women, most often occurring in a normal urinary tract and usually as cystitis; half of all women will experience a UTI in their lifetime. Most UTIs occur in isolation (Fig. 36.35). It is uncommon in men and children; when diagnosed, it often occurs in an abnormal urinary tract. Between 1% and 2% of patients presenting in primary care will have a UTI. UTI is not always uncomplicated; recurrent infection causes considerable morbidity, and infection can lead to life-threatening Gram-negative sepsicaemia and kidney failure.

**Aetiology and pathogenesis**
Infection is most often caused by bacteria from a patient’s own bowel flora (Box 36.25) and usually ascends up the urethra. In women the short urethra makes ascending infection more likely. Rarely, infection may arise from the bloodstream or lymphatics, or by direct extension (e.g. from a vesicocolic fistula).

*More common in young women (20–30%).
*More common in hospital practice.

**Bacterial virulence**
How well an organism adheres to urothelium determines its virulence. The presence of flagella (for motility), aerobactin (used to acquire iron), haemolysin (to form pores) and, above all, the presence of fimbriae (adhesins that attach organisms to the perineum and urothelium) on the bacterial cell surface make *E. coli* such a common pathogen.

**Innate host defence**
Innate host defence prevents UTI in the following ways:
- **Neutrophils.** Bacterial adhesins activate receptors, e.g. Toll receptor 4, on the mucosal surface, resulting in IL-8 production and expression of its receptor, CXCR1, on neutrophil surfaces. Activation of neutrophils is essential for bacterial killing.
- **Urinary osmolality and pH.** Urinary osmolality >800 mOsm/kg and low or high pH reduce bacterial survival.
- **Complement.** Complement activation with mucosal IgA production by uroepithelium (acquired immunity) plays a major role in defence against UTI.
- **Commensal organisms.** Eradication of commensal organisms such as lactobacilli, corynebacteria, streptococci and bacteria by spermicidal jelly or antibiotics results in overgrowth of *E. coli*.
- **Urinary flow.** Good urine flow and normal micturition wash out bacteria. Urine stasis promotes UTI.
- **Uroepithelium.** Mannosylated Tamm–Horsfall proteins, present in the mucus and glyocalyx covering uroepithelium, have antibacterial properties and interfere with bacterial binding to uroepithelium. Cranberry juice and blueberry juice contain a large-molecular-weight factor (pro-anthocyanidins) that prevents binding of *E. coli* to the uroepithelium.
- **Blood group antigens.** Women who are non-secretors of ABH blood group antigens are 3–4 times more likely to have recurrent UTIs.

### Risk factors
- Female gender, especially postmenopausal women.
- New sexual activity, particularly in young women.
- Indwelling urinary catheter or instrumentation of the urinary tract.
- Urinary tract stones.
- Urinary tract stasis (incomplete bladder emptying).
- Diabetes mellitus or immunosuppression.
- Dementia.

### Clinical features
The most typical symptoms of (lower) UTI are:
- frequency of micturition by day and night
- dysuria (painful voiding)
- suprapubic pain and tenderness
- haematuria
- smelly urine.

These are the symptoms of bladder and urethral inflammation, or ‘cystitis’. Loin pain and tenderness, with fever, chills, night sweats and rigors, suggest extension of infection to the pelvis and kidney, known as pyelitis or pyelonephritis. Localization of the site of infection on the basis of symptoms alone is unreliable.

UTI can also present with few or no symptoms (particularly in the immunocompromised), or even with abdominal pain, fever or haematuria in the absence of frequency or dysuria. In the elderly, new confusion may be the only symptom of UTI. In small children, who cannot complain of dysuria, symptoms are often ‘atypical’. The possibility of UTI must always be considered in the frettful, febrile, sick child who fails to thrive.

### Diagnosis
Uncomplicated UTIs in younger women (age ≤65) can be diagnosed in those without known urinary tract abnormalities, recent urinary tract instrumentation, or systemic illness if they exhibit at least two of three cardinal symptoms – dysuria, urgency or frequency – along with an absence of vaginal discharge. Neither urine dipstick testing for leucocyte esterase nor urine culture enhances diagnostic sensitivity. Telephone-based protocols have outcomes similar to those of surgery-based diagnosis and treatment, and such methods are often preferred by patients. Patients with histories of uncomplicated UTIs can be taught to self-diagnose and initiate therapy.

Otherwise, diagnosis is based on culture of a clean-catch midstream specimen of urine and the presence or absence of pyuria. The criteria for the diagnosis of UTI, particularly in symptomatic women, are shown in Box 36.26. Most Gram-negative organisms reduce nitrates to nitrites and produce a red colour in the reagent square. False-negative results are common. Dipsticks that detect significant pyuria depend on the release of esterases from leucocytes. Dipstick tests that are positive for both nitrile and leucocyte esterase are highly predictive of acute infection (sensitivity of 75% and specificity of 82%).

Re-infection may be distinguished from relapsing infection in the following ways:
- **Relapse** is diagnosed by recurrence of bacteriuria with the same organism within 7 days of completion of antibacterial treatment. Treatment failure may suggest associated stones, scarred kidneys, polycystic disease or bacterial prostatitis.
- **Re-infection** is when bacteriuria is absent after treatment for at least 14 days, usually followed, by recurrence of infection with the same or different organisms. This is not due to failure to eradicate infection but is the result of re-invasion of a susceptible tract with new organisms. Approximately 80% of recurrent infections are due to re-infection.

Where culture is negative and symptoms persist, consider:
- **Abacteriuric frequency or dysuria** (‘urethral syndrome’). This is caused by bladder trauma after intercourse; vaginitis, atrophic vaginitis or urethritis in the elderly; and *Chlamydia* infection and tuberculosis in symptomatic young women with ‘sterile pyuria’.
- **Interstitial cystitis**. This is uncommon but distressing, affecting women over the age of 40. Patients present with frequency, dysuria and often severe suprapubic pain but cultures are sterile. Cystoscopy shows typical inflammatory changes with ulceration of the bladder base. It is now thought to be an autoimmune disorder. Treatments include oral prednisolone, bladder instillation of sodium cromoglicate or dimethyl sulphoxide, and bladder stretching under anaesthesia. Unfortunately, relief of symptoms can be difficult to achieve.
- **Predominant frequency** and passage of small volumes of urine (‘irritable bladder’). These may occur after previous UTI.

### Natural history
Serious morbidity is unusual. However, renal scarring can result from recurrent UTI, and dissemination of infection as septicemia can be fatal. In patients with a normal urinary tract (with normal renal imaging), outcomes are very good, and persistent or recurrent infection seldom results in serious kidney damage (uncomplicated UTI). In those with abnormal urinary tracts (stones or stasis), recurrence is more common and outcomes are less good. The combination of infection and obstruction results in severe, sometimes rapid, kidney damage (obstructive pyonephrosis) and is
Urinary tract infection

a major cause of Gram-negative septicaemia from *Pseudomonas* and *Enterobacter* spp. Complicated and uncomplicated infection is compared in Fig. 36.37.

**Acute pyelonephritis**

Fever, loin pain with tenderness and significant bacteriuria usually imply infection of the kidney (acute pyelonephritis). Small renal cortical abscesses and streaks of pus in the renal medulla are often present. Histologically, there is focal infiltration by polymorphonuclear leucocytes and many polymorphs in tubular lumina.

Although, with antibiotics, significant permanent kidney damage in adults with normal urinary tracts is rare, CT scanning can show wedge-shaped areas of inflammation in the renal cortex (Fig. 36.38), where renal function will be impaired.

**Reflux nephropathy**

This was called chronic pyelonephritis or atrophic pyelonephritis, resulting from a combination of:

- vesicoureteric reflux

- infection acquired in infancy or early childhood.

Normally, the vesicoureteric junction acts as a one-way valve (Fig. 36.39), urine entering the bladder from above; the ureter is shut off during bladder contraction, thus preventing reflux of urine. In some infants and children – possibly even in utero – this valve mechanism is incompetent, bladder voiding being associated with variable reflux of a jet of urine up the ureter. A secondary consequence is incomplete bladder emptying, as refluxed urine returns to the bladder after voiding. This latter event predisposes to infection, and the reflux of infected urine leads to kidney damage.

Typically, there is papillary damage, tubulointerstitial nephritis and cortical scarring in areas adjacent to ‘clubbed calyces’.

**Diagnosis** is based on CT scan of the kidneys, which shows irregular renal outlines, clubbed calyces and a variable reduction in renal size. The condition may be unilateral or bilateral, and may affect all or part of the kidney.

Reflux usually ceases around puberty with growth of the bladder base (a thickened bladder wall is able to prevent reflux with bladder contraction). Damage already done persists and progressive renal fibrosis and further loss of function occur in severe cases, even though there is no further infection.

Reflux nephropathy cannot occur in the absence of reflux – it does not begin in adult life. Consequently, women with bacteriuria and a normal urogram can be reassured that kidney damage will not develop.

**Chronic reflux nephropathy** acquired in infancy predisposes to hypertension in later life and, if severe, is a relatively common cause of ESKD in childhood or adult life. Meticulous early detection and control of infection, with or without ureteral re-implantation to create a competent valve, can prevent further scarring and allow normal growth of the kidneys. No proof exists, however, that re-implantation surgery confers long-term benefit.

Continuous antibiotic prophylaxis (CAP), compared with no treatment, significantly reduces the risk of symptomatic UTI in children with chronic reflux nephropathy but at the expense of increased risk for developing antimicrobial-resistant bacterial strains. CAP does not have a significant impact on the occurrence of new renal scarring.
Special investigations

Uncomplicated UTI usually does not require imaging. If infection is recurrent or affects men or children, or if there are unusually severe symptoms, it should be investigated further. Patients with diabetes mellitus and those on immunosuppression benefit from early imaging.

- **Ultrasound** allows the detection of calculi, obstruction, abnormal urinary anatomy and incomplete bladder emptying (post-micturition scan). It is helpful in the assessment of suspected pyelonephritis or an obstructed, infected kidney that may require drainage.
- **CT** is more sensitive for diagnosis and follow-up of complicated renal tract infection. Contrast-enhanced CT allows different phases of excretion to be studied, and can define the extent of disease and identify significant complications or obstruction.
- **MRI** is particularly useful in those with iodinated contrast allergies, offering an ionizing radiation-free alternative in the diagnosis of both medical and surgical diseases of the kidney.
- **Nuclear medicine** has a limited role in the evaluation of UTI in adults. Its main role is in the assessment of renal function and detection of scars by DMSA scan, often prior to surgery.

Management

Management of a single isolated attack

- **The most appropriate antibiotic choices** are trimethoprim–sulfamethoxazole (160/800 mg twice daily for 3–7 days) or nitrofurantoin (100 mg twice daily for 5–7 days). Fluoroquinolones offer no advantage in terms of cure rates; β-lactam antibiotics, such as amoxicillin–clavulanate, are less effective than the first-line recommendations. Most patients who delay antibiotic treatment to encourage spontaneous resolution eventually receive antibiotics and have longer times to resolution. Men with uncomplicated UTIs should be treated as above but for 7–14 days.
- **Shorter 3–5-day courses** with amoxicillin (250 mg three times daily), trimethoprim (200 mg twice daily) or an oral cephalosporin are also used, and modified in light of the result of urine culture and sensitivity testing, and/or the clinical response.
- **Single-shot treatment** with 3 g of amoxicillin or 1.92 g of co-trimoxazole is used for patients with bladder symptoms of more than 36 hours’ duration who have no previous history of UTI.
- **A high (2 L daily) fluid intake** should be encouraged during treatment and for some subsequent weeks. Urine culture should be repeated 5 days after treatment.
- **If the patient is acutely ill with high fever, loin pain and tenderness** (acute pyelonephritis), antibiotics are given intravenously, e.g. aztreonam, cefuroxime, ciprofloxacin or gentamicin, switching to a further 7 days’ treatment with oral therapy as symptoms improve. Intravenous fluids may be required to achieve a good urine output.
- **In patients presenting for the first time with high fever, loin pain and tenderness**, urgent renal ultrasound examination is required to exclude an obstructed pyonephrosis. If this is present, it should be drained by percutaneous nephrostomy (see p. 1350).

Management of recurrent infection

Pre-treatment and post-treatment urinary cultures are necessary to confirm the diagnosis and to establish whether recurrent infection is due to relapse or re-infection.

- **Relapse.** A search should be made for a cause (e.g. stones or scarred kidneys), and treatment modified if possible. Intense or prolonged treatment may be required. If this fails, long-term antibiotics are necessary.
- **Re-infection.** This implies that the patient has a predisposition to peri-urethral colonization or poor bladder defence mechanisms. Contraceptive advice should be offered and the use of a diaphragm or spermicidal jelly discouraged. Atrophic vaginitis should be identified in postmenopausal women, who should be treated (see later). Preventative measures may help:
  - a 2 L daily fluid intake
  - voiding at 2–3-hour intervals, with double micturition if reflux is present
  - voiding before bedtime and after intercourse
  - avoidance of spermicidal jellies and of bubble baths and other chemicals in bath water
  - avoidance of constipation, which may impair bladder emptying.

Evidence of impaired bladder emptying on excretion urography/ultrasound requires urological assessment. If UTI continues to recur, treatment for 6–12 months with low-dose alternating monthly prophylaxis (trimethoprim 100 mg, co-trimoxazole 480 mg, cefalexin 125 mg at night or macrocrystalline nitrofurantoin) is required; it should be taken last thing at night when urine flow is low. Intravaginal oestrogen therapy has been shown to produce a reduction in the number of episodes of UTI in postmenopausal women. Cranberry juice is said to reduce the risk of symptoms and re-infection by 12–20% but studies are limited.

Urinary infections in the presence of an indwelling catheter

Colonization of the bladder by a pathogen is common after a urinary catheter has been in situ for more than a few days, partly due to organisms forming biofilms. So long as the bladder catheter is in place, antibiotics are likely to be ineffective and will encourage the development of resistant organisms. The patient should be treated only if there are symptoms or evidence of infection. The catheter should always be replaced. When changing catheters, a single dose of antibiotic (e.g. gentamicin) is recommended.

Infection by *Candida* is a frequent complication of prolonged bladder catheterization. Treatment should be reserved for patients with evidence of invasive infection and those who are immunosuppressed. The catheter should be removed or replaced. In severe infections, continuous bladder irrigation with amphotericin 50 g/mL is useful.

**Bacteriuria in pregnancy**

Pregnant women should have their urine cultured, as 2–6% have asymptomatic bacteriuria (see p. 1460). Usually harmless in non-pregnant women, bacteriuria in pregnancy can lead to acute pyelonephritis and in late pregnancy may trigger pre-term labour. Ureteric dilation in response to hormonal changes may allow ascending infection. *Bacteriuria must always be treated and shown to be eradicated.* Re-infection may require prophylactic therapy. Tetracycline, trimethoprim, sulphonamides and quinolones are contraindicated in pregnancy. Amoxicillin and ampicillin, nitrofurantoin and oral cephalosporins may be used safely in pregnancy.

**Bacterial prostatitis**

Bacterial prostatitis is a relapsing infection that presents as perineal pain, recurrent epididymo-orchitis and prostatic tenderness, with pus in expressed prostatic secretions. Treatment is for 4–6 weeks with drugs that penetrate into the prostate, such as trimethoprim or ciprofloxacin. Long-term, low-dose treatment may be required. Prostatodynia (prostatic pain in the absence of active infection) may persist long after the infection. Amitriptyline and carbamazepine may alleviate the symptoms.
Rarely, cold abscesses may form in the loin. In males, the disease may present with testicular or epididymal discomfort and thickening.

**Diagnosis** depends on constant awareness, especially in patients with sterile pyuria. Imaging may show cavitations lesions in the renal papillary areas, commonly with calcification. There may also be evidence of ureteral obstruction with hydronephrosis. Culture of mycobacteria from early morning urine samples is not straightforward. Imaging may be normal in diffuse interstitial renal tuberculosis, when diagnosis is made instead by renal biopsy, which demonstrates caseating granuloma with multinucleate giant cells and acid-fast bacilli on Ziehl–Neelsen staining (Fig. 36.40). Some patients present late with small, unobstructed kidneys, when the diagnosis is easy to miss.

**Treatment** is as for pulmonary tuberculosis (see p. 969). Renal ultrasonography and/or CT scanning should be carried out 2–3 months after initiation of treatment, as ureteric strictures may first develop in the healing phase.

**Figure 36.40** Renal tuberculosis. (A) Caseating granulomatous interstitial nephritis showing multinuclear giant cell (arrowed). (B) Ziehl–Neelsen staining showing mycobacteria (arrowed).

### Tuberculosis of the urinary tract

Tuberculous infection is on the increase worldwide, partly due to the reservoir of infection in susceptible HIV-infected individuals and the emergence of drug-resistant strains. Tuberculosis of the urinary tract presents with frequency, dysuria or haematuria. Cortical lesions result from haematogenous spread in the primary phase of infection. Most heal, but in some, infection persists and spreads to the papillae, with the formation of cavitating lesions and the discharge of mycobacteria into the urine. Infection of the ureters and bladder commonly follows, with the potential for development of ureteral strictures and a contracted bladder. Rarely, cold abscesses may form in the loin. In males, the disease may present with testicular or epididymal discomfort and thickening.

**Diagnosis** depends on constant awareness, especially in patients with sterile pyuria. Imaging may show cavitations lesions in the renal papillary areas, commonly with calcification. There may also be evidence of ureteral obstruction with hydronephrosis. Culture of mycobacteria from early morning urine samples is not straightforward. Imaging may be normal in diffuse interstitial renal tuberculosis, when diagnosis is made instead by renal biopsy, which demonstrates caseating granuloma with multinucleate giant cells and acid-fast bacilli on Ziehl–Neelsen staining (Fig. 36.40). Some patients present late with small, unobstructed kidneys, when the diagnosis is easy to miss.

**Treatment** is as for pulmonary tuberculosis (see p. 969). Renal ultrasonography and/or CT scanning should be carried out 2–3 months after initiation of treatment, as ureteric strictures may first develop in the healing phase.

### Xanthogranulomatous pyelonephritis

This is an uncommon chronic interstitial infection of the kidney, most often due to *Proteus*, in which there is fever, weight loss, loin pain and a palpable enlarged kidney. It is usually unilateral and associated with staghorn calculi and UTI. CT scanning shows up intrarenal abscesses as lucent areas within the kidney. Nephrectomy is the treatment of choice; antibacterial treatment rarely, if ever, eradicates the infection.

### Renal carbuncle

Renal carbuncle is an abscess in the renal cortex caused by a blood-borne staphylococcus, usually from a boil or carbuncle of the skin. It presents with a high, swinging fever, loin pain and tenderness, and fullness in the loin. The urine shows no abnormality, as the abscess does not communicate with the renal pelvis, more often extending into the perirenal tissue. Staphylococcal septicemia is common. Diagnosis is by ultrasound or CT scanning. Treatment involves antibacterial therapy with flucloxacinill and surgical drainage.

### Tuberculosis of the urinary tract

Tuberculous infection is on the increase worldwide, partly due to the reservoir of infection in susceptible HIV-infected individuals and the emergence of drug-resistant strains. Tuberculosis of the urinary tract presents with frequency, dysuria or haematuria. Cortical lesions result from haematogenous spread in the primary phase of infection. Most heal, but in some, infection persists and spreads to the papillae, with the formation of cavitating lesions and the discharge of mycobacteria into the urine. Infection of the ureters and bladder commonly follows, with the potential for development of ureteral strictures and a contracted bladder. Rarely, cold abscesses may form in the loin. In males, the disease may present with testicular or epididymal discomfort and thickening.

**Diagnosis** depends on constant awareness, especially in patients with sterile pyuria. Imaging may show cavitations lesions in the renal papillary areas, commonly with calcification. There may also be evidence of ureteral obstruction with hydronephrosis. Culture of mycobacteria from early morning urine samples is not straightforward. Imaging may be normal in diffuse interstitial renal tuberculosis, when diagnosis is made instead by renal biopsy, which demonstrates caseating granuloma with multinucleate giant cells and acid-fast bacilli on Ziehl–Neelsen staining (Fig. 36.40). Some patients present late with small, unobstructed kidneys, when the diagnosis is easy to miss.

**Treatment** is as for pulmonary tuberculosis (see p. 969). Renal ultrasonography and/or CT scanning should be carried out 2–3 months after initiation of treatment, as ureteric strictures may first develop in the healing phase.

### Xanthogranulomatous pyelonephritis

This is an uncommon chronic interstitial infection of the kidney, most often due to *Proteus*, in which there is fever, weight loss, loin pain and a palpable enlarged kidney. It is usually unilateral and associated with staghorn calculi and UTI. CT scanning shows up intrarenal abscesses as lucent areas within the kidney. Nephrectomy is the treatment of choice; antibacterial treatment rarely, if ever, eradicates the infection.
virus can cause acute TIN in the renal graft. Treatment involves eradication of infection with appropriate antibiotics or antiviral agents; in renal transplantation, the immunosuppressive regimen is modified.

### Acute TIN as part of multisystem inflammatory diseases

Several non-infectious inflammatory disorders, such as Sjögren’s syndrome or SLE, can cause acute or chronic TIN rather than glomerulonephritis. Sjögren’s syndrome may additionally present as renal tubular acidosis. Sarcoidosis presents as granulomatous TIN in up to 20% of patients. Associated hypercalcaemia causes AKI. These heterogeneous conditions with TIN generally respond to steroids.

### TIN with uveitis syndrome

Patients with tubulointerstitial nephritis with uveitis (TINU) syndrome present with uveitis, an acute TIN, weight loss, anaemia and a raised ESR of unknown cause. It is common in childhood but has been reported in adulthood, and is more frequently found in women. It may be associated with autoantibodies directed against modified CRP. A prolonged course of steroids leads to improvement in both renal function and uveitis.

### Chronic tubulointerstitial nephritis

The major causes of chronic TIN are given in Box 36.28. Patients present with any of polyuria, nocturia, proteinuria (usually slight, <1 g daily) or uraemia. Chronic TIN may be linked with papillary necrosis (ischaemic damage to the papillae, which then slough into the calyces and urine) when associated with longstanding analgesic use, diabetes mellitus, sickle cell disease or trait. Microscopic or overt haematuria or sterile pyuria also occurs, and occasionally a sloughed papilla may cause ureteric colic or produce acute ureteric obstruction. Histologically, a generalized chronic inflammatory cellular infiltration of the interstitium with tubular atrophy and generalized interstitial oedema or fibrosis is present, and in many cases no cause is found.

IgG4-related TIN is distinguished by very low concentrations of complement and increased serum IgG4. This may lead to immune complex formation.

The radiological appearances must be distinguished from those of reflux nephropathy (Fig. 36.42) or obstructive uropathy.

Tubular damage to the medullary area of the kidney leads to defects in urine concentration and sodium conservation with polyuria and salt wasting. Fibrosis progressing into the cortex leads to loss of excretory function and urea.

### Analgesic nephropathy

The chronic consumption of large amounts of analgesics (classically, phenacetin but now NSAIDs) leads to chronic TIN and papillary necrosis. Analgesic nephropathy is more common in women and typically presents in middle age. Presentation may be with anaemia, CKD, UTIs, haematuria or urinary tract obstruction (owing to sloughing of a renal papilla). Salt- and water-wasting renal disease may occur. Chronic analgesic use also predisposes to the development of uroepithelial tumours. Diagnosis is usually made on clinical grounds combined with the non-pathognomonic appearance on imaging (such as ultrasonography or CT scan), which demonstrates small, irregularly outlined kidneys.

Patients should be encouraged to avoid NSAIDs, and, if necessary, dihydrocodeine or paracetamol may be offered as a reasonable alternative (this may stop further damage and even achieve an improvement). The development of flank pain or an unexpectedly rapid deterioration in renal function should prompt ultrasonography to screen for urinary tract obstruction due to a sloughed papilla.
Corticosteroid treatment High muscle mass and Tetracycline treatment Gastrointestinal bleeding

These findings are characteristic of renal sarcoid but can be seen with any cause (drug or infection) of interstitial nephritis. Renal sarcoidosis generally responds rapidly to steroids.

Chinese herb nephropathy Chinese herbal medicines may contain aristolochic acid, produced as a result of fungal contamination of the product. Histology is similar to that of Balkan nephropathy but the clinical course is aggressive, with relentless progression to ESKD and a high incidence of uroepithelial tumours.

Other forms of chronic TIN
These are rare (see Box 36.28). Diagnosis of all forms depends on a history of drug ingestion or industrial exposure to nephrotoxins. In patients with unexplained renal impairment with normal-sized kidneys, renal biopsy must always be undertaken to exclude a treatable TIN, such as granulomatous TIN due to renal sarcoidosis (Fig. 36.43), which may be the first presentation of sarcoidosis (see p. 985). Renal sarcoidosis generally responds rapidly to steroids.

Hyperuricaemic nephropathy
Acute hyperuricaemic nephropathy (see p. 118), as part of tumour lysis syndrome, causes AKI in patients with very high serum urate concentrations. It may occur prior to treatment of haematological malignancies but more often supervenes after treatment. As the abundant tumour cells lyse in response to chemotherapy, large amounts of nucleoprotein are released with increased uric acid production. Renal failure is due to intrarenal and extrarenal obstruction caused by deposition of uric acid crystals in the collecting ducts, pelvis and ureters.

There may be flank pain or colic, and oliguria or anuria with increasing uraemia. Plasma urate levels are over 0.75 mmol/L and may be as high as 4.5 mmol/L. Diagnosis is based on the hyperuricaemia and the clinical setting. Ultrasound may demonstrate extra-renal obstruction due to stones but may be unremarkable. Allopurinol 100–200 mg three times daily for 5 days is given prior to and throughout treatment with radiotherapy or cytotoxic drugs. A high rate of urine flow must be maintained by oral or parenteral fluid, and the urine kept alkaline by the administration of sodium bicarbonate and acetazolamide, since uric acid is more soluble in an alkaline than an acid medium. Febuxostat, a non-purine analogue inhibitor of xanthine oxidase, can be used if allopurinol cannot be tolerated and eGFR is more than 30 mL/min. Rasburicase, a recombinant urate oxidase (see p. 1392), and pegloticase, a pegylated uricase, are successfully used to lower serum urate concentrations rapidly for both treatment and prevention. In severely oliguric or anuric patients, dialysis is required to lower the plasma urate. There is no convincing direct evidence for chronic hyperuricaemia nephropathy. However, a few observational studies have suggested that elevated levels of uric acid independently increase the risk for new-onset CKD, and that plasma urate reduction with allopurinol has a beneficial effect in slowing the rate of progression of CKD.

Further reading

ACUTE KIDNEY INJURY

Acute kidney injury (AKI) is defined as follows:
- There is an abrupt deterioration in renal function, usually over hours or days.
- It is usually (but not always) reversible over days or weeks.

AKI may cause sudden, life-threatening biochemical disturbances as a medical emergency. Oliguria is often a feature. The distinction between AKI and CKD, or even acute-on-chronic kidney disease, is not always obvious. AKI is usually recognized by a falling urine output and rising serum urea and creatinine, or both. In some situations, urea and creatinine are less accurate predictors of deteriorating renal function (Box 36.29).

AKI may result from:
- pre-renal causes (reduced kidney perfusion leads to a falling GFR)
- renal parenchymal disorders (injury to glomerulus, tubule or vessels)
- post-renal causes (urinary tract obstruction – functioning kidneys cannot excrete urine with back-pressure affecting function).

The Acute Dialysis Quality Initiative group proposed the RIFLE classification (risk, injury, failure, loss, end-stage renal disease) to define AKI better, using either an increase in serum creatinine or a decrease in urine output. RIFLE describes three levels of renal dysfunction (R, I, F) and two outcome measures (L, E). These criteria

Box 36.29 Causes of altered serum urea and creatinine concentration other than altered renal function

- Low muscle mass
- High muscle mass
- Red meat ingestion
- Muscle damage (rhabdomyolysis)
- Decreased tubular secretion (e.g. therapy with cimetidine or trimethoprim)
indicate an increasing degree of renal damage and have a predictive value for mortality.

The Acute Kidney Injury Network (AKIN) proposed a modification of the original RIFLE criteria to include less severe AKI and a time constraint of 48 hours, and gives a correction for volume status before classification.

- **‘R’** in RIFLE is **stage 1** (a serum creatinine rise of ≥26.4 μmol/L: i.e. a 1.5-fold increase within 48 hours).
- **‘I’** is **stage 2**: i.e. a 2–3-fold increase in serum creatinine.
- **‘F’** is **stage 3**: i.e. an increase in serum creatinine of >300% (equal to ≥354 μmol/L).

Urine output data are the same.

Using the same criteria of serum creatinine and urine output, a more recent classification (the Kidney Diseases: Improving Global Outcomes (KDIGO) classification) is shown in **Box 36.30**.

### Epidemiology

Using the KDIGO definition, 1 in 5 adults and 1 in 3 children worldwide experience AKI during a hospital episode of care.

- Community-acquired AKI on admission to hospital affects approximately 5% in the UK (superimposed on CKD in half of these patients).
- Severe AKI (creatinine >500 μmol/L, often requiring dialysis) affects about 130–140 per million population per year.
- About 25% of patients with sepsis and 50% of patients with septic shock will have AKI.

### Pre-renal AKI

Falling renal blood flow leads to a falling GFR. This might be due either to changes in the circulation, or to intrarenal vasomotor changes that drop glomerular perfusion pressures. Common causes of a falling effective circulating volume include (Box 36.31):

- hypovolaemia of any cause, including dehydration or haemorrhage
- hypotension without hypovolaemia, including cirrhosis or septic shock
- low cardiac output, including cardiac failure or cardiogenic shock
- combinations of the above.

Common intra-renal causes include: NSAIDs, ACE inhibitors (Fig. 36.44), amphotericin B and calcineurin inhibitors, often in the context of added changes in renal blood flow.

Usually, the kidney maintains glomerular filtration close to normal, despite wide variations in renal perfusion pressure and volume status – so-called ‘autoregulation’ (prostaglandins, nitric oxide and angiotensin acting on afferent and efferent arterioles). Once autoregulation fails, GFR drops and AKI develops. Over time, reduced outcomes vary: uncomplicated AKI carries a good prognosis, with mortality rates of less than 5–10%. In contrast, AKI complicating non-renal organ system failure (in the intensive treatment unit (ITU) setting) is associated with mortality rates of 50–70%, which have not changed for several decades. Sepsis-related AKI has a significantly worse prognosis than AKI in the absence of sepsis.

### Approaching AKI

#### Pre-renal AKI

Falling renal blood flow leads to a falling GFR. This might be due either to changes in the circulation, or to intrarenal vasomotor changes that drop glomerular perfusion pressures. Common causes of a falling effective circulating volume include (Box 36.31):

- hypovolaemia of any cause, including dehydration or haemorrhage
- hypotension without hypovolaemia, including cirrhosis or septic shock
- low cardiac output, including cardiac failure or cardiogenic shock
- combinations of the above.

Common intra-renal causes include: NSAIDs, ACE inhibitors (Fig. 36.44), amphotericin B and calcineurin inhibitors, often in the context of added changes in renal blood flow.

Usually, the kidney maintains glomerular filtration close to normal, despite wide variations in renal perfusion pressure and volume status – so-called ‘autoregulation’ (prostaglandins, nitric oxide and angiotensin acting on afferent and efferent arterioles). Once autoregulation fails, GFR drops and AKI develops. Over time, reduced outcomes vary: uncomplicated AKI carries a good prognosis, with mortality rates of less than 5–10%. In contrast, AKI complicating non-renal organ system failure (in the intensive treatment unit (ITU) setting) is associated with mortality rates of 50–70%, which have not changed for several decades. Sepsis-related AKI has a significantly worse prognosis than AKI in the absence of sepsis.
blood flow may lead to established parenchymal injury, but if renal perfusion is corrected early, AKI will resolve fully.

A few simple biochemical measures have long been used to prove pre-renal AKI (Box 36.32). Urine specific gravity or osmolality will rise, as solutes are concentrated into smaller urine volumes (the kidney is retaining fluid to improve renal blood flow). Urine sodium will be low, as salt is retained for the same reason. The fractional excretion of sodium ($\text{Fe}_{\text{Na}}$) is a more reliable measure of sodium retention. None of these measures is reliable on its own and laboratory tests are no substitute for clinical assessment (Box 36.33).

**Management of pre-renal AKI**

This largely depends on the underlying cause. Most cases of AKI have an element of hypovolaemia, so prompt fluid resuscitation is most often indicated. When there is uncertainty as to the volume status of a patient, a fluid challenge of 250 mL crystalloid will often prove whether hypotension is fluid-responsive. Crystalloids and particularly balanced volumes (the kidney is retaining fluid to improve renal blood flow). Urine sodium will be low, as salt is retained for the same reason. The fractional excretion of sodium ($\text{Fe}_{\text{Na}}$) is a more reliable measure of sodium retention. None of these measures is reliable on its own and laboratory tests are no substitute for clinical assessment (Box 36.33).

**Post-renal AKI**

Obstruction of the urinary tract may occur at any point from the calyces to the external urethral orifice but commonly takes the form of bladder outflow obstruction (prostate disease in men) or bilateral ureteric obstruction (stones or tumours). The causes and presentation of urinary tract obstruction are dealt with on page 1377. Almost every case of unexplained AKI should result in an ultrasound to exclude obstruction, as, once this is relieved (and if acute), renal function will return to baseline.

**Renal parenchymal AKI**

This is most commonly (80–90%) due to acute tubular necrosis (ATN; see later and Box 36.34). Almost any cause of pre-renal AKI, if prolonged to the point at which renal autoregulation fails (see earlier), will lead to ischaemic ATN. If not ischaemic, then ATN usually results from direct tubular toxins. As a result, ATN is common in hospital practice. Other causes of parenchymal AKI include:

- Disease affecting the intrarenal arteries and arterioles, as well as glomerular capillaries, such as a vasculitis (see p. 1363), accelerated hypertension, cholesterol embolism, HUS, TTP, pre-eclampsia and crescentic glomerulonephritis.
- Acute TIN (see p. 1385). This also occurs when renal tubules are acutely obstructed by crystals, e.g. after rapid lysis of certain malignant tumours following chemotherapy (acute hyperuricaemic nephropathy).
- Acute bilateral suppurative pyelonephritis or pyelonephritis of a single kidney, which can cause acute uraemia.

**Acute tubular necrosis**

Acute tubular necrosis (ATN) (see Box 36.34) occurs due to:

- sustained under-perfusion and reduced renal blood flow of renal tubules, leading to tubular cell death (hence the name), or
- nephrotoxins causing direct injury and cell death in renal tubules.

Factors involved in the development of ATN include:

- Intrarenal microvascular vasoconstriction with falling delivery of $O_2$ and increasing tubular hypoxia:
  - vasoconstriction in response to endothelin, adenosine, thromboxane A$_2$, leukotrienes and sympathetic nerve activity
  - impaired vasoconstriction due to reduced sensitivity to nitric oxide, prostaglandins (PGE$_2$), acetylcholine and bradykinin.
- Increased endothelial and vascular smooth muscle cell structural damage:
  - increased leucocyte–endothelial adhesion, vascular congestion and obstruction, leucocyte activation and inflammation.
- Tubular cell injury. Ischaemic injury results in rapid depletion of intracellular ATP stores, resulting in cell death either by necrosis or apoptosis, with:
  - increased cytosolic cell calcium concentration
  - induction of nitric oxide synthases with increased production of nitric oxide, causing cell death
  - increased production of intracellular proteases such as calpain, which cause proteolysis of cytoskeletal proteins and cell wall collapse
  - tubular obstruction by desquamated viable or necrotic cells and casts
  - loss of cell polarity, i.e. integrins located on the basolateral side of the cell are translocated to the apical surface, which, when combined with other desquamated cells, forms casts, with tubular obstruction and back-leak of tubular fluid.

### Box 36.34 Some causes of acute tubular necrosis

- Haemorrhage
- Burns
- Diarrhoea and vomiting, fluid loss from fistulae
- Pancreatitis
- Diuretics
- Myocardial infarction
- Congestive cardiac failure
- Endotoxic shock
- Snake bite
- Myoglobinemia
- Haemoglobinemia (due to haemolysis, e.g. in falciparum malaria, ‘blackwater fever’)
- Hepatorenal syndrome
- Radiological contrast agents (see p. 1391)
- Drugs, e.g. aminoglycosides, non-steroidal anti-inflammatory drugs, angiotensin-converting enzyme inhibitors, platinum derivatives
- Abruptio placentae
- Pre-eclampsia and eclampsia
Kidney and urinary tract disease

Fig. 36.45 Acute tubular necrosis. Effacement and loss of the proximal tubule brush border, patchy loss of tubular cells and focal areas of proximal tubule dilation (arrowed).

- **Tubular cellular recovery.** Tubular cells have the capacity to regenerate rapidly and to reform the disrupted tubular basement membrane, which explains the reversibility of ATN. Multiple growth factors, including insulin-like growth factor 1, epidermal growth factor and hepatocyte growth factor, and their receptors are upregulated during the regenerative process after injury.
  
  Once established, renal blood flow is much reduced in ATN, particularly blood flow to the renal cortex. Ischaemic tubular damage contributes to a reduction in glomerular filtration as glomereuli contract through afferent arteriolar spasm, filtrate leaks back towards the glomerulus, and tubular obstruction evolves (Fig. 36.45).

  Oliguria is common in the early stages; non-oliguric AKI is usually the result of a less severe renal insult. Recovery of renal function typically occurs after 7–21 days, although recovery is delayed by continuing sepsis. The use of intravenous mannitol, furosemide or ‘renal-dose’ dopamine is not supported by controlled trial evidence.

**Emergency investigation of AKI**

The aim is to define the AKI syndrome – pre-renal, renal or post-renal – and decide if the deterioration in function is all acute or acute-on-chronic kidney disease.

**Pre-renal, renal or post-renal AKI?**

Pre-renal AKI is diagnosed largely on clinical examination, and assessing the volume status is vital; it can be difficult to distinguish pre-renal and renal AKI (particularly since prolonged renal hypoperfusion will lead to ATN). Bladder outflow obstruction is ruled out by clinical examination (a large palpable bladder suggests longstanding outflow obstruction), after inserting a urethral catheter (or flushing of an existing catheter) and draining large urine volumes, or on ultrasound of the kidneys and bladder. Absence of upper tract dilation on renal ultrasonography will, with very rare exceptions, rule out urinary tract obstruction.

**Other investigations** are as follows:

- Urinalysis, urine microscopy, particularly for red cells and red-cell casts (indicative of glomerulonephritis), and urine culture. Urine should be tested for free haemoglobin and myoglobin, where appropriate. uPCR is helpful if parenchymal disease is possible.
- In AKI, it takes 48–72 h before creatinine rises in the plasma; by that time, cell injury is well established and irreversible. Urinary and plasma biomarkers (e.g. kidney injury molecule 1, neutrophil gelatinase-associated lipocalin, insulin-like growth factor-binding protein 7 and tissue inhibitor of metalloproteinases-2) rise within a few hours of AKI and may allow earlier treatment.
- Blood tests include measurement of serum urea, electrolytes, creatinine, calcium, phosphate, albumin, alkaline phosphatase and urate concentrations, as well as a full blood count and examination of the peripheral blood film where necessary. Coagulation studies, blood cultures and measurements of nephrotoxic drug blood levels should be carried out.

**Acute or chronic uraemia?**

The distinction between AKI and longstanding CKD depends on the history and duration of symptoms (a long history of nocturia suggests progressive tubular failure). Previous urinalysis or measurement of renal function is often vital in understanding the length of renal injury. Rapid changes in creatinine or GFR over days or weeks suggest an acute process.

Ultrasound is key; renal size (measured as the pole-to-pole length) and reflectivity (or echogenicity) are helpful, as small, scarred (increased echogenicity) kidneys suggest a longstanding process. The reverse is not true; the kidney may remain normal in size in diabetes and amyloidosis, for instance.

An anaemia of chronic disease, hyperparathyroidism or renal osteodystrophy also suggests CKD.

**Management of AKI**

Early specialist review is advisable. Often unwell, patients with AKI should be monitored in a high-dependency setting.

**General measures**

Good nursing, infection control and physiotherapy are vital. Fluid balance, as intake and output (particularly urine output), will be key to recovery. Daily measurements of weight and lying and standing blood pressure, medication review to withhold nephrotoxins, collateral history and past results will all form part of the management plan.

**Hyperkalaemia**

This may be life-threatening, leading to cardiac dysrhythmias, particularly ventricular fibrillation. Treatment is outlined in Box 9.20.

Intravenous sodium bicarbonate reduces potassium, as it corrects acidosis; it should not be used in volume-overloaded patients, however, because the sodium content may trigger or exacerbate pulmonary oedema. Rapid correction of acidosis in a hypocalcaemic patient may also trigger tetany (the ionized calcium fraction falls as albumin binding increases with a normalizing pH). Ion exchange resins such as patiromer and ZS-9 can be used to prevent chronic hyperkalaemia, but in many patients hyperkalaemia will be controlled only by dialysis or haemofiltration.

**Pulmonary oedema**

Unless a diuresis can be induced with intravenous furosemide, dialysis or haemofiltration will be required.

**Sepsis**

Infection needs to be treated promptly, avoiding nephrotoxic antibiotics. Use of prophylactic antibiotics or barrier nursing is not usually recommended.

**Use of drugs**

Nephrotoxins must be avoided and all drug dosing requires thought; GFR may be changing on a day-by-day basis and dose modification needs to follow. There is a particular risk with anticoagulants (oral and heparins; see pp. 1013–1017).
Fluid and electrolyte balance

Twice-daily clinical assessment is needed. In general, once the patient is euvoalaemic, daily fluid intake should equal urine output plus losses from the gut (including nasogastric loss) plus an allowance of 500 mL daily for insensible loss. Febrile patients will require an additional allowance.

Replacement fluid may be a balanced replacement solution, 0.9% saline (e.g. burns, pancreatitis) or 4% albumin. There are no significant differences between them with respect to death rates, organ failure, need for RRT or duration of hospitalization.

Large-volume fluid infusion or changes in daily weight (reflecting changes in fluid balance) make more regular review necessary. When overload is present, loop diuretics may be useful. Non-oliguric patients with AKI fare better than oliguric patients. However, conversion of oliguria to non-oliguria has not been shown to decrease mortality, and diuretics have not been demonstrated to prevent AKI or improve outcomes.

Nutrition

Salt and potassium should be restricted. Protein intake is sometimes limited to approximately 40 g daily (0.5 g/kg per day) to avoid the need for RRT, but this poses the risk of a negative nitrogen balance. Patients on RRT are managed on a 70 g protein (and not >1.5 g/kg per day) diet, with hypercatabolic individuals requiring a greater nitrogen intake. Ideally, nutrition should be by mouth or nasogastric tube, or, as a last resort, by parenteral feeding (with sustained bowel dysfunction of more than 14 days).

Renal replacement therapy – haemodialysis and haemofiltration

The main indications for blood purification and/or fluid removal are:

- symptomatic uraemia (including pericarditis or tamponade)
- hyperkalaemia not controlled by conservative measures
- pulmonary oedema unresponsive to diuresis
- severe acidosis
- for removal of drugs causing the AKI, e.g. gentamicin, lithium, severe aspirin overdose.

Contemporary RRT options include intermittent haemodialysis or haemodiafiltration (HDF), continuous venovenous haemofiltration (CVVHF) or peritoneal dialysis. It is not clear when to start RRT; however, several trials have questioned the wisdom of early initiation because it fails to improve outcome and in up to 30% of cases dialysis appeared unnecessary because of renal recovery without RRT. There are no data to favour haemodialysis or CVVHF as a superior mode of therapy in AKI. However, there is a consensus that in haemodynamically unstable patients, particularly those on the ITU, continuous treatments like CVVHF are more widely used for systemically unwell patients with AKI. Fluids (including nutrition, blood products or antibiotics) can be administered as volume is ultrafiltered off, preventing swings in volume and delivering more cardiovascular stability. More RRT is not necessarily better; two large trials have failed to show a survival benefit with augmented doses of RRT in critically ill patients.

Haemodialysis is explained on page 1398. CVVHF achieves blood flow using a blood pump to draw and return blood (hence, venovenous) from the lumen of a dual-lumen catheter placed in the jugular, subclavian or femoral vein. Ultrafiltrate (plasma in this case) is continually removed from the patient, usually at rates of up to 1000 mL/h, combined with simultaneous infusion of replacement solution. For instance, in a fluid-overloaded patient, filtrate might be removed at 1000 mL/h and replaced at a rate of 900 mL/h, achieving a net fluid removal of 100 mL/h.

Peritoneal dialysis is also used in the management of AKI, mainly in resource-poor countries. It has low efficiency (removing solutes slowly and less completely), and is not appropriate for patients with intra-abdominal causes or complications of their AKI. Increasing intra-abdominal pressure as peritoneal dialysis fluid is instilled can compromise lung function as well.

Management of the recovery phase

Usually, after 1–3 weeks, renal function improves, with an increase in urine output and better kidney function. If it has been required, dialysis or haemofiltration can be discontinued. A characteristic recovery phase, with a large-volume diuresis, develops as GFR recovers ahead of renal tubular reabsorptive capacity for sodium, potassium and water. Intravenous fluids are often needed to support patients, with replacement sodium chloride and potassium. Typically, the diuretic phase lasts for only a few days.

Other causes of AKI

Rhabdomyolysis

Rhabdomyolysis, or ‘crush syndrome’, occurs when skeletal muscle injury provokes the release of intracellular myoglobin, a direct tubular toxin leading to ATN. Causes include trauma, compartment syndrome, excessive exertion (marathon runners), status epilepticus and muscle toxins (statins, malaria and antimalariais, and snake and insect venom). Rapid rises in potassium, phosphate and lactate accompany elevated muscle enzymes (aspartate aminotransferase, AST); characteristically, creatine phosphokinase (CK) is massively elevated. Early and vigorous fluid resuscitation is vital (injured muscle sequestrs large amounts of fluid, causing hypovolaemic shock). Inflamed, injured muscle may become ischaemic in compartments, and a careful examination for typical ‘woody-hard’ muscle compartments may suggest a need for fasciotomies to release at-risk muscle. Sodium bicarbonate used to alkalinize the urine may limit myoglobin-induced injury.

A similar syndrome can arise with massive haemolysis, where the tubular toxin is haemoglobin rather than myoglobin. As cell breakdown is on a far smaller scale, the biochemical derangements seen with muscle injury may be absent.

Acute cortical necrosis

Renal hypoperfusion results in diversion of blood flow from the cortex to the medulla, with a drop in GFR. Medullary ischaemic damage is largely reversible because tubular cells have the capacity for regeneration. In contrast, glomerular ischaemic injury does not heal with regeneration but with scarring – glomerulosclerosis. Prolonged cortical ischaemia may lead to irreversible loss of renal function termed ‘cortical necrosis’. This may be patchy or complete. Any cause of ATN, if sufficiently severe or prolonged, may lead to cortical necrosis. Cortical necrosis occurs more commonly where the vasculature and endothelium have been damaged (with or without coagulopathy), such as with HUS and with complications of pregnancy.

Contrast nephropathy

In patients with impaired renal function, iodinated radiological contrast media may be nephrotoxic, possibly by causing renal vasocstriction and by exerting a direct toxic effect on renal tubules. The effect is dose-dependent and more commonly seen in procedures that require large amounts of contrast, such as angiography with or without angioplasty. In many patients the effect is mild, transient
and fully reversible. However, it is not benign; even a transient elevation of creatinine following contrast administration is associated with long-term consequences (an increased risk of cardiac events, ESKD and mortality). Risk factors include:

- associated hypovolaemia
- more advanced CKD
- cardiac failure
- diabetic nephropathy
- nephrotoxins (ACE inhibitors, NSAIDs in particular, and the presence of a paraprotein band).

Diabetes per se is not a risk factor. However, metformin can precipitate a lactic acidosis; it should be stopped if creatinine is over 130 μmol/L and not restarted until renal function returns to the baseline level.

**Prevention** is key: minimize the dose of contrast administered, use an iso-osmolar or low-osmolality contrast medium, and ensure patients are pre-hydrated with 1 L of 0.9% saline or 1 L of sodium bicarbonate 1.4% peri-procedure and up to 8–12h post-procedure, avoiding volume overload in susceptible patients. One trial confirmed that fluid administration guided by left end-diastolic pressure was safe and more effective in the prevention of contrast-induced AKI among high-risk patients undergoing cardiac catheterization.

N-acetylcysteine (a potent antioxidant) given 48 h prior to radiological intervention may be of borderline benefit at best. Dopamine, theophylline (an adenosine antagonist) and prophylactic haemodialysis (removing contrast agent from the circulation) are of no benefit.

**Acute phosphate nephropathy**

Administration of oral sodium phosphate solution as bowel preparation for gastrointestinal investigations is a cause of AKI. Oral phosphate solution is contraindicated in patients with CKD, congestive heart failure, gastrointestinal obstruction, and pre-existing electrolyte disorders like hyperkalaemia. Renal biopsy shows abundant calcium phosphate deposits. Treatment is usually supportive and dialysis is carried out if necessary, with good renal recovery.

**Tumour lysis syndrome**

Tumour lysis syndrome (see p. 118) complicates the first treatment of lymphoproliferative tumours; it can occur spontaneously and be found with other cancers. Chemotherapy (or even steroids), causing rapid death of malignant cells, sees the release of intracellular and membrane products, including uric acid, potassium and phosphate. A high filtered uric acid load leads to an obstructive crystal uropathy; serum urate may be 4- or 5-fold the upper limit of normal. The danger is hyperkalaemia; at-risk patients should be pre-hydrated to maintain a good urine output (allowing large urinary potassium losses), and xanthine oxidase inhibitors such as allopurinol may prevent uric acid formation. Rasburicase, a recombinant urase oxidase that does not occur in primates, oxidizes uric acid to soluble allantoin; urate levels can be undetectable after administration.

**Hepatorenal syndrome**

The renal failure observed in hepatorenal syndrome results from profound renal vasoconstriction with histologically normal kidneys (see p. 1298). It only occurs once portal hypertension and ascites have complicated liver disease. Patients are not hypovolaemic, and renal recovery is usually observed after successful liver transplantation.

**Further reading**

**CHRONIC KIDNEY DISEASE**

The term ‘chronic kidney disease’ (CKD) has replaced terms like chronic renal failure or insufficiency. CKD is a descriptive term and is used for deteriorating kidney function of any underlying cause. CKD implies longstanding (>3 months), potentially progressive impairment in renal function. However, in most cases of stage 1–3 CKD, kidney function does not continue to decline over time, and patients do not die as a direct result of kidney disease.

In many cases, there is no effective means to reverse the underlying disease process. There are exceptions where reversal is likely:

- relief of urinary tract obstruction
- immunosuppressive therapy for glomerulonephritis or systemic vasculitis
- treatment of accelerated hypertension
- correction of critical narrowing of renal arteries.

In many other cases of CKD, even if the underlying diagnosis cannot be fully treated, the rate of deterioration in renal function can be slowed (see p. 1398). A list of causes of CKD is given in **Box 36.35**.

### Staging and prevalence

CKD is staged according to the National Kidney Foundation’s Kidney Disease Outcomes Quality Initiative (K/DOQI) and endorsed by International Kidney Disease: Improving Global Outcomes (KDIGO). Staging is intended to reflect patient prognosis and outcomes (Fig. 36.46). If this MDRD-GFR-based system is used (see p. 1346), high prevalences of CKD are now found in population-based surveys, particularly in elderly patients. CKD has an elevated global prevalence.

prevalence, consistently estimated at between 11% and 15%, with the majority at stage 3 (Box 36.36).

Staging is increasingly complex:

• Patients are staged both on eGFR (with a prefix G) and albuminuria (with a prefix A), reflecting the fact that both of these parameters correlate with progressive renal impairment and cardiovascular risk. For instance a patient may be staged as having G3bA3 disease.

• Stage 3 CKD has been divided into two stages (3a and 3b) in recognition of the increased cardiovascular complications seen with more advanced disease.

• It has been advocated that cystatin C (see p. 1346), a more accurate marker of GFR, be used in patients with stage 3 CKD to better stratify risk in this group.

• Confusingly, patients with stage G2 CKD are not thought to have disease unless there is other evidence of kidney damage; this might include haematuria, proteinuria, structurally abnormal kidneys, inherited kidney disease or biopsy changes consistent with kidney disease.

Diagnosis of CKD is becoming more likely as people live longer. There is wide geographical variation in the incidence, prevalence and causes of CKD across the globe. For instance, the most common cause of GN in sub-Saharan Africa is malaria. Schistosomiasis is a common cause of CKD due to urinary tract obstruction in parts of the Middle East, including southern Iraq.

The incidence of ESKD varies between ethnic groups, being 3–4 times as common in people of black African descent in the UK and USA as it is in the white population, and hypertensive nephropathy is a much more frequent cause of ESKD in this group. The prevalence of diabetes mellitus, and hence of diabetic nephropathy, is higher in some Asian groups than in white people. Age is also of relevance: CKD caused by atherosclerotic renal vascular disease is much more common in the elderly than in the young. Over 70% of all cases of CKD are due to diabetes mellitus, hypertension and atherosclerosis.

**Progression**

CKD tends to progress to ESKD, although the rate of progression may be slow. The speed of decline tends to depend on the underlying nephropathy and on control of blood pressure. Patients with chronic glomerular diseases tend to deteriorate more quickly than those with chronic tubulointerstitial nephropathies. Regardless of cause, there may be common pathways to progression in CKD:

• Each kidney has roughly a million nephrons. In CKD, when many nephrons have failed and scarred, the burden of filtration falls to fewer functioning nephrons.

• Functioning (‘remnant’) nephrons experience increased flow per nephron (hyperfiltration), as renal blood flow has not changed, and adapt with glomerular hypertrophy and reduced arteriolar resistance.

• Increased flow, increased pressure and increased shear stress set in motion a vicious circle of raised intraglomerular capillary pressure and strain, which accelerates remnant nephron failure.

• Increased flow and strain may be detected as new or increasing proteinuria.

Angiotensin II produced locally modulates intraglomerular capillary pressure and GFR, causing vasoconstriction of postglomerular arterioles, and increasing the glomerular hydraulic pressure and filtration fraction (see Fig. 36.44). In addition, it indirectly upregulates transforming growth factor-beta (TGF-β), a potent fibrogenic cytokine, increasing collagen synthesis and epithelial cell transdifferentiation to myofibroblasts that contribute to excessive matrix formation. Angiotensin II also upregulates plasminogen activator inhibitor-1 (PAI-1), which inhibits matrix proteolysis by plasmin, with accumulation of excessive matrix and scarring in both the glomeruli and interstitium.

Proteinuria itself may be harmful in the tubulointerstitium. Albumin, in disease, may appear in the urinary space carrying bound
Anaemia in CKD impairs quality of life and wellbeing. A normochromic, normocytic anaemia develops by a number of mechanisms:

- **Erythropoietin deficiency** — this is the most significant mechanism.
- **Increased blood loss** — there may be occult gastrointestinal bleeding, repeated blood sampling, blood loss during haemodialysis, or platelet dysfunction.
- **Bone marrow toxins** — these are retained in CKD, or there is fibrosis secondary to hyperparathyroidism.
- **Haematinic deficiency** — there may be decreased iron, vitamin B₁₂ or folate.
- **Increased red-cell destruction** — red cells have a shortened lifespan in uremia, and haemodialysis itself may cause a degree of haemolysis.
- **ACE inhibitors** — these may cause anaemia in CKD, probably by interfering with the control of endogenous erythropoietin release.

**Management**

Synthetic (recombinant) human erythropoiesis-stimulating agents (ESAs; epoetin-α or β, or the longer-acting darbepoetin-α) have transformed the management of renal anaemia. ESAs can be given subcutaneously or by intravenous injection, at a starting dose of 50 U/kg of epoetin-α three times weekly, or darbepoetin 30 μg weekly. Supplemental intravenous iron may promote a response to erthropoietin and can be given prior to starting ESAs. Haemoglobin is then measured every 2 weeks, and the dose adjusted to maintain a target haemoglobin of 100–120 g/L (see later). As hypertension can be a significant side-effect in 30% of patients new to ESAs, blood pressure should be monitored in the first 6 months, and treated if rising. Peripheral resistance increases in all patients, owing to loss of hypoxic vasodilation and to an increase in blood viscosity. The rare complication of encephalopathy with fits, transient cortical blindness and hypertension can complicate treatment.

Targets and treatment are as follows:

- **Target haemoglobin** is between 100 and 120 g/L. Studies in pre-dialysis CKD patients have not shown any outcome benefits in those treated to achieve higher haemoglobin targets (>120 g/L).
- **Patients who fail to respond** to 300 U/kg weekly of epoetin-α should be screened to exclude associated iron deficiency, bleeding, malignancy, infection, inflammation, or formation of anti-erythropoietin neutralizing antibodies.
- The increased demand for iron by the bone marrow is enormous when an ESA is started. Functional iron deficiency (poor mobilization of iron, despite adequate iron stores with ferritin >500 μg/L) is a common finding in patients with chronic inflammation. Synthesis of hepcidin, an acute phase reactant produced by the liver in response to cytokines (particularly IL-6), inhibits gastrointestinal iron absorption (see p. 329) and sequesters iron in the liver, preventing its release. Intravenous (rather than oral) iron supplements optimize the response to ESAs in CKD. A trial has shown that high-dose intravenous iron and a target ferritin level of around 400 μg/L were safe and associated with a lower ESA requirement.
- **Correcting anaemia with ESAs** improves quality of life, exercise tolerance and sexual and cognitive function in dialysis patients, and leads to regression of left ventricular hypertrophy. By avoiding blood transfusion, the risk is minimized of sensitization to HLA antigens, which may complicate future renal transplantation.
- Several reports of anti-erythropoietin antibody-mediated pure red-cell aplasia in patients receiving subcutaneous ESA therapy (particularly epoetin-α) have been described. Changes in the manufacturing process of the pre-filled syringes used to deliver ESAs have reduced the number of these cases; the rubber stoppers interacted with the drug vehicle to act as an immunological adjuvant, stimulating anti-erythropoietin antibody production in hosts.

Several novel ESAs are in clinical trials. An engineered peptide that stimulates the erythropoietin receptor has been withdrawn because of anaphylaxis in a few patients. Oral agents that inhibit prolyl hydroxylase and prolong the life of hypoxia inducible factor (HIF) 1α, a transcription factor for endogenous production of erythropoietin, have shown promise and will be available to use in near future.

**CKD mineral and bone disorder**

Once called ‘renal osteodystrophy’ but now more appropriately described as a mineral and bone disorder, CKD-MBD encompasses:

- changes in calcium, phosphorus, PTH, FGF23 and vitamin D metabolism
- the various forms of bone disease that may develop alone or in combination in CKD
- the vascular consequences, such as arterial stiffness and calcification, that accompany it.

Altered bone morphology might be described in CKD (Fig. 36.47) as:

- hyperparathyroid bone disease
- osteomalacia
- osteoporosis
- osteosclerosis
- adynamic bone disease.

Most patients with CKD are found on bone biopsy to have mixed bone disease. CKD-MBD is almost universal by late stage 3 CKD. Vascular calcification is common in CKD patients; it is speculated that vascular smooth muscle cells, modulated by ureaemia and/or phosphate, differentiate to an osteoblast-like phenotype, able to synthesize and deposit matrix, which is then mineralized. Calcified vessel walls become increasingly stiff and non-compliant (leading to left ventricular hypertrophy over time), cardiac valves calcify, and soft-tissue calcium is deposited widely. There is an association between vascular calcification and mortality in CKD but a causal link has not yet been proved.

**Pathogenesis of CKD-MBD**

**Phosphate excretion** falls in the very early stages of CKD. Retained phosphate then results in the release of FGF23 and other phosphaturic agents by osteocytes as a compensatory mechanism (see p. 192). FGF23 causes phosphaturia to bring the plasma phosphate
level to within the normal range. FGF23 also downregulates renal 1α-hydroxylase, reducing the action of activated vitamin D in increasing intestinal absorption of phosphate. Despite consistently elevated levels of FGF23, phosphate levels in blood will once again rise as CKD progresses. Elevated FGF23 levels are the strongest independent predictor of mortality in patients with CKD. This underscores the necessity of controlling phosphate levels during the very early stages of CKD.

As CKD progresses, secondary hyperparathyroidism develops:
• Decreased renal production of 1α-hydroxylase results in reduced conversion of 25-(OH)2D3 to the more metabolically active 1,25-(OH)2D3 (1,25-dihydroxycholecalciferol).
• 1,25-(OH)2D3 deficiency results in reduced gut calcium absorption and a fall in calcium.
• Reduced activation of vitamin D receptors in the parathyroid glands by 1,25-(OH)2D3 increases the release of PTH.
• Calcium-sensing receptors, expressed in the parathyroid glands, react rapidly to acute changes in extracellular calcium concentrations, and a low calcium triggers increased PTH release.
• Retained phosphate also indirectly lowers ionized calcium (and probably directly via a putative but unrecognized phosphate receptor), resulting in increased PTH synthesis and release.
• PTH promotes reabsorption of calcium from bone and increased proximal renal tubular reabsorption of calcium. This mechanism attempts to reverse the hypocalcaemia caused by 1,25-(OH)2D3 deficiency and phosphate retention.

This ‘secondary’ hyperparathyroidism leads to increased osteoclastic activity, cyst formation and bone marrow fibrosis (osteitis fibrosa cystica). The typical biochemical findings are hypocalcaemia, hyperphosphataemia, an elevated PTH and a raised serum alkaline phosphatase (as a marker of increased bone turnover). Radiologically, digital subperiosteal erosions and a ‘pepperpot skull’ are seen. Longstanding secondary hyperparathyroidism ultimately leads to hyperplasia of the glands with autonomous or tertiary hyperparathyroidism. PTH release now occurs independently of calcium or 1,25-(OH)2D3 control, and high turnover in bone leads to hypocalcaemia.

Longstanding hyperparathyroidism causes increased bone density (osteo sclerosis), seen particularly in the spine, where alternating bands of sclerotic and porotic bone give rise to a characteristic ‘ruger jersey’ appearance on X-ray.

Deficiency of 1,25-(OH)2D3 and hypocalcaemia can also result in impaired mineralization of osteoid (osteomalacia).

‘Adynamic bone disease’ describes a state in which both bone formation and resorption are depressed and the skeleton becomes inert. Bone turnover is reduced, usually where there is over-treatment with active vitamin D, low PTH (after surgical parathyroidectomy), accumulation of aluminium used as a phosphate binder, or diabetes. There may be hypercalcaemia, particularly if calcium intake is high (excess calcium cannot be laid down in bone); the serum alkaline phosphatase is normal and the PTH is low. X-rays and dual X-ray absorptiometry (DXA) scans show osteopenia. No treatment is of proven benefit.

Osteoporosis is commonly found in CKD, often after transplantation and the use of corticosteroids. Monitoring is with yearly DXA scanning.

Management of CKD-MBD
The aim is to keep serum calcium and phosphate in the normal range as CKD progresses, and once dialysis is needed, to control PTH within 2- to 3-fold the upper limit of normal. This is to ensure that bone turnover continues and adynamic bone does not develop. The less well understood goal is to limit vascular calcification as well, by maintaining good bone health and avoiding calcium exposure.

Calcium, phosphate and PTH should be measured 3-monthly, and some would use imaging to define the extent of vascular calcification (e.g. by X-ray of the lumbar spine or of the abdomen). Treatment and targets, then, aim to reduce phosphate (and preferably limit calcium load), and to control PTH and achieve a normal calcium.

Reduction of phosphate and limiting of calcium load
• Dietary restriction. This is seldom effective alone because so many foods are phosphate-rich. Phosphate-restricted diets lead to protein malnutrition.
• Gut phosphate binders. Sevelamer carbonate, lanthanum carbonate, calcium carbonate and calcium acetate all reduce phosphate absorption and serum phosphate levels when taken with meals. Sevelamer (unlike calcium-containing binders) attenuates vascular calcification and lowers cholesterol levels by 10%; it has not been shown to reduce mortality. Generally, however, adherence to phosphate binders is poor.
• Aluminium-containing gut phosphate binders. These are very effective but absorption of aluminium poses the risk of aluminium bone disease and development of cognitive impairment. They are rarely used in developed countries but are still employed in developing countries because they are extremely cheap.
Kidney and urinary tract disease

- **Tenapanor**, a minimally absorbed, small-molecule inhibitor of the sodium/hydrogen exchanger isoform 3 (NHE3), inhibits both sodium and water transport locally in the gastrointestinal tract, as well as phosphate transport by indirectly inhibiting paracellular absorption of phosphate. It also downregulates intestinal phosphate transporters Na/Pi2b and reduces absorption directly. Clinically, the role of inhibitors of phosphate absorption has not yet been determined.

**Control of PTH and achievement of normal calcium**

- **Calcitriol** (1,25-dihydroxycholecalciferol), vitamin D analogues such as alfacalcidol, or novel vitamin D metabolites (22-oxacalcitrol, paricalcitol, doxercalciferoi). These are given orally to suppress PTH once the level is three times or more above the upper limit of normal. Newer vitamin D analogues, such as paricalcitol (19-nor-1,25 dihydroxyvitamin D₃), may be less likely to lead to hypercalcaemia, but their usefulness over the conventional but less expensive calcitriol or alfacalcidol remains to be established.

- **Calcimimetic agents** (e.g. cinacalcet and etelcalcetide, calcium-sensing receptor agonists, see p. 645). These have also been tried in established secondary hyperparathyroidism with successful suppression of PTH levels and lowering of calcium x phosphate product. Calcimimetics act by activating the calcium-sensing receptor, leading the parathyroid to respond as though serum calcium levels were high, reducing PTH synthesis and release. The long-term safety and efficacy of these agents have been confirmed; however, a controlled trial to assess potential survival benefits on treatment was non-conclusive.

**Calciphylaxis**

Also known as calcific uremic arteriolopathy, this is a rare but serious life-threatening complication in CKD patients. It presents as painful skin patches, plaques and ulcers, with non-healing eschars, panniculitis and dermal necrosis. The characteristic feature on histology is vascular calcification and superimposed small-vessel thrombosis (Fig. 36.48). Risk factors include hyperparathyroidism, elevated serum phosphate, morbid obesity and warfarin use (by inhibiting vitamin K-dependent carboxylation and activation of calcification inhibitor matrix gla protein). Control of hyperparathyroidism is with either surgical intervention or a calcimimetic agent, aiming to drop both calcium and phosphate to low-normal ranges. Sodium thiosulfate (an antioxidant) and bisphosphonates have been tried with variable success. Despite treatment, subsequent infection escalates the risk, as patients are often already frail, and many die within a year of diagnosis.

**Cardiovascular disease**

CKD is a major risk factor for cardiovascular disease, and the greatly increased (16-fold) incidence of cardiovascular disease in CKD compared with the normal population has a significant impact on life expectancy. Sudden cardiac death, myocardial infarction, cardiac failure, stroke and peripheral vascular disease all occur in excess as GFR declines (and the presence of proteinuria adds further to this risk). Renal transplantation reverses the risk seen with stage 5 CKD.

**Risk factors**

- **Hypertension** – very common in CKD.
- **Diabetes mellitus** – the most common cause of CKD.
- **Dyslipidaemia** – universal in uremic patients.
- **Smoking** – as common as in the general population.

**Male gender** – over-represented in patients with CKD.

Also clustering with CKD, ventricular hypertrophy is common, as is systolic and diastolic dysfunction. Left ventricular hypertrophy is a risk factor for early death in CKD, as in the general population. Systolic dysfunction is also a marker for early death. Myocardial fibrosis, abnormal myocyte function, calcium overload and hyperparathyroidism, and carnitine and selenium deficiencies all contribute to the systolic dysfunction seen with the uraemic cardiomyopathy.

**Coronary artery and generalized vascular calcification**

Traditional risk factors (e.g. smoking, diabetes) only partly explain the increased cardiovascular risk in patients with CKD. Coronary artery calcification is more common in patients with ESKD than in normal individuals and it is likely that this contributes to cardiovascular mortality. Peripheral vessel calcification increases vascular stiffness (reduced compliance), which manifests as increased pulse pressure, increased pulse wave velocity, and an increased afterload with advancing left ventricular hypertrophy. Risk factors related to calcification include:

- **A raised (calcium x phosphate) product**, which promotes calcification.
- **Hyperparathyroidism**, which increases intracellular calcium.
- **Uraemia**, which leads to loss of constitutive inhibitors of calcification, with vascular smooth muscle cells acquiring osteoblast-like characteristics.
- **Inflammation**, which further inhibits fetuin (a glycoprotein synthesized by liver, and a potent inhibitor of vascular calcification).

Plain abdominal X-ray (demonstrating ‘pipe-stem’ calcification of large arteries), electron beam or multislice CT of the coronaries, and vascular Doppler can all identify and quantify vascular calcification.

Risk factor modification is similar to that undertaken in patients without CKD, although clear evidence of benefit is less obvious.

**Other cardiovascular risk factors**

Hyperhomocysteinaemia, *Chlamydophila pneumoniae* infection, malnutrition, inflammation, insulin resistance, oxidative stress and elevated endogenous inhibitor of nitric oxide synthase and asymmetric dimethyl arginine (ADMA) all contribute to increased cardiovascular events. High ADMA levels in uraemia are caused, in part, by oxidative stress and can possibly explain the 52% increase in the risk of death and 34% increase in the risk of cardiovascular events in uraemic patients. The use of antioxidants, vitamin E or acetylcysteine has been associated with a significant reduction in all-cause and cardiovascular mortality. However, trials to reduce...
levels of homocysteine with folic acid, $B_6$ and $B_{12}$ supplementation have been unsuccessful.

The conclusion from a study of heart and renal protection (SHARP) in over 9500 CKD patients was that around one-quarter of all heart attacks, strokes and revascularizations could be avoided in CKD by using a combination of ezetimibe and simvastatin to lower blood cholesterol. This combination did not, however, confer any survival advantage or prevent the development of ESKD.

**Pericarditis**

This is common and occurs in two clinical settings:

- **Uraemic pericarditis** is a feature of severe, pre-terminal uraemia or of under-dialysis. Haemorrhagic pericardial effusion and atrial arrhythmias are often associated. There is a danger of pericardial tamponade, and anticoagulants should be used with caution.
- **Pericarditis** may resolve with intensive dialysis.
- **Diasysis pericarditis** occurs as a result of an intercurrent illness or surgery in a patient receiving apparently adequate dialysis.

**Skin disease**

Pruritus (itching) is common and is caused by:

- accumulating nitrogenous waste products of protein catabolism (itching improves following dialysis)
- hypercalcaemia and hyperphosphataemia, or an elevated calcium $\times$ phosphate product
- hyperparathyroidism (even if calcium and phosphate levels are normal)
- iron deficiency.

In dialysis patients, inadequate dialysis is a treatable cause of pruritus. However, for many, the cause of itching is unknown and no effective treatment exists.

Many patients with CKD suffer from dry skin, for which simple aqueous creams are helpful. CKD may also cause porphyria cutanea tarda, a blistering, photosensitive skin rash. This results from a decrease in hepatic uroporphyrinogen decarboxylase combined with decreased clearance of porphyrins in the urine or by dialysis. Pseudoporphyria, a condition similar to porphyria cutanea tarda, a blistering, photosensitive skin rash. This results from decreased serum testosterone levels (only seldom below the normal level). Loss of libido, erectile dysfunction and decreased spermatogenesis are common.

- **Menstrual irregularities**, oligomenorrhoea or amenorrhoea (very few women on dialysis will have periods), which are common, as is loss of libido (see p. 584).
- **Complex abnormalities of growth hormone secretion and action, resulting in impaired growth in uraemic children (pharmacological treatment with recombinant growth hormone and insulin-like growth factor is used).**
- **Altered protein binding** (and increased thyroid-binding globulin loss with proteinuria). These make thyroid function tests difficult to interpret. Thyroid-stimulating hormone (TSH) is the best test of thyroid function. True hypothyroidism occurs with increased frequency in CKD.
- **Posterior pituitary gland function is normal in CKD.**

**Nephrogenic systemic fibrosis**

Nephrogenic systemic fibrosis (NSF) is a systemic fibrosing skin disorder seen only in patients with moderate to severe CKD (eGFR <30 mL/min), particularly those on dialysis. Gadolinium-containing contrast agents, which are excreted exclusively by the kidney, have been implicated in the causation of over 95% of cases of NSF (see p. 1350).

The **diagnosis** is based on biopsy of an involved site, showing proliferation of dermal fibrocytes with excessive collagen deposition. Special testing may show gadolinium.

**NSF** is chronic and unremitting, with 30% having no improvement, 20% having modest improvement and 30% dying. No single or combination therapy offers benefit, except for improving renal function following transplantation. **Prevention** is key and so gadolinium-based contrast agents should be avoided in patents with an eGFR below 30 mL/min or those on dialysis.

**Gastrointestinal complications**

Decreased gastric emptying and an increased risk of reflux oesophagitis, gastritis and peptic ulceration are all common (hypergastrinaemia increases as GFR declines); gastrointestinal tract bleeding is more frequently seen as a result. Constipation is particularly common in patients on continuous ambulatory peritoneal dialysis (CAPD).

Acute pancreatitis occurs more frequently, though elevations of serum amylase of up to three times normal may be found in CKD without any evidence of pancreatic disease, owing to retention of high-molecular-weight forms of amylase normally excreted in the urine.

**Metabolic abnormalities**

**Gout**

Urate is retained as GFR declines, and many drugs used to manage CKD increase the risk of gout. Nephrotoxic NSAIDs are less useful in treatment, though colchicine is helpful for the acute attack. Reduced-dose allopurinol or febuxostat is effective in the prevention of further attacks.

**Insulin**

Insulin is catabolized by, and to some extent excreted via, the kidneys. Moreover, renal glucose production is diminished with progressive CKD. For these reasons, insulin requirements in diabetic patients decrease as CKD progresses. By contrast, end-organ resistance to insulin is a feature of advanced CKD, resulting in modestly impaired glucose tolerance. Insulin resistance may contribute to hypertension and lipid abnormalities.

**Lipid metabolism**

Abnormalities in lipid metabolism are common in CKD and include:

- impaired clearance of triglyceride-rich particles
- hypercholesterolaemia (particularly in advanced CKD).

The situation is further complicated in ESKD, when regular heparinization (in haemodialysis), excessive glucose absorption (in CAPD) and immunosuppressive drugs (in transplantation) may all contribute to lipid abnormalities.

**Endocrine abnormalities**

These include:

- **Hyperprolactinaemia**, which may present with galactorrhoea in men as well as women.
- **Decreased serum testosterone levels** (only seldom below the normal level). Loss of libido, erectile dysfunction and decreased spermatogenesis are common.
- **Menstrual irregularities**, oligomenorrhoea or amenorrhoea (very few women on dialysis will have periods), which are common, as is loss of libido (see p. 584).
- **Complex abnormalities of growth hormone secretion and action, resulting in impaired growth in uraemic children (pharmacological treatment with recombinant growth hormone and insulin-like growth factor is used).**
- **Altered protein binding** (and increased thyroid-binding globulin loss with proteinuria). These make thyroid function tests difficult to interpret. Thyroid-stimulating hormone (TSH) is the best test of thyroid function. True hypothyroidism occurs with increased frequency in CKD.
- **Posterior pituitary gland function is normal in CKD.**

**Muscle dysfunction**

Uraemia appears to interfere with muscle energy metabolism but the mechanism is uncertain. Decreased physical fitness (cardiovascular deconditioning) also contributes.

**Nervous system abnormalities**

Uraemia affects the **central nervous system** as depressed cerebral function, a decreased seizure threshold, asterixis, tremor and myoclonus. Anxiety, depression and impaired cognition also occur. In people with profound uraemia, and high blood urea prior to their first
dialysis, the sudden correction of urea can cause dialysis disequilibrium (urea does not equilibrate rapidly across the blood–brain barrier and, as blood urea falls on dialysis in advance of central nervous system urea, rapid movement of water into the higher-urea environment within the central nervous system leads to osmotic cerebral swelling and even fits). This can be avoided by correcting uraemia gradually by short, repeated haemodialysis treatments or by the use of peritoneal dialysis.

Increased circulating catecholamines lead to downregulation of α-receptors, impaired baroreceptor sensitivity and impaired efferent vagal function in the autonomic nervous system. Overactivity of the sympathetic nervous system may contribute to the hypertension seen in CKD. These abnormalities correct to some extent with regular dialysis and resolve after successful renal transplantation.

Peripherally, median nerve compression in the carpal tunnel is common, usually due to β2-microglobulin-related amyloidosis (see p. 1400). Advanced uraemia leads to a symmetrical polyneuropathy (which may recur in inadequately dialysed patients).

Management of CKD

General measures

- As always, make a diagnosis, and treat any modifiable underlying cause.
- Address cardiovascular risk factors: in particular, smoking cessation, exercise and weight loss.
- Avoid nephrotoxic drugs (see later).
- Arrange systematic follow-up, depending on the stage of CKD, to identify those most likely to progress early.

As stage 3 CKD progresses to stage 4 CKD, attention should be paid to correcting the complications described earlier: anemia, CKD-MBD and metabolic abnormalities. Primary prevention of cardiovascular disease is a major part of CKD management at this stage.

Renoprotection

The multidrug approach to chronic nephropathies has been formalized in an international protocol (see Box 36.12).

Correction of specific complications

Hyperkalaemia often responds to dietary restriction of potassium intake. Drugs that cause potassium retention (see p. 187) should be stopped. Occasionally, it may be necessary to prescribe ion-exchange resins to remove potassium in the gastrointestinal tract. Two new orally active drugs, patiromer and sodium zirconium cyclosilicate, have been successful in controlling hyperkalaemia in phase 3 trials and are now available for use in clinical practice. Emergency treatment of severe hyperkalaemia is described on page 188.

 Correction of acidosis helps to address hyperkalaemia in CKD and may also decrease muscle catabolism. Sodium bicarbonate supplements are effective (4.8 g (57 mmol) of Na+ and HCO3– daily), without significant risk of oedema or hypertension. Correction of metabolic acidosis with sodium bicarbonate at a mean dose of 1.8 g/day also reduces the rate of decline of GFR (slowing progression) in advanced (stage 4 and 5) CKD. Calcium carbonate, also used as a calcium supplement and phosphate binder, has a beneficial effect on acidosis.

 Drug therapy should be reviewed and nephrotoxins avoided in patients with CKD. These include:

- tetracyclines (with the possible exception of doxycycline)

- NSAIDs

- potassium-sparing agents, such as spironolactone and amiloride; these pose particular dangers, as do artificial salt substitutes, all of which contain potassium.

Antibiotics, anticoagulants (particularly anti-thrombin oral anticoagulants, which currently lack a practical monitoring measurement of effect), beta-blockers, oral hypoglycaemics, insulin, antidepressants and analgesics (especially opioids, which can accumulate, leading to an opiate narcosis) often need dose adjustment when prescribed for patients with CKD.

Early referral

Patients need time to adjust to the demands of CKD and its treatment, and to absorb information. Those who share in the decisions about their care, who are able to understand and choose treatments, make the best transition to dialysis or transplantation. As GFR declines below 20 mL/min per 1.73 m2, a dedicated team should counsel patients as to their diet, review medication, encourage risk factor modification, and support them to RRT (or the choice not to undertake dialysis).

If the patient opts for regular haemodialysis, an arteriovenous fistula should be fashioned well in advance of the need for dialysis (when serum creatinine is in the order of 400–500 µmol/L in non-diabetics, and at an even earlier stage in diabetics with poorer vasculature). Such fistulae require several weeks to mature and become usable for vascular access. Veins required for future arteriovenous fistulae should not be rendered useless by cannulation (Fig. 36.49). Patients choosing peritoneal dialysis might have a buried catheter placed and left subcutaneously for some time, able to be externalized on the day dialysis starts.

Where suitable, patients should be offered and prepared for preemptive living donor transplantation as the best option for RRT.

Renal replacement therapy

About 3 million people worldwide either are treated by haemodialysis or peritoneal dialysis, or live with a functioning renal transplant. In the UK, around 53 000 people receive treatment for ESKD; around

Fig. 36.49 Intravenous cannula in exactly the WRONG place. The cannula is shown in a right-handed patient with CKD, who will, in future, need a left (non-dominant arm) radiophalic fistula.
50% have been transplanted, 42% are on haemodialysis and 8% are on peritoneal dialysis.

Dialysis aims to mimic the excretory function of normal kidneys by:
- eliminating (nitrogenous and small molecular) wastes
- maintaining normal electrolyte concentrations
- preventing systemic acidosis
- maintaining a normal extracellular volume.

### Initiation of dialysis

It is not widely agreed when to start dialysis in patients with stage 5 CKD, and trials have suggested that early initiation is not associated with improved survival or clinical outcomes. There is a general tendency to start dialysis at an eGFR close to 10mL/min but this decision is best shared with an individual patient, taking into account symptoms and life plans.

### An informed choice

Many people, particularly if they are frail or living with other comorbidities, will choose not to undergo RRT if able to make a shared, informed decision with their physician and families. For some, the quantity of extended life offered by dialysis is not matched by the perceived impact on the quality of their lives. For others, events and complications of dialysis can make the daily experience of treatment difficult to endure, and they may choose to withdraw from dialysis. Support through their last illness, good symptom control and respect for the individual’s informed choices can allow patients a comfortable end of life after a period of long illness.

### A difficult choice

Across the globe, RRT (like other treatments) can be an expensive option. For many societies, health resources may be allocated to other pressing priorities, or may be available for a defined time period only, or one form of RRT may be preferred over others. The drive for more cost-effective and low-technology solutions to treat renal failure is a pressing need for the specialty worldwide.

### Haemodialysis

#### Basic principles

Anticoagulated blood from a patient is pumped around an extracorporeal circuit and through a biocompatible, semipermeable membrane (the dialyser, or ‘artificial kidney’) before being returned to the circulation. In the dialyser, ultrapure dialysate flowing in the opposite direction is in close contact with blood. Small solutes (but not cells and larger-molecular-weight proteins) can cross the membrane, and move by diffusion down a concentration gradient (Fig. 36.50). A transmembrane pressure allows controlled fluid removal by ultrafiltration (and with fluid, more solute removal by convection).

Over a standard 4-hour session, up to 80L of blood (at around 300mL/min) is circulated through the dialyser; even so, this provides an equivalent GFR of only 10–12mL/min per m². Box 36.37 describes a typical dialysate; dialysis is individually prescribed for any particular patient to obtain optimal results.

### Access

Effective dialysis needs blood flows of between 250 and 450mL/min. In order to achieve this, a surgically fashioned arteriovenous fistula (AVF, Fig. 36.51) is formed, using the radial or brachial artery and the cephalic vein. Large-bore needles are inserted into the arterialized vein of the AVF to take blood to and from the dialysis machine. In patients with poor-quality veins or arterial disease (e.g. diabetes mellitus), synthetic arteriovenous grafts offer an alternative.

For many, an AVF is not an immediate or appropriate solution, and a semi-permanent dual-lumen venous catheter can be inserted under a skin tunnel into the jugular or femoral vein. Although

(B) One way of reminding the anaesthetic, nursing and surgical teams about the presence of an existing arteriovenous fistula in a haemodialysis patient about to undergo surgery. In particular, the fistula should not be compressed during surgery, to avoid thrombosis within it.
easy to place and offering immediate use, there is a significant risk of bloodstream infection (with a foreign body directly accessing the circulation), catheter malfunction (thrombosis), or venous stenosis or occlusion.

For urgent dialysis a temporary (and untunneled) large-bore, double-lumen dialysis catheter may be inserted into a central vein – usually the subclavian, jugular or femoral vein.

**Aims**

- **Maintain euvolaemia** – the ideal (or ‘dry’) weight. Fluid gains (in kilograms) between each dialysis session are the sum of fluid intake less fluid losses over a 48-hour interdialytic interval. A patient who is anuric (with no urine output) who drinks 2 L/day will gain 4 kg if no insensible or stool losses occur. If a patient is weighed before and after each session (with the post-dialysis weight described as the ‘dry’ weight), dialysis can deliver long-term volume and blood pressure control.

- **Maintain electrolytes** in balance. A low dialysate potassium (of 1–3 mmol/L) allows rapid control of hyperkalaemia and a negative potassium balance (of 1–2 mmol/kg per session) over a treatment. Dialysate sodium is carefully controlled to prevent large fluid shifts (at 137–141 mmol/L, although this can be individualized), and calcium fixed to mimic the ionized fraction (and prevent net calcium gain during dialysis).

- **Prevent acidosis**. Dialysate is buffered with bicarbonate at (for example) 36 mmol/L. This will diffuse into blood to correct acidosis during treatment.

- **Balance frequency and duration with quality of life.** Between 4 and 5 h of treatment three times a week is considered ‘adequate’ to maintain volume and solute balance over time. Shorter or less frequent dialysis is usually sufficient only if a patient has considerable residual renal function (usually assessed by measuring 24- or 48-h urine volumes and clearances, then adding this to the dialysis clearance). Recent evidence is pointing towards more frequent dialysis (up to 5–6 dialysis sessions per week) or longer treatment duration (6–8 h three times weekly) as offering more benefit in terms of quality of life, solute clearance and cardiovascular health. However, it is less popular among patients and associated with early loss of residual renal function and vascular access loss.

- **Deliver enough dialysis** (adequacy). The size, number and nature of ‘uraemic toxins’ are not clear, and the only true measure of adequacy is patient mortality and morbidity. Symptoms of under-dialysis are non-specific and include insomnia, itching and fatigue (despite adequate correction of anaemia), restless legs and a peripheral sensory neuropathy. Formal measures using urea as a surrogate calculate the urea reduction ratio (URR, targeting >65% per session) or the eKt/V (where K is the dialyser clearance, t is the duration of dialysis in minutes, and V is the urea distribution volume estimated as total body water) as minimum thresholds required for well-nourished dialysis patients dialysed three times per week. It is unclear whether a higher eKt/V (more dialysis than is thought of as adequate) associates with better outcomes; initial trial data suggest not.

**Specific complications**

- **Access** (either AVF or catheter) malfunction, thrombosis or bleeding.
- Bloodstream infections, which may disseminate to soft tissue (septic arthritis), cardiac valves (endocarditis) or spinal column (vertebritis).
- **Dialysis disequilibrium**, when dialysis is initiated with too rapid early urea removal. Subsequent movement of fluid towards the higher urea seen across the blood–brain barrier can cause cerebral oedema and fitting.
- **Intradialytic hypotension** (where too rapid fluid removal exceeds refill of the circulation from the extravascular space).
- **Dialysis-related amyloidosis**, where failure of clearance of β2-microglobulin, a molecule of 11.8 kDa, leads to amyloid deposits, median nerve compression in the carpal tunnel, a dialysis arthropathy, bone cysts and fractures, pseudotumours and gastrointestinal bleeding.

**Haemofiltration**

Haemofiltration differs from haemodialysis in that there is no dialysate; rather, plasma water (along with suspended solutes) is removed by convection across a high-flux semipermeable membrane. Substitution fluid (with the desired biochemical composition) is then infused to replace (large) fluid losses (Fig. 36.52). Haemofiltration may be preferred in the acute setting, where haemodynamic instability is common (particularly on ITUs). Modern dialysis machines have built-in facilities to generate online ultra-pure water, which has minimized the cost of the procedure. It has also given the clinician the option to use this technique either as haemofiltration or in combination with dialysis as haemodiafiltration (HDF) to increase middle molecule clearance (e.g. β2-microglobulin) and prevent long-term dialysis complications such as dialysis-related amyloidosis, particularly in young, highly sensitized, non-transplantable patients. Post-hoc analysis of several trials has suggested that HDF with a convection component of more than 20 L per session is associated with survival advantage.

**Peritoneal dialysis**

Peritoneal dialysis uses the peritoneal membrane as a semipermeable membrane, avoiding the need for extracorporeal circulation of blood. It is a very simple, low-technology (yet effective) treatment compared to haemodialysis (Fig. 36.53).

- A soft catheter is placed through a skin tunnel into the peritoneal cavity through the midline of the anterior abdominal wall (Fig. 36.54).
- **Dialysate** is run into the peritoneal cavity, usually under gravity.
- **Urea, creatinine, phosphate and other uraemic toxins** pass into the dialysate down their concentration gradients.
- **Water** (with solutes) is attracted into the peritoneal cavity by osmosis, depending on the osmolarity of the dialysate. This is determined by the glucose or polymer (icodextrin) content of the dialysate (Box 36.38). More hypertonic solutions (rising from around 1.5% to 4% glucose) will improve fluid removal.
- **The fluid is exchanged regularly** to repeat the process.

**Fig. 36.52** Principles of haemofiltration.
Chronic kidney disease

Continuous ambulatory peritoneal dialysis (CAPD) has dialysate present within the peritoneal cavity continuously, except during an exchange (done 3–5 times a day using a sterile no-touch technique to connect 1.5–3L bags of dialysate to the peritoneal catheter; each exchange takes 20–40 minutes.

Automated peritoneal dialysis (or nightly intermittent peritoneal dialysis) has a simple exchange machine performing continuous low-volume exchanges each night while the patient is asleep.

Specific complications
- Bacterial peritonitis, presenting as fever, abdominal pain and a cloudy peritoneal dialysate effluent (>100 cells/mm$^3$ on microscopy is suggestive) progressing to frank peritonitis, occurs at the rate of about one episode for every 2 patient-years. Once peritoneal effluent is sent for culture, empirical antibiotic treatment is started. Common causative organisms are listed in Box 36.39.
- Catheter exit site infections may progress to skin tunnel infections and peritonitis.
- Constipation may impair flow of dialysate in and out of the pelvis.
- Hernias are caused by raised intra-abdominal pressure, and dialysate ‘leaks’ into the pleural cavity or scrotum (down a patent processus vaginalis).
- Sclerosing peritonitis is a potentially fatal complication of CAPD, where long-term patients develop progressive thickening of the peritoneal membrane. This occurs in association with adhesions and strictures, turning the small bowel into a mass of matted loops and causing repeated episodes of small bowel obstruction.

Adequacy
Most clinicians aim for a weekly $Kt/V$ of 2.0 (see earlier), coupled with a creatinine clearance of 60L per week. Once patients stop passing urine (and have no residual renal function), peritoneal dialysis inadequacy becomes common, and a switch in technique to haemodialysis may be required.
**Dialysis in the frail**

Dialysis can prolong life but the benefit to any individual, and particularly to frail patients, varies widely. Outcomes in frail elderly people who are undergoing dialysis are poor. Small studies suggest that mortality or quality-of-life outcomes do not differ significantly among selected patients who elect to undergo dialysis, compared to those who decide against dialysis. In one study, over 50% died within the first year of initiating dialysis and around 30% had a decrease in functional status.

**Renal transplantation**

Successful renal transplantation offers the potential for almost complete rehabilitation in ESKD.

- Survival is significantly better compared to dialysis patients on transplant waiting lists.
- Transplantation allows freedom from dietary and fluid restrictions.
- Anaemia and infertility are corrected.
- Any need for parathyroidectomy is reduced.

It is the treatment of choice for any appropriate patients with ESKD. However, the supply of donor organs (in the UK, 44 per million population per year) is exceeded by demand. Donor organs are a scarce and valuable resource that must be used optimally.

Kidney transplantation involves the anastomosis of an explanted human kidney, usually either from a deceased donor or from a living related or unrelated donor, onto the iliac vessels of the recipient (Fig. 36.55). The donor ureter is placed into the recipient’s bladder. Unless the donor is genetically identical (i.e. an identical twin), immunosuppressive treatment is needed, for as long as the transplant remains in place, to prevent rejection. Patient and graft survival has steadily improved with:

- more appropriate patient selection and assessment
- better donor-recipient compatibility
- improvements in surgical techniques
- more efficient immunosuppressive regimens.

Some 80% of grafts now survive for 5–10 years in the best centres, and 50% for 10–30 years. However, the half-life of renal allografts is still 13–16 years. The three most common causes of late graft loss are death of patients with a functioning graft, recurrence of the original (or still) renal disease, and chronic allograft nephropathy.

Considerations in successful kidney transplantation

ABO (blood group) compatibility between donor and recipient is preferred. ABO-incompatible renal transplants (where donor and recipient have different blood groups) are successful with directed immunosuppression (including immunoadsorption to remove pre-formed antibodies, anti-CD20 antibodies to remove B lymphocytes, and intravenous pooled immunoglobulins for immunomodulation or anti-idiotypic antibodies).

Donor and recipient HLA mismatches should ideally be minimized. Nationwide matching schemes for kidneys retrieved from deceased donors form the basis for kidney transplant offers. Complete compatibility at A, B and DR loci offers the best long-term outcomes when compared to multiply mismatched organs (i.e. antigens possessed by the donor and not possessed by the recipient). However, transplanting completely mismatched kidneys, particularly with living donation, is routine and results are as good as, if not better than, properly matched deceased donor kidneys.

Pre-formed (historical) anti-HLA antibodies in recipients, resulting from either sensitization from prior blood transfusions, kidney transplants or past pregnancy in women, tend to predict less good outcomes. This is particularly true if these existing antibodies are donor-specific (or recipient anti-HLA antibodies against donor antigens). Transplantation can still be successful but pre-transplant strategies are necessary to minimize these antibodies (with plasmapheresis, intravenous immunoglobulin and/or the anti-B cell monoclonal antibody rituximab or newly described IgG endopeptidase, which cleaves off IgG).

Organs may be retrieved from donors who have sustained brainstem death or even cardiac arrest. Most countries allow the removal of kidneys and other organs from patients who have suffered irretrievable brain damage (‘brainstem death’) while the heart is still beating (donation after brainstem death, DBD; see p. 236). Due to the shortage of solid organs and increasing numbers of patients waiting for them, several countries now allow the retrieval of organs after cardiac death (donation after cardiac death, DCD), with comparable results to ‘heart-beating’ donations. Increasing use is also made of expanded criteria donors (ECDs) aged over 60 years, or those between 55 and 59 years but with co-morbidity such as hypertension, diabetes, pre-retrieval AKI and intracranial haemorrhage as a cause of death.

**Living related or unrelated donation** offers the best kidney outcomes. Potential living donors undergo comprehensive preoperative evaluation to ensure that they will come to no harm through donating a kidney to another person. Recent evidence suggests that live donors carry a statistically increased risk of CKD/ESKD post donation but the inherent risk is too low for it to be of clinical significance. Young women donors are at increased risk of gestational hypertension or pre-eclampsia in subsequent pregnancies, though without any ill-effects on their children. As a result, all living donors should be consented carefully and monitored regularly.

Timing transplantation so that it takes place prior to dialysis initiation (pre-emptive transplantation) offers benefits to both recipient and graft.

**Immunosuppression for transplantation**

Long-term inhibition of the recipient immune system is needed to prevent immune-mediated injury to grafts recognized as non-self. This is almost universally the case, except where living related donation from an identical twin occurs. Some degree of immunological tolerance does develop and the risk of rejection is highest in the first 3 months after transplantation. In the early months, rejection episodes occur in less than 20% of cadaver kidney recipients on current immunosuppression protocols, and most cases are reversible. A combination of immunosuppressive drugs is usually used (Box 36.40). Individualizing
immunosuppression to a specific recipient remains an inexact science, and preventing the complications of over-immunosuppression is as necessary as preventing rejection. Therapeutic drug monitoring is useful in delivering the most intense immunosuppression in the early post-transplant phase and allows lower target ranges further out.

**Early complications**

**Early (technical) failure**

Oclusion or stenosis of the arterial anastomosis, occlusion of the venous anastomosis and urinary leaks owing to damage to the lower ureter or to defects in the anastomosis between ureter and recipient bladder can occur, despite best surgical technique.

**Acute tubular necrosis**

Delayed graft function (DGF) resulting from ATN is the most common cause of deceased donor graft dysfunction (up to 40–50%), particularly in kidneys from DCD or ECD donors (see earlier). Hypotension or loss of cardiac output will have an understandable impact on the retrieved organ. A prolonged ‘cold ischaemia time’ (the period during which the retrieved organ is cooled on ice in transit and awaits implantation) also leads to delayed graft function due to ATN. Finally, calcineurin inhibitors used to prevent rejection are themselves nephrotoxic where high peak and trough concentrations cause tubular injury. Kidneys transported on a perfusion machine, and controlled hypothermia in deceased donors prior to organ retrieval, have been associated with improvements in DGF rates.

**Acute rejection**

Acute rejection is seen in between 10% and 30% of transplant recipients and usually presents with declining renal function within the first 3 months. Renal biopsy (Fig. 36.56A) can confirm the diagnosis and also assess the severity and type of rejection, but sampling errors do occur. Urinary measurement of RNA is also being used to detect acute cellular rejection (T-cell or antibody-mediated, with or without endothelial injury – so-called ‘vascular rejection’).

Cellular rejection may respond to high-dose intravenous corticosteroids, increased or switched calcineurin inhibition, or the use

**Legend**

- EBV, Epstein–Barr virus; HUS, haemolytic uraemic syndrome; IL-2, interleukin 2; LFTs, liver function tests.
of T-cell-depleting agents such as anti-thymocyte globulin (ATG) or anti-CD52 antibody (Campath). Antibody-mediated rejection (diagnosed by the presence of circulating donor-specific anti-HLA antibodies and evidence of complement activation on renal biopsy by C4d staining, Fig. 36.56B) is usually treated empirically by a combination of intravenous immunoglobulin (to neutralize and promote the clearance of anti-HLA antibodies), plasmapheresis (to remove antibodies) and anti-CD20 antibody administration (to deplete B lymphocytes), with variable success.

More than one rejection within the first 3 months, vascular and/or antibody-mediated rejection, delayed rejection (requirement of dialysis within the first week after transplantation), and failure of serum creatinine to return to baseline (<130 μmol/L) after a rejection episode are associated with worse long-term outcome.

Infection

- Bacterial infections occur early (<1 month postoperatively) and involve the urinary tract, wounds and chest.
- Cytomegalovirus infection develops weeks or months after transplantation in 70% of cytomegalovirus-seronegative recipients receiving grafts from a seropositive donor, and in patients receiving biological agents (antibodies) as induction or therapy for rejection, unless prophylaxis with ganciclovir is given. Opportunistic infections, such as those with Pneumocystis jiroveci, occur and prophylactic co-trimoxazole is given in the early months. These infections also arise in the months after transplantation and are associated with heavier immunosuppressant burdens.
- Polyomavirus infection (BK nephropathy) causes an often aggressive TIN that may lead to graft loss. The only existing therapy is minimization of immunosuppression in the hope of spontaneous viral clearance.

Late complications

- Post-transplantation lymphoproliferative disorders, often associated with Epstein–Barr virus, are more frequent malignancies in patients who received profound immunosuppression. Immunization is minimized and standard chemotherapy offered, with mixed outcomes.
- Immunosuppressive therapy increases the risk of skin tumours, including basal and squamous cell carcinoma. Other cancers that occur at increased frequency include renal, cervical and vaginal malignancies.
- Cardiovascular disease causes 50% of patient deaths after transplantation. Increased hypertension, obesity, diabetes, insulin resistance and lipid disorders all play a role, as does an often long history of CKD.
- Post-transplant osteoporosis may occur as a result of steroid use.
- Recurrent renal disease is surprisingly common. Primary FSGS often recurs and causes early graft loss. Mesangiocapillary GN, diabetic nephropathy and IgA nephropathy also commonly recur, with variable effects on long-term graft survival. Most grafts fail eventually through lasting immunological injury, the toxicities of immunosuppressant drugs, or even both. A common histological finding is interstitial fibrosis and tubular atrophy, a lesion once called chronic allograft nephropathy. There is a growing understanding of the role of subclinical chronic antibody-mediated rejection due to existing or de novo donor-specific antibodies, but non-immunological factors play an important part as well. Progressively irreversible decline in graft function is associated with mild to modest proteinuria (<3g/day), and interventions to change this trajectory currently lack evidence of benefit.

Renal transplantation in HIV patients

Modern anti-retroviral therapy (ART) offers patients with HIV infection a near-normal life expectancy. However, an increasing number develop ESKD, and HIV was considered to be a contraindication to renal transplantation. However, a study of outcomes for 150 HIV-infected patients undergoing renal transplantation has shown that kidney transplantation is safe and effective in these individuals, at least in the short term. The patients in the study had CD4+ T-cell counts of 200 cells/mm$^3$ or more, and undetectable plasma levels of HIV type 1 RNA while on stable ART during the 16 weeks before renal transplantation. Median follow-up was 1.7 years. Survival rates at 1 year (95%) and 3 years (89%) were worse in HIV-infected patients than in the general population of kidney transplant recipients, but better than those in patients aged 65 years and over. Many rejection episodes were glucocorticoid-resistant, suggesting an aggressive response to donor antigens.

Further reading

Solitary or multiple renal cysts are common, especially with advancing age; 50% of those over 50 years of age have one or more such cysts. They have no special significance, except in the differential diagnosis of renal tumours (see p. 1406). These cysts are often asymptomatic and are found on ultrasound examination performed for some other reason. Occasionally, they may cause pain and/or haematuria if large, or bleeding may occur into the cyst. Cystic degeneration (the formation of multiple cysts that enlarge with time) occurs regularly in the non-functioning kidneys of patients with ESKD treated by dialysis and/or transplantation. These acquired cysts have malignant potential.

**Autosomal dominant polycystic kidney disease**

Autosomal dominant polycystic kidney disease (ADPKD) is an inherited disorder that usually presents in adulthood. It is characterized by the development of multiple renal cysts, variably associated with extrarenal (mainly hepatic and cardiovascular) abnormalities. ADPKD is by far the most common inherited nephropathy, with a prevalence rate ranging from 1:400 to 1:1000 in white populations. It accounts for 3–10% of all patients commencing regular dialysis in the West.

Mutations in PKD1 (on chromosome 16) are responsible for 85% of cases, with mutations in PKD2 (on chromosome 4) accounting for the remainder. These genetic abnormalities are distinct from the autosomal recessive form of polycystic disease (due to mutations in the PKHD1 gene on chromosome 6p21.1-p12), which is often lethal in early life.

**PKD1** encodes polycystin 1, involved in cell–cell and/or cell–matrix interactions. **PKD2** encodes polycystin 2, which functions as a calcium ion channel. The polycystin complex occurs in cilia, responsible for sensing flow in the tubule. Disruption of the polycystin pathway results in reduced cytoplasmic calcium, which, in principal cells (see p. 196) of the collecting duct, causes defective ciliary signalling and disoriented cell division, leading to cyst formation. Extra-renal manifestations include an increased level of intracranial aneurysms and polycystic liver disease, which can be severe and associated with significant morbidity. Mis-sense mutations in **GANAB**, encoding glucosidase II subunit α (GLIα), have been discovered to be associated with combined ADPKD and polycystic liver disease. The **GANAB** gene product GLIα is an absolute requirement for maturation and surface and ciliary localization of the ADPKD proteins (PKD1 and PKD2).

Progressive loss of renal function is usually attributed to mechanical compression, apoptosis of the healthy tissue and reactive fibrosis. Renal function declines at a variable rate, depending on the growth and size of cysts; patients with rapidly growing cysts on MRI lose renal function more rapidly. Strategies to slow the growth rate of cysts have been very effective in preserving renal function in animal models. These therapies include the vasopressin V2 receptor inhibitors (vaptans, to reduce cyclic adenosine monophosphate (cAMP) in the principal cells), rosvosetin (a cyclin-dependent kinase inhibitor) and antiproliferative therapy with sirolimus (mammalian target of rapamycin (mTOR) inhibitor).

**Clinical features**

Presenting symptoms occur from any point in the second decade onwards:

- loin pain and/or haematuria from haemorrhage into a cyst, cyst infection or urinary tract stone formation
- loin or abdominal discomfort as the size of the kidneys increases

- subarachnoid haemorrhage associated with berry aneurysm rupture
- complications of hypertension
- complications of associated liver cysts (occur in around 50%)
- symptoms of uraemia and/or anaemia associated with CKD.

**Complications and associations**

- Pain from large cysts can be difficult to manage; surgical decompression is of some benefit in about two-thirds of affected patients.
- Cyst infection is most effectively treated with lipophilic antibiotics that penetrate into infected cysts and are active against Gram-negative bacteria, such as co-trimoxazole and fluoroquinolones.
- Renal calculi occur in 10–20% and are often composed of uric acid and are radiolucent (see Fig. 36.30).
- Hypertension is an early and very common feature of ADPKD. Intrarenal activation of the renin–angiotensin system is thought to be contributory, so ACE inhibitors are logical first-line agents in treatment. Early control of blood pressure is essential as left ventricular hypertrophy is common, and cardiovascular complications are a major cause of death in ADPKD.
- Progressive CKD is the most serious complication of ADPKD. At glomerular filtration rates below 50 mL/min, the rate of decline in GFR averages 5 mL/min each year, which is much faster than in other primary renal disorders. The probability of being alive without requiring dialysis or transplantation by the age of 70 years is in the order of 30%. Survival rates on regular haemodialysis and after renal transplantation in ADPKD are better than those in patients with other primary renal diseases.
- Approximately 30% of patients have hepatic cysts, occasionally massive enlargement of the polycystic liver with pain, infection and, more rarely, compression of the bile duct, portal vein or hepatic venous outflow.
- Some 10% of ADPKD patients have an asymptomatic intracranial aneurysm (see p. 845). The prevalence is twice as high if a family history of aneurysms or intracranial haemorrhage is present. Screening for intracranial aneurysm in ADPKD is recommended for patients aged 18–40 years who have a positive family history.
- Mitral valve prolapse is found in 20% of individuals with ADPKD.

**Diagnosis and screening**

Physical examination commonly reveals large, irregular kidneys and possibly hepatomegaly. Definitive diagnosis is established by ultrasound examination (Fig. 36.57 and Box 36.41). However, such renal imaging techniques may be equivocal, especially in subjects under the age of 15 years. A number of conditions can mimic the clinical and radiological appearance of ADPKD (Box 36.42).

The children and siblings of patients with established ADPKD should, in general, be offered screening. Affected individuals should have regular blood pressure checks and should be offered genetic counselling. Gene linkage analysis can be utilized in many families.

**Management**

No definitive therapy is yet available. Potential strategies include:

- **Vasopressin receptor antagonists**, which act by inhibiting cAMP in principal cells, reduce cyst growth and slow the rate of progression of renal failure; they have been approved for use in patients with annual rate of decline of eGFR of >3 mL/min. Reversible liver toxicity requires close monitoring.
Kidney and urinary tract disease

Effect of lanreotide on kidney function in patients with autosomal dominant polycystic kidney disease (ADPKD)

Octreotide, a long-acting somatostatin analogue (which also inhibits cAMP), has been beneficial in halting the growth of both liver and renal cysts. However, in a recent study the somatostatin analogue lanreotide did not slow decline in kidney function in more than 300 patients with later-stage ADPKD (eGFR 30–60 mL/min) over 2.5 years of follow-up, despite a significant effect on the rate of hTKV growth.

In the HALT-PKD study A, patients with early PKD and eGFR >60 mL/min, when randomized to a low blood pressure group (95/60–110/75 mmHg), had slower annualized increase in total kidney volume and lower albuminuria and left ventricular mass index, compared to the standard blood pressure group (120/70–130/80 mmHg). In late-stage PKD (eGFR 25–60 mL/min), adding an angiotensin receptor blocker to an ACE inhibitor (dual block)

Medullary cystic disease (‘juvenile nephronophthisis’)

Juvenile nephronophthisis develops early in childhood and is inherited in an autosomal recessive manner. Mutations in the genes NPHP1–4, encoding nephrocystin and inversin (both co-localized in the cilia of the renal tubules) lead to multiple cyst formation. Polyuria, polydipsia and growth retardation result from impaired tubular function. A similar condition developing later in childhood (medullary cystic disease) is inherited as an autosomal dominant trait but sporadic cases occur in both conditions. The dominant histological findings are interstitial inflammation and tubular atrophy, with later development of medullary cysts. Diagnosis is based on family history and renal biopsy, the cysts rarely being visible on imaging.

Medullary sponge kidney

Medullary sponge kidney is an uncommon cystic condition presenting as intermittent renal colic, the passage of small stones and haematuria. Although it is most often sporadic, a few affected families have been reported. Dilation of the collecting ducts in the papilla occurs, sometimes with cystic change. In severe cases the medullary area has a sponge-like appearance. The condition may affect one or both kidneys, or only part of one kidney. Cyst formation is commonly associated with the development of small calculi within the cyst. In about 20% of patients there is associated hypercalcuria or renal tubular acidosis (see p. 199). Hemi-hypertrophy of the skeleton has been described in this condition.

CT or IVU (see Fig. 36.28) is diagnostic. Renal function is usually well maintained and CKD is unusual, except where obstructive nephropathy develops owing to the presence of stones in the pelvis or ureters.

TUMOURS OF THE KIDNEY AND GENITOURINARY TRACT

Renal cell carcinoma

Renal cell carcinomas (RCCs) arise from proximal tubular epithelium. They are the most common renal tumour in adults (accounting for 1–2% of all malignancies) and affect men more often than women (2:1). They usually present after 50 years of age (and rarely before the age of 40).
RCCs are highly vascular tumours; microscopically, most are composed of large cells containing clear cytoplasm.

Clinical features
- RCCs are often asymptomatic and discovered incidentally.
- Haematuria, loin pain and a mass in the flank occur.
- Malaise, anorexia and weight loss may be present (30%).
- Some 5% of patients have polycythaemia (see p. 355).
- Around 30% of patients have hypertension (due to secretion of renin by the tumour) and anaemia, due to depression of erythropoietin in approximately the same number.
- Pyrexia occurs in about 20% of patients.
- Approximately one-third present with metastases.
- Rarely, a left-sided varicocele may be associated with left-sided tumours that have invaded the renal vein and caused obstruction to drainage of the left testicular vein.

Diagnosis
Ultrasound may demonstrate a solid lesion. CT scanning is used to identify the renal lesion and involvement of the renal vein or inferior vena cava. MRI is better than CT for tumour staging. Urine cytology for malignant cells is of no value. The ESR is usually raised. Liver biochemistry may be abnormal, returning to normal after surgery.

Management
Medical management of RCC is discussed on page 127. A nephrectomy is performed unless bilateral tumours are present or the contralateral kidney functions poorly, in which case conservative surgery, such as partial nephrectomy, may be indicated. If metastases are present, nephrectomy may still be warranted, since regression of metastases has been reported after removal of the main tumour mass.

Von Hippel–Lindau (VHL) disease
Von Hippel–Lindau (VHL) disease is an autosomal dominant disorder presenting with bilateral RCCs, retinal and cerebellar haemangio/blastomas, phaeochromocytomas, pancreatic neuroendocrine tumours and renal cysts. VHL protein acts as a tumour suppressor by tagging hypoxia-inducible gene products (VEGF, TGF) for degradation. Inactivating mutations of the VHL gene lead to uncontrolled angiogenesis and neoplasia. Mutations of the same tumour suppressor gene are responsible for RCC and VHL.

Nephroblastoma (Wilms’ tumour)
Seen within the first 3 years of life, Wilms’ tumour presents as an occasionally bilateral abdominal mass, rarely with haematuria. Diagnosis is established by ultrasound, CT and MRI. A combination of nephrectomy, radiotherapy and chemotherapy has much improved survival rates, even in children with metastatic disease. Overall, the 5-year survival rate is 90%.

Urothelial tumours
The calyces, renal pelvis, ureter, bladder and urethra are lined by transitional cell epithelium. Transitional cell cancers account for about 3% of deaths from all forms of malignancy. These tumours are uncommon below the age of 40 years, but more common in men (the male:female ratio is 4:1). Bladder tumours are about 50 times as common as those of the ureter or renal pelvis. Predisposing factors include:
- cigarette smoking
- exposure to industrial carcinogens such as β-naphthylamine and benzidine (workers in the petroleum, chemical, cable and rubber industries are at particular risk) or ingestion of aristolochic acid, found in some herbal weight-loss preparations
- exposure to drugs (e.g. phenacetin, cyclophosphamide)
- chronic inflammation (e.g. schistosomiasis, usually associated with squamous carcinoma).

Clinical features
Painless haematuria is the most common presenting symptom (80%) of bladder malignancy, although pain may occur owing to clot retention. Symptoms suggestive of UTI develop in the absence of significant bacteriuria. In patients with bladder cancer, pain also results from local nerve involvement. Presenting symptoms may result from local metastases. Flank pain may occur with urinary tract obstruction in ureteric lesions.

Investigations
- Urine cytology for malignant cells.
- Urinary tumour markers.
- Cystoscopy to assess the tumour burden and for biopsy.
- CT or MRI of the pelvis.

Management
Medical management of urothelial and testicular tumours is discussed on pages 127 and 129, respectively.

DISEASES OF THE PROSTATE GLAND
Benign enlargement of the prostate gland
Benign prostatic enlargement is discussed in detail on page 1480.

Prostatic carcinoma
The pathogenesis, diagnosis and prognosis of prostate cancer are described on page 1480. Management of early disease is outlined on page 1481 and that of later-stage disease on page 128.

THE URINARY TRACT IN THE ELDERLY
Progressive sclerosis of glomeruli occurs with ageing and this, together with the development of atheromatous renal vascular disease, accounts for the progressive reduction in GFR seen as people age. A GFR of 50–60mL/min (about half the normal value for a young adult) may be regarded as ‘normal’ in patients over 80 years of age. The reduction in muscle mass often seen with ageing may mask this deterioration in renal function, as creatinine falls despite a falling GFR. Accurate estimation of GFR in the elderly is necessary, particularly when prescribing drugs wholly or partly excreted by the kidney.

Urinary tract infections
UTIs are common in the elderly, where impaired bladder emptying (due to prostatic disease in men) or a neuropathic bladder (especially common in women) is frequently found. Symptoms may be atypical, with confusion, incontinence, nocturia, smelly urine or a vague change in wellbeing with little in the way of dysuria more common (see p. 1374).

Urinary incontinence
See page 312.

CORE SKILLS AND KNOWLEDGE

Sexually transmitted infections (STIs) are among the most common causes of illness in the world and remain endemic in all societies. They rank among the top five disease categories for which adults seek healthcare worldwide.

Major advances in the treatment of human immunodeficiency virus (HIV) infection have led the global prevalence to increase, even as rates of new infection fall. In those parts of the world with consistent access to effective anti-retroviral therapy, HIV infection has been transformed from a progressively debilitating life-limiting illness characterized by opportunistic infections, into a chronic condition requiring life-long multidisciplinary care.

In many countries the medical specialty of Genitourinary Medicine encompasses sexual health, contraception, HIV care and some public health functions. The specialty is multidisciplinary and holistic; doctors work closely with nurses, health advisers, psychologists, microbiologists, virologists, pharmacists and public health clinicians.

Key skills in this specialty include:
- taking a sexual history and obtaining information for partner notification
- performing a sexual health examination and STI investigations, and correctly interpreting the results
- understanding the principles of anti-retroviral therapy and the holistic approach to outpatient management of HIV infection
- assessing patients with HIV and severe immunosuppression, recognizing important opportunistic infections and acquired immunodeficiency syndrome (AIDS)-defining conditions
- discussing prevention interventions to ensure that people can avoid acquiring or transmitting STIs and HIV.

The best place to experience the outpatient care of people with STIs is in the sexual health clinic, and of those living with HIV in the HIV outpatient clinic. Inpatients with HIV – for example, people presenting with late-stage HIV infection and opportunistic infections – offer opportunities to learn about this spectrum of disease.
Patients presenting with possible STIs or HIV are frequently anxious, embarrassed and concerned about confidentiality. Staff must be alert to these issues and respond sensitively. The clinical setting must ensure privacy and reinforce confidentiality. The clinical history is, of course, tailored to the particular presentation encountered, but many of the points in Box 37.1 are likely to be relevant.

Symptom history relevant to STIs
- STIs may be asymptomatic or present with primarily genital symptoms, the most common being:
  - Urethral discharge in males
  - Vaginal discharge in females
  - Lower abdominal pain in females
  - Genital lumps
  - Genital ulceration
  - Genital itching
  - Rectal symptoms
- Systemic symptoms of fever, skin rash, joint pains and eye symptoms may also be present

Symptom history relevant to HIV
- Acute HIV infection:
  - Fever
  - Malaise
  - Myalgia
  - Lethargy
  - Sore throat
  - Maculopapular rash
- Advanced HIV with immunosuppression:
  - Systemic symptoms: fever, weight loss, anorexia
  - Symptoms related to HIV end-organ damage: cognitive impairment, skin disease, weight loss and gastrointestinal disturbance, symptoms of heart or kidney failure
  - Symptoms of immunosuppression and associated infection/malignancy: fever, cough, breathlessness, diarrhoea, skin changes
- A thorough ‘review of systems’ (see p. 3) is often helpful

Sexual history
- Number and types of recent sexual contacts, with dates
- Gender of partners
- Regular or casual sexual contact with the partner; if regular, how long the couple has been having sex
- Use of condoms
- Any known symptoms or STI diagnosis in the partner
- Sexual practices, e.g. insertive or receptive vaginal, insertive or receptive anal, insertive or receptive pharyngeal, and insertive or receptive oroanal sex
- Whether the patient has ever paid, or has been paid, for sex
- Country of origin of any sexual partners

Previous history of STIs and ongoing risk exposure
- Previous STIs, including dates and treatment received
- HIV testing and results
- Hepatitis A and B, and human papillomavirus (HPV) vaccination status
- Risk factors for ongoing acquisition of HIV and STIs:
  - Frequent partner change
  - Unprotected sex
  - Use of drugs and/or alcohol to a level that reduces safer sex
  - Men having sex with men (MSM)
- Sexual partners from countries with high HIV prevalence
- Offer risk reduction advice and make patients aware of post-exposure HIV prophylaxis following sexual exposure (PEPSE) and pre-exposure prophylaxis (PrEP, see p. 1449)

Wider history
- Full general medical history
- Full drug history, including recent antibacterial or antiviral treatment
- In women, a menstrual, obstetric and cervical cytology screening history, as well as details of current contraception
- Any past or current history of drug or alcohol misuse
Clinical skills for STI and HIV care

The inguinal, genital and perianal areas should be examined using a good light source. Examine the pubic hair for lice and inguinal skin for rashes or lumps. Examine the vagina for erythema, discharge (Figs 37.5 and 37.6), lumps or ulcers. Determine the size, and any tenderness, of the uterus, examine for any cervical motion, or adnexal, tenderness and the presence of any masses. Insert a bivalve vaginal speculum. Perform a bimanual pelvic examination in women with abdominal pain. If systemic symptoms have been identified, a general examination should be performed with inspection of the skin, mouth, pharynx and lymph nodes. Obtain informed consent for the examination and taking of samples. Ensure the examination is carried out in a suitably private place, with a chaperone present.

Specimens for microbiological diagnosis:
Endocervical swabs are taken by inserting the swab a few millimeters into the cervical os (after first removing excess mucus), and rotating for 10-15s. High vaginal swabs are obtained by rotating the swab in the posterior fornix of the vagina for 10-15s. Several swabs may be taken for:
• NAAT (eg diagnosis of Chlamydia infection)
• direct microscopy in clinic (eg looking for ‘clue cells’ in bacterial vaginosis)
• bacterial culture and sensitivities (eg in gonococcal infection)
Swabs from ulcers may be tested by viral PCR for evidence of HSV infection. Additional microbiological testing may be carried out in certain clinical contexts as described in Boxes 37.2, 37.3, 37.4, 37.5, 37.6, 37.7 and 37.8. Additional swabs from the pharynx may be required depending on the patient’s sexual history.

Fig. 37.1 Female genital examination. HSV, herpes simplex virus, NAAT, nucleic acid amplification testing; PCR, polymerase chain reaction.
Obtain informed consent for the examination and taking of samples. Ensure the examination is carried out in a suitably private place, with a chaperone present.

The inguinal and genital areas should be examined using a good light source.

Palpate the groins for lymphadenopathy.

Examine the perianal area for signs of erythema, fissures, lumps, ulcers, pigmentation or hypopigmentation.

Examine the perianal area using a proctoscope in patients with symptoms of rectal pain, bleeding and discharge, and in those with perianal warts extending into the anal canal.

Examine the perianal area for signs of erythema, fissures, lumps, ulcers, pigmentation or hypopigmentation.

Examine the perianal area using a good light source.

The skin of the penile shaft (retracting the prepuce if present) should be examined for rashes, lumps or ulcers (Fig. 37.8).

Examine the urethral meatus.

Inspect for erythema and discharge (Fig. 37.4).

The scrotal contents should be palpated, noting any tenderness or lumps, as well as the consistency of the testes.

If systemic symptoms have been identified, a general examination should be performed with inspection of the skin, mouth, pharynx and lymph nodes.

Specimens for microbiological diagnosis:
Urethral swabs are taken by inserting the swab 2-4cm into the urethra (at least 2h after the patient last passed urine), and rotating for 10-15s. Rectal swabs are obtained by inserting the swab 2-3cm into the rectum, rotating for a few seconds and leaving in place for up to 30s to absorb organisms. Several swabs may be taken for:
• NAAT (eg diagnosis of Chlamydia infection)
• direct microscopy in clinic (eg looking for gonococcus)
• bacterial culture and sensitivities (eg in gonococcal infection)
Swabs from ulcers may be tested by viral PCR for evidence of HSV infection. Additional microbiological testing may be carried out in certain clinical contexts as described in Boxes 37.2, 37.4, 37.5, 37.6 37.7 and 37.8. Additional swabs from the pharynx may be required depending on the patient’s sexual history.

Fig. 37.2 Male genital examination and perianal examination in both sexes. HSV, herpes simplex virus, NAAT, nucleic acid amplification testing; PCR, polymerase chain reaction.
INTRODUCTION

The World Health Organization (WHO) estimates that more than 1 million people acquire an STI every day. Each year, there are an estimated 376 million new infections with one of the four major curable STIs (chlamydia, gonorrhoea, syphilis and trichomoniasis) in adults aged 15–49 throughout the world. These included 6.3 million cases of syphilis, 87 million of gonorrhoea, 127 million of chlamydia and 156 million of trichomoniasis. The estimates suggest that the vast majority of these infections are in low-income countries. The pattern of STIs is usually different in high-income countries: for example, in England in 2018, the most common STIs were chlamydia (218,095; 49% of all new STI diagnoses), genital warts (57,318; 13%), gonorrhoea (56,259; 13%) and genital herpes (33,867; 8%). The highest prevalence of STIs is in young people, men who have sex with men (MSM) and bisexual men, and black and ethnic minority populations. STIs are associated with high-risk sexual behaviour, frequent partner change and inconsistent use of condoms. Increased travel (both within and between countries), recreational drug use and alcohol are also implicated.

Despite their high global incidence and substantial morbidity, STIs remain neglected in clinical practice, public health and research. There have been rapid increases in antimicrobial resistance in Neisseria gonorrhoeae and Mycoplasma genitalium, with the possibility of untreatable cases in the near future. STIs often coexist and the inflammation caused by one STI can increase the risk of acquisition of others; most infections also increase the acquisition and transmission of HIV.

ASYMPTOMATIC STI SCREENING

All STIs can be asymptomatic and multiple infections frequently coexist; hence many people without symptoms attend sexual health clinics to seek sexual health checks and advice. Sexual health checks offer public health, as well as individual, benefits because treatment of asymptomatic infections reduces the period of infectivity, prevents long-term complications and reduces onward transmission.

Increasingly, sexual health clinics are making asymptomatic sexual health checks available online, as routine examination of those with no symptoms yields few additional diagnoses. An electronic medical history is self-completed, to confirm the absence of symptoms, as well as a sexual history and risk assessment for STIs, HIV and other blood-borne viruses, to determine which investigations are needed. The self-sampling kit is posted out to the person with instructions of how to take the samples and package them safely. These are then posted back to the service for testing and the results are returned electronically.

The minimum investigations, even if the person is asymptomatic, are tests for chlamydia, gonorrhoea (including samples from extra-genital sites if indicated by the sexual history), syphilis and HIV. HIV antibody testing should be performed on an ‘opt-out’ basis. If it is declined, the reasons why should be documented. Screening for hepatitis viruses should be performed in those at increased risk, as indicated later.

INVESTIGATION OF STIs

Although the history and examination will guide investigations, remember that multiple infections may coexist and may be asymptomatic. Tests for all STIs are indicated in any patient with a known STI or in those who have been in contact with an STI. The recommended investigations for the different clinical presentations are shown in Boxes 37.2–37.8 and the recommended tests for specific infections are indicated in the following sections.

Screening for hepatitis A and vaccination

A test for antibodies to hepatitis A (with vaccination if negative) should be performed in:

- MSM
- people who inject drugs
- people with chronic hepatitis B or C
- people living with HIV.

Screening for hepatitis B and vaccination

The recommended screening test in those who have not been immunised is immunoglobulin G (IgG) anti-hepatitis B core (anti-HBc), which is a marker of past infection, and/or hepatitis B surface antigen (HBsAg), which identifies currently infected individuals. Screening is recommended for:

- sexual partners of those who are HBsAg-positive
- MSM and their sexual partners
- people who have been sexually assaulted
- sex workers
- people who inject drugs and their sexual partners
- individuals or those with a sexual partner from countries with intermediate or high prevalence of chronic hepatitis B (defined as 2% or more and including all countries outside Western Europe, North America and Australasia)

Box 37.2 Causes of urethral discharge

- Urethritis in men usually presents with a urethral discharge and dysuria
- Urethritis is usually divided into gonococcal (due to N. gonorrhoeae) or non-gonococcal (NGU)

Infective causes

- Chlamydia trachomatis
- Mycoplasma genitalium
- Ureaplasma urealyticum
- Neisseria gonorrhoeae
- Trichomonas vaginalis (TV)
- Herpes simplex virus (HSV)
- Urinary tract infection (UTI)
- Adenoviruses (often associated with conjunctivitis)

Non-infective causes

- Non-specific urethritis (where no cause can be identified)
- Physical or chemical trauma
- Urethral stricture

Questions that help discriminate between causes

- Colour of discharge?
- Any dysuria, urinary frequency, nocturia or haematuria?
- Any testicular pain or swelling?
- Any other symptoms, e.g. genital sores or rash, sore eyes?

Investigations

- Microscopy of urethral discharge, nucleic acid amplification test (NAAT) and culture for N. gonorrhoeae. NAAT for C. trachomatis, NAAT for M. genitalium, serology for syphilis and HIV
- Tests for TV and HSV are not usually performed routinely
- There is no commercial tests available for U. urealyticum
- A mid-stream specimen of urine (MSU) should be taken if symptoms are suggestive of UTI

*Most common cause of NGU. †Second most common cause of NGU. ‡Rarer causes of NGU. §Most frequent non-sexually transmitted cause of NGU.
**Box 37.3 Causes of vaginal discharge**

**Infective causes**

- Vaginal infections
  - Bacterial vaginosis (BV)
  - *Candida albicans*
  - Trichomonas vaginalis (TV)

**Cervical infections**

- Chlamydia trachomatis
- Neisseria gonorrhoeae
- Herpes simplex virus

**Non-infective causes**

- Physiological discharge/cervical ectopy
- Cervical polyps
- Neoplasms
- Retained products (e.g., of conception, tampons)
- Chemical irritation

**Questions that help discriminate between causes**

- Does the discharge have an offensive odour?
- Any vulval itching or soreness?
- Any other symptoms, e.g. dysuria, intermenstrual or postcoital bleeding, abdominal pain?

**Investigations**

- Microscopy of vaginal discharge for BV, candida and TV, culture for candida, nucleic acid amplification test (NAAT; if available) or culture for TV, NAAT for *N. gonorrhoeae* and *C. trachomatis*, serology for syphilis and HIV

---

**Box 37.5 Causes of genital ulcers**

**Infective causes**

- Human papillomavirus (HPV; anogenital warts)
- Molluscum contagiosum
- Sarcoptes scabiei (scabies – excoriated lesions)
- Treponema pallidum
  - Secondary condylomata lata

**Non-infective causes**

- Normal anatomical variants (e.g. papillae, sebaceous glands and skin tags)
- Sebaceous cysts
- Neoplasms

**Questions that help discriminate between causes**

- Where are the ulcers?
- Are they single or multiple?
- Are they itchy or painful?
- How long have they been present?
- Are there any lumps or rashes elsewhere on the skin?

**Investigations**

- Nucleic acid amplification test (NAAT) for Neisseria gonorrhoeae and NAAT for Chlamydia trachomatis, serology for syphilis and HIV
- Diagnoses of anogenital warts and molluscum contagiosum are made on clinical appearances; HPV testing is not appropriate for diagnosing anogenital warts

---

**Box 37.4 Causes of lower abdominal pain**

**Infective causes**

- Pelvic inflammatory disease (PID)
  - *Chlamydia trachomatis*
  - Neisseria gonorrhoeae
  - Mycoplasma genitalium
  - Bacterial vaginosis (BV)
- Urinary tract infection (UTI)

**Non-infective causes**

- Ectopic pregnancy
- Acute appendicitis
- Endometriosis
- Irritable bowel syndrome
- Neoplasms
- Torsion or haemorrhage of ovarian cyst

**Questions that help discriminate between causes**

- Site, character and duration of pain?
- Any vaginal discharge, postcoital or intermenstrual bleeding, or deep dyspareunia?
- Date of last menstrual period (LMP) and contraception used? Is pregnancy possible?
- Any dysuria, urinary frequency, nocturia or haematuria?
- Any nausea, vomiting, diarrhoea or constipation?

**Investigations**

- Microscopy of vaginal discharge for BV and TV, nucleic acid amplification test (NAAT; if available) or culture for TV, NAAT and culture for *N. gonorrhoeae*, NAAT for *C. trachomatis*, NAAT for *M. genitalium*, serology for syphilis and HIV
- A pregnancy test should be performed, as ectopic pregnancy is a differential diagnosis
- A mid-stream specimen of urine (MSU) should be taken if symptoms are suggestive of UTI

---

**Box 37.6 Causes of genital lumps**

**Infective causes**

- *Herpes simplex virus* (HSV)
  - Primary
  - Recurrent
- Treponema pallidum
  - Primary chancre
  - Secondary mucous patches
  - Tertiary gumma
- *Herpes zoster*
- Lympohgranuloma venereum (LGV)
- Chancroid
- Donovanosis (granuloma inguinale)

**Non-infective causes**

- Trauma
- Aphthous ulceration (e.g. as in Behçet’s syndrome)
- Lichen sclerosus
- Erosive lichen planus
- Fixed drug eruptions
- Stevens–Johnson syndrome
- Crohn’s disease
- Neoplasms

**Questions that help distinguish between causes**

- Are the ulcers painful?
- Are they single or multiple?

---

**Notes**

*The most common causes of altered vaginal discharge but *C. trachomatis* and *N. gonorrhoeae* infections must also be considered. *The most common cause worldwide but rare in high-income countries. *Also a common cause (diagnosis usually made on the basis of exclusion of infective causes).
Screening for hepatitis C

Screening for antibodies to hepatitis C is recommended in:
- sexual partners of hepatitis C virus (HCV)-positive people
- people who inject drugs
- MSM who are taking, or are eligible for, pre-exposure prophylaxis (PrEP) for HIV (see p. 1449)
- those who have additional risk factors, e.g. sex associated with trauma or injury, history of recreational drug use or rectal lym
- patients of chronic hepatitis C (as defined earlier for hepatitis B)
- needle-stick injury recipients
- people with chronic hepatitis B or people living with HIV
- those born to a mother infected with HCV.

Investigations for symptomatic patients

These will depend on clinical presentation but should always include tests for chlamydia, gonorrhoea, syphilis and HIV. The re

Management, prevention and control

The treatment of specific conditions is covered in the appropriate sections. Most sexual health clinics give directly observed therapy
- reducing the numbers of sexual partners, avoiding overlapping relationships, using condoms correctly and consistently, and avoid
treating for enteritis must be performed if the clinical presentation can be very similar. The most common causes of proctitis are rectal pain, rectal bleeding, constipation and tenesmus. For those who change their sexual partners frequently, regular sexual health checks (approximately 3-monthly)
are advisable. Once people develop symptoms, they should be encouraged to seek medical advice as soon as possible to reduce complications and spread to others.

Further reading

SPECIFIC INFECTIONS

HIV/AIDS

This is discussed on page 1425.

Hepatitis B

This is discussed on page 1277. Sexual contacts should be screened and immunized if they are not immune.

Chlamydia trachomatis

Chlamydia trachomatis (CT) is the most common STI in the UK; up to 10% of sexually active people below the age of 25 years are infected. It infects the urethra, endocervix, rectum, pharynx and conjunctiva. As up to 80% of women and 50% of men may be asymptomatic, it is frequently unrecognized and therefore untreated. Pelvic inflammatory disease, the main complication of CT, can result in tubal infertility, ectopic pregnancy and chronic pelvic pain, causing significant morbidity and cost to health services.

Clinical features

The exact incubation period is unclear but is thought to be between 7 and 21 days.

In men, CT can cause an anterior urethritis with a mucopurulent urethral discharge (worse on waking, when there may be crusting at the meatus) and dysuria. The infection can ascend along the vas deferens, leading to epididymo-orchitis.

In women, the most common site of infection is the endocervix but the urethra can also be infected. Symptoms may include increased vaginal discharge, dysuria, postcoital or intermenstrual bleeding, and lower abdominal pain. Examination of the cervix may reveal mucopurulent cervicitis and/or contact bleeding. Ascending infection into the uterus and fallopian tubes causes endometritis and acute salpingitis (pelvic inflammatory disease). In pregnancy, CT is associated with preterm birth, postpartum infection, and neonatal mucopurulent conjunctivitis and pneumonia due to vertical transmission during vaginal delivery.

Rectal infection, through receptive anal sex, may be asymptomatic but can cause proctitis. Reactive arthritis (see p. 450) can occur with CT infection, particularly in human leucocyte antigen (HLA)-B27-positive individuals.

Diagnosis

Nucleic acid amplification tests (NAATs) are the diagnostic tests of choice for CT, as they have sensitivities of 90–99%. In men, first-voided urine (FVU) samples or urethral swabs, and in women vulvo-vaginal swabs (VVSs) or endocervical swabs, are used. Self-taken VVSs are as sensitive at detecting CT as clinician-taken VVSs but FVU samples in women are less sensitive than VVSs and endocervical swabs. The advantage of male FVU samples and self-taken VVSs is that they are non-invasive (meaning they can be obtained by the patient without the need for an examination), so are ideal for asymptomatic chlamydia screening.

MSM who practise receptive anal sex and receptive oral sex should have rectal and pharyngeal swabs for CT NAAT performed.

Management

Doxycycline 100mg twice daily for 7 days is the recommended regimen for uncomplicated infection; azithromycin 1g stat, followed by 500mg daily for 2 days, is used if doxycycline is contraindicated. Azithromycin is recommended in pregnant or lactating women in WHO, USA, UK and Australian guidelines but the manufacturers advise use only if adequate alternatives are not available. Doxycycline is contraindicated in pregnancy. Longer courses of antibiotics are required for complicated infections (see pelvic inflammatory disease and epididymo-orchitis later). Epidemiological treatment pending test results is usually offered to those who have had recent sex with someone who has confirmed CT infection, as the infection rate can be up to 50%. Abstinence from sex for at least 7 days, or until treatment is completed, should be advised. Sexual contacts must be traced, notified and treated, as many infections are asymptomatic.

A follow-up consultation (possibly by telephone) should assess adherence to therapy and partner notification. A routine test of cure is not necessary after treatment, except in pregnant women or where symptoms persist or re-infection is suspected. NAATs may remain positive for some time after treatment, as they detect non-viable organisms, so a test of cure should be deferred until 6 weeks after the start of treatment.

Gonorrhoea

Neisseria gonorrhoeae is a Gram-negative intracellular diplococcus (Fig. 37.3), which infects the urethra, endocervix, rectum, pharynx and conjunctiva. Up to 50% of infected women and 10% of infected men are asymptomatic. Co-infection with CT is common, occurring in 20% of men and 40% of women with gonococcal infection (GC).

Clinical features

The incubation period is 2–14 days, most symptoms in males occurring between 2 and 5 days.

In men, GC can cause anterior urethritis with mucopurulent or purulent urethral discharge and dysuria (Fig. 37.4). The discharge can be profuse, causing staining of underwear. Complications include ascending infection, leading to epididymo-orchitis.

Fig. 37.3 Neisseria gonorrhoeae. Gram-negative intracellular diplococci. (Courtesy of Dr B. Goh.)
**In women**, symptoms may include increased vaginal discharge, dysuria, postcoital or intermenstrual bleeding, and lower abdominal pain. Examination of the cervix may reveal mucopurulent or purulent cervicitis and/or contact bleeding. Complications include Bartholin’s abscesses, and ascending infection into the uterus and fallopian tubes causes endometritis and acute salpingitis (pelvic inflammatory disease). In pregnancy, GC is associated with preterm birth, postpartum infection, and neonatal purulent conjunctivitis due to vertical transmission during vaginal delivery.

Rectal infection, through receptive anal sex, may be asymptomatic but can cause proctitis. GC septicaemia (disseminated gonococcal infection, DGI) is a rare complication presenting as fever, tenosynovitis, arthritis and characteristic erythematous skin lesions with necrotic centres.

**Diagnosis**

NAATs are the diagnostic test of choice for *N. gonorrhoeae*, as they have better sensitivity than culture. However, as *N. gonorrhoeae* antimicrobial resistance is increasing, and ceftriaxone-resistant isolates have been identified in the UK and globally, culture on selective media should be performed prior to any treatment for GC being given. In men, FVU samples or urethral swabs, and in women VVSs or endocervical swabs, are the specimens of choice for GC NAATs. Self-taken VVSs are as sensitive at detecting GC as clinician-taken VVSs. FVU samples in women should not be used, as they are less sensitive than VVSs and endocervical swabs. As male FVU samples and self-taken VVSs are non-invasive, they are ideal for asymptomatic screening. MSM who practise receptive anal sex and receptive oral sex should have rectal and pharyngeal swabs for GC NAATs taken. A urethral swab in men, an endocervical swab in women, and rectal and pharyngeal swabs in both are the specimens to use for culture.

Microscopy of Gram-stained urethral and endocervical secretions may demonstrate intracellular, Gram-negative diplococci, allowing rapid diagnosis. The sensitivity ranges from 90–95% in urethral specimens from symptomatic men to 37–50% in endocervical specimens. Microscopy should not be used for pharyngeal specimens. The sensitivity of blood and synovial fluid cultures is poor, so NAATs from the genital tract, rectum and pharynx remain the tests of choice for investigations of DGI.

**Management**

Treatment should be given to those who have positive microscopy, a positive NAAT or a positive culture for GC. Antibiotic-resistant strains of *N. gonorrhoeae* are increasing and so culture should have been taken prior to treatment. When antimicrobial susceptibility is not known prior to treatment, single-dose ceftriaxone 1 g i.m. is recommended in the UK. If confirmed susceptibility is known in advance of treatment, ciprofloxacin 500 mg single dose should be used. If there is a history of penicillin anaphylaxis or established cephalosporin allergy, spectinomycin 2 g i.m. with azithromycin 2 g, or gentamicin 240 mg i.m. with azithromycin 2 g, should be used. Both of these regimens can be used in pregnancy. Longer courses of antibiotics are required for complicated infections (see pelvic inflammatory disease and epididymo-orchitis later). Epidemiological treatment (treatment based on known exposure) pending test results can be offered to those who have had sex within the past 14 days with someone who has confirmed GC infection. Abstinence from sex for at least 7 days, or until treatment has been completed, should be advised. All sexual contacts should be notified, tested, and treated if positive.

A follow-up assessment and test of cure using GC NAAT should take place 14 days after treatment.

**Non-gonococcal urethritis and *Mycoplasma genitalium***

Non-gonococcal urethritis (NGU) in men is characterized by a urethral discharge and dysuria. There are a number of causes, many of which are sexually transmitted; the most common of these is *C. trachomatis*, which was discussed earlier. Up to 25% of NGU is caused by *Mycoplasma genitalium* (Mgen). Other causes are *Ureaplasma urealyticum*, *Trichomonas vaginalis* (TV), adenoviruses, and herpes simplex viruses (HSV) 1 and 2, in that order of frequency. Studies investigating the aetiology of NGU have consistently identified no known cause in over 60% of cases. Non-sexually transmitted causes of NGU may be urinary tract infections (UTIs) and strictures.

**Clinical features**

The incubation period is usually 2–3 weeks. The main symptom is a mucopurulent urethral discharge (worse on waking, when there may be crusting at the meatus). Dysuria is common but not universal. Discomfort or itching within the urethra may be present.

**Diagnosis**

Microscopy of Gram-stained urethral secretion showing five or more polymorphonuclear leucocytes per high-power (×1000 oil-immersion lens) field is diagnostic. Men who are symptomatic but have no objective evidence of urethritis should be re-examined and tested after holding their urine overnight. NAAT for *N. gonorrhoeae*, *C. trachomatis* and *M. genitalium* should be performed in all men with symptoms of urethritis, on an FVU sample. Mgen-positive specimens should be tested for macrolide resistance mutations. Testing for TV and HSV is not routinely performed and there is no commercial test available for *U. urealyticum*. A mid-stream specimen of urine (MSU) should be taken if symptoms are suggestive of a UTI (urinary frequency, nocturia, urgency, haematuria).

**Management**

First-line therapy for NGU is doxycycline 100 mg twice daily for 7 days. Abstinence from sex for at least 7 days should be advised. All sexual contacts should be notified, tested and treated. Follow-up is indicated only if CT or Mgen is confirmed or if symptoms persist.

**Recurrent/persistent NGU**

This is defined as persistent or recurrent symptomatic urethritis occurring 30–90 days following treatment of acute NGU, and occurs in 10–20% of cases. The aetiology is probably multifactorial but Mgen and TV are likely causes. It is necessary to ensure that there is still objective evidence of urethritis, that there was good adherence.
to NGU treatment with sexual abstinence, and that sexual partners were also treated. If there is no objective evidence of urethritis, patients should be reassured and further antibiotic therapy avoided. Subsequent treatment needs to cover *M. genitalium* and TV. The recommended treatment is azithromycin 1 g orally as a single dose, followed by 500 mg daily for 2 days with metronidazole 400 mg twice daily for 5–7 days. This should be started within 2 weeks of finishing the doxycycline if the patient is Mgen-positive and macrolide-sensitive. If the patient is Mgen-positive and macrolide-resistant, or if treatment with azithromycin has failed, moxifloxacin 400 mg daily for 10 days should be given. Current sexual partners of those infected with Mgen should also be tested (using a VSS in women) and treated with the same antibiotic regimen as their sexual partner. Abstinence from sex until both have finished their treatment should be advised. All who were Mgen-positive should have a test of cure 5 weeks after the start of treatment.

**Pelvic inflammatory disease**

Pelvic inflammatory disease (PID) results when infections ascend from the cervix or vagina into the upper genital tract. It is most frequent in young (under 25 years) sexually active women. It includes endometritis, salpingitis, tubo-ovarian abscess and pelvic peritonitis. *C. trachomatis* and *N. gonorrhoeae* account for about 25% of UK cases and *M. genitalium* for 10–13% of cases. Anaerobes have also been implicated in the aetiology. Even in women with laparoscopically proven PID, often no bacterial cause is found. PID has serious long-term sequelae due to tubal damage and pelvic adhesions, resulting in tubal infertility, increased risk of ectopic pregnancy and chronic pelvic pain. The risk of sequelae increases with more severe and multiple episodes of PID. Tubal infertility occurs in 10–12% of women after one episode of PID and increases to 50–60% after three or more episodes. The risk of ectopic pregnancy is increased 6–10-fold, and abdominal or pelvic pain for longer than 6 months occurs in 18% of women.

**Clinical features**

The onset of symptoms often occurs in the first part of the menstrual cycle. Lower abdominal pain, usually bilateral, is the most common symptom, with increased vaginal discharge, irregular bleeding, deep dyspareunia and dysuria being present in some women. There may be a mucopurulent cervical discharge with contact bleeding. Lower abdominal tenderness and adnexal and cervical motion tenderness on bimanual examination are the most common signs.

**Diagnosis**

The diagnosis is usually made on the clinical findings of lower abdominal pain, with supportive symptoms of increased vaginal discharge and abnormal bleeding, and cervical motion and/or adnexal tenderness on bimanual examination. However, such a clinical diagnosis has a specificity of only 65–70%. The differential diagnosis includes ectopic pregnancy, acute appendicitis, endometriosis, UTI and irritable bowel disease.

Investigations should include microscopy of Gram-stained vaginal discharge (for bacterial vaginosis, BV) and of an endocervical specimen (for evidence of inflammatory cells and intracellular, Gram-negative diplococci suggestive of gonorrhoea), NAAT and culture for *N. gonorrhoeae*, and NAAT for *C. trachomatis* and *M. genitalium*. A pregnancy test should be performed on all women suspected of having PID, as ectopic pregnancy is a differential diagnosis. An MSU should be taken if symptoms are suggestive of a UTI (urinary frequency, nocturia, urgency, haematuria).

**Management**

Early diagnosis and treatment reduce the risk of long-term sequelae and so empirical treatment should be started before microbiology results are known. A broad-spectrum antibiotic regimen is needed to cover the main bacterial causes. The recommended first-line treatment is single-dose ceftriaxone 1 g by intramuscular injection, with doxycycline 100 mg twice daily and metronidazole 400 mg twice daily for 14 days. Alternatives are ofloxacin 400 mg twice daily and metronidazole 400 mg twice daily for 14 days; or moxifloxacin 400 mg daily for 14 days (this should be first-line if the patient is Mgen-positive). Abstinence from sex for at least 14 days should be advised. All sexual contacts should be notified, tested and treated.

Those with moderate or severe clinical findings should be reviewed within 2–3 days to ensure that they are improving on treatment. Lack of response requires further investigation and possible admission for intravenous therapy and/or surgical intervention. All women should be reviewed after 2–4 weeks in order to assess symptom resolution, adherence to therapy and partner notification.

**Epididymo-orchitis**

Acute epididymo-orchitis is a clinical syndrome consisting of pain, swelling and inflammation of the epididymis that can extend into the testis. It is caused mainly by extension of infection from the urethra or the bladder. In men under 35 years, *C. trachomatis* and *N. gonorrhoeae* are the main causes and *M. genitalium* also appears to be implicated. In men over 35 years, it is more commonly a complication of a UTI. Mumps is another cause of epididymo-orchitis in non-immune men. The most common differential diagnosis is torsion of the spermatic cord, which is a urological emergency.

**Clinical features**

The typical presentation is subacute onset of unilateral scrotal pain and swelling. There may also be symptoms of a urethral discharge and dysuria but these are often absent. On examination, there is tenderness and usually palpable swelling of the epididymis. There may also be some tenderness and swelling of the testicle, with oedema and erythema of the overlying scrotal skin. A urethral discharge may be present.

**Diagnosis**

The diagnosis is usually made on the clinical findings described. The main differential diagnosis is testicular torsion.

**Investigations**

These include a NAAT and culture for *N. gonorrhoeae* and a NAAT for *C. trachomatis* and *M. genitalium*. If microscopy of Gram-stained urethral secretions shows 5 or more polymorphonuclear leucocytes per high-power (×1000 oil-immersion lens) field, this indicates the diagnosis of NGU. If intracellular Gram-negative diplococci are present, this is suggestive of GC. An MSU should be taken if symptoms are suggestive of a UTI (urinary frequency, nocturia, urgency, haematuria) and in older men.

**Management**

As empirical treatment should be started before microbiology results are known, a broad-spectrum antibiotic regimen is needed to cover the main bacterial causes. In younger men, where an STI is the likely diagnosis, the recommended regimen is single-dose ceftriaxone 1 g i.m. with doxycycline 100 mg twice daily for 14 days. If the patient is Mgen-positive, moxifloxacin 400 mg daily for 14 days should be given. Where a UTI is the more likely diagnosis, ofloxacin 200 mg twice daily for 14 days should be prescribed. Abstinence
from sex for at least 14 days should be advised. All sexual contacts should be notified, tested and treated.

Patients are reassessed after 3 days if there is no improvement in their symptoms, as this requires further investigations. All should be seen after 2 weeks in order to assess symptom resolution, adherence to therapy and partner notification.

**Bacterial vaginosis**

Bacterial vaginosis (BV) is the most frequent cause of vaginal discharge among women of childbearing age. A BV prevalence of 9% was reported in women attending general practice for cervical cytology screening and in 15% of pregnant women in the UK. BV develops when the normal lactobacilli-dominant vaginal flora are replaced by an overgrowth of other bacteria, including Gardnerella vaginalis, anaerobes, mycoplasmas and Mobiluncus spp. It is not regarded as a sexually transmitted disease. BV in pregnancy is associated with an increased risk of miscarriage and preterm birth. It also increases the risk of acquisition and transmission of HIV. Up to 50% of women with BV have no symptoms. It is not necessary to look for or treat asymptomatic BV.

**Clinical features**

The symptoms are an increased vaginal discharge and offensive fishy odour. On examination, there is a creamy-white homogeneous discharge, which may be slightly frothy (due to the volatile amine production by the bacteria, which is responsible for the characteristic odour) (Fig. 37.5). Visible inflammatory changes are not seen with BV.

**Diagnosis**

The most accurate method of diagnosis is microscopy of Gram-stained vaginal discharge, as the characteristic pattern of the BV bacteria is easily distinguished from the normal lactobacilli-dominant vaginal flora. It is possible to diagnose BV just on clinical criteria but this is less specific. All three of the following should be present for the diagnosis to be made:

- characteristic creamy-white homogeneous vaginal discharge
- raised vaginal pH of >4.5 (measured using narrow-range pH paper)
- characteristic fishy odour (which can be released by mixing the vaginal discharge with 10% potassium hydroxide).

Many of the clinical symptoms and signs of BV are similar to those of TV and so women with recurrent BV should have a TV NAAT to ensure they do not have undiagnosed TV.

**Management**

The recommended treatment is oral metronidazole 400mg twice daily for 7 days. A single dose of metronidazole 2g can also be used but this is less effective. Alternative topical treatments are intravaginal metronidazole 0.75% gel for 5 nights, or intravaginal clindamycin 2% cream for 7 nights. High-dose metronidazole should be avoided in pregnancy but the 7-day oral course can be safely prescribed, as can either of the intravaginal regimens.

BV recurrences are frequent, with about 50% of women experiencing a recurrence within 12 months of completing metronidazole therapy. Simultaneous treatment of the male partner does not reduce the rate of recurrence, and treatment of male partners is not indicated.

**Candidiasis**

*Candida* is a ubiquitous organism and is not classified as an STI. Vulvovaginal *Candida* infection is extremely common; about 75% of women have at least one episode of symptomatic candidiasis in their lifetime. Predisposing factors for symptomatic infection include pregnancy, diabetes, the use of broad-spectrum antibiotics and corticosteroids, and immunosuppression. *Candida albicans* causes 90% of vaginal yeast infections, with *Candida glabrata* and other *Candida* species causing the remainder. Male sexual partners of women with candidiasis can contract transient penile colonization (and may develop penile rashes) following sex due to direct inoculation from the vagina.

**Clinical features**

*In women*, the main symptom is vulval itching, which is present in nearly all symptomatic women. An increased thick, white vaginal discharge, vulval burning, external dysuria and superficial dyspareunia may also be present. On examination, vulval erythema, fissuring and oedema may be present. There may be the typical white, curdy, adherent plaques on the vaginal walls (Fig. 37.6) but the discharge may be minimal.

*In men*, there may be a transient penile irritation and rash immediately following sex, but some men experience more persistent balanoposthitis. On examination, there may be erythema of the foreskin and glans penis, or a spotty, red, itchy rash on the glans, with an accumulation of white discharge under the foreskin. In severe cases, there may be fissuring and phimosis of the foreskin.

**Diagnosis**

Microscopy of a Gram-stained vaginal smear, or a suprapreputial smear, identifies the fungal pseudohyphae and spores in 50% of cases of candidiasis. Culture of vaginal, or subpreputial, swabs has almost 100% sensitivity. Diabetes should be excluded in men with severe balanoposthitis.

**Management**

There are a number of short-course oral and intravaginal antifungal agents available, all with efficacies of 80–85%. Recommended treatments are the oral triazole drugs, such as fluconazole 150mg as a single dose or itraconazole 200mg twice daily for 1 day, and
intravaginal imidazole pessaries or creams, such as clotrimazole pessary 500mg as a single dose, miconazole vaginal ovule 1.2g as a single dose or econazole pessary 150mg nightly for 1–3 nights. These treatments can be supplemented with antifungal cream applied to the vulva. Males can be treated with either oral therapy or topical antifungal cream. Nystatin pessaries 200000 units nightly for 14 nights are the treatment of choice for *C. glabrata* and other non-*albicans* yeasts. Intravaginal treatments are safe in pregnancy but oral therapies should not be used.

Recurrent candidiasis (four or more symptomatic episodes in 1 year) occurs in up to 5% of healthy women of reproductive age. It frequently requires weekly oral fluconazole 150mg, or clotrimazole pessary 500mg, for up to 6 months in order to prevent recurring symptoms. There is no evidence that treatment of male partners reduces recurrences in women, so male partners do not need treatment unless they also have symptoms.

**Trichomoniasis**

*Trichomonas vaginalis* (TV) infection is the most common STI worldwide but it is much rarer in Western Europe and Australasia. The organism is a flagellated protozoon that is sexually transmitted. In women, it infects the vagina and urethra; in men, it infects the urethra and subpreputial sac. Nearly all infected men are asymptomatic, as are 10–50% of women. TV in pregnancy is associated with an increased risk of preterm birth and low birth weight, and it increases the risk of acquisition of HIV.

**Clinical features**

In women, the most common symptoms are an increased purulent vaginal discharge and malodour. There may also be vulvar pruritus, external dysuria and dyspareunia. On examination, there may be vulval erythema with inflamed vaginal mucosa. The discharge is yellow or grey and frothy, and can be profuse. The cervix may have multiple small haemorrhagic areas, which have given rise to the description 'strawberry cervix'.

In men, the majority have no symptoms, although they may complain of urethral discharge, irritation and dysuria.

**Diagnosis**

Phase-contrast microscopy of vaginal discharge identifies the motile protozoa in up to 50% of infected females. There may also be vulval pruritus, external dysuria and dyspareunia. On examination, there may be vulval erythema with inflamed vaginal mucosa. The discharge is yellow or grey and frothy, and can be profuse. The cervix may have multiple small haemorrhagic areas, which have given rise to the description 'strawberry cervix'.

The diagnosis is made on the clinical appearances. HPV testing is not appropriate for diagnosing anogenital warts. The main differential diagnoses are molluscum contagiosum and the condylomata lata of secondary syphilis. Atypical lesions should be biopsied, particularly in older patients, as pre-malignant and malignant lesions can look similar to warts. Investigations should include NAAT for *N. gonorrhoeae* and *C. trachomatis*, and serology for syphilis and HIV, as co-infection with other STIs is common.

**Management**

The treatment of choice is metronidazole 400mg twice daily for 7 days. Single-dose metronidazole 2g can be used but it is less effective. As TV infects areas beyond the vagina (e.g. the urethra), intravaginal metronidazole gel has poor cure rates and should not be used. High-dose metronidazole should be avoided in pregnancy but the 7-day oral course can be safely prescribed.

Abstinence from sex for at least 7 days should be advised. All sexual contacts should be notified, tested and treated. Tests of cure are recommended only if the patient remains symptomatic following treatment or if symptoms recur.

Occasionally, TV can become resistant to metronidazole and other nitroimidazoles. This is usually relative rather than absolute and may be overcome by high-dose metronidazole or tinidazole therapy.

**Human papillomavirus – anogenital warts**

Anogenital warts are painless, benign, epithelial tumours and constitute a common STI. The causative agent is human papillomavirus (HPV) types 6 and 11. Genital HPV infection is acquired by direct skin-to-skin contact during sex with a person who has either clinical or subclinical infection. Subclinical infection is very common in young, sexually active people, with rates of up to 20%. Anogenital warts are the "tip of the iceberg", occurring in only about 1% of those with subclinical infection.

Warts due to HPV 6 and 11 do not undergo malignant transformation. The main oncogenic HPV types are 16 and 18. These lead to subclinical infection, not genital warts, and cause the majority of cases of cervical and other anogenital cancers (see p. 530). Neomates may acquire HPV from an infected birth canal, which may result either in anogenital warts or in laryngeal papillomatosis.

**Clinical features**

Anogenital warts have a long incubation period; the average is 3 months but it can extend to years. The warts first appear at sites of trauma during sex. In males, this is around the prepuce and glans; from there, they can spread to the urethra and down the penile shaft. In women, they usually start at the fourchette and then spread to the vulva and perineum (Fig. 37.7). Perianal lesions are common in both sexes but more common in MSM. Warts on mucous membranes tend to be soft and non-keratinized, whereas those on the hair-bearing skin tend to be firm and keratinized. Warts tend to increase in size and number during pregnancy or in immunosuppressed patients.

**Diagnosis**

The diagnosis is made on the clinical appearances. HPV testing is not appropriate for diagnosing anogenital warts. The main differential diagnoses are molluscum contagiosum and the condylomata lata of secondary syphilis. Atypical lesions should be biopsied, particularly in older patients, as pre-malignant and malignant lesions can look similar to warts. Investigations should include NAAT for *N. gonorrhoeae* and *C. trachomatis*, and serology for syphilis and HIV, as co-infection with other STIs is common.

**Management**

There are a number of treatments available for anogenital warts but all of them have significant failure and relapse rates. The choice of treatment depends on the number, type and distribution of lesions. Topical podophyllotoxin (0.5% solution or 0.15% cream used twice daily for 3 consecutive days per week) acts as a cytotoxic agent and is useful for non-keratinized warts; keratinized warts respond better to ablative therapy, such as cryotherapy or laser.
electrocautery. Imiquimod enhances the local immune response when applied to skin infected with HPV (5% cream used daily, three times a week) and is effective in both types of wart. Podophyllotoxin and imiquimod have the advantage of being self-applied home therapies.

Podophyllotoxin and imiquimod should not be used in pregnancy. Pregnant women, those co-infected with HIV and those with other causes of immunosuppression may have a poorer response to treatment.

The use of condoms should be advised in new relationships, as they protect against the transmission of HPV infection and genital warts. Current sexual partners may have undetected genital warts so may benefit from a sexual health assessment.

Follow-up is recommended in order to monitor the response to treatment and to assess the need for any change of therapy.

Prevention and vaccination
There are very effective vaccines against HPV:
• A bivalent vaccine protects against HPV types 16 and 18, which are the most common high-risk types.
• A quadrivalent vaccine protects against types 6, 11, 16 and 18, which covers the most common high-risk types and those that cause genital warts.
• A vaccine protecting against nine virus types, which contains the same HPV antigens as the quadrivalent vaccine plus five additional high-risk types (31, 33, 45, 52 and 58) is also available. They are given over 6 months in three divided doses and have excellent safety profiles, with almost 100% serological response that is maintained over a number of years. Vaccination is most beneficial in those who have not yet been exposed to HPV infection; hence most national vaccination programmes target those aged 12–13 years. All programmes vaccinate girls and some also include boys.

The best evidence of the effect of HPV vaccination is from Australia, where there has been a school-based quadrivalent HPV vaccination programme in girls since 2007 and boys since 2013. There has been a rapid reduction of 90% in genital warts and 50% in high-grade cervical lesions.

Molluscum contagiosum
Molluscum contagiosum (see p. 672) is a large DNA virus. It causes small (typically 2–5 mm in diameter), benign, smooth papules with central umbilication. It is spread via direct skin-to-skin contact. When it is transmitted sexually, the lesions are usually multiple and present on the labia majora, penile shaft, pubic region, lower abdomen and upper inner thighs.

Diagnosis
The diagnosis is made on the characteristic clinical appearance. As this is a sexually acquired condition, investigations for other STIs should include NAAT for N. gonorrhoeae and C. trachomatis, and serology for syphilis and HIV.

Management
Molluscum infection is often self-limiting, resolving naturally. Treatment options, if required, are cryotherapy, podophyllotoxin cream or imiquimod cream. The creams have the advantage of being self-applied home therapies. Podophyllotoxin and imiquimod should be avoided in pregnancy. Patients should be advised about the risks of auto-inoculation of the virus and discouraged from shaving or waxing the pubic hair in order to prevent further spread. No routine follow-up or partner notification is required, unless any other STIs are identified.

Herpes simplex
Genital herpes (see also p. 514) is the most common cause of genital ulceration in all countries worldwide. The peak incidence for primary infection is in 16–24-year-olds. Women acquire the infection more frequently than men, probably because of the larger surface area of susceptible mucous membrane on the vulva. Transmission occurs from the mucous membrane of a person who is shedding herpes simplex virus (HSV), many of whom will be asymptomatic. Only about 20% of people with serological evidence of genital herpes give a clinical history of herpes, suggesting that many individuals have subclinical infection.

Genital herpes can be due to HSV type 1 or type 2. It is possible to be co-infected with both. HSV-1 infection may be spread from an infected genital tract or from orolabial lesions via orogenital sex. HSV-2 is almost always transmitted via genital-to-genital contact. In the UK, more than 50% of primary HSV is due to HSV-1.

During the primary infection, the virus ascends the peripheral sensory nerves supplying the area of inoculation and establishes latency in the dorsal root ganglia, thus allowing future reactivation and recurrences.

Clinical features
The initial episode is the first occurrence of either HSV-1 or HSV-2. This is subdivided as described here, depending on whether or not the person has had prior exposure to the other HSV type.

Primary genital infection is the first ever exposure to either HSV type 1 or 2. It typically presents with multiple painful, shallow ulcers (Fig. 37.8). There is usually tender inguinal lymphadenopathy and systemic symptoms of viraemia, including fever, myalgia and headache. In women, external dysuria and vulval pain are the main symptoms. Ulcers may be present on the cervix and can have the appearance of a malignancy. Rectal infection may lead to severe proctitis with pain and bleeding (this is mainly seen in MSM). The lesions start to heal over a period of 10–21 days, even without treatment. Neurological complications can include aseptic meningitis and autonomic neuropathy leading to urinary retention. However, primary infection can be asymptomatic.

Non-primary genital infection occurs in people with previous HSV-1 or HSV-2 who then acquire the other type of genital HSV. There is some cross-protection from the prior HSV infection, resulting in a milder illness than in primary infection. Non-primary genital infections are more likely to be asymptomatic than primary infections.

Recurrent genital herpes is due to reactivation of previous HSV-1 or HSV-2 infection. HSV-2 recurs more frequently than HSV-1. The median recurrence rate in the subsequent year

Fig. 37.8 Herpes simplex rash on the penis. (Courtesy of Dr B. Goh.)
following a primary or non-primary infection is about one recurrence for HSV-1 and about four recurrences for HSV-2. The recurrences may be preceded by a prodrome of tingling, itching or pain in the area. On examination, there are usually a few ulcers confined to a small area and systemic symptoms are rare. Recurrences are not always noticed and asymptomatic, subclinical viral shedding can occur. However, all of these reactivated episodes are potentially infectious. Long-term studies show that symptomatic recurrences and subclinical viral shedding gradually decrease with time.

The clinical presentation of primary infection in immunosuppressed patients (including those with HIV and pregnant women) is usually more severe, with increased frequency of symptomatic and subclinical recurrences. Rarely, the infection can disseminate, causing a systemic life-threatening condition.

Genital herpes increases the acquisition and transmission of HIV and is a significant attributable risk in the spread of HIV. Many people with recurrent HSV develop psychological and psychosexual problems, and fear rejection on disclosure of their infection to sexual partners.

Diagnosis

HSV DNA detection using polymerase chain reaction (PCR) on a swab taken from the ulcer is the diagnostic method of choice. This can distinguish between HSV-1 and HSV-2. Tests for other STIs should be performed, including NAAT for *N. gonorrhoeae* and *C. trachomatis*, and serology for syphilis and HIV.

Blood tests for HSV type-specific antibodies can be used to diagnose prior HSV-1 and HSV-2 infections when the clinical history is suggestive of genital herpes but confirmation by HSV DNA detection has not been possible. The presence of HSV-2 antibodies is indicative of genital herpes but the presence of HSV-1 antibodies cannot differentiate between genital and orolabial infections.

Management

**Initial episode**

Saltwater bathing or sitting in a warm bath is soothing and may allow women to pass urine more comfortably. Topical anaesthetic agents can also be used to ease micturition. Recommended antiviral therapies are aciclovir 400 mg three times daily, valaciclovir 500 mg twice daily or famciclovir 250 mg three times daily, all for 5 days. Aciclovir is the drug of choice in pregnancy and breast feeding. If lesions are already healing, antiviral therapy will have little added effect. Secondary bacterial infection occasionally occurs and should be treated.

The natural history of HSV infection should be explained, including recurrences, subclinical viral shedding, and the potential for sexual transmission with both of these infections. Patients should be advised to avoid sex during the prodrome and recurrences. Subclinical viral shedding is most common during the first 12 months following initial HSV-2 infection and in those with frequent symptomatic recurrences. Condoms and suppressive treatment reduce the risk of transmission from subclinical viral shedding but neither completely prevents it. Consequently, disclosure should be advised in all relationships.

**Recurrence**

The appropriate management will depend on the number and severity of recurrences. As recurrences tend to be less severe and self-limiting, they can sometimes be managed with saltwater bathing and topical anaesthetic agents.

**Episodic treatment**

When recurrences are infrequent but severe, episodic antiviral therapy, started early by the patient, will reduce the duration and severity but will not reduce the number of recurrences. Recommended episodic regimens are aciclovir 400 mg three times daily, valaciclovir 500 mg twice daily or famciclovir 250 mg three times daily, all for 5 days. Shorter-course therapies are also effective: aciclovir 800 mg three times daily for 2 days, famciclovir 1 g twice daily for 1 day or valaciclovir 500 mg twice daily for 3 days can be used.

**Suppressive treatment**

In those with six or more recurrences per year, long-term suppressive therapy is effective at stopping or reducing the recurrences. The decision whether to start suppressive treatment depends on the number of recurrences and the inconvenience of daily treatment. Recommended regimens are aciclovir 400 mg twice daily, valaciclovir 500 mg daily or famciclovir 250 mg twice daily for a maximum of 12 months. Therapy should then be discontinued in order to assess the frequency of recurrences. If they are still frequent, suppressive treatment can be restarted.

Frequent recurrences are associated with psychological and psychosexual morbidity; support and counselling are often needed.

**HSV in pregnancy**

The main risk of HSV in pregnancy is vertical transmission. Despite antiviral treatment, neonatal HSV has high mortality and high morbidity in those who survive. The primary episode of genital HSV in late pregnancy poses the highest risk of transmission, and caesarean section should be the recommended mode of delivery for all, but particularly for women within 6 weeks of the expected delivery date. Women who present with an initial episode of HSV in the third trimester should continue with daily suppressive aciclovir 400 mg three times daily (increased due to the altered pharmacokinetics of the drug in pregnancy) until delivery. Those presenting with an initial episode of HSV in the first or second trimester can be given suppressive aciclovir from 36 weeks’ gestation. This reduces recurrences and subclinical viral shedding, and therefore the need for a caesarean section.

The risk of neonatal herpes with recurrent HSV is small, even if lesions are present at the time of delivery. The Royal College of Obstetricians and Gynaecologists in the UK suggests that caesarean section is not indicated in such women, but daily suppressive aciclovir from 36 weeks’ gestation should be considered.

**Syphilis**

Syphilis is a chronic systemic disease caused by *Treponema pallidum* (TP), a motile spirochaete. It is mainly transmitted by direct contact with an infectious lesion and enters the new host through breaches in squamous or columnar epithelium, usually during sex. Primary infection of non-genital sites may occur but is rare. It can also be transmitted by infected blood products or from mother to child during pregnancy; hence syphilis is classified as acquired or congenital. *Acquired syphilis* is further subdivided into primary, secondary and early latent (also referred to as early or infectious syphilis, and indicating that infection has been acquired during the last 2 years), late latent (infection for more than 2 years) and tertiary syphilis (the most destructive stage, which includes cardiovascular and neurological syphilis and gummatous lesions of any organ). *Congenital syphilis* is also further subdivided into early (diagnosed within the first 2 years of life) and late (diagnosed over the age of 2).

The incidence varies significantly with geographical location. It is more common in low- and middle-income countries; in high-income
countries, it is mainly confined to MSM and is increasing. For instance, diagnoses of infectious syphilis in England between 2008 and 2017 increased by 148% and most cases were in MSM. However, syphilis still affects large numbers of pregnant women worldwide. It was estimated that, in 2016, 988,000 pregnant women were infected worldwide with syphilis, resulting in over 350,000 adverse birth outcomes, including 200,000 stillbirths and newborn deaths.

**Clinical features**

**Primary syphilis**

Between 9 and 90 days (mean 21 days) after exposure, a papule develops at the site of inoculation. This ulcerates to become a painless, firm ulcer (chance). There is usually also a painless regional lymphadenopathy. The primary lesion may go unnoticed, especially if it is on the cervix or within the rectum. Healing occurs spontaneously within 2–6 weeks.

**Secondary syphilis**

This occurs in 25% with untreated primary syphilis. Between 6 and 10 weeks after the appearance of the primary lesion, constitutional symptoms, including fever, sore throat, malaise and arthralgia, may appear due to septicemia. Hence, any organ may be affected, and hepatitis, nephritis, arthritis, meningitis, uveitis, interstitial keratitis and retinal involvement have all been described.

Common signs include:

- widespread skin rash (present in 75%), which can involve the whole body, including the palms and soles – typically, a non-itchy, maculopapular rash that may have a coppery colour (Fig. 37.9)
- generalized lymphadenopathy (present in 50%)
- condylomata lata, which are moist, wart-like plaques found in the perianal area and other moist body sites
- mucosal lesions in the mouth and on the genitalia presenting as distinct mucous patches or becoming confluent to form ‘snail-track ulcers’.

Without treatment, the symptoms and signs of secondary syphilis resolve but may recur, especially in the first year of infection.

**Latent syphilis**

Latent syphilis is diagnosed on the basis of reactive syphilis serology in someone who has no symptoms and has not been treated. It is divided into early latent (defined as within 2 years of infection acquisition, or within 1 year in the USA) and late latent syphilis (present for 2 or more years), as sexual transmission can occur in early latency but not in late latent disease. Latent syphilis may persist for years or may even be life-long.

**Tertiary syphilis**

About one-third of people with untreated latent syphilis will develop tertiary syphilis within 2–30 or more years of contracting the infection. Gummatous syphilis (with inflammatory, granulomatous, destructive lesions) is the most benign and commonly involves the skin and bones, but lesions can occur in any organ. Cardiovascular syphilis causes aortitis, aortic regurgitation, aneurysm of the ascending aorta and stenosis of the coronary artery ostia. Neurosyphilis causes chronic meningovascular damage and endarteritis of the small vessels of the brain and spinal cord, presenting as ‘general paralysis of the insane’ and tabes dorsalis.

**Syphilis in pregnancy and congenital syphilis**

Syphilis can be transmitted transplacentally at any stage of pregnancy. The risk of transmission is dependent on the stage of maternal infection and can be up to 100% in early syphilis, and even up to 10% with late infection. The WHO estimates that untreated early syphilis in pregnancy results in rates of second-trimester miscarriage or stillbirth of 25%, preterm birth before 32 weeks’ gestation of 13%, neonatal death of 11% and congenital syphilis among the infants born of 20%. Detection and treatment of syphilis early in pregnancy prevent congenital syphilis and neonatal death at term, and reduce adverse pregnancy outcomes.

Signs of early congenital syphilis occur in the neonatal period and include a rash, condylomata lata, mucous patches, nasal discharge, hepatosplenomegaly and periostitis. Late syphilis (occurring after 2 years of age) can present with neurological or gummatous lesions but also includes the ‘stigmata of congenital syphilis’, resulting from early damage to developing structures, particularly teeth and bones. These are Hutchinson’s teeth, sabre tibia, bossing of the frontal and parietal bones, and saddle nose.

**Diagnosis**

*T. pallidum* cannot be cultured but it can be identified by dark-ground microscopy of secretions from a primary chancre or condylomata lata; however, sensitivity is dependent on highly skilled microscopists. Some laboratories are able to test swabs for TP using PCR but serological testing remains the main laboratory diagnosis.

Most laboratories use a treponemal enzyme immunoassay (EIA) to detect IgG and IgM as a screening test. If this is positive, a further treponemal test and a non-treponemal test are performed.

**Treponemal tests**

*T. pallidum* haemagglutination (TPHA) and *T. pallidum* particle agglutination (TPPA) assays are highly specific for treponemal disease but usually remain positive for life, even after treatment, so are unable to differentiate between prior treated infection and re-infection.

**Non-treponemal tests**

The Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin (RPR) tests become positive within 3–4 weeks of the primary infection. They are quantifiable tests that can be used to monitor treatment response and evidence of re-infection. They are not specific to syphilis and false-positive results may occur in other conditions, particularly in other infections and autoimmune diseases.

Examination of the cerebrospinal fluid (CSF) for evidence of neurosyphilis is indicated in those patients with positive syphilis serology who demonstrate neurological signs and symptoms.
**Management**

Treponemocidal levels of an antibiotic are required for at least 7 days in early syphilis to cover the slow division time of the organism (30h). In late syphilis, treponemes may divide even more slowly and so longer therapy is required. Ideally, a long-acting penicillin should be given intramuscularly.

**Early syphilis (primary, secondary and early latent)**

- Benzathine penicillin G 2.4 MU i.m. single dose.  
  **In penicillin allergy:**  
  - Doxycycline 100 mg twice daily for 14 days.

  The **Jarisch–Herxheimer reaction** is caused by release of inflammatory cytokines and occurs in 50% of patients with primary syphilis and up to 90% with secondary syphilis. It occurs about 8 hours after the injection and usually consists of mild fever, malaise and headache lasting several hours.

**Late latent, cardiovascular and gummatous syphilis**

- Benzathine penicillin G 2.4 MU i.m. three doses at weekly intervals.  
  **In penicillin allergy:**  
  - Doxycycline 100 mg twice daily for 28 days.

**Neurosyphilis**

- Procaine penicillin 2.4 MU i.m. daily plus probenecid 500 mg orally four times daily for 14 days.  
  **In penicillin allergy:**  
  - Doxycycline 200 mg twice daily for 28 days.

**Pregnancy**

- Penicillin can be safely used in pregnancy but doxycycline should not be used.

**Syphilis and HIV**

The diagnosis and management of syphilis in HIV-co-infected patients remain unaltered; however, if disease is untreated, it may advance more rapidly than in HIV-negative patients and there is a higher incidence of neurosyphilis.

**Prognosis and follow-up**

Those being treated for early syphilis should abstain from sex for at least 14 days and sexual contacts must be traced and investigated. There should be regular follow-up within the first year using repeat VDRL/RPR titres to establish the ‘fourfold fall’, which demonstrates adequately treated syphilis.

The prognosis of syphilis depends on the stage at which the infection is treated. Early syphilis has an excellent outlook, but once permanent damage has occurred in tertiary syphilis, the damage will not be reversed, although further progression will be halted.

**Lymphogranuloma venereum**

Lymphogranuloma venereum (LGV) is an STI caused by the invasive serovars, L1, L2 and L3, of *Chlamydia trachomatis*. It is endemic in several tropical areas, including southern Africa, India, South-east Asia and the Caribbean, where it accounts for 2–10% of genital ulcer disease. It used to be rare in Western Europe but since 2003 has become endemic among MSM, particularly those with HIV. It is frequently associated with other STIs and acute hepatitis C infection. The main presentation in MSM is with rectal symptoms; genital infections are rarely seen. LGV should be considered in MSM with suspected inflammatory bowel disease, as the clinical presentation can be very similar and the histological findings of LGV proctitis are similar to those of other causes of granulomatous proctitis, such as Crohn’s disease.

**Clinical features**

There are three clinical stages. The primary lesion may be transient and is frequently unnoticed. In the genital area, it takes the form of a painless papule or shallow ulcer appearing at the area of inoculation, 7–30 days after exposure. The main presentation in MSM is proctitis with symptoms of rectal pain, mucopurulent discharge, rectal bleeding, constipation and tenesmus. Some also report systemic symptoms, such as fever and malaise.

The secondary lesions are enlarged, tender regional lymph nodes. With genital LGV, they are usually unilateral and affect the inguinal and femoral nodes. When both are involved, the ‘groove sign’ develops due to the inguinal ligament separating the two enlarged lymph node systems. The nodes may become matted with bubo formation, which may rupture.

The tertiary stage is a chronic inflammatory response with tissue destruction. In the rectum, it can cause fistulae, strictures and granulomatous fibrosis, mimicking Crohn’s disease. There may also be scarring of the genital area, and destruction of local lymph nodes can lead to genital lymphoedema.

**Diagnosis**

A swab should be taken from the genital ulcer base, or from the rectal mucosa, for *C. trachomatis* NAAT. If this is positive, genotyping for LGV should be performed. Testing for the other causes of genital ulcers (see Box 37.5) or rectal symptoms (see Box 37.8) should include a swab for HSV and TP PCR, and serology for syphilis, which should be repeated after the 3-month window period. A NAAT for *N. gonorrhoeae* and *C. trachomatis* on FVU, or a VVS, and serology for HIV should be performed, and serology for hepatitis C should be considered in MSM in view of the frequent co-infection of acute hepatitis C with LGV.

**Management**

First-choice treatment is doxycycline 100 mg twice daily for 21 days or erythromycin 500 mg four times daily for 21 days. Patients should be advised to abstain from sex until completion of treatment. Sexual contacts should be notified, examined, tested and treated. Follow-up should continue until all symptoms and signs have resolved, which is usually by 3–6 weeks.

**Chancroid**

Chancroid is caused by *Haemophilus ducreyi*. It used to be one of the most common causes of genital ulcers worldwide but its incidence has now decreased markedly. It is extremely rare in high-income countries.

**Clinical features**

Chancroid has a short incubation period of 4–7 days. Tender papules develop at the site of inoculation, which rupture into painful, ragged-edged ulcers with necrotic bases that bleed easily. The usual sites of infection are the prepuce and glans penis in men and the labia minora and fourchette in women. There is often painful inguinal lymphadenopathy, which can develop into large buboes that suppurate.

**Diagnosis and management**

Detection of *H. ducreyi* DNA using PCR is the most sensitive diagnostic test but there are no commercial assays available for this. A
‘probable diagnosis’ may be made if the patient has the appropriate clinical picture, without evidence of syphilis or HSV.

Testing for the other causes of genital ulcers should be undertaken (see Box 37.5) and should include an ulcer swab for HSV and TP PCR, an ulcer swab for C. trachomatis NAAT with genotyping for LGV if positive, and serology for syphilis, which should be repeated after the 3-month window period. A NAAT for N. gonorrhoeae and C. trachomatis on FVU, or a VVS, and serology for HIV should also be performed.

Single-dose regimens include ceftriaxone 250 mg i.m. or azithromycin 1 g orally. Multiple-dose regimens are ciprofloxacin 500 mg twice daily for 3 days or erythromycin 500 mg four times daily for 7 days. Multiple-dose regimens should be used in HIV patients, as treatment failures have been reported with single-dose therapy. Patients should be advised to abstain from sex for at least 7 days and be followed up at 3–7 days, when the ulcers should be healing. HIV-infected patients should be monitored closely, as healing may be slower. Sexual partners should be notified, examined, tested and treated epidemiologically, as asymptomatic carriage has been reported.

**Donovanosis**

Donovanosis (also known as granuloma inguinale) is exceedingly rare and is confined to a few countries in South-east Asia, southern Africa, parts of India and Brazil. It is caused by *Klebsiella granulomatis*.

**Clinical features**

Nodules at the site of inoculation develop into friable, non-painful ulcers or hypertrophic lesions that increase in size. There is enlargement of the inguinal lymph nodes, which may ulcerate.

**Diagnosis and management**

The diagnosis is made on the presence of Donovan bodies using Giemsa or Silver stains in scrapings or biopsies of the lesions. Donovan bodies are the encapsulated intracellular Gram-negative rods of *K. granulomatis* visible within mononuclear cells. Screening for all other STIs should be undertaken.

Antibiotic treatment should be given for a minimum of 3 weeks and until the lesions have healed. Regimens include azithromycin 1 g weekly or 500 mg daily, or doxycycline 100 mg twice daily. Patients should be advised to abstain from sex for at least 3 weeks and be followed up until the lesions have fully resolved. Sexual partners should be notified, examined, treated and treated epidemiologically, as asymptomatic carriage has been reported.

**Pediculosis pubis**

The pubic louse (*Phthirus pubis*) is able to attach tightly to the pubic and coarse body hair. It can also attach to eyelashes and eyebrows. It is host-specific and is transferred by close bodily contact. Although infestation may be asymptomatic, the most common complaint is of itch due to hypersensitivity to the louse bites.

**Diagnosis and management**

Lice may be seen on the pubic and body hairs. They resemble small scabs or freckles but can be seen moving. The eggs (nits) are laid at the hair base and are strongly adherent to the hairs. Screening for other STIs should include NAAT for *N. gonorrhoeae* and *C. trachomatis*, and serology for syphilis and HIV.

Treatment should be applied to all areas of the body, including facial hair if present. Permethrin 1% should be left on for 10 minutes and malathion 0.5% should be left on for 12 hours. A second application is usually advised after 7 days. Permethrin is safe in pregnancy. Sexual partners should be examined and treated if infected.

**Scabies**

This is discussed on page 674.

**EPIDEMIOLOGY AND PATHOGENESIS**

**Epidemiology**

Since the first description of AIDS in 1981 and identification of the causative organism, HIV, in 1983, more than 78 million people are estimated to have been infected and 39 million people have died. At the latest estimate, 36.9 million people worldwide were living with HIV infection (representing 0.8% of adults aged 15–49 years), of whom 21.7 million are accessing anti-retroviral therapy (ART). Highly active ART has dramatically reduced mortality for those who are able to access care, transforming HIV from a universally fatal infection into a long-term, manageable condition, with a consequent rise in global prevalence. Effective ART also reduces onward transmission, and since 2001 new infections globally have fallen by 38%; there is, however, considerable geographical diversity, with infection rates continue to rise in Eastern Europe and parts of Central Asia. HIV is a major contributor to the global burden of disease, being the leading cause of disability-adjusted life-years for people aged 30–45 years and the leading cause of death for women aged 15–49 years.

In 2014 the United Nations Programme on HIV/AIDS (UNAIDS) established new global targets for a scale-up in HIV treatment to help end the AIDS epidemic by 2030. These ‘90-90-90’ ambitions are that:

- 90% of all people living with HIV know their HIV status
- 90% of people with diagnosed HIV infection receive sustained ART
- 90% of all people receiving ART achieve viral suppression

**HIV in sub-Saharan Africa**

Sub-Saharan Africa remains the region most seriously affected by the HIV epidemic. While southern and eastern Africa is home to 6.2% of the global population, this figure includes over half of the
world's population living with HIV, and 43% of new HIV infections each year occur in this region. Swaziland has the world's highest prevalence of HIV, with 27.2% of adults aged 15–49 infected. In sub-Saharan Africa, HIV infection is almost twice as common in young women (average prevalence 3.2%) than in men (1.6%). The reasons behind this are complex. The predominant route of HIV transmission in the region is through heterosexual sexual intercourse.

Despite the scale of the challenge faced in this region, progress is being made towards the ‘90-90-90’ goals, with an estimated 2.9 million people initiating anti-retroviral agents (ARVs) in the region in 2017.

**HIV in high-income countries**

Although the rate of new diagnoses is falling in many higher-income countries, the prevalence of HIV is rising: for example, there has been a decline in new diagnoses in the UK since 2015, with 4363 people newly diagnosed in 2017, but falling death rates and continuing new infections mean that the total number of people living with HIV continues to rise. In 2017, 101600 people in the UK were estimated to be living with HIV; of these, 92% had received the diagnosis and 98% of those diagnosed were on treatment, of whom 97% were virally suppressed.

The fall in new infection rates is due to a combination of factors, including increased and repeat testing, rapid initiation of effective therapy for those testing HIV-positive, and greater use of pre-exposure prophylaxis (PrEP) for those who are HIV-negative but at significant risk of acquiring the virus (see p. 1449). Of those diagnosed with HIV in the UK, MSM and heterosexual populations from sub-Saharan Africa are the two largest groups of people living with the disease; 30% are women. As mortality rates fall, the population living with HIV is becoming older, with more than 1 in 3 now aged 50 years and over.

Late diagnosis is the most common cause of HIV-related morbidity and mortality in the UK. Although the number of people diagnosed late (with a CD4 count of <350 cells/mL within 3 months of diagnosis) has declined from 52% in 2004 to 43% in 2017, this figure remains stubbornly high. Reducing late diagnosis and undiagnosed HIV through wider testing access, particularly in those patients presenting with clinical conditions that are associated with HIV and those living in areas with a high HIV serum prevalence, is critical to both individual and public health.

**The changing face of the epidemic**

With effective ART, increasing numbers of people with HIV are living with long-term, sustained viral suppression. In countries where ART is consistently accessible, AIDS-defining illnesses have given way to non-communicable conditions as the major health problems for people with HIV. Although chronic health conditions accumulate in general through life, higher levels of multimorbidity occur in people with HIV at a younger age than in those who are HIV-negative, and frailty and its associated disabilities also appear to occur at a younger age. Leading causes of hospital admission of people with HIV in Europe in 2017 included respiratory illness, psychiatric conditions, and cardiovascular, renal and neurological disorders. Data from the UK show that 75% of those living with HIV have at least one other long-term condition, including mental health problems, hypertension, lipid disorders and diabetes. The prevention, identification and treatment of co-morbidities through an integrated, outcomes-focused, person-centred approach are now central to HIV care.

**Pathology**

Whom to test for HIV infection, and where to do it, are summarized in Box 37.9.

**Routes of acquisition**

Despite the fact that HIV can be isolated from a wide range of body fluids and tissues, the majority of infections are transmitted sexually via semen, cervical secretions and blood. The most significant marker for transmission risk is the HIV viral load, which is highest in acute infection and reduced by effective ART. HIV-associated stigma and discrimination, gender-based violence and, in some countries of the world, the legal position for those at especially high risk can all impede access to appropriate services and increase the risks of transmission and acquisition of HIV.

**Sexual intercourse (vaginal and anal)**

Globally, heterosexual intercourse accounts for the vast majority of infections, and coexistent STIs, especially those causing genital ulceration, enhance transmission. Passage of HIV appears to be more efficient from men to women, and to the receptive partner in anal intercourse, than vice versa. Once the viral load is consistently reduced below the limit of detection by effective ART, HIV cannot be transmitted to sexual partners. Male circumcision has been shown to reduce both acquisition and transmission. In the UK, sex between men accounts for over half of the new diagnoses reported but there is a consistent rate of heterosexual transmission. In Central and sub-Saharan Africa, the epidemic has always been heterosexual, and more than half of HIV-positive adults in these regions are women. South-east Asia and the Indian subcontinent are experiencing an explosive epidemic, driven by heterosexual intercourse and a high incidence of other STIs.

**Vertical transmission (transplacental, perinatal, breast-feeding)**

Vertical transmission is the most common route of HIV infection in children. European studies suggest that, with no intervention, 15% of babies born to HIV-positive mothers are likely to acquire HIV, although rates of up to 40% have been reported from Africa and the USA. Increased vertical transmission is associated with an advanced stage of infection in the mother, maternal viral load, prolonged and premature rupture of membranes, and chorioamnionitis. Transmission can occur in utero, although the majority of infections take place perinatally. Breast-feeding has been shown to double the risk of vertical transmission in the pre-treatment era, but with considerable reduction in risk when women are using effective ART. In high-income countries, interventions to reduce vertical transmission, including screening for infection in pregnancy, use of ARVs and avoidance of breast-feeding, have led to a dramatic fall in the numbers of infected children. In the UK the risk of vertically transmitted infection is 1:1000. The lack of access to these interventions in resource-poor countries where 90% of infections occur is a major global issue.

**Contaminated blood, blood products and organ donations**

Screening of blood and blood products was introduced in 1985 in Europe and North America. Prior to this, HIV infection was associated with the use of clotting factors (for haemophilia) and with blood transfusions. In some parts of the world where blood products may not be screened and in areas where the rate of new HIV infections is very high, transfusion-associated transmission continues to occur.
Box 37.9 HIV testing: UK guidelines on where and who to test

Universal: clinical settings in which all patients should be offered HIV testing:
- Genitourinary medicine/sexual health clinics
- Antenatal services
- Termination of pregnancy services
- Drug dependency programmes
- Healthcare services for tuberculosis, hepatitis B, hepatitis C and lymphoma
- Primary care in high-prevalence areas where diagnosed HIV infection is ≥2 per 1000 resident population
- People in prison

People in whom HIV testing is recommended
- All patients diagnosed with a sexually transmitted infection
- Sexual partners of men and women known to be HIV-positive
- Men who have disclosed sexual contact with other men
- Female sexual contacts of men who have sex with men
- People reporting a history of injecting drug use
- Men and women known to be from a country of high HIV prevalence (>1%)
- Men and women who report sexual contact abroad or in the UK with individuals from countries of high HIV prevalence
- Patients presenting for healthcare when HIV enters the differential diagnosis (see Box 37.10)

HIV-associated indicator conditions

Respiratory
- Tuberculosis, Pneumocystis jiroveci/pneumonia, bacterial pneumonia, aspergillosis

Neurology
- Cerebral toxoplasmosis, primary cerebral lymphoma, cryptococcal meningitis, progressive multifocal leucoencephalopathy, aseptic meningitis, meningocephalitis, cerebral abscess, space-occupying lesion of unknown cause, Guillain–Barré syndrome, transverse myelitis, peripheral neuropathy, dementia

Dermatology
- Kaposi’s sarcoma, severe/recalcitrant seborrhoeic dermatitis, severe/recalcitrant psoriasis, multidermatomal/recurrent herpes zoster

Gastroenterology
- Persistent cryptosporidiosis, oral candidiasis, oral hairy leukoplakia, chronic diarrhoea of unknown cause, weight loss of unknown cause, Salmonella, Shigella, Campylobacter, hepatitis B infection, hepatitis C infection

Oncology

Gynaecology
- Cervical cancer, vaginal intraepithelial neoplasia, cervical intraepithelial neoplasia, grade 2 or above

Haematology
- Any unexplained blood dyscrasia, including thrombocytopenia, neutropenia and lymphopenia

Ophthalmology
- Cytomegalovirus retinitis, infective retinal diseases including herpèsviruses and toxoplasma, any unexplained retinopathy

Ear, nose and throat
- Lymphadenopathy of unknown cause, chronic parotitis, lymphoepithelial parotid cysts

Other
- Mononucleosis-like syndrome (primary HIV infection), pyrexia of unknown origin, any lymphadenopathy of unknown cause, any sexually transmitted infection

* AIDS-defining condition.

Contaminated needles (intravenous drug misuse, injections and needle-stick injuries)

The practice of sharing needles and syringes for intravenous drug use continues to be a major route of HIV transmission in parts of South-east Asia, Latin America and Eastern Europe. Successful education and needle exchange schemes can reduce the rate of transmission by this route. Iatrogenic transmission from re-use of needles and syringes in low- and middle-income countries is reported. Healthcare workers have a risk of approximately 0.3% following a single needle-stick injury with known HIV-positive blood, although data were obtained before widespread use of effective ART and the associated reduction in viral load.

There is no evidence that HIV is spread by social or household contact or by blood-sucking insects such as mosquitoes and bed bugs.

The virus

HIV belongs to the lentivirus group of the retrovirus family. There are two types, HIV-1 and HIV-2. HIV-1 is the most frequently occurring strain globally. HIV-2 is almost entirely confined to West Africa, although there is some spread to Europe, particularly France and Portugal. HIV-2 has only 40% structural homology with HIV-1 and, although associated with immunosuppression and AIDS, appears to take a more indolent course than HIV-1. Many of the drugs that are used in HIV-1 are ineffective in HIV-2. The structure of HIV is shown in Fig. 37.10.

Retroviruses are characterized by possession of the enzyme reverse transcriptase, which allows viral RNA to be transcribed into DNA and then incorporated into the host cell genome. Reverse transcription is an error-prone process with a significant rate of mis-incorporation of bases. This, combined with a high rate of viral...
Sexually transmitted infections and human immunodeficiency virus

turnover, leads to considerable genetic variation and a diversity of viral subtypes or clades. On the basis of DNA sequencing, HIV-1 is divided into four distinct strains, which represent four independent cross-species transfers: three (M, N and O) are based on the chimpanzee-related strains of simian immunodeficiency virus (SIV) and one (P) may represent chimpanzee to gorilla to human transmission.

- **Group M (major) subtypes** (98% of infections worldwide) exhibit a high degree of diversity, with subtypes (or clades), denoted A–K. There is a predominance of subtype B in Europe, North America and Australia, but areas of Central and sub-Saharan Africa have multiple M subtypes, clade C being the most common. Recombination of viral material generates an array of circulating recombinant forms (CRFs), which increase the genetic diversity and are becoming more common.

- **Group O (outlier) subtypes** are highly divergent from group M and are largely confined to small numbers that are centred on Cameroon.

- **Group P**, related to gorilla strains of SIV, has been identified from a patient from Cameroon.

**Pathogenesis**

The interrelationship between HIV and the host immune system is the basis of the pathogenesis of HIV disease. At the time of initial exposure, the virus is transported by dendritic cells from mucosal surfaces to regional lymph nodes, where permanent infection is established, usually by one ‘founder virus’. The host cellular receptor that is recognized by HIV surface glycoprotein gp120 is the CD4 molecule, which defines the cell populations that are susceptible to infection (Fig. 37.11). The interaction between CD4 and HIV gp120 surface glycoprotein, together with host chemokine CCR5

---

**Fig. 37.11 HIV entry and replication in CD4 T lymphocytes.**

(a) **Binding:** the virus binds to host CD4 receptor molecules via the envelope glycoprotein gp120 and co-receptors CCR5 and CXCR4. (b) **Fusion:** a subsequent conformational change results in fusion between gp41 and the cell membrane. (c) **Reverse transcription:** entry of the viral capsid is followed by uncoating of the RNA. DNA copies are made from both RNA templates. DNA polymerase from the host cell leads to the formation of double-stranded DNA (dsDNA). (d) **Integration:** in the nucleus, virally encoded DNA is inserted into the host genome. (e) **Transcription:** regulatory proteins control transcription (an RNA molecule is now synthesized from the DNA template). (f) **Budding:** the virus is re-assembled in the cytoplasm and budded out from the host cell.
or CXCR4 co-receptors, is responsible for HIV entry into cells. Although CCR5 CD4 memory T lymphocytes within all body systems are susceptible to infection and depletion, those found in the gastrointestinal tract are heavily infected early in the process. These lymphocytes become rapidly depleted, leading to compromised mucosal immune function, and thus allowing microbial lipopolysaccharides to enter the circulation. HIV infection that is independent of CD4 receptors can occur in astrocytes and renal epithelial cells, leading to end-organ damage.

Studies of viral turnover have demonstrated a virus half-life in the circulation of about 6 hours. To maintain observed levels of plasma viraemia, $10^{10}$–$10^{9}$ virus particles need to be released and cleared daily. Virus production by infected cells lasts for about 2 days and is probably limited by the death of the cell, owing to direct HIV effects. This links HIV replication to the process of CD4 destruction and depletion. Progressive loss of activated CD4 T lymphocytes due to killing by CD8 cells is a key factor in the immunopathogenesis of HIV. Natural killer cells are involved in the host immune response, although escape mutations within the virus population compromise their antiviral effects. The production of neutralizing antibodies, which, in some people, can be against several viral subtypes, occurs at about 12 weeks after infection.

Resulting cell-mediated immunodeficiency leaves the host open to infections with intracellular pathogens, while coexisting antibody abnormalities predispose to infections with encapsulated bacteria. HIV is associated with immune activation, a long-term inflammatory state, which is a key driver of disease progression. T-cell activation is observed from the earliest stages of infection, which, in turn, leads to an increase in the numbers of susceptible CD4-bearing target cells that can become infected and destroyed. This inflammatory state is associated with HIV itself, with co-pathogens such as cytomegalovirus, and with the translocation of microbial products, in particular lipopolysaccharides, from the gut into the systemic circulation following HIV destruction of normal mucosal immunity. Raised levels of inflammatory cytokines and coagulation system activation occur. These inflammatory responses may remain, despite effective ART, and play a role in HIV-associated end-organ damage, as well as raising the risks of myocardial infarction and some malignancies.

---

**CLINICAL FEATURES OF UNTREATED HIV INFECTION**

The features of HIV infection can be divided into the early/acute and long-term phases. The spectrum of disorders associated with HIV infection is broad and is the result of direct HIV effects, HIV-associated immune dysfunction and the drugs used to treat the condition, as well as coexisting morbidity and co-infections. With early intervention using effective ART, the majority of people with HIV in high-income settings begin treatment while asymptomatic, before the onset of significant immunosuppression, and therefore progression to an AIDS-defining event is now uncommon. Without treatment, immunosuppression progresses and the patient becomes susceptible to an increasing range of opportunistic infections and tumours, certain of which meet the criteria for the diagnosis of AIDS (Box 37.10).

Several HIV classification systems exist, the two most frequently used being the WHO and Centers for Disease Control (CDC) classification (Box 37.11). Their major application is in public health monitoring and surveillance rather than in routine clinical care. The CDC classification (Stages 0–3) includes a combination of HIV-positive laboratory results, the CD4 count and the presence of clinical AIDS-defining conditions. Immunological and clinical markers in combination with a positive HIV antibody test are incorporated in the WHO classification system.
Early HIV infection: incubation, seroconversion and acute illness

Early infection refers to the 6-month period following HIV acquisition, and is marked by rapid viral replication resulting in high levels of HIV circulating in the plasma and genital tract, and consequently by high infectiousness. This time is increasingly recognized as a key period for intervention, both to reduce long-term sequelae and to cut onward transmission.

The 2–4 weeks immediately following infection may be silent, both clinically and serologically. In a number of people, a self-limiting acute viral illness, which may be confused with glandular fever, occurs 3–6 weeks after exposure. Symptoms include fever, arthralgia, myalgia, lethargy, lymphadenopathy, sore throat, mucosal ulcers and, occasionally, a transient, faint pink, maculopapular rash. Neurological symptoms are common and include headache, photophobia, myelopathy, neuropathy and, in rare cases, encephalopathy. The illness lasts up to 3 weeks and recovery is usually complete.

This is a crucial point at which to make a diagnosis of HIV; however, HIV is frequently not considered in the differential diagnosis in patients presenting with such non-specific, viral symptoms.

Laboratory abnormalities in the early phase of infection include lymphopenia with atypical reactive lymphocytes noted on the blood film, thrombocytopenia and raised liver transaminases. CD4 lymphocytes may be markedly depleted and the CD4:CD8 ratio reversed. With increasingly sensitive assays, a majority of people with HIV develop detectable antibodies within the first 2–4 weeks of early infection. However, antibodies to HIV may be absent during the earliest stages of infection, although the level of circulating viral RNA is high and p24 core protein may be detectable. NAAT assays of HIV RNA may be diagnostic 7 days before a p24 antigen test and 12 days before a sensitive HIV antibody test. If early or acute HIV infection is suspected but standard diagnostic tests are negative, repeat testing in 7 days and referral for expert advice is recommended.

Clinical latency

The rate of clinical progression of untreated HIV is variable. The majority of people with HIV infection are asymptomatic for a substantial but variable length of time. However, the virus continues to replicate and the person remains infectious. Most people with HIV have a gradual decline in CD4 count over a period of approximately 10 years before progression to symptomatic disease or AIDS (Fig. 37.12). Others progress much more rapidly, with continued high levels of viral RNA and a rapid decline in CD4 count over 2–5 years. Other ‘long-term non-progressors’ may continue to replicate and the person remains infectious. This time is increasingly recognized as a key period for intervention, both to reduce long-term sequelae and to cut onward transmission.

Older age is associated with more rapid progression. Gender and pregnancy per se do not appear to influence the rate of progression, although women may fare less well for a variety of reasons. A subgroup of patients with asymptomatic infection have persistent generalized lymphadenopathy (PGL), defined as lymphadenopathy (~1 cm) at two or more extra-inguinal sites for more than 3 months in the absence of causes other than HIV infection. The nodes are usually symmetrical, firm, mobile and non-tender. There may be associated splenomegaly. The architecture of the nodes shows hyperplasia of the follicles and proliferation of the capillary endothelium. Biopsy is rarely indicated. The presence of PGL does not seem to affect disease progression, although as the disease progresses, nodes may disappear.

Symptomatic HIV infection

As HIV infection progresses, the viral load rises, the CD4 count falls and the patient develops an array of symptoms and signs. The clinical picture is due to:

- the direct result of HIV causing end-organ damage
- the result of HIV-associated immunosuppression

End-organ effects of HIV

Neurological disease

Infection of the nervous tissue occurs at an early stage and clinical neurological involvement increases as HIV advances. Manifestations include AIDS dementia complex (ADC), sensory polyneuropathy and aseptic meningitis (see p. 871). These conditions have become much less common since the introduction of ART. The pathogenesis is thought to be due both to the release of neurotoxic products by HIV itself and to cytokine abnormalities secondary to immune dysregulation.

ADC has varying degrees of severity, ranging from mild memory impairment and poor concentration through to severe cognitive deficit, personality change and psychomotor slowing. Changes in affect are common and depressive or psychotic features may be present. The spinal cord may show vacuolar myelopathy histologically. In severe cases, computed tomography (CT) scanning of the brain shows atrophic change of varying degrees. Magnetic resonance imaging (MRI) changes consist of white-matter lesions of increased density on T2-weighted sections. Electroencephalography (EEG) shows non-specific changes consistent with encephalopathy. The CSF is usually normal, although the protein concentration may be raised. Patients with mild neurological dysfunction may be unduly sensitive to the effects of other insults, such as fever, metabolic...
addition to these conditions, the skin is a common site of opportunistic infections (see p. 676).

Haematological complications
These are common in advanced HIV infection.

- **Anaemia** usually mild, normochromatic and normocytic.
- **Neutropenia** is common and usually mild.
- **Isolated thrombocytopenia** may occur early in infection and be the only manifestation of HIV for some time. Platelet counts are often moderately reduced but can fall dramatically to 10−20 × 10^9/L, producing easy bleeding and bruising. Circulating antiplatelet antibodies lead to peripheral destruction. Megakaryocytes are increased in the bone marrow but their function is impaired. Effective ART usually produces a rise in platelet count. Thrombocytopenic patients undergoing dental, medical or surgical procedures may need therapy with human immunoglobulin, which gives a transient rise in platelet count, or with platelet transfusion. Steroids are best avoided.

- **Pancytopenia** occurs because of underlying opportunistic infection or malignancies, in particular *M. avium-intracellulare* (MAI), disseminated cytomegalovirus and lymphoma.
- **Other complications** involve myelotoxic drugs, which include lamivudine (anaemia, neutropenia), ganciclovir (neutropenia), systemic chemotherapy (pancytopenia) and co-trimoxazole (granulocytosis).

Gastrointestinal effects
Weight loss and diarrhoea are common in people with advanced untreated HIV infection (see Box 32.36). Wasting is a common feature of advanced HIV infection, which, although originally attributed to direct HIV effects on metabolism, is frequently a consequence of anorexia. There is a small increase in resting energy expenditure in all stages of HIV, but weight and lean body mass usually remain normal during periods of clinical latency when the patient is eating normally.

HIV enteropathy with varying degrees of villous atrophy has been described with chronic diarrhoea when no other pathogen has been found. Hypochlorhydria is reported in patients with advanced HIV disease and may have consequences for drug absorption and bacterial overgrowth in the gut. Rectal lymphoid tissue cells are the targets for HIV infection during penetrative anal sex and may be a reservoir for infection to spread through the body.

Renal complications
**HIV-associated nephropathy** (HIVAN; see p. 1356), although rare, can cause significant renal impairment, particularly in more advanced disease. It is most frequently seen in black male patients and can be exacerbated by heroin use. It causes a collapsing variant of focal segmental glomerulosclerosis, along with a tubulopathy due to direct viral infection of tubular cells. The course is usually relentlessly progressive and renal replacement therapy is often required.

Other renal pathology seen in HIV includes **HIV-immune complex kidney disease** (HIVICK), which can present with a range of glomerular abnormalities, IgA nephropathy and thrombotic microangiopathy (TMA).

Many **nephrotoxic drugs** are used in the management of HIV-associated pathology: for example, foscarinet, amphotericin B, pentamidine and sulfadiazine. Tenofovir is associated with Fanci-ni’s syndrome (see p. 337).
Respiratory complications

The upper airway and lungs serve as a physical barrier to airborne pathogens and any damage will decrease the efficiency of protection, leading to an increase in upper and lower respiratory tract infections. The sinus mucosa may also function abnormally in HIV infection and is frequently the site of chronic inflammation. Response to antibacterial therapy and topical steroids is usual but some patients require surgical intervention. A similar process is seen in the middle ear, which can lead to chronic otitis media.

Lymphoid interstitial pneumonitis (LIP) is well described in paediatric HIV infection but is uncommon in adults. There is an infiltration of lymphocytes, plasma cells and lymphoblasts in alveolar tissue. Epstein–Barr virus may be present. The patient presents with dyspnoea and a dry cough, which may be confused with Pneumocystis infection (see p. 1443). Reticular nodular shadowing is seen on chest X-ray. Therapy with steroids may produce clinical and histological benefit in some patients.

Endocrine complications

Various endocrine abnormalities have been reported, including reduced levels of testosterone and abnormal adrenal function. The latter assumes clinical significance in advanced disease when intercurrent infection superimposed on borderline adrenal function precipitates clear adrenal insufficiency, requiring replacement doses of gluco- and mineralocorticoid. Cytomegalovirus is also implicated in adrenal-deficient states.

Cardiac complications

A recent systematic review and meta-analysis showed that people living with HIV are twice as likely to develop cardiovascular disease as the general population. Although lipid dysregulation has been associated with ARV medication, the observation has been made that high-density lipoprotein (HDL) levels are lower in those with untreated HIV infection than in HIV-negative controls. In a large international study (SMART), ischaemic heart disease was more common in those who took intermittent ARV therapy than in those who maintained viral suppression. Cardiomyopathy has been associated with HIV and may lead to congestive cardiac failure, although, in the ART era, cardiomyopathy related to ischaemic disease is becoming more common. Lymphocytic and necrotic myocarditis has been described. In cases of diagnostic uncertainty, ventricular biopsy can be undertaken to ensure that other treatable causes of myocarditis are excluded.

Conditions associated with HIV immunodeficiency

Immunodeficiency (see p. 59) allows the development of opportunistic infections (Box 37.13; see also Box 37.21). These are diseases caused by organisms that are not usually considered pathogenic, by known pathogens with unusual presentations, and by tumours that may have an oncogenic viral aetiology. Susceptibility increases as the patient becomes more immunosuppressed, and CD4 T-lymphocyte numbers are used as markers to predict the risk of infection. Patients with CD4 counts of more than 200 cells/mm³ are at low risk for the majority of AIDS-defining conditions (see Box 37.10), while a hierarchy of thresholds for specific infectious risks can be constructed as the CD4 count fails.

Mechanisms of this increasing susceptibility to infection include:
- defective T-cell function against protozoa, fungi and viruses
- impaired macrophage function against intracellular bacteria such as Mycobacteria and Salmonella
- defective B-cell immunity against encapsulated bacteria such as Streptococcus pneumoniae and Haemophilus

Many of the organisms causing clinical disease are ubiquitous in the environment or are already carried by the patient.

Diagnosis in an immunosuppressed patient may be complicated by a lack of typical signs, as the inflammatory response is impaired. Examples are lack of neck stiffness in cryptococcal meningitis or minimal clinical findings in early Pneumocystis jirovecii pneumonia. Multiple pathogens may coexist. Indirect serological tests are frequently unreliable. Specimens should be obtained from the appropriate site for examination and culture in order to make a diagnosis.

In an individual patient, the clinical consequences of HIV-related immune dysfunction will depend on at least three factors:
- **Microbial exposure of the patient throughout life.** Many clinical episodes represent reactivation of previously acquired infection, which has been latent. Geographical factors determine the microbial repertoire of an individual patient. Those organisms requiring intact cell-mediated immunity for their control are most likely to cause clinical problems.
- **Pathogenicity of organisms encountered.** High-grade pathogens, such as Mycobacterium tuberculosis, Candida and the herpesviruses, are clinically relevant, even when immunosuppression is mild, and will thus occur earlier in the course of HIV infection. Less virulent organisms occur at later stages of immunodeficiency.
- **Degree of immunosuppression of the host.** When patients are severely immunocompromised (CD4 count <100 cells/mm³), disseminated infections with organisms of very low virulence, such as MAI and Cryptosporidium, are able to establish themselves. These infections are very resistant to treatment, mainly because there is no functioning immune response to clear organisms. This hierarchy of infection allows for appropriate intervention with prophylactic drugs.

### Box 37.13 Major HIV-associated pathogens

**Protozoa**
- Toxoplasma gondii
- Cryptosporidium parvum
- Microsporidia spp.
- Leishmania donovani
- Isospora belli

**Viruses**
- Cytomegalovirus
- Herpes simplex
- Varicella zoster
- Human papillomavirus
- Human herpes virus-8
- JC polyomavirus

**Fungi and yeasts**
- Pneumocystis jirovecii
- Cryptococcus neoformans
- Candida spp.
- Dermatophytes (Trichophyton)
- Aspergillus fumigatus
- Histoplasma capsulatum
- Coccioidioides immitis

**Bacteria**
- Salmonella spp.
- Mycobacterium tuberculosis
- M. avium-intracellulare
- Streptococcus pneumoniae
- Staphylococcus aureus
- Haemophilus influenzae
- Moraxella catarrhalis
- Rhodococcus equi
- Bartonella quintana
- Nocardia

---

**Clinical approach to the patient with HIV**

**HIV testing**

HIV testing may be carried out in a number of settings (see p. 1449), and infection is diagnosed either by detection of virus-specific antibodies (anti-HIV) or by direct identification of viral material. Modern
‘fourth-generation’ tests, which are now the standard of care in many countries, test for anti-HIV antibodies and the p24 antigen simultaneously.

Detection of anti-HIV antibodies
This is the most commonly used marker of infection. The routine tests used for screening are based on enzyme-linked immunosorbent assay (ELISA) techniques, which may be confirmed with Western blot assays. Up to 3 months (mean 6 weeks) may elapse from initial infection to antibody detection (serological latency, or the ‘window period’). These antibodies to HIV have no protective function and persist for life. As with all IgG antibodies, anti-HIV will cross the placenta. All babies born to HIV-positive women will thus have the antibody at birth. In this situation, anti-HIV antibody is not a reliable marker of active infection, and will be gradually lost over the first 18 months of life in uninfected babies.

A serological testing algorithm for recent HIV seroconversions (STARHS) can be used to identify recently acquired infection. A highly sensitive ELISA that is able to detect HIV antibodies 6–8 weeks after infection is used on blood from patients with a positive oral fluid test, in parallel with a less sensitive (detuned) test that identifies later HIV antibodies within 130 days. A positive result on the sensitive test and a negative ‘detuned’ test are indicative of recent infection, while positive results on both tests point to an infection that is more than 130 days old. The major application of this is in epidemiological surveillance and monitoring.

Detection of viral p24 antigen
The p24 antigen (p24ag) is a protein from the HIV viral capsid that can be detected in blood shortly after infection, but which has usually disappeared by 8–10 weeks after exposure (see Fig. 37.12). It can be a useful marker in individuals who have been infected recently but have not had time to mount an antibody response. Anti-p24 antibodies (anti-p24) can be detected from the earliest weeks of infection and through the asymptomatic phase. It is frequently lost as the disease progresses.

Genome detection assays
Nucleic acid-based assays that amplify and test for components of the HIV genome are available. These assays are used to aid the diagnosis of HIV in the babies of HIV-positive mothers or in situations where serological tests may be inadequate, such as in early infection when antibody may not be present, or in subtyping HIV variants for medico-legal reasons. (See the discussion of viral load monitoring on p. 1434.)

Isolation of virus in culture
This is a specialized technique available in some laboratories as a diagnostic aid and a research tool.

Initial assessment
People are newly diagnosed with HIV in many different settings and need to be transferred rapidly to effective specialist care. All those with a new diagnosis of HIV should be reviewed by an HIV clinician within 2 weeks of diagnosis, or earlier if the patient is symptomatic or has other acute needs. A full medical history, physical examination and laboratory evaluation should be undertaken in all newly diagnosed patients to determine the stage of infection and the presence of co-morbidities and co-infections, and to assess overall physical, mental and sexual health. The initial assessment should also include details of the patient’s socioeconomic situation, relationships, family and social support networks, and substance misuse, together with contact tracing and partner notification. Specialist advice should be sought if there are children who require testing. Baseline investigations will depend on the clinical setting, but those appropriate for an asymptomatic person in the UK are shown in Box 37.14.

Genotype determination
Viral genotype analysis is recommended for all newly diagnosed patients with HIV. Clear genotype variations exist within HIV, not only are there variations between viral subtypes but also well-identified point mutations are associated with resistance to ARVs. New infections with drug-resistant variants of HIV may be seen. The most appropriate sample is the one closest to the time of diagnosis and the results are used to guide the selection of ART agents.
Patients are regularly monitored, depending on clinical, virological and treatment stage.

For people with HIV who have chosen not to initiate therapy, monitoring should take place 2–4 times per year, with longer intervals for those with higher CD4 counts, to assess progression of the infection and to discuss treatment options.

For people starting therapy and those on established effective therapy, monitoring is described on page 1438.

**Immunological monitoring**

Absolute numbers (and relative proportions) of CD4 lymphocytes are monitored. The absolute CD4 count and its percentage of total lymphocytes fall as HIV progresses. These figures bear a relationship to the risk of occurrence of HIV-related pathology, and patients with counts of less than 200 cells/mm³ are at greatest risk. Rapidly falling CD4 counts and those at or below 350 cells/mm³ are an indication for immediate initiation of ART. Factors other than HIV (e.g. smoking, exercise, intercurrent infections and diurnal variation) also affect CD4 numbers. Once the patient is virologically stable on ART with a CD4 above 350 cells/mm³, CD4 counts are performed at approximately yearly intervals. For those not taking ART, 4–6-monthly intervals are appropriate, unless values are approaching critical levels for intervention, in which case they are performed more frequently.

**Virological monitoring**

The HIV viral load (HIV RNA) is monitored, which has both prognostic and therapeutic value. HIV replicates at a high rate throughout the course of infection, many billions of new virus particles being produced daily. The rate of viral clearance is relatively constant in any individual and thus the level of viraemia is a reflection of the rate of virus replication.

Three HIV RNA assays for viral load are in current use:

- branched-chain DNA (bDNA)
- reverse transcription polymerase chain reaction (RT-PCR)
- nucleic acid sequence-based amplification (NASBA).

Results are given in copies of viral RNA/mL of plasma, or converted to a logarithmic scale, and there is good correlation between tests. The most sensitive test is able to detect as few as 20 copies of viral RNA/mL. Transient increases in viral load are seen following immunizations (e.g. for influenza and pneumococcus) or during episodes of acute intercurrent infection (e.g. tuberculosis), and viral load measurements should not be carried out within a month of these events.

By about 6 months after seroconversion to HIV, the viral setpoint for an individual is established and there is a correlation between HIV RNA levels and long-term prognosis, independent of the CD4 count. Those patients with a viral load consistently above 100,000 copies/mL have a 10 times higher risk of progression to AIDS over the ensuing 5 years than those with counts consistently below 10,000 copies/mL.

HIV RNA is the standard marker of anti-retroviral treatment efficacy (see later). Both duration and magnitude of virus suppression are pointers to clinical outcome. The aim of therapy is to secure long-term virological suppression, and a rising viral load in a patient whose adherence is assured indicates drug failure.

Baseline measurements are followed by repeat estimations at intervals of 4–6 months. Following initiation of ART or changes in therapy, a reduction in viral load should be seen by 4 weeks, reaching a maximum at 10–12 weeks, when repeat viral load testing should be carried out (see Fig. 37.12).

**Monitoring other aspects of health**

Regular assessment is needed to monitor for intercurrent medical problems, medications, vaccinations, recreational drug use, sexual history, reproductive decision-making, cervical cytology and social situation, including support networks, employment, benefits and accommodation. Depression and anxiety are common among people living with HIV and can have a deleterious impact on health-related quality of life, as well as adherence to medication regimens, meaning that mood and cognitive function should be routinely and regularly assessed. Psychological support may be needed, not only for the patient but also for family, friends and carers.

Regular reviews of sexual and reproductive health, together with advice on reducing the risk of HIV transmission, must be provided and future sexual practices discussed. Information is required to allow people to make informed choices about childbearing. The implications for sexual partners and existing family members should be considered and diagnostic testing offered as necessary.

Regular monitoring of weight, body mass index, metabolic and bone markers, blood pressure and cardiovascular risk is required. Dietary assessment and advice should be freely accessible. General health promotion advice on smoking, alcohol, diet, drug misuse and exercise should be given, particularly in light of the increased risk of cardiovascular and metabolic co-morbidities associated with HIV and its treatment.

**Further reading**

**MANAGEMENT OF HIV-POSITIVE PATIENTS**

Effective ART has transformed clinical outcomes for people with HIV, extending life expectancy towards that of the general population, bringing down morbidity and cutting onward transmission. Current management strategies aim to maximize wellbeing with sustained viral-suppressive therapy within a long-term condition model, with appropriate attention to the prevention and treatment of HIV-associated co-morbidities (Box 37.15).

With access and adherence to potent, tolerable ARVs within a managed clinical setting, life expectancy for people with HIV approaches that of the general population. Nevertheless, there is still no cure for HIV and patients live with a chronic, potentially infectious and sometimes unpredictable condition. Limitations on ART efficacy include the inability of existing drugs to clear HIV from certain intracellular pools, the occurrence of drug side-effects, adherence requirements, complex drug–drug interactions and the emergence of resistant viral strains. Even with complete viral suppression, ART does not fully restore health, and treated infection is associated with a variety of complications and co-morbidities, including cardiovascular disease, some cancers and impaired mental health. Measures...
The treatment of HIV using ART (Box 37.16) continues to evolve and improve. Increased potency, reduced toxicity, greater convenience of formulation, and availability of compounds with different mechanisms of action, coupled with a better understanding of drug resistance, have combined to improve HIV clinical and virological outcomes consistently. An increase in the numbers of compounds available and the high risk of drug-drug interactions combine to make HIV treatment complex, and better clinical outcomes have been closely linked to physician expertise and the numbers of patients under direct care. With increasing numbers of compounds now available as generics, some drug costs are falling, and commissioners are increasingly focusing on the cost-effectiveness of the newer agents to justify their use. Regularly updated treatment guidelines are produced in the UK by the British HIV Association (BHIVA) and in the USA by the Department of Health and Human Services (DHHS). The most up-to-date versions can be found on their websites (see Further reading) and the current version must be used in all circumstances.

The key practical principles of prescribing ARVs are given in Box 37.17.

When to start ART

ART should be offered to everyone who is HIV-positive, irrespective of CD4 count, and started as soon as the patient is ready, which may be at the time of diagnosis. The move away from CD4-guided treatment initiation is based on clinical trial data demonstrating benefits of ART on morbidity and mortality, even when CD4 counts are above 500, together with the impact of effective therapy on reducing onward transmission.

- In patients with an AIDS-defining condition or an opportunistic infection, ART should be initiated within 2 weeks of starting treatment for intercurrent conditions.
- For people with primary HIV infection, treatment should be started immediately.

The evidence that treatment reduces infectiousness should be discussed with all patients with HIV. Their full involvement in therapeutic decision-making is essential for success. Various national guidelines and treatment frameworks exist (e.g. guidelines from BHIVA and the DHHS, recommendations from the International Antiviral Society, IAS). Laboratory marker data, including viral load, genotype, CD4 counts, co-morbidities and current medications, together with individual circumstances, underpin therapeutic decision-making. In situations where therapy is recommended but the patient elects not to start, more intensive clinical and laboratory monitoring is advisable.

Although the benefits of ART in HIV infection are indisputable, treatment is likely to be life-long and requires a long-term commitment to high levels of adherence. With newer agents and improved formulations, many of the difficulties associated with earlier ART regimens have markedly diminished. The major risks of therapy include short- and longer-term side-effects, drug-drug interactions and the potential for development of resistant strains of virus. Special situations (co-infection with hepatitis B and C, seroconversion, pregnancy, post-exposure prophylaxis) in which ARV agents may be used are described on page 1440.

Which drugs to start

The drug regimen used for starting therapy must be individualized to suit each patient’s needs, clinical situation and lifestyle. Treatment is always initiated with three drugs: two nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs) in combination, and a third agent – either an integrase inhibitor, a boosted protease inhibitor or a non-nucleoside reverse transcriptase inhibitor (NNRTI, Box 37.18; see also Box 37.16). The availability of fixed-dose co-formulations reduces pill burden, increases convenience and facilitates adherence.

Nucleoside/nucleotide reverse transcriptase inhibitors

Nucleoside reverse transcriptase inhibitors (NRTIs) are nucleoside analogues that inhibit the synthesis of DNA by reverse transcription and also act as DNA chain terminators. They were the first group of agents to be used against HIV and need to be phosphorylated intracellularly for activity to occur. Nucleotide reverse transcriptase inhibitors (NtRTIs), such as tenofovir, have a similar mechanism of
Sexually transmitted infections and human immunodeficiency virus

<table>
<thead>
<tr>
<th>Drug class</th>
<th>Drugs</th>
<th>Comments</th>
</tr>
</thead>
<tbody>
<tr>
<td>Nucleoside and nucleotide reverse transcriptase inhibitors (NRTIs)</td>
<td>Tenofovir, abacavir, lamivudine, emtricitabine</td>
<td>Tenofovir associated with renal dysfunction. Abacavir associated with hypersensitivity reactions in at-risk individuals (HLA-B*5701). Abacavir plus lamivudine should only be used when baseline VL is &lt;100 000 copies/mL. The combination of tenofovir plus emtricitabine is a preferred first-line regimen in most regions.</td>
</tr>
<tr>
<td>Non-nucleoside reverse transcriptase inhibitors (NNRTIs)</td>
<td>Efavirenz, nevirapine, etravirine, rilpivirine</td>
<td>Efavirenz can cause central nervous system toxicity (usually time-limited). Nevirapine can cause severe hepatotoxicity in patients with higher CD4 cell counts (&gt;250 cells/mm³ for women and &gt;400 cells/mm³ for men). Rilpivirine should be used only when baseline VL is &lt;100 000 copies/mL. Efavirenz is given twice daily and has generally been used as a second-line regimen.</td>
</tr>
<tr>
<td>Integrase inhibitors or integrase strand transfer inhibitors (INSTIs)</td>
<td>Raltegravir, dolutegravir, elvitegravir</td>
<td>Integrase inhibitors are generally well tolerated and have fewer adverse effects than other ARV classes. Raltegravir is taken twice daily. Elvitegravir requires boosting by cobicistat.</td>
</tr>
<tr>
<td>Protease inhibitors</td>
<td>Fosamprenavir, atazanavir, darunavir, lopinavir, saquinavir (ritonavir)</td>
<td>Most protease inhibitors are extensively metabolized by the cytochrome P450 3A system; ritonavir is generally given at low doses (100–200 mg per day) to inhibit P450 and boost the co-administered protease inhibitors. Most protease inhibitors are associated with hyperlipidaemia and other metabolic abnormalities such as insulin resistance. Long-term protease inhibitor exposure has been associated with increased risk of cardiovascular disease.</td>
</tr>
<tr>
<td>CCR5 inhibitors</td>
<td>Maraviroc</td>
<td>Maraviroc is active only in patients who do not have virions that use CXCR4 for cell entry. A specialized assay is therefore needed to screen for co-receptor tropism. By contrast with other ARVs, maraviroc binds to a host rather than a viral target.</td>
</tr>
<tr>
<td>Fusion inhibitors</td>
<td>Enfuvirtide</td>
<td>Enfuvirtide must be given subcutaneously twice daily and is very expensive; generally used only in patients who have no other therapeutic options.</td>
</tr>
</tbody>

<sup>a</sup>Some drugs, such as zidovudine, stavudine and nevirapine, are generally used in low-income countries because of cost considerations. These are not recommended as preferred agents in resource-rich regions in view of their potential toxic effects. HLA, human leucocyte antigen; VL, viral load. (Modified from Volberding PA, Deeks SG. Antiretroviral therapy and management of HIV infection. Lancet 2010; 376:49–62.)

**Box 37.17 Prescribing anti-retroviral drugs (ARVs): practice points**

<table>
<thead>
<tr>
<th>Characteristics of ARVs</th>
<th>Practice points</th>
</tr>
</thead>
<tbody>
<tr>
<td>Adherence for the long term is key to success</td>
<td>Make treatment decisions in partnership with the patient. Check for any factors that may compromise accurate adherence. Ensure that the proposed drug regimen fits with lifestyles. Clarify that the patient is fully conversant with the requirements and understands the reasons for strict adherence. Check access to appropriate storage conditions for some agents.</td>
</tr>
<tr>
<td>Should not be stopped suddenly</td>
<td>Make sure that mechanisms are in place to ensure adequate drug supplies, e.g. regular clinic appointments, repeat prescriptions, home delivery of medications. Beware unexpected time away from home, e.g. holidays, intercurrent hospital admissions, immigration detention, police detention. If there is an urgent medical indication to stop, obtain advice from specialist physician or pharmacist.</td>
</tr>
<tr>
<td>Can be compromised by the introduction of other medications, including other ARVs and vice versa</td>
<td>Take care with direct-acting antiviral (DAA) therapies in hepatitis C (expert advice required). Be careful with enzyme inducers, e.g. rifampicin, rifabutin, warfarin and nevirapine, which reduce the effective levels of some ARVs. Remember that methadone levels may be reduced by efavirenz. Note that some ARVs block the metabolism of other agents, which may reach toxic levels, e.g. steroids, statins. Always check potential interactions before adding new agents; see <a href="http://www.hiv-druginteractions.org">www.hiv-druginteractions.org</a>. Remember that therapeutic drug monitoring may be necessary.</td>
</tr>
<tr>
<td>Can interact adversely with some herbal, complementary and recreational agents</td>
<td>Note that herbal remedies that induce cytochrome P450, e.g. St John’s wort and Chinese herbal remedies, reduce levels of some ARVs. Check potential interactions before adding new agents; see <a href="http://www.hiv-druginteractions.org">www.hiv-druginteractions.org</a>. Remember that therapeutic drug monitoring is necessary.</td>
</tr>
<tr>
<td>May produce additive toxicities when given with other medications</td>
<td>For example, note that corticosteroid (inhaled and systemic) levels may be elevated, statins may cause increased muscle toxicity, there may be increased hepatotoxicity with anti-tuberculosis medication, and increased myelosuppression with chemotherapy or high-dose co-trimoxazole.</td>
</tr>
<tr>
<td>Are associated with a range of adverse drug reactions, which may be confused with other pathology</td>
<td>For example, note that rash, fever, nausea and diarrhoea may all be caused by intercurrent pathology and/or ARVs.</td>
</tr>
<tr>
<td>May exacerbate co-morbidities</td>
<td>Examples include hepatic dysfunction due to hepatitis B and C, cardiovascular risk, osteoporosis.</td>
</tr>
</tbody>
</table>
Having demonstrated very good durability over time, and potency at low CD4 counts and in high viral loads, **efavirenz** is now recommended as an alternative rather than a preferred option in the UK due to its CNS side-effects, such as dysphoria, insomnia and an association with increased risk of suicide. **Rilpivirine** has been directly compared with efavirenz and shown to be virologically superior and better tolerated when used in patients with a viral load below 100,000 copies/mL. On this basis the British guidelines have moved rilpivirine from an alternative to a preferred third agent. Rilpivirine must be taken with food and has interactions with acid-reducing agents; proton pump inhibitors are contraindicated.

**Etravirine** is a second-generation NNRTI with some activity against drug-resistant strains, and is useful in the treatment of ART-experienced patients. Rash is the most common adverse effect.

**Nevirapine**, although safe and effective for those already established on therapy, is no longer a preferred option for those starting ART in the UK. The small risk of serious hepatic or cutaneous toxicity is now unjustified in light of the wide choice of other effective agents. If it is being considered, it must not be used in women with a CD4 count above 250 cells/mm³ or men with a CD4 count of more than 400 cells/mm³, as there is an increased risk of hepatotoxicity and rash.

### Protease inhibitors

Protease inhibitors (PIs) act competitively on the HIV aspartyl protease enzyme, which is involved in the production of functional viral proteins and enzymes. As a consequence, viral maturation is impaired and immature dysfunctional viral particles are produced. Most of the PIs are active at very low concentrations and, *in vitro*, are found to have synergy with reverse transcriptase inhibitors. However, there are differences in toxicity, pharmacokinetics, resistance patterns and also cost, which influence prescribing. Cross-resistance can occur across the PI group.

Clinically significant interactions with the cytochrome P450 system are used to therapeutic advantage, by ‘boosting’ blood levels of PI through blocking drug breakdown using small doses of ritonavir or cobicistat. This increases the half-life of the active drug, allowing greater drug exposure, fewer pills, enhanced potency and a minimized risk of resistance. The disadvantages include a greater pill burden, other drug–drug interactions and increased risk of lipid abnormalities, particularly raised fasting triglycerides. PIs have been linked with abnormalities of fat metabolism and control of blood sugar, and some have been associated with deterioration in clotting function in people with haemophilia. In general, PIs have a higher genetic barrier to resistance than other drug classes, and newer PIs such as darunavir have activity against viruses resistant to the older drugs in the class.

Boosted **atazanavir** and **darunavir** are most commonly used as first-line therapy. Each can cause gastrointestinal disturbance and lipid abnormalities. Atazanavir increases unconjugated bilirubin levels and may produce icterus. Symtuza is a once-daily, fixed-dose single tablet containing darunavir, cobicistat, emtricitabine and tenofovir alafenamide, and is the first PI-based single-tablet regimen to reach the market.

### Integrase strand transfer inhibitors

Integrase strand transfer inhibitors (INSTIs) act as selective inhibitors of HIV integrase, which blocks viral replication by preventing insertion of HIV DNA into the human DNA genome. Several are in clinical use and are effective in treatment of both drug-experienced and drug-naïve patients, with tolerability and safety profiles that

<sup>a</sup>Drugs listed in alphabetical order.

<sup>b</sup>Abacavir is contraindicated if an individual is HLA-B*57:01-positive.

<sup>c</sup>Use recommended only if baseline viral load <100,000 copies/mL, except when initiated in combination with dupotegravir, in which case abacavir/lamivudine can be used at any baseline viral load.

<sup>d</sup>Use recommended only if baseline viral load <100,000 copies/mL.

action but require only two intracellular phosphorylation steps for activity, as opposed to the three steps for nucleoside analogues.

Usually, two drugs of this class are combined to provide the ‘backbone’ of an ART regimen. Several fixed-dose NRTI combinations are available, which helps reduce the pill burden. The choice of which two NRTIs should form the backbone of therapy is influenced by efficacy, toxicity and ease of administration. The availability of the once-daily, one-tablet, fixed-dose combinations, including Truvada (tenofovir/emtricitabine) and Kivexa (abacavir/lamivudine), has led to the prescription of one of these as the two-NRTI backbone for the majority of patients who are naive to medication. Kivexa should be used only in those who are HLA-B*5701-negative. Data comparing Truvada and Kivexa in naive patients have demonstrated the non-inferiority of Kivexa at viral levels of less than 100,000 copies/mL. In patients with high viral levels, Kivexa should be reserved for use when Truvada is contraindicated. NRTIs have been associated with mitochondrial toxicity (see p. 1440), as a consequence of their effect on the human mitochondrial DNA polymerase, and this can lead to kidney and bone disease with long-term use.

**Tenofovir alafenamide** (TAF) is a prodrug of tenofovir. Its use results in lower plasma concentrations of tenofovir (the active drug) than the traditional tenofovir formulation (tenofovir disoproxil fumarate, TDF) while achieving virological non-inferiority; this reduces the potential for renal and bone toxicity. Many different fixed-dose formulations incorporating TAF and other anti-retroviral drugs are now available.

### Non-nucleoside analogues

Non-nucleoside reverse transcriptase inhibitors (NNRTIs) interfere with reverse transcriptase by direct binding to the enzyme. They are generally small molecules that are widely disseminated throughout the body and have a long half-life. They affect cytochrome P450 and consequently have a wide-range of drug–drug interactions. They are ineffective against HIV-2, and the level of cross-resistance across the class is very high. All have been associated with rashes and elevation of liver enzymes. Second-generation NNRTIs, such as etravirine and rilpivirine, which have fewer adverse effects, have some activity against viruses resistant to other compounds of the NNRTI class.
are superior to those of NNRTIs and PIs. For these reasons, INSTIs such as raltegravir and dolutegravir are increasingly chosen as the third agent in ARV regimens.

**Raltegravir**, the first licensed compound in this drug class, has high anti-HIV activity for both treatment-naive and treatment-experienced patients, with a favourable side-effect profile and few drug interactions. **Dolutegravir**, a second-generation INSTI with a good side-effect profile, has a higher genetic barrier to resistance than raltegravir and can be dosed once daily. Dolutegravir is associated with a small increase in creatinine as it blocks tubular secretion. A fixed-dose tablet of dolutegravir co-formulated with abacavir and lamivudine (Truimeq) is available.

**Elvitegravir** is metabolized via the cytochrome P450 pathway, requiring co-administration of a cytochrome-P450 blocker to secure adequate plasma concentrations, thus increasing the drug–drug interaction potential. Single-tablet co-formulations exist with tenofovir, emtricitabine and cobicistat (Strivid). **Bictegravir** is the newest in the INSTI class with potency against strains with integrase resistance.

### Co-receptor blockers

**Maraviroc** is a chemokine receptor antagonist that blocks the cellular CCR5 receptor entry by CCR5 tropic strains of HIV. These strains are found in earlier HIV infection and, with time, adaptations (against which maraviroc is ineffective) allow the CXCR4 receptor to become the more dominant form. The drug is metabolized by cytochrome P450 (3A), giving the potential for drug–drug interactions. Tropism assays to establish that the patient is carrying a CCR5 tropic virus are required before treatment is used.

### Fusion inhibitors

**Enfuvirtide** is the only licensed compound in this class of agents. It is an injectable peptide derived from HIV gp41 that inhibits gp41-mediated fusion of HIV with the target cell. It is synergistic with NRTIs and PIs. Although resistance to enfuvirtide has been described, there is no evidence of cross-resistance with other drug classes. Because it has an extracellular mode of action there are few drug–drug interactions. Side-effects relate to the subcutaneous route of administration in the form of injection site reactions.

### Post attachment inhibitors

**Ibalizumab**, a humanized monoclonal antibody administered intravenously, blocks HIV cell entry, which has been shown to be effective in people with multidrug-resistant HIV, for which it is licensed. It requires intravenous administration every 14 days.

### Monitoring therapy

Success rates for initial therapy using modern ARVs are very high: by 4 weeks of therapy the viral load should have dropped by at least 1 log10 copies/mL, and by 12–24 weeks should be fully suppressed (<50 copies/mL). Patients are reviewed 2–4 weeks after starting therapy to check for adverse drug effects and ensure good adherence. The viral load is measured at 1, 3 and 6 months after starting ART and a suboptimal response at any time point demands a full assessment and possible change in therapy.

Once clinically stable and virologically suppressed on therapy, the viral load should be routinely measured every 6 months. CD4 count should be repeated at 3 months after starting ART and then every 3–4 months. Once the viral load is below 50 copies/mL and the CD4 count has been above 350 cells/μL2 for at least 12 months, monitoring frequency may fall to 6-monthly or even longer (Box 37.19).

### Drug resistance

Resistance to ARVs (Box 37.20) results from mutations in the protease, reverse transcriptase and integrase genes of the virus. HIV has a rapid turnover, with 109 replications occurring per day. The error rate is high, resulting in genetic diversity within the population of virus in an individual, which will include drug-resistant mutants. When drugs only partially inhibit virus replication, there will be a selection pressure for the emergence of drug-resistant strains. The rate at which resistance develops depends on the frequency of pre-existing variants and the number of mutations required. Resistance to most NRTIs and PIs occurs with an accumulation of mutations, while a single-point mutation will confer high-level resistance to NNRTIs. There is evidence for the transmission of HIV strains that are resistant to all or some classes of drug. Studies of primary HIV infection have shown prevalence rates of between 2% and 20%. Prevalence of primary mutations associated with drug resistance in chronically infected patients not on treatment ranges from 3% to 10% in various studies.

HIV anti-retroviral drug resistance testing is routine clinical management in patients at diagnosis and before starting therapy, and for whom therapy is failing. The tests are based on PCR amplification of the virus and give an indirect measure of drug susceptibility in the predominant variants. Such assays are limited by both the starting concentration of virus and their ability to detect minority strains.

For results to be useful in situations where therapy is failing, samples must be analysed when the patient is on therapy, as once the selection pressure of therapy is withdrawn, wild-type virus becomes the predominant strain and resistance mutations present earlier may no longer be detectable.
Adherence

Patients’ beliefs about their personal need for medicines and their concerns about treatment affect how and whether they take them. Adherence to treatment is pivotal to success. Levels of adherence below 95% have been associated with poor virological and immunological responses with older compounds having poor absorption and low bioavailability; however, the newer ARVs are more forgiving. For some compounds, trough levels are barely adequate to suppress viral replication, and missing even a single dose will result in plasma drug levels falling dangerously low. Patchy adherence facilitates the emergence of drug-resistant variants, which, in time, will lead to virological treatment failure.

Factors implicated in poor adherence may be associated with the medication, the patient or the provider:

- **Medication-related factors** include side-effects, the degree of complexity and pill burden, and the inconvenience of the regimen.
- **Patient factors** include the level of motivation and commitment to the therapy, psychological wellbeing, level of available family and social support, and health beliefs. Supporting adherence is a key part of clinical care.
- **Provider factors** include the level of education patients are given about their condition and treatment, which is a fundamental requirement for good adherence, as is education of clinicians in adherence support techniques.

The acceptability and tolerability of the regimen, together with an assessment of adherence, should be documented at each visit. Provision of acute and ongoing multidisciplinary support for adherence within clinical settings should be universal. Medication-alert devices may be useful for some patients.

Treatment failure

Failure of ART – that is, persistent viral replication causing immunological deterioration and eventual clinical evidence of disease progression – is caused by a variety of factors, such as poor adherence, limited drug potency, and food or other medication that may compromise drug absorption. There may be drug interactions or limited penetration of drug into sanctuary sites such as the CNS, permitting viral replication. Side-effects and other patient-related elements contribute to poor adherence.

Changing therapy

A rise in viral load, new clinical events that imply progression of HIV infection or the development of new co-morbidities are all reasons to review therapy. Virological failure – that is, two consecutive viral loads of over 400 copies/mL in a previously fully suppressed patient – requires investigation. Viral genotyping should be used to help select future therapy, choosing at least two new agents to which the virus is fully sensitive. If a new suitable treatment option is available, it should be started as soon as possible.

Treatment failure in highly treatment-experienced patients poses considerable challenges but new classes of ARV, with activity against drug-resistant strains of HIV, make long-term virological suppression a realistic objective, even in heavily pre-treated patients.

If the patient has a viral load below the limit of detection and a change needs to be made because of intolerance of a particular drug, then a switch should be made to another sensitive drug within the same class. Simplification of complex regimens may be considered if adherence is problematic.

Stopping therapy

ARVs may have to be stopped if there is, for example, cumulative toxicity or potential drug interactions with medications needed to
deal with another more pressing problem. If adherence is poor, stopping completely may be preferable to continuing with inadequate dosing, in order to reduce the development of viral resistance. Poor quality of life and the views of the patient should be discussed.

The NRTIs efavirenz and nevirapine have long half-lives and, depending on the other components of the regimen, may need to be stopped before the other drugs in the mixture to reduce the risk of drug resistance. If this is not possible, a boosted PI may be used for several weeks, either as a substitute for the NNRTI or as monotherapy, to cover the period of subtherapeutic levels.

Complications and long-term safety of ART

As efficacy and tolerability of ARVs have improved and longevity for people with HIV has increased, long-term safety has become increasingly important. Side-effects can be a problem in ART (see Box 37.16). Some are acute and associated with initiation of medication, while others emerge after longer-term exposure to drugs.

Allergic reactions

Allergic reactions occur with greater frequency in people with HIV infection and have been documented with all the ARVs. Abacavir is associated with a potentially fatal hypersensitivity reaction, strongly linked to the presence of HLA-B*5701, usually within the first 6 weeks of treatment. There may be a discrete rash and often a fever, coupled with general malaise and gastrointestinal and respiratory symptoms. The diagnosis is clinical and symptoms resolve when abacavir is withdrawn. Rechallenge with abacavir can be fatal and is contraindicated. In the UK, routine screening for the HLA-B*5701 allele has reduced the incidence of abacavir hypersensitivity. Allergies to NNRTIs (often in the second or third week of treatment) usually present with a widespread maculopapular pruritic rash, often with a fever and disordered liver biochemical tests. Reactions can resolve, even with continuing therapy, but drugs should be stopped immediately in any patient with mucous membrane involvement or severe hepatic dysfunction.

Lipodystrophy and metabolic syndrome

A syndrome of lipodystrophy occurs in patients with HIV on ART, comprising characteristic morphological changes and metabolic abnormalities. The main characteristics include:

- a loss of subcutaneous fat in the arms, legs and face (lipodystrophy)
- deposition of visceral, breast and local fat
- raised total cholesterol, HDL cholesterol and triglycerides
- insulin resistance with hyperglycaemia.

The syndrome is potentially associated with increased cardiovascular morbidity. The highest incidence occurs in those taking combinations of NRTIs and PIs. The older drugs, stavudine and zidovudine, are associated with the lipoatrophy component of the process. Dietary advice and increase in exercise may improve some of the metabolic problems and help body shape. Statins and fibrates are recommended to reduce circulating lipids. Simvastatin is contraindicated, as it has high levels of drug interactions with PIs.

Mitochondrial toxicity and lactic acidosis

Mitochondrial toxicity, mostly involving the older drugs stavudine and didanosine, in the nucleoside analogue class, leads to raised lactate and lactic acidosis, which has, in some cases, been fatal. NRTIs inhibit gamma-DNA polymerase and other enzymes that are necessary for normal mitochondrial function. Symptoms are often vague and insidious, and include anorexia, nausea, abdominal pain and general malaise. Venous lactate is raised and the anion gap is typically widened. This is a serious condition, requiring immediate cessation of ART and provision of appropriate supportive measures until normal biochemistry is restored. All patients should be alerted to the possible symptoms and encouraged to attend hospital promptly.

Bone metabolism

A variety of bone disorders have been reported in HIV: in particular, low bone mineral density (BMD) and fragility fractures. The prevalence of these conditions has varied widely in different studies. Although untreated HIV is believed to have a direct impact on bone metabolism, a fall in BMD has been associated with starting ART and is most noticeable in tenofovir-containing regimens. This may be due to direct effects of the drug on bone or an indirect renal-mediated effect. Tenofovir alafenamide appears to have far less effect on bone health. Fracture risk using the FRAX score (see Box 19.8) should be assessed at baseline in all patients over 50 years of age and postmenopausal women, or in the presence of other risk factors.

Immune reconstitution inflammatory syndrome

Paradoxical inflammatory reactions (immune reconstitution inflammatory syndrome, IRIS) may occur on initiating ART. This usually occurs in people who have been profoundly immunosuppressed and begin therapy. As their immune system recovers, they are able to mount an inflammatory response to a range of pathogens, which can include exacerbation of symptoms with new or worsening clinical signs. Examples include unusual mass lesions or lymphadenopathy associated with mycobacteria, including deteriorating radiological appearances associated with tuberculosis infection. Inflammatory retinal lesions in association with cytomegalovirus, deterioration in liver function in chronic hepatitis B carriers, and vigorous vesicular eruptions with herpes zoster have also been described. To avoid this situation, certain pathogens, in particular Mycobacterium tuberculosis and Cryptococcus, should be treated for several weeks to reduce the microbiological burden before ARVs are initiated.

Specific therapeutic situations

Acute HIV infection

ART should be started immediately in patients presenting with acute HIV. This stage of disease may represent a unique opportunity for therapy, as there is less viral diversity and the host immune capacity is still intact. There is evidence to show that the viral load can be reduced substantially by effective therapy at this point. People with severe symptoms during primary HIV infection may gain a clinical improvement on ARVs.

Pregnancy

In the UK the mother-to-child HIV transmission rate is 1% for all women diagnosed prior to delivery and 0.1% for women on ART with a viral load of less than 50 copies/mL. Management of HIV-positive pregnant women requires close collaboration between obstetric, medical and paediatric teams. The management aim is to deliver a healthy, uninfected baby to a healthy mother without prejudicing the future treatment options of the mother. Although considerations regarding the pregnancy must be factored into clinical decision-making, pregnancy per se is not a contraindication to providing optimum HIV-related care for the woman. HIV-positive women are still advised against breast-feeding.
although with effective suppressive ART the risk of transmission is extremely small. Delivery by caesarean section reduced the risk of vertical transmission in the pre-ART era, but if the woman is on effective ART and the labour is uncomplicated, vaginal delivery carries no additional risk. Women conceiving on an effective ART regimen should continue on their medication. For women naive to therapy who require treatment of their own HIV, whether pregnant or not, triple therapy is the regimen of choice. Risk of vertical transmission increases with viral load. Although the fetus will be exposed to drugs, the chances of reducing the viral load, and hence preventing infection, are greatest with a potent triple therapy regimen in the mother. In this situation, treatment should start as soon as possible and continue during delivery. The baby should receive zidovudine for 4 weeks postpartum and the mother should remain on ARVs with appropriate monitoring and support.

For the small numbers of women who do not wish to take ART treatment for their own health, ART, initiated at the beginning of the second trimester if the baseline viral load is above 30,000 HIV RNA copies/mL, should be offered to reduce transmission to the fetus, and consideration should be given to starting earlier if the viral load is above 100,000 HIV RNA copies/mL.

**Post-exposure prophylaxis**

The time taken for HIV infection to become established after exposure offers an opportunity for prevention. Animal models provide support for the use of triple ARVs for post-exposure prophylaxis (PEP) but there are no prospective trials to inform the best approach and each situation should be evaluated on a case-by-case basis to estimate the potential risk of infection and potential treatment benefit.

Healthcare workers may be treated following occupational exposure to HIV, as may those exposed sexually. The risk of acquisition of HIV following exposure is dependent on the risk that the source is HIV-positive (this is often unknown in a sexual exposure) and the risk of transmission of the particular exposure. PEP may be useful up to 72 hours after possible exposure. In the UK the standard regimen is Truvada plus raltegravir, although this may be varied depending on what is known about the source. When the source patient is known to have an undetectable HIV viral load (<200 copies/mL), PEP is not recommended.

Treatment is given for 4 weeks and the recipient should be monitored for toxicity. The at-risk patient should be tested for established HIV infection before PEP is dispensed. Rapid point-of-care tests are particularly useful in this setting. PEP following sexual exposure should not be seen as a substitute for other methods of prevention, although people with HIV and a fully suppressed viral load are not infectious. PreP is discussed on page 1449.

**Towards cure**

Current therapy, although effective, is life-long, expensive and complex. There is increasing interest in the possibilities of a cure for HIV: either a ‘functional’ cure, which would mean long-term control of the virus without the use of drugs, or a ‘sterilizing’ cure, which would require all HIV-containing cells to be eliminated. Several reports of successful interventions exist. These include two patients with HIV infection who underwent stem-cell transplants for treatment of coexisting malignancies, as well as aggressive interventions very early in the course of the infection, which may allow immune function to be preserved. Ways are being explored in which latently infected T cells could be purged. The possibilities are being studied of making cells resistant to new HIV infection, using gene manipulation to alter the CCR5 receptor that mediates viral entry into the cell.

Despite some early encouraging results, it is clear that there is still a very long way to go and, at least for the moment, there is no realistic alternative to life-long ART.

**Further reading**

**SPECIFIC CONDITIONS ASSOCIATED WITH HIV INFECTION**

The treatment of opportunistic infections in immunosuppressed patients is most commonly seen either in regions of the world where ART is not available, in previously undiagnosed patients who are diagnosed late and have presented with advanced infection (<200 CD4+ cells/mL), or in patients not adhering to prescribed treatment.

In parallel, the types of infection seen in the context of HIV have altered, with fewer episodes of the ‘classic’ opportunistic infections, such as Pneumocystis pneumonia and cytomegalovirus, but an increase in community-acquired infections such as Strep. pneumoniae and Haemophilus influenzae (Box 37.21).

Immune reconstitution with ART may produce unusual responses to opportunistic pathogens and confuse the clinical picture. Thus, prevention and treatment of opportunistic infections remain integral parts of the management of HIV infection.

**Prevention of opportunistic infection in patients with HIV**

**Avoidance of infection**

Exposure to certain organisms can be avoided in those known to be HIV-positive and immunosuppressed. Attention to food hygiene will reduce exposure to Salmonella, toxoplasmosis and Cryptosporidium, and protected sexual intercourse will reduce exposure to HSV, hepatitis B and C viruses, and papillomaviruses. Cytomegalovirus-negative patients should be given cytomegalovirus-negative blood products. Travel-related infection can be minimized with appropriate advice.

**Immunization strategies**

Guidance on the appropriate use of vaccines in HIV (Box 37.22) is available from BHIVA (see Further reading). Immunization may not be as effective in immunosuppressed HIV-positive individuals.

Hepatitis A and B vaccines should be given to those without natural immunity who are at risk, particularly if there is coexisting liver pathology, such as hepatitis C.

*COPD, chronic obstructive pulmonary disease; CT, computed tomography.*

**Chemoprophylaxis**

In the absence of a normal immune response, many opportunistic infections are hard to eradicate using antimicrobials and the recurrence rate is high. Primary and secondary chemoprophylaxis can be used to reduce the incidence of some opportunistic infections. Advantages must be balanced against the potential for toxicity, drug interactions and cost, with each medication added to what are often complex drug regimens.

- Primary prophylaxis is effective in reducing the risk of *Pneumocystis jiroveci*, toxoplasmosis and MAI.
- Primary prophylaxis is not normally recommended against cytomegalovirus, herpesviruses or fungi.

With the introduction of ART and immune reconstitution, ongoing chemoprophylaxis can be discontinued in those patients with CD4 counts that remain consistently above 200 cells/mm³. In areas where effective ART may not be available, long-term secondary...
**Cryptococcosis**

The most common presentation of cryptococcal infection (see p. 560) in the context of HIV is meningitis, although pulmonary and disseminated infections can also occur. The organism, Cryptococcus neoformans, is widely distributed, often in bird droppings, and is usually acquired by inhalation. The onset may be insidious with non-specific fever, nausea and headache. As the infection progresses, the conscious level is impaired and changes in affect may be noted. Fits or focal neurological presentations are uncommon. Neck stiffness and photophobia may be absent, as these signs depend on the inflammatory response of the host, which, in this setting, is abnormal.

Diagnosis is made on examination of the CSF (perform a CT scan before lumbar puncture to exclude space-occupying pathology). Indian ink staining shows the organisms directly and CSF cryptococcal antigen is positive at variable titre. It is unusual for the cryptococcal antigen to become negative after treatment, although the levels should fall substantially. Cryptococci can also be cultured from CSF and/or blood.

Factors associated with a poor prognosis include a high organism count in the CSF, a low white cell count in the CSF, and an impaired consciousness level at presentation.

Initial treatment is usually with intravenous liposomal amphotericin B (4.0 mg/kg per day) with or without flucytosine as induction, although intravenous fluconazole (400 mg daily) is useful if renal function is impaired or if amphotericin side-effects are troublesome. Steroids should be avoided. Following 2 weeks of intravenous amphotericin/flucytosine, therapy should be continued with fluconazole for up to 8 weeks.

Patients diagnosed with cryptococcal disease should receive ART, starting at approximately 2 weeks after commencement of cryptococcal treatment, to minimize the risk of IRIS. Long-term maintenance therapy with fluconazole should be continued for up
to 1 year and until the viral load is suppressed and the CD4 count is consistently above 100 cells/mm³.

Candidiasis
Mucosal infection with Candida, particularly in the mouth (see p. 559), is common in immunosuppressed HIV-positive patients. Candida albicans is the usual organism, although C. krusei and C. glabrata also occur. Pseudomembranous candidiasis, consisting of creamy plaques in the mouth and pharynx, is easily recognized, but erythematous Candida appears as reddened areas on the hard palate or as atypical areas on the tongue. Angular cheilitis can occur in association with either form. Vulvovaginal Candida may be difficult to treat. Oesophageal Candida infection produces odynophagia (see p. 1172).

Fluconazole or itraconazole is the agent of choice for treatment. Disseminated Candida is uncommon in the context of HIV infection, but if present, fluconazole is the preferred drug; amphotericin, voriconazole or caspofungin can also be used. C. krusei may colonize patients who have been treated with fluconazole, as it is fluconazole-resistant. Amphotericin is useful in the treatment of this infection, and an attempt to type Candida from clinically azole-resistant patients should be made. The most successful strategy for managing HIV-positive patients with candidiasis is effective ART.

Aspergillosis
Infection with Aspergillus fumigatus (see p. 993) is rare in HIV, unless there are coexisting factors, such as lung pathology, neutropenia, transplantation or glucocorticoid use. Spores are air-borne and ubiquitous. Following inhalation, lung infection proceeds to hematogenous spread to other organs. Sinus infection occurs.

Voriconazole is the preferred treatment, with liposomal amphotericin B (3mg/kg i.v. daily) as an alternative. Caspofungin is also effective.

Histoplasmosis, blastomycosis, coccidioidomycosis and Penicillium marneffei infection
These fungal infections are geographically restricted but should be considered in HIV-positive patients who have travelled to areas of high risk. The most common manifestation is with pneumonia, which may be confused with Pneumocystis jirovecii in its presentation (see earlier), although systemic infection is reported, particularly with Penicillium, which can also produce papular skin lesions. Treatment is with amphotericin B.

Protozoal infections
Toxoplasmosis
Toxoplasma gondii (see p. 571) most commonly causes encephalitis and cerebral abscess in the context of HIV, usually as a result of reactivation of previously acquired infection. The incidence depends on the rate of seropositivity to toxoplasmosis in the particular population. High antibody levels are found in France (90% of the adult population). About 25% of the adult UK population is seropositive to Toxoplasma.

Clinical features include a focal neurological lesion and convulsions, fever, headache and possible confusion. Examination reveals focal neurological signs in more than 50% of cases. Eye involvement with chorioretinitis may also be present. In most, but not all, cases of Toxoplasma, serology is positive. Typically, contrast-enhanced CT scan of the brain shows multiple ring-enhancing lesions. A single lesion on CT may be found to be one of several on MRI. A solitary lesion on MRI, however, makes a diagnosis of toxoplasmosis unlikely.

Diagnosis is by characteristic radiological findings on CT and MRI. Single photon emission computed tomography (SPECT) may also be helpful for differentiating toxoplasmosis from primary CNS lymphoma. In most cases, an empirical trial of anti-toxoplasmosis therapy is instituted; if this leads to radiological improvement within 3 weeks, it is considered diagnostic. The differential diagnosis includes cerebral lymphoma, tuberculosis or focal cryptococcal infection.

Treatment is with pyrimethamine for at least 6 weeks (loading dose 200mg, then 50mg daily), combined with sulfadiazine and folic acid. Clindamycin and pyrimethamine or atovaquone may be used in patients allergic to sulphonamide.

ART should be initiated as soon as the patient is clinically stable, approximately 2 weeks after acute treatment has begun, to minimize the risk of IRIS.

Cryptosporidiosis
Cryptosporidium parvum (see p. 573) can cause a self-limiting acute diarrhoea in an immunocompetent individual. In HIV infection it can cause severe and progressive watery diarrhoea, which may be associated with anorexia, abdominal pain, and nausea and vomiting. In the era of ART, the infection is rare. Cysts attach to the epithelium of the small bowel wall, causing secretion of fluid into the gut lumen and failure of fluid absorption. It is also associated with sclerosing cholangitis (see p. 1299). The cysts are seen on stool specimen microscopy using Kinyoun acid-fast stain and are readily identified in small bowel biopsy specimens. Nitazoxanide and paromomycin may have some effect; however, immune restoration with effective ART is the treatment of choice and usually leads to remission.

Microsporidiosis
Enterocytozoon bieneusi and Septata intestinalis are causes of diarrhoea. Spores can be detected in stools using a trichrome or fluorescent stain that attaches to the chitin of the spore surface. ART and immune restoration constitute the treatment of choice and can have a dramatic effect.

Leishmaniasis
Leishmaniasis (see p. 570) occurs in immunosuppressed HIV-positive individuals who have been in endemic areas, which include South America, tropical Africa and much of the Mediterranean. Symptoms are frequently non-specific, with fever, malaise, diarrhoea and weight loss. Splenomegaly, anaemia and thrombocytopenia are significant findings. Amastigotes may be seen on bone marrow biopsy or splenic aspirates. Serological tests exist for Leishmania but they are not reliable in this setting.

Treatment is with liposomal amphotericin, the drug of choice, and ART once the patient is stable. Relapse is common without ART, in which case long-term secondary prophylaxis may be given.

Viral infections
Hepatitis B and C virus co-infection with HIV
Because of the comparable routes of transmission of hepatitis viruses (see pp. 1277 and 1282) and HIV, co-infection is common, particularly in MSM, drug users and those infected by blood products. A higher prevalence of hepatitis viruses is found in those with HIV infection than in the general population. Globally, estimates
suggest that 5–15% of people with HIV have chronic hepatitis B virus (HBV) infection and about one-third have hepatitis C virus (HCV) infection. In the UK, 6.9% of adults with HIV are also estimated to be HBsAg positive. A global epidemic of acute hepatitis C has been observed over the past decade among HIV-positive MSM.

As treatment advances have improved HIV prognosis, hepatitis virus co-infection has become an increasingly significant cause of morbidity and mortality, making the management of HIV and hepatitis co-infection a key aspect of clinical care.

All those with newly diagnosed HIV should be screened for hepatitis A, B and C; for those without evidence of immunity, hepatitis A and B vaccines should be provided.

Patients with HIV and hepatitis co-infection are more likely to have rapid liver disease progression than people with mono-infection. In all patients with chronic HCV/HIV and HBV/HIV infections, liver disease should be staged (see p. 1275). For those who are likely to have cirrhosis, appropriate monitoring for complications of portal hypertension and HCV screening should be performed. Patients with HIV and liver disease should be jointly managed by clinicians from HIV and hepatitis backgrounds. For people with end-stage liver disease, care should be based in specialist centres, ideally with links to a transplant unit.

In co-infected patients, the hepatotoxicity associated with certain ARVs may be potentiated. Advice on alcohol use and safer sexual practices should be given to all co-infected patients.

**Hepatitis B infection**

Hepatitis B infection (see p. 1277) does not appear to influence the natural history of HIV or responses to anti-HIV treatment; however, in HIV co-infected patients, there is a significantly reduced rate of hepatitis B e antigen (HBeAg) clearance, the HBV viral load is higher, and the risk of developing chronic infection is increased. In those with resolved or controlled hepatitis B infection, disease may reactivate. Liver disease occurs most commonly in those with high HBV DNA levels indicative of continuing replication. In HBV infection, detection and quantification of HBV DNA act as a marker of viral activity and are predictive of response to treatment. Baseline HBV resistance testing may guide interventions in those previously exposed to antiviral drugs.

Decisions about whether HBV and/or HIV require treatment must be based on assessment of both viruses. All treatments for HBV that include agents with concomitant anti-HIV activity, including tenofovir and emtricitabine, must be used within an effective anti-HIV regimen. UK guidelines recommend that ART inclusive of anti-HBV-active agents should be initiated in all co-infected patients with a CD4 count of less than 500 cells/mm$^3$, with evidence of fibrotic liver damage or with active HBV replication. Patients with a CD4 of 500 cells/mm$^3$ or more, an HBV DNA of less than 2000 IU/mL, and minimal or no evidence of fibrosis can be given the option to commence treatment or to be monitored not less than 6-monthly with HBV DNA and measurement of alanineaminotransferase (ALT), and at least yearly for evidence of fibrosis. Initiation of ART may result in a flare of HBV, resulting from the improved immune function.

**Hepatitis C infection**

Hepatitis C is associated with more rapid progression of HIV infection and the CD4 responses to ART in co-infected patients may be blunted. Hepatitis C progression is both more likely and more rapid in the presence of HIV infection, and the hepatitis C viral load tends to be elevated. The drug-related hepatotoxicity may be worse in those with HCV co-infection. Assessment of co-infected patients requires full clinical and laboratory evaluation and staging of both infections. For HCV, both viral load and genotype will influence therapeutic decision-making.

**Treatment** is a rapidly changing and complex field with the arrival of potent direct-acting antivirals (DAAs) for the treatment and cure of hepatitis C.

All HIV/HCV co-infected patients should commence ART. If HCV therapy is planned, ART should be started first in most instances, ideally 4–6 weeks before starting treatment for HCV.

The drug options for treatment of HCV in individuals with co-infection are similar to the choices for those infected with HCV alone (see p. 1283), and are dependent on stage of disease, HCV genotype and co-administered ART. The introduction of DAAs for HCV has changed the treatment landscape. The latest HCV agents are given for 12 weeks, with response rates of more than 90%.

When DAAs are chosen, there is some restriction on ARV choice due to drug-drug interactions. Careful selection of the most effective combination of antivirals is required and expert opinion should be sought. Online information resources (see Further reading) provide data on possible interactions.

All those with HIV/HCV co-infection who defer treatment should undergo hepatic elastography (see p. 1270) or an alternative non-invasive form of monitoring at least annually.

**Acute hepatitis C** has increased in people with HIV, particularly MSM, and recognized epidemics have been reported in a number of countries, including the UK. UK guidelines recommend that patients without a decrease of $>2$ log$10$ in HCV RNA at week 4 post diagnosis of acute infection, or with a positive HCV RNA at week 12 post diagnosis of acute infection, be offered therapy. Immune responses to HCV do not protect against re-infection, and high rates of re-infection have been reported following both therapeutic and spontaneous clearance. Patients who initially clear HCV but have evidence of re-emergent virus should be assessed for relapse or re-infection; relapse is treated as for chronic HCV and re-infection is managed as for acute hepatitis C.

**Cytomegalovirus infection**

Cytomegalovirus (CMV, see p. 524) has been the cause of considerable morbidity and mortality in HIV-positive individuals, especially in the later stages of disease when the CD4 count is consistently below 100 cells/mm$^3$. The availability of ART has dramatically altered the epidemiology, as a majority of patients start ARVs before they are at risk for CMV disease. The major problems encountered are retinitis, colitis, oesophageal ulceration, encephalitis and pneumonitis. CMV infection is associated with an arteritis, which may be the major pathogenic mechanism. CMV also causes polyradiculopathy and adrenalitis.

**CMV retinitis**

This occurs once the CD4 count is below 50 cells/mm$^3$. Although usually unilateral to begin with, the infection may progress to involve both eyes. Presenting features depend on the area of retina involved (loss of vision being most common with macular involvement) and include floaters, loss of visual acuity, field loss and scotomata, orbital pain and headache.

Examination of the fundus (Fig. 37.13) reveals haemorrhages and exudates, which follow the vasculature of the retina (so-called ‘pizza pie’ appearances). The features are highly characteristic and the diagnosis is made clinically. Retinal detachment and papillitis may occasionally occur. If untreated, retinitis spreads within the eye, destroying the retina within its path. Routine fundoscopy should be carried out on all HIV-positive patients to look for evidence of early infection. Any patient with symptoms of visual disturbance should
have a thorough examination with pupils dilated; if no evident pathology is seen, a specialist ophthalmological opinion should be sought.

Treatment for CMV should be started as soon as possible, with either oral valganciclovir (900 mg twice daily), intravenous ganciclovir (5 mg/kg twice daily) or intravenous foscarnet (90 mg/kg twice daily), given for at least 3 weeks or until retinitis is quiescent. If immunosuppression is not reversed, reactivation is common, leading to blindness. The major side-effect of ganciclovir is myelosuppression, and foscarnet is nephrotoxic. Maintenance therapy may be required until ART is instituted and has improved immune competence. Valganciclovir, an oral prodrug of ganciclovir, has some long-term benefit when used as maintenance therapy, but a lower efficacy than intravenous ganciclovir. Ganciclovir can be given directly into the vitreous cavity but regular injections are required. A sustained-release implant of ganciclovir can be surgically inserted into the affected eye. Cidofovir is available for use when the drugs described are contraindicated. It has renal toxicity.

CMV gastrointestinal conditions
CMV colitis usually presents with abdominal pain, often generalized or in the left iliac fossa, diarrhoea that may be bloody, generalized abdominal tenderness and a low-grade fever. Dilated large bowel may be seen on abdominal X-ray. Sigmoidoscopy shows a friable or ulcerated mucosa; histology shows the characteristic ‘owl’s eye’ cyttoplasmic inclusion bodies (see Fig. 20.14).

Treatment is with intravenous ganciclovir (5 mg/kg twice daily) for 14–28 days; when the patient is stable, optimization of ART improves symptoms and the histological changes are reversed. Restoration of immune competence with ART removes the need for maintenance therapy.

Other sites along the gastrointestinal tract are also prone to CMV infection: for example, ulceration of the oesophagus, usually in the lower third, causes odynophagia. CMV can also cause hepatitis.

CMV neurological conditions
CMV encephalopathy has clinical similarities to that caused by HIV itself, although it tends to be more aggressive in its course. CMV polyradiculopathy can affect the lumbosacral roots, leading to muscle weakness and sphincter disturbance. The CSF demonstrates an increase in white cells, which, surprisingly, are almost all neutrophils. Although progression may be arrested by anti-CMV medication, functional recovery may not occur. Diagnosis may be based on MRI and CSF PCR. Treatment is with ganciclovir. ART should be started after anti-CMV treatment.

Herpesvirus infection
Herpes simplex primary infection (see p. 1421) occurs with greater frequency and severity, presenting in an ulcerative rather than vesicle form in profoundly immunosuppressed individuals. Genital, oral and occasionally disseminated infection is seen. Viral shedding may be prolonged in comparison with immunocompetent patients.

Varicella zoster virus infection
Varicella zoster can occur at any stage of HIV but tends to be more aggressive and longer-lasting in the more immunosuppressed patient. Multidermatomal zoster may occur.

Treatment with aciclovir is usually effective. Frequent recurrences need suppressive therapy. Aciclovir-resistant strains (usually due to thymidine kinase-deficient mutants) in HIV-positive patients have become more common. Such strains may respond to foscarnet.

Herpesvirus 8 (HHV-8) is the causative agent of Kaposi’s sarcoma (see p. 1448).

Epstein–Barr virus infection
Patients with HIV have been shown to have high levels of Epstein–Barr virus (EBV) colorization (see p. 524). There are increased EBV titres in oropharyngeal secretions and high levels of EBV-infected B cells. The normal T-cell response to EBV is depressed in HIV. EBV is strongly associated with primary cerebral lymphoma and non-Hodgkin lymphoma (see later). Oral hairy leukoplakia caused by EBV is a sign of immunosuppression first noted in HIV but now also recognized in other conditions. It appears intermittently on the lateral borders of the tongue or the buccal mucosa as a pale, ridged lesion. Although it is usually asymptomatic, patients may find it unsightly and occasionally painful. The virus can be identified historically and on electron microscopy. There is a variable response to treatment with aciclovir.

Human papillomavirus infection
Human papillomavirus (HPV; see p. 672) produces genital, plantar and occasionally oral warts, which may be slow to respond to therapy and recur repeatedly. HPV is associated with the more rapid development of cervical and anal intraepithelial neoplasia, which in time may progress to squamous cell carcinoma of the cervix or rectum in HIV-positive individuals. HPV vaccination should be given (see p. 530).

Polyomavirus infection
JC virus, a member of the papovavirus family, which infects oligodendrocytes, causes progressive multifocal leucoencephalopathy (PML, see p. 529). This leads to demyelination, particularly within the white matter of the brain. The features are of progressive neurological and/or intellectual impairment, often including hemiparesis or aphasia. The condition is usually inexorably progressive but a stuttering course may be seen. Radiologically, the lesions are usually multiple and confined to the white matter. They do not enhance with contrast and do not produce a mass effect. MRI (Fig. 37.14) is more sensitive than CT and reveals enhanced signal on T2-weighted images of the lesions. MRI appearances and JC virus detection by PCR in a CSF sample are usually sufficient for diagnosis and avoid the need for a tissue diagnosis requiring brain biopsy. There is no specific treatment. Effective ART is the only intervention that has been shown to deliver both clinical and radiological remission.
Bacterial infections

Bacterial infection in HIV is common. Cell-mediated immune responses normally control infection against intracellular bacteria, such as mycobacteria. The abnormalities of B-cell function associated with HIV lead to infections with encapsulated bacteria, as reduced production of IgG2 cannot protect against the polysaccharide coat of such organisms. These functional abnormalities may be present well before there is a significant decline in CD4 numbers and so bacterial sepsis may be seen at early stages of HIV infection. *Strep. pneumoniae*, *H. influenzae* and *Moraxella catarrhalis* infections are examples. Bacterial infection is often disseminated and, although usually amenable to standard antibiotic therapy, may reoccur. Long-term prophylaxis is required if recurrent infection is frequent.

*Mycobacterium tuberculosis* infection

Many parts of the world that have a high prevalence of tuberculosis (TB, see p. 967), such as Africa, also have high rates of HIV infection, both of which are increasing. The respiratory transmission of TB means that both HIV-positive and HIV-negative people are being infected. TB can cause disease when there is only minimal immunosuppression and thus often appears early in the course of HIV infection. HIV-related TB frequency represents reactivation of latent TB, but there is also clear evidence of newly acquired infection and hospital-acquired spread in HIV-positive populations.

The pattern of disease differs with immunosuppression:

- Patients with relatively well-preserved CD4 counts have a clinical picture similar to that seen in HIV-negative patients with pulmonary infection.
- In more advanced HIV disease, atypical pulmonary presentations occur, which are often extrapulmonary, affecting lymph nodes, bone marrow or liver. TB bacteraemia may be present.

**Diagnosis** depends on demonstrating the organisms in appropriate tissue specimens. The response to tuberculin testing is blunted in HIV-positive individuals and is unreliable. Sputum microscopy may be negative, even in pulmonary infection, and culture techniques are the best diagnostic tool.

*M. tuberculosis* infection usually responds well to standard treatment regimens, although the duration of therapy may be extended, especially in extrapulmonary infection. Multidrug-resistant and extensive drug-resistant TB (see p. 971) is a problem, particularly in the USA, where it is developing into a health danger. Cases from HIV units in the UK have been reported. Compliance with anti-tuberculous therapy needs to be emphasized. Treatment of TB (see later) is not curative and long-term isoniazid prophylaxis may be given. In patients from TB-endemic areas, primary prophylaxis may prevent the emergence of infection.

**Drug–drug interactions** between anti-retroviral and anti-tuberculous medications are complex and are a consequence of enzyme induction or inhibition. Rifampicin is a potent inducer of cytochrome P450, which is also the route for metabolism of anti-HIV PIs. Using both drugs together results in a reduction in circulating PI with reduced efficacy and increased potential for drug resistance. Some PIs themselves block cytochrome P450, which leads to potentially toxic levels of rifampicin and problems such as uveitis and hepatotoxicity. The NNRTI class also interacts variably with rifamycins, requiring dose alterations. Additionally, there are overlapping toxicities between ART regimens and anti-tuberculous drugs: in particular, hepatotoxicity, peripheral neuropathy and gastrointestinal side-effects. Rifabutin has a weaker effect on cytochrome P450 and may be substituted for rifampicin. Dose adjustments must be made for drugs used in this situation to take account of these interactions.

**Paradoxical inflammatory reactions** (IRIS, see p. 1440), which can include exacerbation of symptoms, new or worsening clinical signs, and deteriorating radiological appearances, have been associated with the improvement of immune function seen in HIV-positive patients starting ART in the face of *M. tuberculosis* infection. They are most commonly seen in the first few weeks after initiation of ART in patients recovering from TB and can last several weeks or months. The syndrome does not reflect inadequate TB therapy and is not confined to any particular combination of ARVs. It is vital to exclude new pathology in this situation. However, delaying ART increases the risks of further opportunistic events. Allowing at least 2 weeks of anti-tuberculous therapy before commencing ART allows some reduction in the burden of mycobacteria. If the CD4 count is below 100 cells/mm³, then ARVs should be started at about 2 weeks of anti-tuberculous medication. If the CD4 count is over 200 cells/mm³, initiation of ART may be delayed for at least 6 weeks after the start of anti-tuberculous therapy.

*Mycobacterium avium-intracellulare* infection

Atypical mycobacteria, particularly *M. avium-intracellulare* (MAI), generally appear only in the very late stages of HIV infection when patients are profoundly immunosuppressed. MAI is a saprophytic organism of low pathogenicity that is ubiquitous in soil and water. Entry may be via the gastrointestinal tract or lungs with dissemination via infected macrophages.

The major clinical features are fevers, malaise, weight loss, anorexia and sweats. Dissemination to the bone marrow causes anaemia. Gastrointestinal symptoms may be prominent with diarrhoea and malabsorption. At this stage of disease, patients frequently have other concurrent infections, so differentiating MAI is difficult on clinical grounds. Direct examination and culture of blood, lymph node, bone marrow or liver indicate the diagnosis most reliably.

MAI is typically resistant to standard anti-tuberculous treatments, although ethambutol may be useful. Drugs such as rifabutin in combination with clarithromycin or azithromycin reduce the burden of organisms and, in some, ameliorate symptoms. A common combination is ethambutol, rifabutin and clarithromycin. Addition of amikacin to a drug regimen may produce a good symptomatic response. Primary prophylaxis with rifabutin or azithromycin may delay the appearance of MAI, but no corresponding increase in survival has been shown.

Fig. 37.14 MRI scans showing progressive multifocal leucoencephalopathy.
**Infections due to other organisms**

*Influenza virus A (IVA)* is no more frequent in HIV-positive people, but has been associated with an increased severity and complication rate, in particular when CD4 counts are low. Oral oseltamivir 75mg twice daily for 5 days should be used as treatment. People with HIV should be vaccinated annually against IVA. Prophylaxis with oseltamivir is used in unvaccinated individuals with a CD4 count below 200 cells/mm³.

*Salmonellae* (non-typhoidal, see p. 540) are much less frequent pathogens in HIV infection if effective ART is being used. They are able to survive within macrophages, this being a major factor in their pathogenicity. Organisms are usually acquired orally and frequently cause disseminated infection. Gastrointestinal disturbance may be disproportionate to the degree of dissemination, and once the pathogen is in the bloodstream, any organ may be infected. *Salmonella* osteomyelitis and cystitis have been reported. Diagnosis is from blood and stool cultures. Despite increasing reports of resistance, a majority of isolates are sensitive to oral ciprofloxacin 500mg twice daily for 5 days. Education on food hygiene should be provided.

**Skin conditions**, such as folliculitis, abscesses and cellulitis, are common and are usually caused by *Staph. aureus*. Periodontal disease, which may be necrotizing, causes pain and damage to the gums. It is more common in smokers but no specific causative agent has been identified. Therapy is with local debridement and systemic antibiotics.

*Strongyloides* (see p. 577), a nematode found in tropical areas, may cause a hyper-infection syndrome in HIV-positive patients. Larvae are produced, which invade through the bowel wall and migrate to the lung and occasionally to the brain. Albendazole or ivermectin may be used to control infection. Gram-negative septicaemia can develop.

**Scabies** (see p. 674) may be much more severe in HIV infection. It may be widely disseminated over the body and appear as atypical, crusted papular lesions known as ‘Norwegian scabies’, from which mites are readily demonstrated. Superadded staphylococcal infection may occur. Treatment with conventional agents, such as lindane, may fail and ivermectin has been used to good effect in some patients.

**Neoplasms**

HIV infection is associated with an increased risk of cancer, the most tightly linked being Kaposi’s sarcoma, non-Hodgkin lymphoma and cervical cancer, which are AIDS-defining illnesses. Other cancers that have an association with infectious agents, such as liver and anal cancer and Hodgkin lymphoma, although not AIDS-defining, are significantly more common in HIV-positive patients. Patterns are changing and there has been a marked reduction in AIDS-defining malignancy in association with effective ART. The increased longevity of people with HIV increases the risks for development of cancers that are associated with older age. Some data suggest that ART may provide some prevention benefits for non-AIDS-defining malignancies.

**Kaposi’s sarcoma**

Kaposi’s sarcoma (KS, see p. 692) in association with HIV (epidemic KS) behaves more aggressively than that associated with HIV-negative populations (endemic KS). The incidence has fallen significantly since the introduction of ART. Human herpesvirus 8 (HHV-8) is involved in the pathogenesis. KS skin lesions are characteristically pigmented and well circumscribed, occurring in multiple sites. KS is a multicentric tumour consisting of spindle cells and vascular endothelial cells, which together form slit-like spaces in which red blood cells become trapped. This process is responsible for the characteristic purple hue of the tumour. In addition to the skin lesions, KS affects lymphatics and lymph nodes, the lung and gastrointestinal tract, giving rise to a wide range of symptoms and signs. Most patients with visceral involvement also have skin or mucous membrane lesions. Visceral KS carries a worse prognosis than disease confined to the skin. KS is seen around the eye (Fig. 37.15), particularly in the conjunctivae, which can cause periorbital oedema.

ART leads to regression of lesions. Local radiotherapy gives good results in skin lesions and is helpful in lymph node disease. In aggressive disease, systemic chemotherapy is indicated.

**Lymphoma**

A significant proportion of patients with HIV develop lymphoma, mostly of the non-Hodgkin, large B-cell type (see p. 401). These are frequently extranodal and often affect the brain, lung and gastrointestinal tract. Many of these tumours are strongly associated with EBV, with evidence of expression of latent gene nuclear antigens such as EBNA 1–6, some of which are involved in the immortalization of B cells and drive a neoplastic pathway. HIV-associated lymphomas are frequently very aggressive. Patients often present with systemic ‘B’ syndromes and progress rapidly, despite chemotherapy. Primary cerebral lymphoma is variably responsive to radiotherapy but overall carries a poor prognosis. Lymphomas occurring early in the course of HIV infection tend to respond better to therapy and carry a better prognosis, occasionally going into complete remission.

**Cervical carcinoma**

Women with HIV are at increased risk of cervical cancer caused by oncogenic subtypes of HPV. Annual cervical cytology is indicated to monitor for pre-malignant changes.

**Further reading**

HIV is now a manageable chronic condition with a life expectancy that can match that of the general population, in those who start effective ART early enough. Initiating treatment when infection is more advanced compromises clinical outcomes, and is the most important predictor of morbidity and mortality. In 2017 in the UK:

- an estimated 8% of people with HIV were undiagnosed
- 43% of people newly diagnosed with HIV were diagnosed late (CD4 count below the threshold to start therapy, <350 cells/mm$^3$)
- 23% had a CD4 count <200 cells/mm$^3$ at the time of diagnosis, putting them at high risk of HIV-associated pathology (see Fig. 37.12).

**Expanding HIV testing**

Expansion of testing is a key intervention to achieve good clinical outcomes and a reduction in the rate of new infections. UK Guidelines on HIV testing from BHIVA and the National Institute for Health and Care Excellence (NICE) include clinical settings in which HIV testing should be universally offered, together with a list of clinical situations and diagnoses (indicator conditions) that are highly predictive of HIV infection and in which HIV testing should be recommended (see Box 37.9). Testing should be recommended for all new registrants in primary care and for patients admitted to acute medical care in areas where HIV seroprevalence is over 2/1000 population.

An increasing array of point-of-care HIV antibody tests are available that are sensitive and specific and easy to use, can test either blood or oral fluids, and give results within minutes. Home sampling approaches, with specimens sent to a central laboratory and results given over the telephone, have been shown to increase testing rates in some populations, and changes in legislation have allowed the sale of home testing kits for HIV in the UK.

However, because of a significant false-positive rate, it is crucial for all reactive point-of-care tests to be followed up with confirmatory serological assays, and for arrangements to be made to ensure that patients who are found to be HIV-positive have rapid routes into specialist care. HIV testing also offers the opportunity for appropriate prevention interventions for people who test HIV-negative.

**Strategies for reducing HIV transmission**

HIV is a completely preventable infection, yet new HIV infection continues to arise. Combinations of behavioural, biomedical and structural approaches are required, with interventions appropriate for the particular population at risk. Models of the epidemic in the UK suggest that a majority of new infections are transmitted from people who are unaware of their HIV status or have recently acquired HIV. Reduction of the high rates of undiagnosed infection through scaling-up of testing and early initiation of effective treatment is therefore central to an effective prevention response.

For those at high risk of acquisition, an additional emphasis on the need for repeat testing is required, as those with early infection and a high viral load are particularly infectious. Vaccine development has been hampered by the genetic variability of the virus and the complex immune response that is required from the host, with disappointing results from trials of candidate agents.

Consistent condom use and education for behaviour change have been key strategies. Provision of clean injecting equipment for people who inject drugs has been successful in those countries where it has been implemented.

Medically performed circumcision has been shown in African studies of HIV-negative heterosexual men to reduce the female-to-male transmission of HIV by at least 50%. A more modest reduction in HIV incidence in HIV-negative women following circumcision of HIV-positive male partners has been demonstrated but only at 2 years after the procedure.

Use of effective ART by people with HIV has been demonstrated to reduce onward transmission substantially: for instance, the Partner and Partner 2 studies reported zero transmissions during condomless sex from a positive partner on fully suppressive ART to their HIV-negative partner. These data have been used to support the message ‘$U=U$’ (undetectable equals untransmittable) campaign, reinforcing the benefits of testing and early treatment. Partner notification schemes are helpful but can be sensitive and controversial. Availability and accessibility of confidential HIV testing provide an opportunity for individual health education and risk reduction to be discussed.

**Pre-exposure prophylaxis**

The use of ARVs by people who are HIV-negative prior to potential exposure (pre-exposure prophylaxis, PrEP) typically consists of oral tenofovir-emtricitabine (TDF-FTC), taken either daily or on demand prior to potential exposure to HIV. When used consistently, it has been shown to be highly successful and safe, in both MSM and heterosexual men and women, with up to a 90% reduction in the risk of HIV acquisition. On the basis of these results, PrEP, with appropriate safety monitoring, is recommended as an effective HIV prevention strategy; however, work is still ongoing to scale up access for all those who could benefit from PrEP within the National Health Service in England.

**Global strategies**

Understanding and changing behaviour is crucial but notoriously difficult, especially in areas like sex, HIV and AIDS, which carry many taboos. Stigma, poverty, punitive legislation, social unrest and war all contribute to the spread of HIV. Ongoing investment in and prioritization of HIV requires political will – not always readily available – if the progress that has been made is to be sustained.

Bibliography

Obstetric medicine refers to the care of pregnant women with medical problems. These include the 10% of women who enter pregnancy with pre-existing diseases (such as asthma, epilepsy, hypertension and diabetes), as well as those with diseases that arise acutely in pregnancy (such as pneumonia and venous thrombosis).

Obstetric medicine is a new and growing medical specialty, comprised of physicians who specialize in providing care to pregnant women with medical problems, and who increasingly work alongside specialist obstetricians (who have also received specialist training in obstetric medicine), specialist obstetric anaesthetists and midwives. Historically (and currently in many centres without an obstetric physician), this care was provided by general obstetricians alongside general adult physicians. Training programmes in most medical specialties require trainees to learn about the care of patients within the specialty in the context of pregnancy. General practitioners also have a crucial role, as they provide continuity of care before and after the pregnancy.

Special skills necessary for physicians to practise obstetric medicine include:
- an in-depth knowledge of which medications and radiological investigations are compatible with pregnancy and breastfeeding
- the ability to take a detailed obstetric history and a grasp of its relevance to chronic medical disease
- an understanding of how to interpret blood results and other investigations in pregnancy.

Opportunities to learn obstetric medicine may arise by completing training attachments in obstetrics and gynaecology, by attending obstetric medicine multidisciplinary team meetings or clinics, if they exist, and by seeking out pregnant women who are under close surveillance because of coexisting medical problems. There is now a post CCT credential in obstetric medicine available through RCP London.

Prescribing in pregnancy

History
Many symptoms are normal in pregnancy. These include fatigue, nausea, vomiting, palpitations, breathlessness, gastro-oesophageal reflux, constipation and oedema. A careful history is required to discriminate breathlessness due to pathology such as a pulmonary embolism from that which is physiological. Typically, pathological symptoms may arise suddenly, differ from those experienced in previous pregnancies or be particularly severe. Even with significant experience, differentiating pathological from physiological symptoms in pregnancy can be challenging.
Examination

Physiological changes occurring in pregnancy are illustrated in the figure opposite. They contribute to the production of signs accompanying all normal pregnancies, including a relative resting tachycardia of up to 100 beats/min, relative hypotension (a systolic blood pressure of 90 mmHg is not unusual) and oedema.

Investigations

Blood tests need interpreting based on pregnancy normal ranges, which differ from those outside pregnancy because of underlying changes in physiology. Serum creatinine falls below 70 µmol/L, there is a physiological anaemia related to haemodilution, and alkaline phosphatase is raised because of placental production (Box 38.1).

Screening

Healthcare systems vary as to which screening tests are carried out during pregnancy, according to the local prevalence of different diseases and the availability of resources. Box 38.2 describes tests routinely performed in the UK. Clinic appointments are usually made at booking (generally 8–12 weeks’ gestation), and then at 16, 20, 25, 28, 31, 34, 36, 38, 40, 41 and 42 weeks of gestation in healthy women, with fetal ultrasound at 12 and 20 weeks.

Confirmation of pregnancy

- Urine beta-human chorionic gonadotrophin (β-hCG) testing kits are highly sensitive for confirming pregnancy in the context of a missed period (and need not be repeated if a woman has performed a test that has proved positive at home)
- A serum β-hCG level is not used in routine practice for diagnosing pregnancy but is used in managing certain conditions, including ectopic pregnancy and molar pregnancy

Infectious diseases

- Human immunodeficiency virus (HIV), hepatitis B and syphilis are screened for as early as possible in pregnancy so that treatment can be instituted to reduce the risk of transmission to the fetus

Obesity

- Body mass index (BMI) is calculated from height and weight measured at the booking visit
- Lifestyle advice to encourage healthy behaviour is given at this point and repeated throughout pregnancy

Hypertension and pre-eclampsia

- Blood pressure measurement and urine dipstick examination are performed at each antenatal appointment
- Women with hypertension or proteinuria are monitored much more closely; renal and liver function is measured

Anaemia

- A full blood count is measured at booking and at the 28-week visit
- Haemoglobin targets are lower during pregnancy
- General iron, folate and vitamin B₁₂ concentrations are also measured if anaemia is diagnosed

Gestational diabetes mellitus (GDM)

- An oral glucose tolerance test (OGTT) is offered to high-risk women, including those with previous GDM, previous high-birth-weight babies, or a family history of type 2 diabetes

Blood group and Rhesus status

- Blood group is recorded, in case there is a transfusion requirement during labour
- Women who are Rhesus-negative are offered anti-D in the third trimester to prevent formation of Rhesus antibodies (from transfer of Rhesus-positive blood from a Rhesus-positive baby), which may cause haemolytic disease of the newborn in a subsequent pregnancy (see p. 353)

Screening for inherited diseases

- Thalassaemia and sickle-cell screening is offered in all pregnancies to those at high risk; the main purpose is to identify (via partner screening if the woman is a carrier) the risk of disease in the fetus, which can be confirmed by chorionic villous sampling

Screening for fetal chromosomal abnormalities

- See page 15
### Physiological changes in pregnancy

#### Haematology
- ↑ Plasma volume (by 50%)
- ↓ Haemoglobin
- ↓ Platelets
- ↑ Fibrinogen (by 50%)
- ↑ Clotting factors VIII, IX, X
- Venous stasis (L>R)

#### Respiratory
- ↑ Oxygen consumption (by 20%)
- ↑ Minute ventilation (by 40–50%)
- ↑ \( PO_2 \)
- ↓ \( PCO_2 \)
- ↓ Forced vital capacity (third trimester)

#### Cardiac
- ↑ Cardiac output (by 40%)
- ↑ Stroke volume
- ↑ Heart rate (by 10–20 b.p.m.)
- ↓ Blood pressure (↓ in first and second trimesters)
- ↓ Systemic vascular resistance (by 25–30%)
- ↓ Serum colloid osmotic pressure (by 10–15%)

#### Renal
- ↑ Renal blood flow (by 60–80%)
- ↑ Glomerular filtration rate (by 55%)
- ↑ Protein excretion (up to 300 mg / 24 h)
- ↓ Serum creatinine (max = 70 µmol/L)
- Glycosuria
- Physiological hydronephrosis (R>L)

#### Gastroenterology
- ↓ Gut motility
- ↑ Alkaline phosphatase
- ↓ Albumin (by 20–40%)

#### Endocrine
- Impaired glucose tolerance
- Insulin resistance
- ↑ Prolactin (10-fold)
- ↑ Cortisol
- ↑ Renin, angiotensin, aldosterone

#### General
- Fatigue
- Weight gain
- Nausea/vomiting
- Constipation
- Breathlessness
- Palpitations
- Ankle oedema

#### Skin
- Palmar erythema
- Dry skin
- Telangiectasia
- Pruritus (in 20%)
INTRODUCTION

The prevalence of medical conditions that complicate pregnancy is increasing, partly because:

- women in Western countries are delaying childbearing until they are older
- 50% of pregnant women are now overweight or obese, resulting in more patients with diabetes, hypertension and associated co-morbidities
- women with chronic medical diseases, such as congenital heart disease, diabetes, chronic kidney disease (CKD) and cystic fibrosis now survive into their childbearing years because of better medical care
- widening access to assisted conception services, including the use of donor eggs, means that age is no longer a barrier to pregnancy.

Maternal death (during or soon after pregnancy) in the UK is now more often due to medical complications than obstetric ones. Confidential enquiries show that inadequate knowledge and care are implicated in one-quarter of deaths from medical conditions in pregnancy.

The anatomical and physiological changes that occur as an adaptation to normal pregnancy can result in a number of symptoms and signs. These overlap with the clinical features associated with diseases outside pregnancy. Most of the symptoms and signs are benign, but clinicians need to be aware of those that warrant further investigation and may be associated with disease.

Women with pre-existing disease should be made aware of the normal adaptation to pregnancy, as symptoms may worsen or improve, depending on the body system involved. The stress of pregnancy may also result in previously subclinical disease presenting for the first time.

Infectious diseases are a major problem in pregnancy, particularly in low- and middle-income countries (see individual diseases in Chapter 20). There is increased mortality in both the mother and the fetus.

HYPERTENSIVE DISORDERS

During normal pregnancy, there is a reduction in blood pressure due to a fall in systemic vascular resistance; this is maximal by weeks 22–24.

Chronic/pre-existing hypertension

This is present at the initial booking visit or before 20 weeks, or if the patient is already taking medication for hypertension.

Management

- **Angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor blockers (ARBs) and chlorothiazide agents** that are associated with congenital abnormalities should be discontinued.
- **Dietary salt** intake should be kept low (2 g or 100 mmol daily).
- **Aspirin** 75 mg should be given from 12 weeks until birth to women at moderate or high risk of pre-eclampsia (see later).
- **Oral labetalol** is first-line therapy during pregnancy. Second-line agents are methyldopa and nifedipine. Treatment may be required for several weeks postpartum.
- **Target blood pressure** is <135 mmHg systolic and <85 mmHg diastolic. Delivery should be considered after 34 weeks gestation and before 38 weeks gestation. Difficulty controlling the blood pressure is an indication for delivery.

In **breast-feeding**, ACE inhibitors, beta-blockers and nifedipine are safe. Methyldopa should be avoided because of the risk of depression.

Gestational hypertension

This is defined as blood pressure of >140/90 mmHg after 20 weeks’ gestation in a previously normotensive woman.

Investigations and management

- **Blood tests**, including full blood count, serum creatinine and electrolytes, calcium, liver biochemistry and liver function tests.
- Estimated glomerular filtration rate (eGFR) is not validated for use in pregnancy.
- **Blood pressure measurements** once a week.
- **Urine tests** for protein, as there is an increased risk of pre-eclampsia developing.
- **Treatment of moderate hypertension** (159–150/109–100 mmHg) with oral labetalol.
- **Admission to hospital** if blood pressure is ≥160/110 mmHg. Treatment may be required for several weeks postpartum.

Pre-eclampsia

Pre-eclampsia is a common direct (obstetric) cause of maternal and perinatal death, and a significant cause of maternal and neonatal morbidity. The risk factors are shown in Box 38.3. It is a heterogeneous multisystem endothelial disorder that has widespread effects.

There is good evidence that low-dose aspirin is beneficial in patients with a moderate to high risk of developing pre-eclampsia; it is safe in pregnancy and is usually stopped 10 days to 4 weeks before delivery.

Clinical features

Pre-eclampsia varies in severity, timing, progression and order of onset of different clinical features. Symptoms include:

- severe headache
- visual blurring or flashing
- nausea and vomiting
- severe epigastric or right upper quadrant pain
- rapidly progressive oedema of the hands, feet and face.

Signs include new hypertension at more than 20 weeks, oedema and proteinuria (>0.3 g/24 h or urinary protein:creatinine ratio >30 mg/mmol on a ‘spot’ sample); these are the most common manifestations of pre-eclampsia. Hyper-reflexia may be seen.

Pre-eclampsia (including eclampsia) may present ante-, intra- or postpartum. Postpartum disease is more likely to be associated with symptoms. Complications and crises are shown in Box 38.4.
Liver disease

Liver function is not impaired in pregnancy. Any liver disease (see Ch. 34), from whatever cause, can occur incidentally and coincide with pregnancy. For example, viral hepatitis accounts for 40% of all cases of jaundice during pregnancy. Pregnancy does not necessarily exacerbate established liver disease but it is uncommon for women with advanced liver disease to conceive.

The following effects are seen:

- Plasma and blood volumes increase during pregnancy but the hepatic blood flow remains constant.
- The proportion of cardiac output delivered to the liver therefore falls from 35% to 29% in late pregnancy; drug metabolism can thus be affected.
- The size of the liver remains constant.
- Liver biochemistry remains unchanged, apart from a rise in serum alkaline phosphatase from the placenta (up to 3–4 times increased), and a decrease in total protein and albumin concentration owing to increased plasma volume.
- Triglycerides and cholesterol levels rise, and caeruloplasmin, transferrin, α1-antitrypsin and fibrinogen levels are elevated owing to increased hepatic synthesis.
- During pregnancy and particularly postpartum, there is a tendency to hypercoagulability, and acute Budd–Chiari syndrome (see p. 1304) can occur.

There are a number of liver diseases that complicate pregnancy: hyperemesis gravidarum, intrahepatic cholestasis and acute fatty liver.

Hyperemesis gravidarum

Pathological vomiting during pregnancy can be associated with liver dysfunction and jaundice. Liver dysfunction resolves when vomiting subsides.

Intrahepatic cholestasis of pregnancy

This condition of unknown aetiology usually presents with pruritus alone in the third trimester. It has a familial tendency and there is a higher prevalence in Scandinavia, Chile and Bolivia.

Investigations

Liver biochemistry shows raised aminotransferases, which occasionally can be very high. The hallmark is raised serum bile acids but serum bilirubin and gamma-glutamyl transferase (γ-GT) may also be slightly raised. Jaundice is rare. Liver biopsy is not indicated but would show centrilobular cholestasis.

Management and prognosis

Treatment is symptomatic with ursodeoxycholic acid 1–2 g daily in divided doses. Prognosis is usually excellent for the mother but there is increased fetal loss, which has been shown to correlate with higher (>100 μmol/L) bile acid levels. The condition resolves after delivery. Recurrent cholestasis may occur during subsequent pregnancies or with the ingestion of oestrogen-containing oral contraceptive pills.

Acute fatty liver of pregnancy

Acute fatty liver of pregnancy (AFLP) is a rare but serious condition occurring in the third trimester and affecting 1 in 6000–20 000 pregnancies. It is more common in women with multiple gestations. Patients present with abdominal pain, vomiting and jaundice. Polyuria and thirst due to diabetes insipidus may occur because of reduced breakdown of placenta-derived vasopressinase. AKI
and lactic acidosis are commonly seen. In fulminant AFLP patients, encephalopathy, coagulopathy and hypoglycaemia can occur. AFLP may be associated with features of pre-eclampsia.

**Investigations**
- Full blood count.
- Serum electrolytes and creatinine.
- Serum glucose I.
- Serum uric acid ↑.
- Liver biochemistry – shows hepatocellular damage (raised serum aminotransferases and raised bilirubin).
- Coagulopathy.
- Liver biopsy – rarely performed and not necessary for diagnosis but would show fine droplets of fat (microvesicular) in the hepatocytes with a little necrosis.

**Management**
Treatment is as for acute liver failure (see p. 1286). N-acetyl cysteine is safe in pregnancy. Immediate delivery may save both the baby and the mother. Early diagnosis and treatment have reduced the mortality to less than 20%.

## CARDIAC DISEASE

Cardiac disease, both congenital and acquired, is commonly encountered in pregnancy and is mostly benign. Many women experience palpitations and breathlessness due to awareness of physiological sinus tachycardia, ventricular premature/ectopic beats and increased minute ventilation.

Cardiac disease, predominantly acquired, is the most common cause of maternal death in the UK. The main conditions causing severe morbidity and mortality are as follows:
- **Myocardial infarction** in pregnant women is more often due to coronary artery dissection or thrombus than in non-pregnant women. Intervention with primary angioplasty and coronary artery stenting is appropriate.
- **Peripartum cardiomyopathy** is defined as the development of heart failure with left ventricular ejection fraction (LVEF) <45% at the end of pregnancy or in the months following delivery, where no other cause of heart failure is found. It is a dilated cardiomyopathy (see p. 1122) and is more common in obese and multiparous women. It should be treated with conventional heart failure therapy (including thromboprophylaxis), except that ACE inhibitors and ARBs are withheld until after delivery. Nearly half of these patients will recover to normal within 6 months.
- **Pulmonary hypertension** (see p. 115) and fixed pulmonary vascular resistance are dangerous and often (10–20%) fatal in pregnancy.

A number of serious cardiac conditions constituting absolute or relative contraindications to pregnancy are shown in **Box 38.5** and include a dilated aortic root of more than 4.5 cm, severe left heart obstruction from critical mitral or aortic stenosis, and severe impairment of left ventricular function.

Women with significant heart disease need multidisciplinary care in a specialist centre by obstetricians, cardiologists and anaesthetists who have expertise in the care of heart disease in pregnancy. Agreed management plans should be documented.

If pregnancy is contraindicated, then appropriate contraceptive advice is essential. The levels of risk associated with pregnancy for individual conditions are summarized in **Box 38.5**, based on the European Society of Cardiology guidelines.

### Pregnancy and prosthetic heart valves

See page 1103.

**Any strategy for anticoagulation** for a pregnant woman with a mechanical heart valve is associated with risks to the mother and/or fetus. **Pre-pregnancy counselling** is essential, explaining that warfarin is the safest option for the mother but associated with a 5% risk of warfarin embryopathy and increased risks of miscarriage, stillbirth and fetal intracranial haemorrhage. The alternative is full anticoagulant doses of low-molecular-weight heparin (LMWH), given twice daily and titrated upwards in pregnancy, based on regular monitoring of anti-factor Xa levels.

### Further reading
Pulmonary embolism is the most common direct cause of death in pregnancy and the puerperium. Pregnancy and especially the puerperium are associated with a sixfold increased risk of thrombosis. Although the risks are highest after emergency caesarean section, women with risk factors (Box 38.6) are at risk antenatally, especially if admitted to hospital, and after vaginal delivery.

Diagnosis

Objective diagnosis of deep vein thrombosis (DVT) and pulmonary embolism (PE) must be made in those with a suggestive history and risk factors. D-dimers are not useful in pregnancy, as the levels are often raised. DVT is much more common in the left leg (ratio 9:1) than the right in pregnancy because the gravid uterus compresses the left common iliac vein, which lies under the right common iliac artery. Ventilation/perfusion (V/Q) scans and computed tomography pulmonary angiograms (CTPAs) are associated with negligible radiation to the fetus and are safe, but V/Q scans are preferred, as they do not irradiate the maternal breast and increase the risk of breast cancer.

Management

Treatment of venous thromboembolism (VTE) in pregnancy involves:

- larger doses of LMWHs, e.g. enoxaparin
- avoidance of warfarin and new oral anticoagulants
- continuance of LMWH for the rest of the pregnancy and the puerperium.

Decisions regarding thromboprophylaxis in pregnancy relate to past history of VTE, the presence of thrombophilia and other risk factors (see Box 38.6).

Women with previous VTE should receive antenatal and postnatal thromboprophylaxis with LMWH. This should begin as early in pregnancy as possible. LMWH and warfarin are safe in lactating mothers.

Further reading

Respiratory disease

Asthma

The treatment of asthma (see p. 949) in pregnant women does not differ from that in the non-pregnant patient. Pregnancy itself does not usually influence the severity of asthma. For the majority of women, asthma has no adverse effect on pregnancy outcome.

- Poorly controlled severe asthma presents more of a risk to the fetus than the medication used to prevent or treat it. This small risk is minimized with good control.
- Education and reassurance, ideally prior to pregnancy, concerning the safety of asthma medications during pregnancy are integral parts of management.
- Decreasing or stopping inhaled anti-inflammatory therapy during pregnancy causes a deterioration in disease control.
- Inhaled, oral and intravenous steroids, inhaled, nebulized and intravenous short- and long-acting β2-agonists, and the leukotriene receptor antagonist montelukast are safe to use in pregnancy and while breast-feeding. Early data for omalizumab would suggest no adverse effects in pregnancy but there are no pregnancy data available for the newer biologic agents.
- Effective control of the disease process and its accompanying symptoms is a priority. An increase in the dose or frequency of inhaled steroids should be the first step if symptoms are not optimally controlled on the current dose of inhaled steroids and the inhaler technique is good.

Pneumonia

The bacteria that cause pneumonia (see p. 963) are no different in pregnancy. Chest X-rays are safe in pregnancy. Most antibiotics are safe to use in pregnancy and during lactation. Aminoglycosides should not be used unless essential and tetracycline/doxycycline should not be given. Varicella and influenza A pneumonia may be fatal in pregnancy and active steps must be taken to prevent chickenpox infection. Non-immune pregnant women exposed to varicella in pregnancy should be given varicella zoster immunoglobulin (VZIG). If a pregnant woman does contract chickenpox, she should be treated with aciclovir as soon as possible.

All pregnant women should receive immunization against seasonal influenza and influenza A H1N1.

Tuberculosis

Tuberculosis (TB) is particularly common in Asia and Africa. A chest X-ray should be performed if TB is suspected and the advice of a respiratory physician should be sought. Extrapulmonary TB is as common as pulmonary TB in pregnancy. The diagnosis must be confirmed bacteriologically, which may necessitate bronchoscopy or biopsy, which unfortunately is often delayed because of inappropriate reluctance to perform invasive investigations in pregnancy. The neonate should be given bacille Calmette–Guérin (BCG) vaccination.
Sarcoidosis
The course of sarcoidosis is unaltered by pregnancy. Flare-up of the disease is more likely postpartum. Erythema nodosum may occur in a normal pregnancy. Serum ACE is not reliable for the diagnosis of sarcoidosis in pregnancy. Systemic steroids should be used if indicated (see p. 988).

Cystic fibrosis
Women with cystic fibrosis often reach childbearing age with adequate lung function, or will have received a lung transplant and be able to consider pregnancy. Pre-pregnancy counselling, with consideration of lung function and concomitant diabetes, is required. Joint care with a cystic fibrosis centre should be maintained throughout pregnancy. Pregnancy outcome is related to pre-pregnancy lung function. Perinatal outcome is usually good but preterm delivery rates are high. Maternal outcome is variable, and worse in the presence of pulmonary hypertension. Specialist dietary advice with additional energy supplements should be given. Chest physiotherapy can and should be continued in pregnancy and infective exacerbations should be treated aggressively. There is an increased risk of gestational diabetes.

Severe restrictive lung disease
Women with severe lung disease are better able to tolerate pregnancy than women with severe cardiac insufficiency. If the forced vital capacity (FVC) is over 1 L, a successful pregnancy is usually possible but individual assessment is necessary. Immunosuppression for diffuse parenchymal lung disease should be continued in pregnancy. Respiratory diseases complicated by pulmonary hypertension have a poor prognosis in pregnancy.

NEUROLOGICAL DISEASE

Epilepsy
Birth defects
The overall risk of birth defects in babies of mothers who take one antiepileptic drug (AED) is around 7%, compared with 3% in women without epilepsy. The risk with lamotrigine and levetiracetam appears to be low. In most women, the frequency of seizures is not altered in pregnancy, provided there is compliance with AEDs. Free drug levels tend to fall in pregnancy and increased doses of AEDs, particularly lamotrigine, may be required. The risk to the fetus of uncontrolled seizures is greater than the risks of continuing AED treatment; poorly controlled epilepsy and recurrent seizures are associated with adverse outcomes for the fetus, such as an increased risk of sudden unexpected death in epilepsy (SUDEP). If drugs cannot be safely stopped, monotherapy is preferable at the minimum effective dose. Sodium valproate is associated with a higher rate of serious malformations (e.g. neural tube defects) and long-term neurodevelopmental defects (e.g. a reduced IQ, increased risk of autism spectrum disorder and attention deficit disorder, ADHD), and should be stopped or substituted if necessary prior to conception.

Management
Counselling before conception is essential. Folic acid (5 mg/day) supplements should be taken before conception and throughout the first trimester. Antenatal screening for congenital abnormalities is necessary.

Breast-feeding
Mothers taking AEDs need not, in general, be discouraged from breast-feeding, though manufacturers are often hesitant in assuring that there is no risk to the baby.

Contraception
AEDs which induce hepatic enzymes (e.g. carbamazepine, phenytoin and phenobarbital) reduce the efficacy of oral contraceptives. A combined contraceptive pill containing a higher dose of oestrogen or the progesterone-only pill provides greater contraceptive security. An intrauterine device or barrier method of contraception is often used in preference to oral contraceptives.

Migraine
Migraine can occur as a pregnancy-related phenomenon in women without a prior history of migraine. Those with pre-existing migraine often improve in pregnancy. Hemiplegic migraine, particularly aura without headache, can mimic transient ischaemic attacks (TIAs). Ergotamine should be avoided in pregnancy. Sumatriptan may be used to treat migraine. Low-dose aspirin, beta-blockers, tricyclic antidepressants and pizotifen are used for prophylaxis. Greater occipital nerve (GON) injections are safe in pregnancy.

Multiple sclerosis
Pregnancy has no effect on the long-term prognosis of multiple sclerosis. Relapses are less likely during pregnancy but more likely in the postpartum period. Prophylactic treatments, such as interferon beta, glatiramer and natalizumab, are usually avoided in pregnancy and breast-feeding, but benefit may outweigh risk for some women. Discontinuation of natalizumab may result in flare-ups in pregnancy and is not advised, but the injections can be spaced and interrupted in late pregnancy to avoid excessive transfer to the fetus. All women should receive vitamin D supplements of at least 2000 units daily. Those with disability may require extra help during pregnancy and while caring for the infant following delivery. There is no contraindication to epidural anaesthesia, except that documentation of pre-existing neurological deficit in the legs is necessary to avoid any postpartum exacerbation of multiple sclerosis being inappropriately attributed to the regional block.

Myasthenia gravis
The course of myasthenia gravis in pregnancy is unpredictable, but in women with stable disease pregnancy outcome is usually normal. Postpartum exacerbations occur in 30% of women. Usual immunosuppressant therapy with steroids, azathioprine, IVIG and calcineurin inhibitors should be continued. Plasmapheresis is not contraindicated in pregnancy. Increased doses of long-acting anticholinesterases may be required. Many drugs should be avoided in myasthenia gravis and an experienced obstetric anaesthetist should be consulted. Transient neonatal myasthenia gravis may develop in up to 10% of neonates born to myasthenic mothers due to transplacental passage of immunoglobulin G acetylcholine receptor antibodies.

Stroke
The risks of arterial ischaemic stroke, cerebral venous thrombosis and intracranial haemorrhage are increased, particularly in the puerperium. In pregnant women, the prevalence of haemorrhagic stroke equals that of ischaemic stroke, in contrast to non-pregnant women, in whom ischaemic stroke is more common (>75% of strokes). Causes of stroke in pregnancy are listed in Box 38.7.

Sarcoidosis
Cystic fibrosis
Severe restrictive lung disease
Epilepsy
Birth defects
Management
Breast-feeding
Contraception
Migraine
Multiple sclerosis
Myasthenia gravis
Stroke
Depression
Depression in pregnancy and the puerperium is discussed on page 777.

ENDOCRINE DISEASE

Diabetes mellitus
Pre-existing diabetes during pregnancy and gestational diabetes are discussed on page 739.

Thyroid and parathyroid disease

Thyrotoxicosis
Untreated thyrotoxicosis (see p. 614) is dangerous for both the mother and her fetus, increasing the risk of miscarriage, fetal growth restriction and preterm delivery. Graves’ disease affects about 0.2% of pregnancies and often improves during pregnancy, but there is a risk of flare-up postpartum. Both carbimazole and propylthiouracil (PTU) cross the placenta, and in high doses may cause fetal hypothyroidism and goitre. The lowest possible maintenance dose of antithyroid drug should be used. Guidelines advise avoidance of carbimazole in the first trimester, due to the risk of teratogenesis. PTU is usually not given because of the risk of liver failure in the general population, but may be used specifically in women planning pregnancy or in the first trimester. Women do not need to be swapped from one antithyroid drug to another before or during pregnancy; they should remain on whichever drug is controlling their disease. For those with good control of thyrotoxicosis on doses of carbimazole of less than 15mg/day or PTU less than 150mg/day, the maternal and fetal outcome is usually good and unaffected by the thyrotoxicosis. Women may safely breast-feed on these doses of antithyroid drugs. Beta-blockers are safe to use in the short term, if required for control of thyrotoxic symptoms. Neonatal or fetal thyrotoxicosis due to transplacental passage of thyroid-stimulating antibodies is rare, but occurs most commonly in women with active disease in pregnancy and those with high levels of thyroid-stimulating antibodies.

Hypothyroidism
Hypothyroidism (see p. 611) affects about 1% of pregnancies. Untreated hypothyroidism is associated with infertility, an increased rate of miscarriage, and fetal loss. For those on adequate replacement therapy, maternal and fetal outcome is usually good and is unaffected by the hypothyroidism. Very little thyroxine crosses the placenta and the fetus is not at risk of thyrotoxicosis from maternal thyroxine replacement therapy. Provided they are euthyroid at the beginning of pregnancy, most women do not usually require any adjustment to thyroxine dose during pregnancy or in the puerperium. Any dose increase should be based on thyroid function tests, interpreted using reference ranges for pregnancy (4.0mU/L is taken as the upper limit for thyroid-stimulating hormone (TSH) after 7 weeks’ gestation). There is no evidence to support older recommendations for a target TSH of less than 2.5mU/L.

Subclinical hypothyroidism affects 5% of the general population and is more common in women, particularly those who have anti-thyroid antibodies. Studies fail to demonstrate a consistent association between any adverse pregnancy outcome and subclinical hypothyroidism in pregnancy, and there is insufficient evidence that thyroxine replacement in subclinical hypothyroidism benefits pregnancy outcome.

Postpartum thyroiditis is more common in women with a family history of hypothyroidism, thyroid peroxidase antibodies and type 1 diabetes. Presentation is usually between 3 and 4 months postpartum. Disease may present with symptoms of hyper- or hypothyroidism but a high index of suspicion is needed. The condition is caused by a destructive autoimmune lymphocytic thyroiditis. Most patients recover spontaneously and treatment is not always required. Postpartum thyroiditis often recurs and is a significant predictor of future hypothyroidism.

Hyperparathyroidism
Hypercalcaemia may be improved by pregnancy and the fetal demand for calcium. The risks to the mother are from acute pancreatitis and hypercalcaemic crisis, especially postpartum, when maternal transfer of calcium to the fetus stops abruptly. There is an increased risk of miscarriage, intrauterine death and preterm labour. Fetal mortality rates are up to 40% when the maternal hypercalcaemia is severe (>3.5mmol/L). Up to 25% of women with hyperparathyroidism develop hypertension or pre-eclampsia. The risk to the neonate is from tetany and hypocalcaemic convulsions, caused by suppression of fetal parathyroid hormone (PTH) by high maternal calcium levels. Acute neonatal hypocalcaemia usually presents 5–14 days after birth but may be delayed by up to 1 month if the infant is breast-fed. The ideal treatment is surgery and this may be safely performed in pregnancy, though it is usually delayed until the second trimester.

Further reading

Pituitary disease
See page 592.

Prolactinomas
Prolactinomas are the most common pituitary tumours encountered in pregnancy but rarely cause problems. The prolactin level should not be measured during pregnancy, as it is invariably raised. Those with microprolactinomas usually have no problems in pregnancy. The risk of tumour enlargement during pregnancy is increased with macroprolactinomas. Dopamine receptor agonists are safe for use in pregnancy and are usually continued in women with macroprolactinomas. Visual fields should be measured in each trimester in those with macroprolactinomas. If tumour enlargement is suspected, magnetic resonance imaging (MRI) of the pituitary is indicated. If women with macroprolactinomas wish to breast-feed, their dopamine receptor agonists may be discontinued in the last few weeks of pregnancy and during breast-feeding, but serial visual field examinations and pituitary MRI are required, and cabergoline or bromocriptine should be re-introduced if there is concern regarding tumour expansion.

Box 38.7 Some causes of stroke in pregnancy

Ischaemic
- Cardiac causes, e.g. arterial emboli or arrhythmias
- Peripartum cardiomyopathy (see p. 1124)
- Paradoxical embolus (in situations causing increased right atrial pressure compared with left) through an atrial septal defect or patent foramen ovale
- Aortic/carotid artery dissection
- Antiphospholipid syndrome
- Sickle-cell disease

Haemorrhagic
- Pre-eclampsia/eclampsia

Depression
Depression in pregnancy and the puerperium is discussed on page 777.

Hyperparathyroidism
Hypercalcaemia may be improved by pregnancy and the fetal demand for calcium. The risks to the mother are from acute pancreatitis and hypercalcaemic crisis, especially postpartum, when maternal transfer of calcium to the fetus stops abruptly. There is an increased risk of miscarriage, intrauterine death and preterm labour. Fetal mortality rates are up to 40% when the maternal hypercalcaemia is severe (>3.5mmol/L). Up to 25% of women with hyperparathyroidism develop hypertension or pre-eclampsia. The risk to the neonate is from tetany and hypocalcaemic convulsions, caused by suppression of fetal parathyroid hormone (PTH) by high maternal calcium levels. Acute neonatal hypocalcaemia usually presents 5–14 days after birth but may be delayed by up to 1 month if the infant is breast-fed. The ideal treatment is surgery and this may be safely performed in pregnancy, though it is usually delayed until the second trimester.

Further reading

Pituitary disease
See page 592.

Prolactinomas
Prolactinomas are the most common pituitary tumours encountered in pregnancy but rarely cause problems. The prolactin level should not be measured during pregnancy, as it is invariably raised. Those with microprolactinomas usually have no problems in pregnancy. The risk of tumour enlargement during pregnancy is increased with macroprolactinomas. Dopamine receptor agonists are safe for use in pregnancy and are usually continued in women with macroprolactinomas. Visual fields should be measured in each trimester in those with macroprolactinomas. If tumour enlargement is suspected, magnetic resonance imaging (MRI) of the pituitary is indicated. If women with macroprolactinomas wish to breast-feed, their dopamine receptor agonists may be discontinued in the last few weeks of pregnancy and during breast-feeding, but serial visual field examinations and pituitary MRI are required, and cabergoline or bromocriptine should be re-introduced if there is concern regarding tumour expansion.
Diabetes insipidus
Established or subclinical diabetes insipidus (DI, see p. 641) may worsen in pregnancy due to increased vasopressinase production by the placenta, or decreased vasopressinase breakdown by the liver. Extended fluid deprivation tests should be avoided in pregnancy and close observation with paired urine and plasma osmolality measurements may be sufficient to exclude DI. Desmopressin is safe for use in pregnancy for diagnosis or treatment of DI. Transient DI may occur in pregnancy and is often associated with acute fatty liver of pregnancy and, more rarely, with pre-eclampsia and HELLP syndrome (see p. 1455).

Hypopituitarism
Hypopituitarism (see p. 595) is rare in pregnancy but may be caused by:
- pituitary surgery
- radiotherapy
- pituitary or hypothalamic tumours
- pituitary haemorrhage
- postpartum pituitary infarction (Sheehan’s syndrome)
- lymphocytic hypophysitis.

Sheehan’s syndrome usually presents after delivery following postpartum haemorrhage and may lead to partial or complete pituitary failure. There may be a delay in diagnosis, as the symptoms may be attributed to the postpartum state. Lymphocytic hypophysitis is an uncommon autoimmune disorder due to extensive infiltration of the anterior pituitary by chronic inflammatory cells, predominantly lymphocytes, causing pituitary expansion. Anti-pituitary antibodies have been described and this condition is associated with autoimmune thyroiditis or adrenals in 20% of cases. It is most common in late pregnancy and the postpartum period. It presents with features suggestive of an expanding pituitary tumour and 85% of cases have endocrine hypofunction.

Adrenal disease
See also page 598.

Conn’s syndrome and hyperaldosteronism
This is rare in pregnancy but hypertension, particularly in the absence of a positive family history, and hypokalaemia are indications for screening. High levels of progesterone in pregnancy may antagonize aldosterone and ameliorate the hypokalaemia. Renin and aldosterone levels are increased in pregnancy, and diagnosis requires the use of pregnancy-specific normal ranges. Hypertension is controlled in the usual way with labetalol, methyldopa or nifedipine, and hypokalaemia is treated with potassium supplementation or potassium-sparing diuretics. Amiloride is safe to use in pregnancy and high doses (e.g. 20 mg) may be needed. Spironolactone, which is used as a potassium-sparing diuretic in Conn’s syndrome outside pregnancy, should be avoided: it may cause feminization of a male fetus because it is an antiandrogen. Surgery for adrenal adenomas can usually be safely deferred until after delivery.

Phaeochromocytoma and paraganglioma
Phaeochromocytoma and paraganglioma (see p. 608) are rare but dangerous causes of hypertension in pregnancy. Women with hypertension associated with unusual features of palpitations, anxiety, sweating or headache should be screened. Management involves adequate α-blockade with phenoxybenzamine to control hypertension, followed by β-blockade, if required, to control tachycardia. Alpha-blockade is imperative prior to delivery. Surgical removal is the only cure, and optimal timing of tumour resection depends on the point of gestation at which the diagnosis is made. There is an increasing vogue to delay tumour resection until the puerperium.

RENAL DISEASE

Urinary tract infection
See page 1381.

Bacteriuria in pregnancy
The urine of all pregnant women must be cultured, as 2–6% have asymptomatic bacteriuria. While asymptomatic bacteriuria in the non-pregnant female seldom leads to acute pyelonephritis and often does not require treatment, acute pyelonephritis frequently occurs in pregnancy under these circumstances. Failure to treat may thus result in severe symptomatic pyelonephritis later in pregnancy, with the possibility of preterm labour. Therefore, bacteriuria must always be treated and be shown to be eradicated. Re-infection may require prophylactic therapy. Tetracycline, sulphonamides and 4-quinolones must be avoided in pregnancy. Trimethoprim should be avoided in the first trimester. Amoxicillin, nitrofurantoin and cephalosporins may safely be used in pregnancy.

Chronic kidney disease
Women with CKD are at increased risk of pre-eclampsia, fetal growth restriction (FGR), preterm delivery and caesarean section; their perinatal mortality rate is increased. These obstetric complications and the risk of permanent deterioration in renal function are increased by the presence and severity of any renal impairment or hypertension.

In women with moderate or severe renal impairment (CKD stage 3–5, GFR 15–45 mL/min/1.73 m²), 60–90% of infants are born preterm and there is a risk of accelerated decline in renal function of 20–50% in the mother.

An increase in the degree of proteinuria is very common in pregnancy and does not necessarily imply pre-eclampsia or worsening renal disease.

Management
Management should include regular monitoring of blood pressure, renal function and fetal wellbeing. In view of the increased risk of pre-eclampsia, treatment is with low-dose aspirin (75 mg daily from week 12 to delivery), especially in those with hypertension and renal impairment or a previous poor obstetric history.

Renal transplantation
If graft function is normal, pregnancy outcome is excellent and there is no adverse long-term effect on renal allograft function or survival. The chance of successful pregnancy outcome is reduced and the risk of long-term deterioration in graft function increased with poor baseline graft function. Pregnancy outcome is optimal in those without hypertension, proteinuria or recent episodes of graft rejection.

The doses of immunosuppressive drugs are maintained at pre-pregnancy levels. Prednisolone, azathioprine, ciclosporin and tacrolimus are safe for use in pregnancy without any reported increase in the risk of congenital malformations. Mycophenolate mofetil and sirolimus are contraindicated. Prophylactic antibiotics should be given for recurrent urinary tract infection and to cover any surgical procedure. The risks of pre-eclampsia, graft rejection, FGR, preterm delivery and infection are increased. Caesarean section is required only for obstetric indications but the rate is increased.
Acute kidney injury
Because serum creatinine falls in pregnancy, AKI is defined as an abrupt deterioration in renal function with a serum creatinine of more than 90 μmol/L. Mild degrees of AKI are not uncommon, particularly in the immediate postpartum period. The most common underlying causes are:

- infection: septic abortion, puerperal sepsis, acute pyelonephritis
- blood loss: postpartum haemorrhage, placental abruption
- volume contraction: pre-eclampsia, eclampsia, hyperemesis gravidarum, diarrhoea
- post-renal failure: ureteric damage or obstruction
- drugs: NSAIDs, antibiotics (e.g. aminoglycosides).

Women with pre-eclampsia are particularly prone to pulmonary oedema and therefore management protocols include fluid restriction, even in the presence of oliguria. If these patients develop AKI, this is usually rapidly reversible on recovery and less dangerous than pulmonary oedema, which may result if the AKI is treated with repeated fluid challenges. In this respect, therefore, the management of AKI differs from that outside pregnancy.

SKIN DISORDERS

Common skin changes that occur in pregnancy include striae (see p. 679), spider naevi, melasma (pigmentation on the face) and linea nigra (midline pigmentation on the abdomen). A shift in maternal immune profile from predominantly Th1 to Th2 may underlie the tendency for atopic dermatitis to develop or worsen during pregnancy. Psoriasis usually improves. Up to 20% of pregnant women will develop pruritus, which is most common on the lower legs. Intrahepatic cholestasis (see pp. 1272 and 1455) of pregnancy should be excluded by performing liver function tests and measuring bile acid levels.

The specific dermatoses of pregnancy are classified as shown in Box 38.8.

Further reading

RHEUMATIC DISEASE

Some 50% of women with rheumatoid arthritis go into remission in pregnancy and 50% will flare during the postpartum period. Many disease-modifying anti-rheumatic drugs (DMARDs) are not contraindicated in pregnancy. Women should take advice from their rheumatologist and obstetrician prior to conception. Box 38.9 shows the use of drugs for rheumatoid arthritis in pregnancy.

Further reading

PRESCRIBING IN PREGNANCY

Many clinicians are understandably reluctant to prescribe drugs for pregnant women. This relates mainly to concern regarding teratogenic risk. The following general principles should be remembered:

- Older generic drugs. Use older generic drugs within each class, since there are likely to be more data on use in pregnancy.
- Dosages. Resist the temptation to prescribe lower doses. Pregnant women usually need higher doses because of increased renal and liver clearance.

| Box 38.8 Classification of specific dermatoses of pregnancy |
|-----------------|-----------------|-----------------|
| **Dermatosis** | **Description** | **Management** |
| Atopic eruption of pregnancy | See p. 660 | Topical steroids and oral antihistamines |
| Atopic eczema | Usually starts on abdomen in third trimester but may persist for some months after delivery | |
| Prurigo of pregnancy | Clustered excoriated papules (prurigo-like lesions) occur on abdomen and extensor surfaces of limbs | |
| Pruritic folliculitis of pregnancy | Cause unknown | |
| | Can recur in subsequent pregnancies | |
| | Itchy folliculitis, looks similar to steroid-induced ‘acne’ | |
| Polymorphic eruption of pregnancy (pruritic urticated papules of pregnancy) | A relatively common, intensely itchy rash that starts on abdomen, often within striae, in third trimester | Symptomatic topical therapy and antihistamines helpful until after delivery, when rash resolves |
| | Associated with multiple births | |
| | Uncomfortable but harmless | |
| Pemphigoid gestationis | A rare disease analogous to bullous pemphigoid (see p. 686) | Systemic steroid therapy required |
| | Associated with prematurity and stillbirth; transplacental passage of pathogenic immunoglobulin G (IgG) antibodies can lead to transient blistering in the neonate | |
| | Often starts around umbilicus with itchy, inflamed papules; then blistering appears and eruption may become generalized | |
| | Onset in the first or second trimester; typically flares postpartum | |
| | Diagnosis confirmed with direct immunofluorescence (see p. 686) | |
| | Recurrences may occur with subsequent pregnancies and oral contraceptive pill, which should be avoided | |
• **Disease control.** Control of underlying diseases, such as arthritis, inflammatory bowel disease, epilepsy, asthma and thyrotoxicosis, with appropriate drug therapy is likely to reduce adverse fetal and neonatal outcomes, including preterm birth and growth restriction.

• **Treatment for unfamiliar diseases.** Always ask the specialist physician, ‘What would you do if this woman was not pregnant?’ Then assess the risks of this strategy in pregnancy.

• **Risks to the fetus.** These must be balanced against potential benefits to the mother (and therefore indirectly the fetus).

The **teratogenic potential** of some drugs classified as ‘absolutely contraindicated’ (see Box 12.6) is sufficiently high to justify discussion of termination of a pregnancy following inadvertent exposure: these include mycophenolate mofetil, sodium valproate and thalidomide. For others, there are theoretical reasons to avoid their use in pregnancy, but they carry a low risk of teratogenesis and therefore there is no justification for termination (e.g. rubella vaccine, simvastatin, ACE inhibitors).

For drugs that are *relatively contraindicated*, there are situations in which use is appropriate and where no safer alternative exists: for example, warfarin in women with prosthetic heart valves or AEDs in women with epilepsy.

• **Beta-blockers** should not be used as first-line treatment for hypertension, but may be indicated to control tachyarrhythmias, for migraine prophylaxis, thyrotoxicosis and mitral stenosis, and in those at risk of aortic dissection.

• **Diuretics** should be avoided in the treatment of hypertension but are appropriate in the treatment of pulmonary oedema.

**Further reading**

Women experience specific illnesses related to their physiology and reproductive health, as well as having increased rates of common mental illnesses relative to men. About 1 in 20 women aged between 30 and 49 years consult their doctor each year because of menstrual problems, and 1 in 6 couples experience subfertility. Women in the UK will have a median of 1.8 children in their lifetime and 1 in 3 will have an abortion, although globally there are huge disparities in both of these rates.

The majority of gynaecological disorders are dealt with in primary care; referral is required if initial treatments have been ineffective or are contraindicated, or if gynaecological cancer is suspected. Outpatient services are often provided in one-stop Rapid Access Clinics, which allow a consultation, ultrasound and procedures such as hysteroscopy or colposcopy to be performed on the same day. Specialist clinics often employ specialist nurses to improve continuity of care and perform procedures.

Key skills in women’s health include:

- taking a gynaecological history and performing speculum and bimanual examinations
- understanding contraception: the benefits and risks of different forms, and the physiological effects and drug interactions of hormonal preparations
- being familiar with the presentations of and treatment strategies for the common gynaecological cancers.

Experience of the conditions covered in this chapter can be gained in general gynaecological and antenatal clinics, early pregnancy and emergency gynaecology units, and a multitude of specialist clinics, including those for suspected gynaecological cancers, menopause and fertility disorders.
Ensure that you have a confidential area in which to take a history and conduct an examination. You will need to ask direct but sensitive questions about intimate issues, and women may not feel comfortable talking about these in front of family members or friends (Box 39.1).

### Examination

The vaginal (bimanual) examination and the speculum examination (Fig. 39.1) are crucial for diagnosing the cause of a number of gynaecological symptoms, including vaginal discharge, intra- or postmenopausal bleeding, and dyspareunia. First of all, consider the preliminaries listed in Box 39.2. Because these examinations may represent invasive, intimate and potentially uncomfortable experiences for a woman, it is essential to gain competence on pelvic training simulators.

### Box 39.1 Taking a gynaecological history

#### Periods
- Age when periods began and stopped (if postmenopausal)
- Any significant changes in periods during that time
- Last menstrual period (LMP)
- Heavy or painful periods: most importantly, as perceived by the woman herself, but also gauged by semi-objective measures, e.g. whether she needs to take days off work, and the frequency with which sanitary towels require changing
- Regularity of periods: usual length of cycle and duration of bleeding

#### Pregnancies
- Outcomes of all pregnancies, beginning with the first and working chronologically; ask sensitively, as there may have been adverse outcomes and difficult decisions. Avoid confusing gravida/parity jargon; a chronological list is more useful

#### Medical history
- Past medical and surgical history
- Personal and family history of gynaecological and breast disorders
- Current and past medications: in women of childbearing age, focus on those that can affect pregnancy, e.g. sodium valproate

#### Cervical cancer risk factors
- Uptake of cervical screening: if so, date and outcomes of last screening. N.B. Women in same-sex relationships are also at risk of cervical cancer
- History of human papillomavirus (HPV) vaccination in younger women: introduced in the UK in 2008 for girls aged 12–13; extended to boys of the same age in 2018, chiefly to achieve herd immunity and reduce transmission to women

#### Sexual history
- All sexual partners and types of intercourse in the preceding 6 months
- Any history of sexually transmitted infections (STIs) and pelvic infections
- Current and past use of contraception

#### As appropriate
- Any history of sexual abuse or non-consensual sexual activity:
  - If the abuse or incident occurred recently, a forensic medical examination may be required to collect samples to support future criminal prosecution. An example of good practice exists in London, where the Havens provide a 24-hour service to organize this (see ‘Further reading’)
  - If the abuse or incident occurred some time ago, establish whether the woman has reported it to the police; if not, offer her support to do so now if she wishes. Also consider the need for psychological support
- Any history of female genital mutilation (FGM):
  - Ask all women who have grown up in countries where the practice is widespread, chiefly in Africa and the Middle East. The different types of FGM are listed in Box 39.7; they are linked to various health problems later in life

### Box 39.2 Preliminaries to a vaginal or speculum examination

- Ensure that the environment is comfortable and private.
- Wash your hands.
- Introduce yourself (name and role) to the patient, confirming their details.
- Make sure that a chaperone is present (ideally, a female chaperone should support a male clinician) and record their name in the notes.
- Explain the proposed procedure clearly and answer any questions that the patient may have.
- Obtain explicit consent; explain that the patient may change her mind at any time.
- Ask whether there is any possibility that the patient might be pregnant.
- Put on gloves.
- Ask the patient to remove her underwear and lie on the examination couch with her heels drawn to her buttocks and her knees out to the sides (the modified lithotomy position).
- Provide a sheet or modesty blanket and ensure that the door is closed and locked.
Clinical skills for women’s health

Bimanual examination

- Inspect vulva:
  - Ulcers
  - Vaginal discharge
  - Masses (malignant or abscesses)
- Enter vagina using two lubricated fingers
- Assess vagina (including the fornices) for masses or irregularities
- Assess cervix:
  - Masses
  - Os (open/closed)
  - Pain on palpation – ‘cervical excitation’
- Assess uterus:
  - Place second hand on lower abdomen
  - Use internal fingers in posterior fornix to push uterus upwards and palpate between hands
  - Assess size, shape and position
- Assess adnexa:
  - Place internal fingers into left lateral fornix
  - Place other hand to palpate deeply in left iliac fossa
  - Move internal fingers towards other hand to assess for tenderness and masses
  - Repeat on right
- Close the encounter:
  - Stop examination, remove gloves
  - Offer paper towels and encourage patient to dress
  - Summarize findings and next steps
  - Document procedure and chaperone identity

Speculum examination

- Inspect vulva (see left)
- Insert speculum:
  - Warn patient you will now insert speculum
  - Lubricate speculum (if possible, also warm metal speculums)
  - Part labia using thumb and first finger of non-dominant hand
  - Insert the speculum sideways, rotate 90 degrees once inside (so handle faces upwards)
  - Open speculum blades and visualize cervix
  - Tighten locking nut to hold blades open
- Assess cervix:
  - Os (open/closed)
  - Ulcers
  - Masses
  - Discharge
- Perform any necessary diagnostic procedures:
  - Swabs for conventional culture or nucleic acid amplification tests (NAATs)
  - Smear test for cytology
- Remove speculum:
  - Loosen locking nut
  - Partially close blades, taking care not to trap vaginal wall between blades
  - Rotate 90 degrees and withdraw speculum
- Close the encounter (see left)
- Ensure all samples are sent for appropriate tests

Fig. 39.1 Bimanual and speculum examination.
INTRODUCTION

Women are affected by both general and gender-specific medical problems. They have predictable long-term reproductive healthcare needs and more frequent interactions with health services than men. Some 82% of women born in 1971 will have one or more children during their lives; this has decreased from almost 89% of women born in 1944. In addition to complications relating to pregnancy and childbirth (see Ch. 38), and to genital tract and breast cancers (see p. 1474 and p. 121), women also have a higher lifetime risk of common mental illnesses, anaemia and osteoporosis (see Ch. 25, p. 327 and p. 477).

Women are also adversely affected by domestic violence and sexual violence to a far greater extent than men. These determinants of ill-health and morbidity remain largely unrecognized alongside more general socioeconomic and environmental factors.

THE LIFE COURSE APPROACH

A life course approach (Fig. 39.2) addresses the long-term effects of biological, social and behavioural exposures during gestation, childhood, adolescence and young adulthood on health, wellbeing and disease in later life and across generations. This perspective recognizes that early life events can have an impact on long-term outcomes, that the circumstances of pregnancy can have an impact on the health of the offspring, and that early interventions may reduce the risk and severity of disease.

Women’s reproductive and sexual health needs are largely predictable across their lifespan. The vast majority want to enjoy healthy sexual relationships and to control their own fertility.

Sexual health education

Relationships and sex education became statutory in primary and secondary schools in the UK from September 2019. It provides information on:
- what a healthy relationship should feel like
- consent, empowering girls to say no to unwanted attention and how to seek help if they are concerned
- optimal methods of contraception to avoid unplanned pregnancy
- risks of sexually transmitted infections (STIs, see Ch. 37)
- vaccination and screening programmes to prevent adult disease.

For example, human papillomavirus (HPV) vaccination for girls aged 11–13 years and Chlamydia trachomatis screening for those under 25 are linked to the prevention of cervical cancer, ectopic pregnancy and tubal infertility. These encounters provide early opportunities to discuss the long-term benefits of adopting a healthier lifestyle before embarking on a first pregnancy.

Early sex education has been shown to reduce the teenage pregnancy rate. In the UK, the Teenage Pregnancy Strategy has been an exemplar of sustained, coordinated local and national action and has led to the lowest rate of conceptions in under-18s since 1969, although England’s teenage birth rate remains higher than that in other Western European countries. Teenage mothers have some of the worst obstetric outcomes, besides which 90% drop out of school and 20% become pregnant again in their teenage years.

Pre-pregnancy counselling

Forty per cent of pregnancies in the UK are unplanned and opportunities to provide general preconceptual advice on diet, weight,
exercise, smoking, alcohol use and folic acid intake are often missed until women become pregnant. Pre-pregnancy counselling allows a review of general health and recent medication, and ensures that a management plan for the pregnancy is in place.

The 2018 MBRRACE-UK report into maternal mortality in 2014–16 (see ‘Further reading, p. 1474) highlighted the fact that 68% of women who died were known to have identified pre-existing medical or mental health problems before they became pregnant, and 66% of the increased risk of maternal deaths in the UK could be attributed to these co-morbidities.

Around 20% of women in the UK now remain childless, either by choice or otherwise. A smaller, but growing, number of women are pursuing assisted conception, such as in vivo fertilization (IVF), to overcome their age-related decline in fertility, of which the British Fertility Society has highlighted that few women are aware. These women are at increased risk of serious complications during pregnancy due to medical co-morbidities. Access to IVF is recommended by the National Institute for Health and Care Excellence (NICE) but is currently restricted by many primary healthcare providers; local referral criteria and available funding are a source of inequality.

**The physiological response to pregnancy**

Complications in pregnancy that arise due to a woman’s physiological response to pregnancy can reveal information about her future risk of disease. For example:

- **Pre-eclampsia** and hypertension in pregnancy resolve after delivery but are associated with higher cardiovascular mortality in later life (pre-eclampsia is associated with an odds ratio of 2.0 for cardiovascular disease).
- Roughly 50% of women with gestational diabetes will develop type 2 diabetes within 10 years, and children born of diabetic pregnancies are more likely to develop diabetes. These women should be screened annually for diabetes and placed on a diabetes risk register in primary care.
- **Teenage pregnancies** and premature deliveries repeat across generations.
- Perinatal mental illness affects 1 in 5 women and is the leading direct cause of maternal death up to 1 year postnatally; it is associated with low birth weight and impaired intellectual development, as measured by lower IQ at age 3 years.

Pregnancy should be viewed as the Healthcare Opportunity of Two Lifetimes (HOOTL, Fig. 39.3), which offers major potential for population health gain and is the first step on the way to tackling and interrupting the cross-generational transmission of ill-health.

### The postnatal visit

The postnatal visit is an ideal time to plan future healthcare needs for mother and baby, and can have a positive impact on lifestyle issues such as obesity, exercise, dental health, contraception, smoking and drug misuse. Review of the recent pregnancy will provide valuable information on the risk of future morbidity and provides an opportunity for prevention of diabetes, cardiovascular disease and recurrent pregnancy complications.

### The normal menstrual cycle

**Definitions and some disorders**

- **Puberty** (see p. 632). The mean age of menarche is 12.8 years but it may take several years for the menstrual cycle to establish a regular pattern. The initial cycles are usually anovulatory and frequently unpredictable.
- **Precocious puberty** (see p. 636). This is defined as menses or breast development before the age of 8 years.
- **Delayed puberty** (see p. 636). This is defined as the absence of secondary sex characteristics after 14 years. It may be due to a central defect (including anorexia, excessive exercise, chronic illness or pituitary tumour) or to a failure of gonadal function (Turner’s syndrome, XX gonadal dysgenesis).
- **Amenorrhea** (see p. 628). This is defined as primary in a girl who fails to menstruate by 16 years of age, and secondary when the menses stop for more than 6 months in a normal female who is not pregnant, lactating or menopausal.
- **Menorrhagia**. This is defined as menses with abnormally heavy or prolonged bleeding.
- **Premenstrual syndrome (PMS)** (see p. 772). This is extremely common. In 5–15%, the severity of the progesterone-induced bloating, weight gain, mastalgia, headaches, depression and irritability in the luteal phase are so debilitating that lifestyle and personal relationships are adversely affected. Treatment success, using lifestyle modifications, hormonal preparations, cognitive behavioural therapy, selective serotonin reuptake inhibitors (SSRIs) and surgery, is highly variable.
**Premature ovarian insufficiency (POI)** (see p. 628). This is defined as cessation of periods before 40 years of age and occurs in 1% of women.

**Menopause.** The average age of menopause among Western women is 51 (see below).

**Postmenopausal bleeding (PMB).** The majority of cases of PMB are due to benign atrophic vaginitis and respond to topical oestrogens. Approximately 10% of cases of PMB will have some sort of pathology, such as atypical hyperplasia or cancer, requiring staging and usually surgical clearance of the uterus and ovaries, with or without adjuvant therapy. Investigation is by ultrasound to assess endometrial thickness, proceeding to tissue sampling when it exceeds 3–5 mm. Women on tamoxifen for breast disease may have irregular, thickened and cystic endometrium, and require hysteroscopy and directed tissue biopsy.

### Menopause

The menopause, or cessation of periods, naturally occurs at about the age of 45–55 years. Female life expectancy has increased significantly over the last century, with many women now living into their eighties or nineties. During the fifth decade, follicle stimulating hormone (FSH) concentrations and then luteinizing hormone (LH) concentrations begin to rise, probably as follicle supply diminishes. Oestrogen levels fall and the menstrual cycle becomes disrupted. Most women notice a gradual change to irregular, scanty periods, although sudden amenorrhoea or menorrhagia occurs in some. Eventually, the menopausal pattern of low oestriadiol levels with grossly elevated LH and FSH levels (usually >50 and >25 U/L, respectively) is established. Premature menopause may also occur as a result of surgery, or of radiotherapy to the ovaries, or due to ovarian disease.

### Clinical features

In women over 45 years, the following can be diagnosed without laboratory tests:

- **perimenopause** based on vasomotor symptoms and irregular periods
- **menopause** in women who have not had a period for at least 12 months and are not using hormonal contraception
- **menopause** based on symptoms in women without a uterus

Features of oestrogen deficiency are hot flushes (which occur in most women and can be disabling), vaginal dryness and atrophy of the breasts. There may also be loss of libido, loss of self-esteem, non-specific aches and pains, sleep disturbance, irritability, depression, loss of concentration, and weight gain.

Women show a rapid loss of bone density in the 10 years following the menopause (osteoporosis; see p. 477), and the premenopausal protection against ischaemic heart disease disappears.

### Management

Explanation should include:

- the stages of the menopause
- common symptoms
- lifestyle changes to help general health and wellbeing
- the benefits and risks of treatments
- the long-term implications of menopause

Treatment options include:

- **hormonal,** e.g. hormone replacement therapy
- **non-hormonal,** e.g. clonidine
- **non-pharmaceutical,** e.g. cognitive behavioural therapy.

---

**Box 39.3 Risks and benefits of hormone replacement therapy (HRT)**

<table>
<thead>
<tr>
<th>Potential benefits</th>
<th>Potential risks</th>
</tr>
</thead>
<tbody>
<tr>
<td>Symptomatic improvement in most menopausal symptoms for the majority of women. Oestrogen-deficient symptoms respond well to oestrogen replacement; the vaguer general symptoms may or may not improve. Vaginal symptoms also respond to local oestrogen preparations.</td>
<td>Significant increase in the risk of breast cancer (+26%) but no change in breast cancer mortality. This is primarily a risk of combined oestrogen-progesterone HRT. Some studies suggest that breast cancers diagnosed on HRT are easier to treat effectively.</td>
</tr>
<tr>
<td>Protection against fractures of wrist, spine and hip, secondary to osteoporosis (−24–33%) (see p. 477), owing to protection of predominantly trabecular bone (see p. 473).</td>
<td>Significant increase in the risk of endometrial cancer when unopposed oestrogens are given to women with a uterus.</td>
</tr>
<tr>
<td>Significant reduction in the risk of large bowel cancer (−33%).</td>
<td>Significant increase in the risk of ischaemic heart disease (+29%) and stroke (+41%).</td>
</tr>
<tr>
<td>Possible increase in general wellbeing, although hopes for a reduction in the incidence of Alzheimer’s disease have not been confirmed.</td>
<td>Inconvenience of withdrawal bleeds, unless a hysterectomy has been performed or regimens used that include continuous oestrogen and progesterone.</td>
</tr>
</tbody>
</table>

**Hormone replacement therapy**

Symptomatic patients should usually be treated but the previous widespread use of hormone replacement therapy (HRT) has been thrown into doubt by a number of large prospective studies that have reported in recent years. The overall benefits and risks are dependent on whether oestrogen alone or oestrogen and progesterone are combined, and are summarized in the most recent NICE guidance (Box 39.3). Absolute risks and benefits for individual women clearly depend on their background risk of a specific disease, and there is as yet no evidence on the relative risks of different hormone preparations or routes of administration (oral, transdermal or implant), excepting a lower risk of venous thromboembolism with transdermal preparations. Overall, the Women’s Health Initiative (WHI) study estimated that, over 5 years of treatment, one extra woman in every 100 would develop an illness that would not have occurred, had she not been taking HRT. However, the decision about whether or not a woman takes HRT is now very much an individual one and is based on:

- the severity of the woman’s menopausal symptoms
- her personal risk of conditions that may be prevented or made more likely by HRT
- individual patient choice.

HRT is not recommended purely for prevention of postmenopausal osteoporosis in the absence of menopausal symptoms. **Symptomatic** treatment is the main indication, with the lowest effective dose being given for short-term rather than long-term treatment.

**Selective oestrogen receptor modulators** (SERMs, e.g. raloxifene) offer a potentially attractive combination of positive oestrogen effects on bone and cardiovascular system with no effects on oestrogen receptors of uterus and breast, and a possible reduction in breast cancer incidence; long-term outcome studies are still awaited, however.
The Women’s Health Initiative and Million Women Study suggested an association between longer-term usage of HRT and an increased risk of breast cancer, stroke and venous thromboembolism, but this has recently been challenged. The incidence of ischaemic heart disease increases after the menopause but this is 10 years later than in men.

### Contraception

Control of fertility has positive effects on a woman’s health and wellbeing. Those who lack access to contraceptive methods are at increased risk of mortality and morbidity, due to obstetric complications and the consequences of illegal abortion. More than 30% of maternal deaths and 10% of child mortality can be prevented by ensuring a 2-year interval between each pregnancy.

Women require expert advice about the safest and most suitable methods of contraception available to them at different ages. In general, contraception is extremely safe, although some methods do have rare but serious side-effects. The combined oestrogen–progestogen pill also protects against both ovarian and endometrial cancer, and many hormonal methods help control heavy or painful periods. Barrier methods prevent STIs and protect against cervical cancer.

The efficacy of any contraceptive method depends on how it works and how easy it is to use. A wide choice of contraception options is now available. They include barrier methods (condoms, diaphragms), the combined oestrogen–progestogen or progestogen-only pill, long-acting progestogen injection or implant, and intrauterine systems. Each has its advantages and disadvantages.

### Hormonal contraception

Hormonal contraception (delivered by several routes, including pills, transdermal patches, subdermal implants and intrauterine coils) provides either a combination of oestrogen and progesterone, or progesterone alone, with different risk and benefit profiles:

- **Combined oestrogen and progesterone contraceptives** act to prevent ovulation, make the endometrium hostile to implantation, and alter the cervical mucus. They are highly effective but only if used correctly and consistently. Minor side-effects may lead to discontinuation and include headaches, mood swings, bloating, weight gain and breast tenderness. The more significant risks relate to cardiovascular disease, including venous thromboembolism (three- to fivefold increase), myocardial infarction and stroke (rare). These preparations are contraindicated in many women, including those at high risk of cardiovascular disease and venous thromboembolism.

- **Progestogen-only preparations** avoid the side-effects of oestrogen and are suitable for women who are breast-feeding, are older, are smokers and have cardiovascular risks (hypertension, diabetes). They act on cervical mucus and the endometrium, but higher-dose preparations also inhibit ovulation. Common side-effects include irregular bleeding, simple ovarian cysts, breast tenderness and acne.

Preparations of hormonal contraception include:

#### The combined oral contraceptive pill

The combined oestrogen–progestogen pill is widely used for contraception and has a low failure rate (<1 per 100 woman-years). ‘Pills’ contain 20–40 μg of oestrogen, usually ethinylestradiol, together with a variable amount of one of several progestogens. The mechanism of action is twofold:

- suppression by oestrogen of gonadotrophins, thus preventing follicular development, ovulation and luteinization
- progestogen effects on cervical mucus, making it hostile to sperm, and on tubal motility and the endometrium.

Side-effects of these preparations are shown in **Box 39.4.** Most of the serious ones are rare and are less common with typical modern 20–30 μg oestrogen pills, although evidence suggests that thromboembolism may be slightly more common with ‘third-generation pills’ containing desogestrel and gestodene (approximately 30/100 000 woman-years compared with 15/100 000 on older pills and 5/100 000 on no treatment). While some problems require immediate cessation of the pill, other milder side-effects must be judged against the hazards of pregnancy occurring with inadequate contraception, especially if other effective methods are not practicable or acceptable.

Hazards of the combined pill are increased in smokers, the obese and those with other risk factors for cardiovascular disease (e.g. hypertension, hyperlipidaemia, diabetes), especially in women aged over 35 years (avoid if over 50 years).

#### The ‘mini-pill’

The ‘mini-pill’ (progestogen-only, usually norethisterone) is less effective than the combined pill but is suitable for women who are breast-feeding, are older, are smokers, have other cardiovascular risk factors or cannot tolerate the combined pill because of side-effects such as loss of libido (see **Box 39.4**).

#### Long-acting reversible contraception

Long-acting reversible contraceptive (LARC) methods, such as implants, injectables and intrauterine devices, all have lower failure rates than user-dependent contraception and tend to have better continuation rates as they cannot be easily abandoned. They have also been shown to be more cost-effective than oral contraceptives. LARC methods generally deliver progestosterone-only contraception, and include:

- Subdermal implants (e.g. Nexplanon), which are inserted in the upper arm using local anaesthetic and last for 3 years. They are a highly effective method of long-term contraception and offer a rapid return of fertility after removal. Irregular bleeding is common.
- Injectable (e.g. Depo-Provera), which are given intramuscularly and are effective for 12 weeks. Side-effects include weight gain, irregular periods or amenorrhoea, and delays in return of fertility of up to 6 months.
- Intrauterine systems (e.g. the Mirena coil, which is effective for 5 years—see later).

#### Barrier methods

Condoms, diaphragms, spermicides and sponges, which require users to remember to employ them correctly every time they have sexual intercourse, have the highest failure rates but offer protection against STIs.
Women’s health

Ultrasound findings
PV bleeding ‘late failure’ rate, quoted as 1:2000 and 1:200, respectively. Male sterilization can be carried out under local anaesthetic.

Intrauterine contraceptive devices
Intrauterine contraceptive devices (IUDs) are a highly effective and increasingly popular method of contraception that is independent of intercourse and user compliance. The device is inserted into the uterine cavity by trained healthcare personnel and a thread is left protruding from the cervix into the vagina, which allows the IUD to be removed by traction.

Copper IUDs are cheap, licensed for 5–10 years of use and cause less menstrual disruption than the older plastic models. They have a toxic effect on both egg and sperm before fertilization occurs.

Levonorgestrol-releasing intrauterine systems (e.g. Mirena) are licensed for contraception, the treatment of heavy menstrual bleeding, and use as part of HRT regimens. The duration of use is 3–5 years, depending on the device, during which time many women become amenorrheic. Irregular vaginal spotting is common initially but may resolve. Some women complain of greasier skin, breast tenderness and mood swings but these symptoms often settle with time.

Emergency contraception
Emergency contraception can be used following unprotected intercourse. Levonorgestrol is available over the counter in the UK and needs to be taken within 72 hours. Ulipristal acetate can be used up to 120 hours after intercourse but is available on prescription only. Insertion of a copper IUD within 5 days is highly effective.

Permanent contraception
This may be achieved by male or female sterilization but both carry a late failure rate, quoted as 1:2000 and 1:200, respectively. Male vasectomy can be carried out under local anaesthetic.

Adverse effects and drug interactions of oral contraceptives

- General
  - Weight gain
  - Loss of libido
  - Pigmentation (chloasma)
  - Breast tenderness
  - Increased growth rate of some malignancies

- Cardiovascular
  - Increased blood pressure
  - Deep vein thrombosis
  - Myocardial infarction
  - Stroke (migraine is a risk factor)

- Gastrointestinal
  - Nausea and vomiting
  - Abnormal liver biochemistry
  - Gallstones increased
  - Hepatic tumours

- Nervous system
  - Headache
  - Migraine
  - Depression

- Drug interactions
  - Antibiotics
  - Barbiturates
  - Carbamazepine
  - Phenytion
  - Rifampicin
  - St John’s wort

Common reasons for stopping oral contraceptives.
Reduced contraceptive effect owing to enzyme induction.

Miscarriage
Miscarriage is a pregnancy that ends spontaneously before the fetus reaches a viable gestational age. The term includes all pregnancy losses between the time of conception and 24 weeks of gestation. Sporadic miscarriage is the most common complication of pregnancy and the majority of cases are due to random genetic abnormalities in the embryo or fetus. The incidence of clinically recognized miscarriage is generally quoted as 15–20%, but the total number of very early conceptions that are lost is in the region of 50%. The miscarriage rate decreases with advancing gestation, reaching 10% by 8 weeks and 3% after a heartbeat is seen on ultrasound scan. By 13 weeks (the start of the second trimester), no more than 1% of viable pregnancies are lost.

Maternal age at conception and previous reproductive history are strong and independent risk factors for miscarriage. The risk of fetal loss rises steeply after the age of 35 years, reaching 75% by 45 years, as the increase in poor-quality oocytes leads to chromosomally abnormal conceptions. Delayed childbearing has resulted in increased rates of miscarriage, ectopic pregnancy, stillbirth and other later complications of pregnancy. Less common factors contributing to early pregnancy loss are uterine abnormalities, infections, medical/endocrine disorders and exposure to drugs and chemicals.

The different types of miscarriage can be classified by the clinical presentation and the results of investigations (Box 39.5). Vaginal bleeding in early pregnancy is common and the differential diagnosis includes:
- a threatened, inevitable or incomplete miscarriage
- bleeding from a viable pregnancy
- ectopic pregnancy
- lower genital tract pathology
- trophoblastic disease.

PV, per vaginam.
Sensitive home pregnancy testing kits have identified many biochemical pregnancies that fail to implant successfully and resolve spontaneously as a delayed and/or heavy menstrual period.

A detailed clinical history must be taken and examination performed in women presenting with vaginal bleeding in pregnancy:

- **Speculum examination** (see p. 1464) assesses the state of the cervix and excludes lower genital tract pathology such as cervical polyps or ectropion.
- **Transvaginal ultrasound** determines the location, gestation, nature and viability of the pregnancy. It also offers the woman valuable reassurance if fetal heart activity can be shown.

Bleeding and pain associated with products of conception that are distending the cervical canal can be very severe, and should be promptly removed with sponge forceps. Serial measurements of serum beta-human chorionic gonadotrophin (β-HCG) levels may be necessary when the site of pregnancy is unknown.

Severe pain localized to either iliac fossa and peritonism are suggestive of ectopic pregnancy and may warrant urgent laparoscopic assessment and treatment. However, many ectopic gestations resolve spontaneously by being resorbed or miscarried from the tube into the peritoneal cavity.

**Management**

This depends on clinical presentation and patient choice. Most miscarriages can be managed expectantly, although urgent surgical evacuation may be required if the bleeding becomes heavy.

- **Follow-up urinary pregnancy test or pelvic scan** confirms whether the miscarriage is complete.
- **Prostaglandins** (oral or vaginal misoprostol) to induce uterine contractions and expulsion are cheap and effective.
- **Subsequent surgical evacuation of the uterus** is required for a small number of women.

The recommended first-line management for miscarriage in the UK is expectant for 7–14 days, although the initial choice of strategy depends on the woman’s preference, her risk of haemorrhage, previous adverse events and evidence of infection. Medical management of miscarriage in the UK is with 800 μg misoprostol; mifepristone is no longer routinely used. Surgical management of miscarriage (or evacuation of the retained products of conception, ERPC) can be performed by suction under general anaesthesia or by manual vacuum aspiration (MVA) under local anaesthesia. It is associated with a small but definite morbidity, including uterine perforation, cervical trauma, intrauterine adhesion formation and postoperative pelvic infection.

**Recurrent miscarriage**

Recurrent miscarriage (RM), the loss of three or more consecutive pregnancies, affects 1–2% of women trying to conceive and is associated with significant psychological morbidity. Investigation includes a search for parental translocations and for anatomical, infective, endocrine, immune and thrombophilic causes. Most cases remain unexplained, which conveys a good prognosis for future pregnancy outcome.

Currently, the most treatable cause of RM is the antiphospholipid syndrome (see p. 459), which is present in 15–20% of all women with RM. When it is managed with low-dose aspirin and heparin, a live birth rate of more than 75% can be achieved.

Women with a history of recurrent miscarriage are at greater risk of pre-eclampsia, fetal growth restriction and prematurity when they achieve a successful pregnancy because all of these problems are determined by the quality and depth of early implantation. These patients are also more likely to suffer strokes at an earlier age than women with no miscarriage history.

Miscarriages can cause acute anxiety, depression, denial, anger, blame, severed relationships and a sense of loss and inadequacy. Compassionate counselling services and access to support groups for women who have experienced pregnancy loss are needed.

**Stillbirths**

Various definitions exist for stillbirth as distinct from miscarriage, and generally are based on gestational age (varying from 20 to 28 weeks). The World Health Organization (WHO) defines stillbirth as a pregnancy loss with a fetal weight of 1000 g or more, an assumed equivalent of 28 weeks’ gestation. Worldwide, there were 2.6 million third-trimester stillbirths in 2015. Although there was a reduction in maternal and child mortality, both targeted in the Millennium Development Goals (MDGs, see p. 278), the number of stillbirths annually remains high, sadly with little reduction in the past decade. Intrapartum losses are extremely high, at 1.3 million, many of which are preventable.

**Further reading**

**HEAVY MENSTRUAL BLEEDING**

Heavy menstrual bleeding (HMB) accounts for 1 in 5 gynaecology clinic consultations and is the most common cause of iron deficiency anaemia. Objective methods to quantify menstrual blood loss are inaccurate and therefore clinical assessment, based on the woman’s perception of blood loss and how it impacts on her quality of life, is needed. Periods characterized by the passage of large blood clots, severe pain or flooding that prevents the woman leaving home require investigation and management. The 2018 NICE guidance provides clear and practical advice on assessment and management (see ‘Further reading’).

Briefly, it is necessary to take a detailed menstrual and general medical history. On examination, signs of anaemia should be sought. Abdominal and pelvic examination is carried out to exclude pelvic masses, visualize the cervix, perform a smear if needed, and take swabs if infection is suspected. Investigations to consider are:

- **full blood count and iron studies** – to assess the need for iron replacement and, in extreme cases, blood transfusion
- **a haematological opinion** – if the history is consistent with a coagulation disorder
- **ultrasound scan** – if a pelvic mass is palpated or the bleeding pattern suggests endometrial pathology
- **endometrial biopsy** (at the outpatient clinic or at hysteroscopy in women aged >45 years) – for irregular or intermenstrual bleeding and where drug therapy fails
- **ultrasound and haematological investigation** – young women presenting with menorrhagia from their first period.

Selecting the most appropriate treatment for HMB involves patient preference, risk/benefit analysis of the available options, the woman’s fertility and contraceptive requirements, and any contraindications to medical or surgical therapies.
Management

First-line medical therapies
Choice depends on women’s preference and the presence of fibroids and any co-morbidities. Strategies include:

- **Levonorgestrel intrauterine system** (LNG-IUS or Mirena coil). This has revolutionized the treatment of HMB. It results in a 95% reduction in blood loss (30% of women are amenorrhoeic within 1 year of insertion), is an effective contraceptive, improves dysmenorrhoea and has few side-effects. It should be considered in the majority of women with HMB as an alternative to surgical treatment. Some women are troubled by irregular bleeding and persistent spotting for the first 3–9 months after insertion.

- **Tranexamic acid.** This antifibrinolytic agent is associated with a 50% reduction in HMB.

- **Mefenamic acid.** This non-steroidal anti-inflammatory drug (NSAID) is associated with a 25% reduction in bleeding and is taken during the menses.

- **Combined oral contraceptive pill.** This has the added advantage of providing effective contraception but may be contraindicated in women with risk factors for thromboembolism or breast cancer, smokers over the age of 35 and the obese.

- **Oral progestogens.** Taken on days 6–26 of the menstrual cycle, these may regulate the bleeding pattern, but are not contraceptive and can cause breakthrough bleeding.

- **Ulipristal acetate.** This can be added to the choice of strategies in women with fibroids >3 cm, acknowledging the risk of rare but serious liver injury. Gonadotrophin-releasing hormone (GnRH) agonist drugs act on the pituitary and result in amenorrhoea. They are suitable only for short-term use because they produce a hypo-oestrogenic state that predisposes to osteoporosis.

Surgical treatments
Surgical treatments for HMB should generally be offered only when medical treatments have failed and when women have completed their family.

- **Endometrial ablation techniques.** These destroy the endometrial lining to a depth that prevents cyclical regeneration. The second-generation microwave and thermal ablation techniques are highly successful in treating HMB and are undertaken as day-case procedures.

- **Hysterectomy.** Removal of the uterus may be via abdominal, vaginal or laparoscopic routes, depending on the size of the uterine body, the degree of laxity of the pelvic muscular floor and the skill set of the surgeon. Histology of the uterus is normal in about 40% of cases. The vaginal and laparoscopic surgical procedures usually mean shorter hospital stays and a faster return to normal activities.

Uterine fibroids (leiomyomata)
These are the most common solid pelvic tumours in women of reproductive age. The prevalence increases with age and is higher in Afro-Caribbean women. Heavy and/or prolonged periods, pressure symptoms due to the pelvic mass, and reproductive dysfunction are common presenting symptoms. The mechanism(s) by which fibroids cause HMB are poorly understood but submucosal lesions within the uterine cavity are particularly troublesome.

Management
Treatment is surgical excision, with magnetic resonance-guided focused ultrasound or uterine artery embolization (UAE), for which the uterine arteries are selectively catheterized via a femoral approach and microbeads are injected until flow is demonstrably reduced. There is a small risk of menopause where the ovarian circulation arises dominantly from the uterine arteries; this should be screened for with angiography prior to embolization. Pregnancy after UAE carries an increased risk of abnormal placental implantation and generally this approach should be considered only if future pregnancy is not intended.

GnRH agonists can be used to alleviate HMB as a short-term measure or to shrink the overall size and vascularity of the fibroids prior to surgery.

Recent data on the incidence of sarcoma within fibroids (0.05–0.29%) has led to changes in counselling for non-hysterectomy management of fibroids: after laparoscopic myomectomy, fibroids are morcellated to allow removal, and the risks of sarcoma must be presented in a balanced way when considering management.

ABORTION/TERMINATION OF PREGNANCY

Unintended pregnancy is common and abortion is one of the most frequently performed gynaecological procedures. One in three women will have an abortion in their lifetime. However, abortion remains a controversial subject, mostly related to cultural, moral and religious beliefs.

Every year, an estimated 210 million pregnancies occur worldwide: 80 million are unplanned and 50 million are terminated by abortion, 20 million of them illegally. Where abortion for unintended pregnancy is illegal, it is invariably unsafe and frequently has tragic sequelae. Approximately 70,000 maternal deaths occur each year due to unsafe abortion, 99% of them in developing countries.

In developed countries that have legalized abortion, the procedure is extremely safe. The risk of death from an early surgical termination of pregnancy is less than 1 per 100,000, which is far lower than the maternal mortality associated with a full-term pregnancy. Abortion was legalized in the UK in 1967 and 95% of the 190,000 procedures performed yearly are for Clause C of the Abortion Act, which states that the pregnancy has not exceeded its 24th week and that continuance of the pregnancy would involve risk, greater than if the pregnancy were terminated, of injury to the physical or mental health of the pregnant woman. Only 1% of abortions are done because of a risk that the child would be born handicapped.

**Induced abortion** can be undertaken surgically under local or general anaesthesia or using drug regimens that induce miscarriage. The type of procedure is generally dictated by the gestation of the pregnancy, availability of methods and the wishes of the woman concerned. The earlier an abortion is performed, the safer it is. Currently, 91% of abortions in the UK are carried out before 13 weeks’ gestation.

**Early medical abortion** (before 9 weeks’ gestation), using misoprostol to expel the products, achieves a complete abortion in over 80% of cases. Asthma and cardiac disease are contraindications to medical abortion. Most women remain in the clinical facility for 4–6 hours after the misoprostol insertion to abort the pregnancy, but some units support women so that they can remain at home during an early medical abortion. UK legislation passed in 2018 allows misoprostol to be taken at home for abortion, and clinical service change will probably follow.

**Surgical abortions** before 14 weeks are usually performed as suction terminations under general anaesthesia. Preoperative priming of the cervix with oral or vaginal misoprostol reduces the risk of
cervical trauma and haemorrhage. Early abortions before 7 weeks can be performed with an MVA syringe under local anaesthesia.

With modern early abortion techniques and routine screening for pelvic infection in high-risk women, the risk of future subfertility is extremely low. Later medical and surgical abortions are associated with more complications: in particular, incomplete procedures, pelvic infection and trauma to the genital tract. Contraception should be discussed before the abortion and started immediately after the procedure to avoid a further unplanned pregnancy.

Many women are emotionally vulnerable following an abortion. Feelings of guilt and regret are frequently mixed with relief that the ordeal is over. There is no evidence of an increase in serious psychiatric disease after abortion. Psychological problems can be minimized with careful counselling before the procedure and access to post-abortion support services.

URINARY INCONTINENCE

Urinary incontinence (UI) is common and has a negative impact on a woman’s quality of life. One in three women over the age of 60 years suffers from some urinary leakage and the majority are too embarrassed to seek help, despite the fact that the symptoms can often be alleviated by simple, non-pharmacological interventions. As the average age of populations in developing countries continues to rise, UI will become an even more prevalent problem, placing an increasingly large demand on healthcare resources.

NICE guidelines offer a simple classification of female UI (Box 39.6). Other factors that may predominate, especially in elderly women, such as functional incontinence secondary to immobility, are discussed on page 312.

Lifestyle interventions, including weight loss, smoking cessation, caffeine reduction and timed fluid restriction, can alleviate the symptoms of UI significantly. Physiotherapy and bladder retraining may be helpful in cases of stress and urgency, respectively, and for mixed UI. In postmenopausal women, oestrogen deficiency exaggerates many urinary symptoms, and topical vaginal or systemic HRT is a treatment option.

Referral for specialist management may include detailed assessment of the pelvic floor and any prolapse, urinary tract imaging and urodynamic evaluation where appropriate. Discussion of further management is based on the type of incontinence, the woman’s preferences and future fertility wishes.

DOMESTIC ABUSE AND VIOLENCE

Domestic violence is the cause of considerable hidden morbidity and mortality. One in four women in England and Wales experience some form of domestic abuse or violence – whether it be psychological, physical, sexual, financial or emotional – during their lifetime. One in ten women experience rape. Domestic violence accounts for one-third of violent crimes, and the cost of domestic violence in human and economic terms is enormous: an estimated £23 billion per annum in the UK alone.

There are several groups of people who are more vulnerable to becoming victims. Around 30% of domestic abuse begins or escalates during pregnancy. After road accidents, domestic abuse is the second leading cause of trauma during pregnancy, and pregnant women are more likely to have multiple sites of injury. The prevalence among women requesting a termination of pregnancy is six times higher than among women attending antenatal clinics. The disabled are also at greater risk of abuse: the odds of being a victim of violence are twofold higher in people with a physical disability and threefold higher in those with a mental illness. Sex workers, trafficked women and certain ethnic groups also have a higher prevalence of domestic violence.

Victims of domestic abuse are significantly more likely to commit suicide. Domestic violence and abuse are serious health concerns, and healthcare professionals are particularly well placed to identify abuse and intervene, as the victims frequently present to departments of Emergency Medicine, Psychiatry, and Obstetrics and Gynaecology. Healthcare professionals have a role to play in tackling the problem and are often the first and only point of contact to whom the isolated and vulnerable victim reaches out. All healthcare workers need to be trained to recognize the signs of violence and abuse, use targeted questioning, and know how to act and refer to ensure the women’s safety.

The key actions to reduce violence against women and girls are shown in Fig. 39.4.

Female genital mutilation

A cultural form of violence against women commonly seen in obstetric and gynaecological practice is female genital mutilation (FGM). A classification of FGM is shown in Box 39.7. In recent years the problems associated with FGM have become apparent in the UK. FGM was made illegal in the Female Genital Mutilation Act 2003; however, the only prosecution in the UK to date involved a doctor, who was found not guilty. It is estimated that 21,000 young women are at risk of FGM.

FGM has wide-ranging physical sequelae. Acutely, these include severe pain, abscess formation, sepsis, tetanus, haemorrhage,

| Protection – delivering an effective criminal justice system: |
| Investigation; prosecution; victim support and protection; perpetrator programmes |

| Provision – helping women and girls to continue with their lives: |
| Effective advice and support; emergency and acute services; refugees and safe accommodation |

| Prevention – changing attitudes and preventing violence: |
| Awareness-raising campaigns; safeguarding and educating children and young people; early identification/intervention and training |

Fig. 39.4 Key actions to reduce violence against women and girls. (After National Institute for Health and Care Excellence. NICE Public Health Guidance 50: Domestic Violence and Abuse: Multi-Agency Working, NICE 2014.)
urinary retention and blood-borne virus transmission. Chronically, dyspareunia, chronic pain, dysmenorrhoea, urinary tract infection and urinary outflow obstruction, post-traumatic stress disorder and difficulty conceiving all complicate FGM. In a subsequent pregnancy, the chances of caesarean section, postpartum haemorrhage, stillbirth and neonatal death are all higher.

Further reading

GYNAECOLOGICAL CANCERS

The most common genital tract tumours found in women are ovarian, endometrial and ovarian cancers (see p. 130). Each presents different challenges:

- ovarian cancer tends to present late and non-specifically, and most cases require specialist surgery and chemotherapy
- endometrial cancer is linked to increased peripheral androgen conversion to oestriol in adipose tissue and incidence will continue to increase with obesity
- cervical cancer can be screened for and there is now a vaccine for the causative agent – HPV.

An outline of these cancers is presented in Box 39.8. Suspected cancers should be referred urgently to secondary care, usually to a rapid access gynaecology or colposcopy clinic where diagnostic imaging and histology can be obtained, often on the same day.

INTRODUCTION

Men, like women, suffer with all manner of health problems, but there are particular disparities between the sexes in the rates of many common disorders. This chapter begins by surveying these differences and the particular health needs of men. It goes on to cover a range of disorders specific to the male urogenital tract, including diseases of the prostate, penis and testes. These disorders are common, especially benign and malignant prostate disease in middle-aged and older men.

Some patients are looked after in primary care but urologists manage others in secondary care, commonly in an outpatient setting but also as inpatients in emergency situations. Much of urological surgery is performed as a day-case procedure, and urologists are supported by nurse specialists in delivering services.

Key skills to develop include:

- history-taking for lower urinary tract symptoms
- examination of the prostate gland
- urinary catheterization, which is a core skill for all doctors.

Key medications in urology include alpha-blockers (e.g. tamsulosin), and hormonal drugs to treat symptomatic prostate disease (5-α-reductase inhibitors such as finasteride).

Key urological emergencies that all doctors need to recognize include testicular torsion, acute urinary retention, paraphimosis and priapism.

CORE SKILLS AND KNOWLEDGE

Lower urinary tract symptoms (LUTS) are commonly said to fall into two distinct groups – storage and voiding – and carefully eliciting the nature of a patient’s problems may suggest the underlying disorder (Box 40.1).

- Storage LUTS are caused by disorders that affect the storage of urine, and suggest irritation or inflammation of the lining of the bladder. Causes include lower urinary tract infection (UTI), other forms of cystitis, sexually transmitted infections, bladder stones and prostatitis.
- Voiding LUTS are caused by disorders that affect the voiding of urine, with benign and malignant prostate diseases the most common causes. Chronic urinary retention caused by neurological problems (e.g. multiple sclerosis) is often asymptomatic, as there is abnormal sensation of bladder fullness; it may be detected only on abdominal palpation or imaging. The passing of frequent, small volumes of urine should always raise the possibility of urinary retention with ‘overflow’ voiding, particularly if it is accompanied by lower abdominal pain and tenderness, and a palpable bladder.

Box 40.1 Lower urinary tract symptoms (LUTS)

Storage LUTS

- Dysuria: pain or burning on urination
- Frequency: the passing of small volumes of urine at frequent intervals
- Urgency: a sudden urge to pass urine
- Urge incontinence: urgency leading to involuntary loss of urine
- Nocturia: waking at night to pass urine

Voiding LUTS

- Hesitancy: a longer than usual wait for urine flow to begin
- Weak stream
- Intermittency: urine flow that stops and starts
- Terminal dribbling: weak urine flow continues after an attempt is made to stop
- Straining: the need to increase abdominal pressure in order to urinate
**Examination**

A urologist is able to estimate the size of the prostate gland by comparing the prostate volume on ultrasound or magnetic resonance imaging (MRI) with what is felt on digital rectal examination (DRE, Fig. 40.1). A fleshy-feeling prostate is likely to be benign, whereas a hard, craggy gland is more likely to be malignant.

**Investigations: bladder scanning**

Portable bladder scanners use basic ultrasound technology to allow the volume of urine in a patient’s bladder to be assessed at the bedside by ward staff not trained in formal diagnostic ultrasound scanning. Although individual models vary, generally use is very simple (Fig. 40.2 and Box 40.2). Such scanners are often available on wards and can be used for:
- diagnosing urinary retention
- assessing successful voiding after a trial without catheter
- assessing whether a patient’s bladder empties completely after voiding.

A bladder volume of more than 150 mL after attempted voiding is considered significant. In acute urinary retention, volumes of more than 1 L may be seen, and urgent urethral catheterization is required (Box 40.3 and Fig. 40.3).

**Box 40.2 Bladder scanning**

- Switch on the bladder scanner.
- Apply aqueous gel to the head of the transducer.
- Palpate the symphysis pubis and place the scanner 3 cm above this, pointing down into the pelvis.
- Hold the transducer steady while pressing the scanning button; this will reveal the bladder volume on screen.
- Repeat the procedure three times, with slight alterations in the position of the transducer.
- Record the highest volume in the patient’s medical record.

**Box 40.3 Male catheterization**

- Obtain consent
- Employ an aseptic no-touch technique.
- Clean the glans penis with an antiseptic solution.
- Instil lidocaine anaesthetic gel into the urethra.
- After 5 min, insert an appropriately sized catheter (generally 14F/16F/18F) through the external urethral meatus. When the catheter is inserted to the hilt, urine drains out.
- Inflate the catheter balloon with 10 mL saline and withdraw the catheter until the balloon is snug against the bladder neck.
- Note the volume of urine drained.
- Replace the foreskin, if present, over the glans penis.

INTRODUCTION

Disparities between men’s and women’s health

In high-income countries there remain stark disparities between men’s and women’s health. These differences are highlighted in data from England and Wales (Box 40.4).

Men are their own worst enemies

Many of the health disparities between the sexes can be attributed to the fact that men have lower levels of health literacy than women, and are therefore less likely to acknowledge problems, seek help, or utilize resources such as a general practitioner or pharmacist. It is suggested that fear of having illness confirmed, with the potential perceived loss of masculinity, results in men maintaining an appearance of being in control and bearing up, instead of being honest, reporting symptoms, seeking help and accepting interventions.

These UK trends are seen in most parts of the world, where health outcomes among boys and men continue to be substantially worse than those among girls and women. Globally, women live an average of 6 years longer, ranging from 5.3 years longer in sub-Saharan Africa to >10 years longer in Russia. Despite these differences, few countries have addressed the burden that men’s health disparities entail.

Advocates of such concerted global action point to the huge differences, few countries have addressed the burden that men’s health disparities entail. Men’s health outcomes among boys and men continue to be substantially worse than those among girls and women. Globally, women live an average of 6 years longer, ranging from 5.3 years longer in sub-Saharan Africa to >10 years longer in Russia. Despite these differences, few countries have addressed the burden that men’s ill-health creates by adopting national, male-centred strategies. Advocates of such concerted global action point to the huge transformative impacts that these changes might bring socially and economically. Closing the gap would benefit all of the world’s population, regardless of gender, as male ill-health has significant effects on the psychological wellbeing of women too, as well as the health, finances and social cohesiveness of the family.

Further reading

SPECIFIC DISEASES OF MEN

The top five causes of male deaths, according to the UK Office for National Statistics (2017), are dementia and Alzheimer’s disease, ischaemic heart disease, cerebrovascular disease, chronic respiratory disease and lung cancer. Prostate cancer is, however, the most common cancer in UK males, followed by lung and colorectal cancers.

DISEASES OF THE PROSTATE GLAND

Prostatitis

Prostatitis describes inflammation of the prostate gland. It can be divided into acute prostatitis, which is uncommon, and the much more common chronic prostatitis.

Acute prostatitis

This presents with the symptoms of a severe UTI, including dysuria, frequency, malaise, fever and genital region pain. The prostate is found to be swollen and tender on digital rectal examination. Infectious agents include various gram negative organisms responsible for urinary tract infection, and organisms that cause sexually transmitted infection such as Chlamydia trachomatis and Neisseria gonorrhoeae. Hospital admission is required for antibiotic treatment. If the condition is left untreated, sepsis may result.

Chronic prostatitis

Chronic disease may affect up to 10–15% of men. Most of these patients have chronic non-bacterial prostatitis, termed chronic prostatitis or chronic pelvic pain syndrome. A diagnosis can be made if symptoms have been present for more than 3 months. The condition generally occurs in men aged 30–50 years. Typically, the clinical features wax and wane over several years but may include a combination of pain, urinary symptoms and sexual dysfunction, with pain being the main feature. It may be experienced in the penis, scrotum, perineum or anus. Voiding difficulties are common. There may be erectile dysfunction and/or pain on ejaculation.

The cause is unknown. Investigations are undertaken to exclude other diagnoses.

Management is difficult. Options include antibiotics (even where there is no microbiologically proven infection), alpha-blockers such as tamsulosin, 5-alpha-reductase inhibitors such as finasteride, non-steroidal anti-inflammatory drugs (NSAIDs) and prostate massage under general anaesthesia. Dietary manipulation may be of value, as may stress reduction. A chronic pain specialist may be involved. Many men seek complementary therapies.

Box 40.4 Health disparities between the sexes (England and Wales, 2015)

**Mortality**

- Mortality rates are higher for men than for women in every age group under the age of 85 years. In 2015, age-standardized mortality rates (ASMRs) were 1156.4 and 863.8 deaths per 100,000 population for men and women, respectively.
- Men are more likely than women to die prematurely: 19% of all male deaths but only 12% of women’s deaths were in those under 65 years.
- This difference is accentuated in the 15–34 age group, where 67% of all deaths were male, representing 1.65% of all male deaths but only 0.75% of female deaths.

**Cancer**

- The biggest single cause of death in men and women remains cancer. It accounts for nearly one-third of all male deaths but only one-quarter of female deaths.

**Mental health and suicide**

- 1:8 men in the UK suffer from one of the common mental health conditions, compared to 1:5 women.
- However, men are 50% more likely than women to be detained under the Mental Health Act and treated compulsorily. Men are far less likely to access psychological therapies than women.
- Men account for 76% of all suicides; suicide is the single biggest cause of death in men under 35 years.
- Research suggests that men have less access to the social support of friends, relatives and the wider community.

**Alcohol, illicit drugs and crime**

- Men are three times more likely to become problem drinkers; alcohol dependence affects 8.7% of men compared to 3.3% of women.
- Men are more likely to use, and to also die from, illicit drugs: 4.2% of men but only 1.4% of women report frequent drug use.
- Men make up 95% of the prison population, committing 86% of violent crime.
Benign enlargement of the prostate gland

Benign prostatic enlargement occurs most often in men over the age of 60 years. The aetiology is not established but the condition is unknown when there is hypogonadism, confirming the androgen dependency of the condition. Microscopically, hyperplasia affects the glandular and connective tissue elements of the prostate. Enlargement of the gland stretches and distorts the urethra, obstructing bladder outflow.

Clinical features

Frequency of urination, usually first noted as nocturia, is a common early symptom. Difficulty or delay in initiating urination, with variability and reduced forcefulness of the urinary stream and post-void dribbling, are often present (voiding LUTS). Acute retention of urine (see later) or retention with overflow incontinence may occur. Occasionally, severe haematuria results from rupture of prostatic veins or is a consequence of bacteriuria or stone disease.

Examination and investigations

Abdominal examination for bladder enlargement is performed, together with a digital rectal examination (DRE); a benign prostate characteristically feels smooth. Investigations should include:
- urine culture
- measurement of serum prostate-specific antigen (PSA)
- renal function tests
- ultrasound
- measurement of the urinary flow rate.

Pressure-flow studies (urodynamics or cystometry) are not routinely indicated.

Management

The severity of symptoms is assessed by the self-administered International Prostate Symptom Score, which is based on seven questions about urinary symptoms and one concerning quality of life. Management is outlined in Box 40.5.

If surgery is needed, minimally invasive day-case procedures include the insertion of implants to maintain urethral patency (e.g. the Urolift system), and transurethral needle ablation of the prostate in which low-frequency radio waves are used to induce necrosis in the enlarged prostate gland.

Deterioration in renal function or the development of upper tract dilatation usually requires surgery.

Prostate cancer

Prostatic carcinoma accounts for 7% of all cancers in men and is the sixth most common cancer in the world. Malignant change within the prostate becomes increasingly common with advancing age. By 80 years, 80% of men have malignant foci within the gland but most of these appear to lie dormant. Histologically, the tumour is almost invariably an adenocarcinoma.

Prostate cancer is the most common male-specific cancer in the UK. Some 47 000 men develop it every year, representing 1 in every 8 men, with deaths running at 12 000 per year. It is particularly common in men aged over 50 years, in men with a family history of prostate or breast cancer, and in black men (where the risk is 1 in 4).

Pathogenesis

Genetic studies have shown that the homeobox gene HOXB13 predisposes to prostate cancer. Genome-wide association studies have identified over 100 single-nucleotide polymorphisms (SNPs) associated with it. The BRCA2 gene, associated with breast cancer in women, confers a 5–7 times higher risk.

Clinical features and diagnosis

Most men with early prostate cancer do not have any symptoms. The diagnosis is suggested by the finding of a raised serum prostate-specific antigen (PSA) and/or an abnormal-feeling prostate gland on DRE. Where there are symptoms, they are similar to those of a benignly enlarged prostate gland: namely, features of urinary voiding (slow flow and hesitancy) and urinary storage (frequency and urgency).

A serum PSA level of more than 3 ng/mL is abnormal but a measurement of between 3 and 10 ng/mL can be due to benign hypertrophy, prostatitis or cancer. Levels of more than 10 ng/mL suggest malignant disease.

Investigations include a multiparametric MRI (mpMRI) scan of prostate, followed in most instances by a prostate biopsy. Currently, this most commonly takes the form of a transrectal ultrasound-guided biopsy (Fig. 40.4), but this is being superseded in several centres by transperineal ultrasound-guided biopsy, which has better diagnostic accuracy and carries a reduced risk of sepsis.

Prostate cancer commonly metastasizes to bone. These metastases appear as osteosclerotic lesions on X-ray and are also detected by isotopic bone scans.

Prognosis

The histological appearances are graded according to the combined Gleason score (Fig. 40.5). Together with the serum PSA level, and accurate staging of the local extent of disease with pelvic MRI (dynamic contrast) and transrectal ultrasound, this score can identify prognostic groups (Box 40.6). Treatment decisions must balance the age and performance status of the patient with the predicted behaviour of the cancer (future developments in gene profiling will allow better prognostication). This allows the selection of patients with a good prognosis for non-aggressive treatment; they may reasonably choose to be kept under an active surveillance programme.

About 95% of men in England diagnosed with prostate cancer between 50 and 69 years of age survive their disease for 5 years or more, and overall prostate cancer survival is improving.
Management
See Figure 40.6.

Localized disease
Patients with disease localized to the prostate that requires treatment can be managed by curative surgery (typically, robotically assisted radical prostatectomy), external beam radiotherapy, or brachytherapy (with radioactive iodine implants), which all achieve equivalent survival rates but differ in the spectrum of unwanted side-effects, including incontinence and sexual dysfunction. Radiotherapy tends to be used more frequently in older patients who wish to avoid surgery.

In the UK, treatment options are determined jointly by multidisciplinary clinical teams and informed patients. A key priority is the avoidance of unnecessary overtreatment (the rate of which has fallen to 8% in the UK, according to the National Prostate Cancer Audit 2017).

Discussion between patients and clinicians are vital to enable a treatment choice that is most appropriate to the patient’s circumstances. In many with lower-risk disease (combined Gleason scores of 6 or less, Box 40.7), localized prostate cancer may be managed expectantly using the strategy of active surveillance, in which regular PSA tests are supplemented with repeat mpMRI and repeat prostatic biopsies, to establish whether the cancer is becoming more aggressive and thus warrants active therapy.

Traditionally, therapies with curative intent have targeted the whole gland. However, there is developing interest in focal therapies for prostate cancer, along the lines of a ‘lumpectomy’ for breast cancer. High-intensity focused ultrasound and cryotherapy are just two of the technologies used to ablate the part of the prostate harbouring the cancer.

**Box 40.6 Prostate cancer: prognostic factors**

At initial diagnosis
- Clinical stage
- Biopsy Gleason grade
- Serum PSA level

Post surgery
- Surgical/pathological stage
- Surgical margins
- Extracapsular spread, extension to seminal vesicles or lymph nodes

Metastatic, hormone-resistant disease
- Performance status
- Serum PSA
- Haemoglobin, albumin, alkaline phosphatase and lactate dehydrogenase level

**Fig. 40.4 Transrectal ultrasound-guided biopsy of the prostate**
Prior to the biopsy the patient is given prophylactic antibiotics. An ultrasound probe is introduced into the rectum to visualize the prostate. Using ultrasound as a guide, local anaesthetic is then infused into the tissue surrounding the prostate. This allows for core biopsies to be taken from the prostate comfortably. (From Pagana K et al. Mosby’s Canadian Manual of Diagnostic and Laboratory Tests, 2nd Canadian edn, 2019, Elsevier, with permission.)

**Fig. 40.5 Gleason’s Pattern Scale.** The Gleason is a grading scale that runs from 1 to 5, the number indicating the extent of differentiation of the adenocarcinoma cells of the prostate. Due to the multifocal and heterogeneous nature of prostate cancer, the Gleason score is calculated by adding together the two most prevalent grades. For example, Gleason 3 + 4 = 7 would mean that the most dominant cell type is Gleason 3, followed by Gleason 4, and the two combined give an overall value of Gleason 7. An overall Gleason score of 2–6 is considered as well differentiated, Gleason 7 is moderately differentiated and 8–10 is poorly differentiated. (1) Small, uniform glands. (2) More space (stroma) between glands. (3) Distinct infiltration of cells from glands at margins. (4) Irregular masses of neoplastic cells with few glands. (5) Lack of occasional glands, sheets of cells. (Redrawn after Kirby RS, Brawer MK, Denis LJ (eds), Prostate Cancer: Fast Facts, 3rd edn. Abingdon: Health Press; 2001.)

**Locally advanced and metastatic disease**

Management of prostate cancer in cases where surgery is not possible is discussed on page 128. It is based around endocrine therapy to achieve androgen blockade, alongside systemic chemotherapy.

**Screening**

See Chapter 14 for a review of the evidence for prostate cancer screening.

**Further reading**

**DISEASES OF THE PENIS**

**Benign diseases of the penis**

**Phimosis**

Phimosis is a condition in which the contracted foreskin (prepuce) has a tight, narrow orifice and cannot be retracted over the glans of the penis (Fig. 40.7). A physiological phimosis is present at birth, but through penile growth, erection and accumulation of epithelial debris (smegma) under the foreskin, separation occurs, enabling the foreskin to be retracted. By the age of 17, only 1% of boys will have a phimosis. Pathological phimosis is caused by recurrent balanitis (inflammation of the glans penis) and inflammatory conditions such as balanitis xerotica obliterans (BXO).

While physiological phimosis is usually asymptomatic, patients may present with ballooning of the foreskin on passing urine. If the man is sexually active, there may be trauma to the foreskin during coitus. Pathological phimosis secondary to infection or inflammation may cause pain, dysuria, bleeding or pus discharge from the orifice. If the phimosis is due to BXO, there will be hypopigmentation or discoloration of the foreskin associated with pruritic plaques on the foreskin and glans.

In adults, phimosis is usually pathological and any associated infection should be treated. The main treatment in adults is circumcision but children should be managed as conservatively as possible. Corticosteroid cream, in addition to antibiotics, is effective for treating underlying balanitis and softening the phimosis. The indications for circumcision in children are BXO, recurrent balanitis and recurrent UTIs in those with urinary tract abnormalities (e.g. vesico-ureteric reflux, posterior urethral valves or neuropathic bladder dysfunction).

**Paraphimosis**

Paraphimosis is seen when there is an inability to return the retracted foreskin to its resting position (see Fig. 40.7). Existing phimosis or prolonged retraction produces a tight ring of tissue at the corona. Consequent venous congestion, oedema and swelling of the glans can progress to arterial occlusion and necrosis. This should be regarded as an emergency and should be managed urgently. Treatment of paraphimosis is with persistent manual compression of the oedematous glans with subsequent attempts to return the retracted foreskin to its normal position. Should this manoeuvre fail, a dorsal slit or circumcision is the definitive management.

**Malignant disease of the penis**

**Penile cancer**

Over 95% of penile malignancies are squamous cell carcinomas arising from the epithelium of the inner prepuce or the glans. In industrialized countries, penile cancer is uncommon, with an overall incidence of around 1/100,000 males in Europe and the USA. In contrast, in some other parts of the world such as South America,
South-east Asia and parts of Africa, the incidence is much higher and can account for 1–2% of malignant disease in men. Penile cancer is common in regions with a high prevalence of human papillomavirus (HPV); some cases are attributed to HPV-related carcinogenesis, most commonly HPV subtypes 6, 16 and 18. It is not linked to human immunodeficiency virus (HIV) infection or acquired immunodeficiency syndrome (AIDS). Other known risk factors are phimosis, chronic penile inflammation (BXO or balanitis), smoking and multiple sexual partners. Neonatal circumcision dramatically reduces the frequency of penile cancer.

The aims of treatment of the primary tumour are complete tumour removal with as much organ preservation as possible, without compromising oncological control. Local recurrence has little influence on long-term survival, so organ preservation strategies are justified (European Association of Urology (EAU) guidelines 2018, see ‘Further reading’). Radiotherapy and laser ablation are organ-preserving management options in patients with superficial disease. Radiotherapy and chemotherapy are most often used in the palliative setting. Chemotherapy is frequently cisplatin-based and is usually based on fluorouracil or a taxane.

**TESTICULAR AND SPERMATIC CORD DISEASE**

**Benign diseases of the testicle**

**Testicular torsion**

Testicular torsion is the lateral to medial (inward) twisting of the spermatic cord. This results in strangulation of the blood supply to the testis and the epididymis, and is a time-sensitive true urological emergency. Testicular torsion occurs most often in the neonatal period and around puberty (peak incidence at 13–15 years of age). These patients usually present with a short history (less than 12 h) of severe, sudden-onset hemi-scrotal pain, which sometimes wakes them from sleep and can radiate to the groin, loin or epigastrium. The pain is associated with nausea and vomiting, and an altered, broad-based ‘cowboy’ gait. On examination, there may be an absent cremasteric reflex (unreliable in older children and adults), and the testicle may be high-riding and in a horizontal position. The testicle itself can be swollen and tense, and is exquisitely tender. Elevation of the testicle does not ameliorate the symptoms (negative Prehn’s sign).
Diagnosis is usually based on the clinical presentation alone. Doppler ultrasound cannot rule out the presence of testicular torsion and delays definitive treatment, so should not be relied on for diagnosis in acute presentations.

Management is immediate surgical exploration in patients presenting with less than 24 hours of pain. Delay can result in permanent ischaemic damage to the testicle. Detorsion and bilateral orchidopexy (fixation of the testicle to prevent recurrent torsion) are performed in the presence of a viable testicle. If the testicle is non-viable, orchidectomy and contralateral orchidopexy are carried out.

**Epididymitis and orchitis**

**Epididymitis** is an acute or chronic inflammatory condition of the epididymis. It often involves the testicle and as such is referred to as **epididymo-orchitis**. Patients who present acutely can have symptoms that mimic testicular torsion. Epididymitis is usually caused by a bacterial infection that ascends from the urethra or the bladder. In sexually active men the infective organism is usually *Neisseria gonorrhoeae* (see p. 1416), *Chlamydia trachomatis* (see p. 1416) or a coliform bacterium. In older men and children the infective organisms are usually common urinary tract pathogens like *Escherichia coli*. On presentation the duration of pain is usually longer than that of testicular torsion and is of gradual onset. The pain can be associated with symptoms of urethritis, cystitis or prostatitis. On examination the patient may have a fever and appear systemically unwell. The epididymis will be tender and swollen on palpation. The hemiscrotum is often swollen and warm to the touch, and erythematous skin changes can be seen. Urinalysis may also show signs of infection.

Patients should be treated for the most likely organism, and scrotal elevation is advised to reduce swelling. Advice should be provided on warning signs for potential complications, such as abscess formation, infarction of testis, chronic pain, chronic infection and infertility. In patients with parotid swelling, a viral mumps orchitis should be considered (see p. 525) and a thorough vaccination history taken.

**Hydrocele and epididymal cyst**

A **hydrocele** is an abnormal collection of fluid within the tunica vaginalis of the scrotum or along the spermatic cord (Fig. 40.8). It is usually painless but the testicle is difficult to palpate due to the tense fluid collection. The superior margin of the hydrocele is palpable. The fact that the clinician can ‘get above’ the lump differentiates a hydrocele from an inguinal hernia. It is also possible to transilluminate it.

**Epididymal cysts** are benign, fluid-filled cystic swellings that arise from the head of the epididymis. If the cyst contains spermatozoa, it is referred to as a spermatocele (see Fig. 40.8). It is often multiloculated, unlike a hydrocele. However, a spermatocele too develops over a long period of time and the superior margin can be palpated.

Surgical excision of either a hydrocele or epididymal cyst is indicated if it is large and uncomfortable.

**Varicocele**

A varicocele is dilation of the pampiniform plexus of veins surrounding the testis and extending up into the spermatic cord (see Fig. 40.8). Varicoceles are usually small and asymptomatic. They occur more commonly on the left side due to drainage of the gonadal vein into the left renal vein. When symptomatic, patients describe a dragging sensation or a dull ache in the scrotum. Rarely, a varicocele can be a sign of renal malignancy.

**Undescended testes (cryptorchidism)**

Testicular descent occurs in two phases:
- at 7–8 weeks’ gestation the testes descend from the genital ridge to the internal inguinal ring
- at 24–28 weeks’ gestation the testes pass through the inguinal canal into the scrotum.

Failure at any stage of descent is termed cryptorchidism or undescended testes. This is the most common endocrinological disease in the male newborn period. Incidence varies between 1.0% and 4.6% in full-term neonates, with rates as high as 45% in preterm neonates (EUA guidelines, see ‘Further reading’). These patients have an eight-fold higher risk of testicular cancer and a 4% life-long risk of cancer in the intra-abdominal testis. They have reduced fertility, although this improves if orchidopexy is performed before 2 years of age. They are also at increased risk of testicular torsion and inguinal hernia formation.

**Malignant disease of the testicle**

**Testicular germ cell tumours**

Testicular cancer represents 1% of male neoplasms and 5% of urological tumours, with 3–10 new cases occurring per 100,000 males per year in Western societies. It is the most common solid cancer in young men in Western populations (see p. 129).

**Clinical features**

Most men usually present with a painless unilateral testicular or scrotal mass. Up to 27% can have pain or a dragging sensation as their first symptom. A detailed history will uncover the 11% of cases that present with back and flank pain due to metastases and the 7% that present with gynaecomastia, if the tumour secretes human chorionic gonadotropin (hCG).

Of note, 10% of cases of testicular cancer can mimic epididymo-orchitis. On encountering these acutely presenting patients, it is imperative to carry out a general abdominal examination, looking for supraclavicular lymphadenopathy and a palpable abdominal mass.

**Investigations and management**

These are described on page 129.
LACK OF LIBIDO AND ERECTILE DYSFUNCTION

Lack of libido is a loss of sexual desire. In some instances this is due to low serum testosterone levels, but more commonly the testosterone is normal and reduced libido is attributed to psychological factors or lifestyle stresses. Erectile dysfunction is a complex phenomenon that is defined as the persistent inability to attain and maintain an erection sufficient to permit satisfactory sexual performance (EAU guidelines 2018, see ‘Further reading’). Low libido and erectile dysfunction may occur together or separately, and each can precipitate the other. Both are common symptoms in hypogonadism, but most people with either symptom have normal hormone levels and in many patients there is no definable organic cause.

Erectile dysfunction may affect a person’s physical and psychological health, and can have a significant impact on the quality of life of patients and their partners. Common causes are listed in Box 40.8.

The presence of nocturnal emissions and frequent satisfactory morning erections make hormonal disease unlikely. Psychogenic erectile dysfunction is commonly a diagnosis of exclusion. In addition to the various aetiologies considered individually, in most cases there is more than one pathological element and often a psychological component.

Management

A detailed medical and sexual history should be obtained from the patient and, if available, their partner. This should be followed by physical examination of the genitourinary system and the suspected aetiological system - for instance, checking peripheral pulses in the legs. Laboratory tests should be performed according to the patient’s history and risk factors.

Modifiable or reversible risk factors, such as lifestyle choices (e.g. smoking, obesity or lack of exercise), can be tackled first, and offending drugs should be stopped if possible. Treatment or management of underlying systemic disease, such as diabetes mellitus, hypertension and the causes of hypogonadism, can also have a positive effect on the management of erectile dysfunction.

First-line therapies

The treatment algorithm for erectile dysfunction is a delicate balance between the invasiveness and efficacy of any given intervention. The mainstay of first-line therapy is an oral phosphodiesterase type 5 inhibitor (PDE5I), such as sildenafil, tadalafil, vardenafil and avanafil. These drugs cause smooth muscle relaxation and thus increase penile arterial blood flow, which enables a man to achieve an erection. The time from ingestion of medication to effectiveness can vary, depending on which medication is prescribed, but is generally between 15 and 60 minutes. PDE5Is are contraindicated in any patient using any form of organic nitrate (e.g. nitroglycerine, isosorbide mononitrate or isosorbide dinitrate). They are also contraindicated in anyone who has had a myocardial infarction, stroke or life-threatening arrhythmia in the preceding 6 months. Their use is also contraindicated in resting hypotension (blood pressure <90/50 mmHg), hypertension (blood pressure >170/100 mmHg), unstable angina, angina with sexual intercourse and severe congestive heart failure.

Vacuum erection devices provide passive engorgement of the corpora cavernosa. A constrictor ring is then placed at the base of the penis to retain blood within the corpora. This non-invasive option is contraindicated in patients with bleeding disorders or those on anticoagulation. It can be offered to well-informed patients who have infrequent sexual intercourse and co-morbidities requiring non-invasive, drug-free management of erectile dysfunction.

Topical and intra-urethral alprostadil application is the last of the first-line therapies. Topical alprostadil is applied to the glans and absorbed via the urethral meatus. An alprostadil pellet can also be administered intra-urethrally as an alternative.

Second-line therapies

Patients who do not respond to oral drugs or other first-line therapies may be offered intracavernous alprostadil injections. Intracavernous administration of vasoactive drugs was the first medical treatment developed for erectile dysfunction. Dedicated outpatient training for a patient or his partner by a specialist member of the urology team is needed to ensure correct technique.

Third-line therapies

The surgical implantation of a penile prosthesis may be considered in patients who do not respond to pharmacotherapy or who prefer a permanent solution.

If no organic disease is found or if there is clear evidence of psychological problems, the couple should receive psychosexual counselling.

PRIAPISM

A priapism is a long-lasting painful erection. Without prompt resolution, permanent damage to the penile tissue occurs, resulting in permanent erectile dysfunction. It thus constitutes a urological emergency. Priapism most commonly affects people with sickle cell disease. Other causes include some treatments for erectile dysfunction, blood disorders and recreational drugs. Treatment in the first instance is by insertion of a needle into a corpus cavernosum to withdraw blood.

THE AGEING MALE

In the male, there is no sudden ‘change of life’ and no direct equivalent of the female menopause. However, there is a progressive loss of sexual function with reduction in morning erections and frequency of intercourse.

The age of onset varies widely. Typically, overall testicular volume diminishes and sex hormone binding globulin (SHBG) and gonadotrophin levels gradually rise, but other men present with low or borderline testosterone without elevation of luteinizing hormone/follicle stimulating hormone (LH/FSH). Low testosterone certainly increases the risk of osteoporosis and, in some studies, is associated with increased cardiovascular risk. It remains unclear to what extent general symptoms of lack of energy, drive, muscle strength and general wellbeing may relate to these hormonal changes; a recent trial of testosterone replacement showed no benefit for general symptoms, although there was an improvement in sexual function. Loss of libido and erectile dysfunction are, however, common symptoms, even when hormone levels are normal, and long-term outcome studies of testosterone replacement are still awaited. Therefore, the decision to offer testosterone replacement to an ageing male is currently based on full clinical and biochemical assessment and thorough discussion of the potential risks (including prostate disease), as well as benefits. If testosterone is unequivocally low (<7 pmol/L) and there are symptoms specific to androgen deficiency (low libido, erectile dysfunction and loss of early morning erections), most authorities would recommend replacement. However, few would treat if testosterone is over 12 pmol/L with normal LH/FSH. Clinically, a large proportion of cases are in the borderline range (7–12 pmol/L), which can lead to difficulties in reaching a firm diagnosis. There is an increasing move towards measuring fast- ing testosterone levels, as food intake may decrease testosterone, leading to an incorrect diagnosis of androgen deficiency.

General measures to keep healthy include:

- eating a good diet containing fruit and vegetables
- taking regular exercise
- keeping below the maximum ‘safe’ drinking level of 14 units per week
- maintaining a healthy weight
- engaging in physical check-ups, such as blood pressure assessment.

The authors advocate regular PSA blood tests from the age of 45 years but acknowledge that this is controversial. Making use of other screening opportunities, such as those for bowel cancer and aortic aneurysm, is also recommended.
Air pollution is one of the biggest problems facing the world. It has become a public health emergency as it leads to chronic diseases and exacerbates respiratory, cardiac and other medical problems. According to the World Health Organization, air pollution causes over 7 million premature deaths per year, mainly from heart disease, stroke, chronic obstructive pulmonary disease, lung cancer, and acute respiratory infections in children. Annually, pollution is the cause of over 1.6 million deaths in China, 1.24 million in India in 2017 and 135,000 in Pakistan, and figures are rising. There are 29,000 deaths each year in the UK due to air pollution. It is also the single largest environmental risk in Europe, causing 800,000 premature deaths. It has been estimated that air pollution kills more people in a year than malaria and HIV combined, and about ten times more deaths than road accidents in some countries. Atmospheric air pollution, due to the burning of coal for energy and heat, has been a feature of urban living in high-income countries for at least two centuries.

Air pollution consists of black smoke and sulphur dioxide ($\text{SO}_2$) and, from combustion of hydrocarbon fuels in motor vehicles, nitrogen oxides (NO and NO$_2$), diesel particulates, polyaromatic hydrocarbons and ozone, a secondary pollutant generated by photochemical reactions in the atmosphere. Levels of NO$_2$ can be high in poorly ventilated kitchens and living rooms where gas is used for cooking and in open fires.

Particulate matter consists of coarse particles (10–2.5 μm in aerodynamic diameter), produced by construction work and farming, and fine particles (<2.5 μm) generated from burning fossil fuels. Fine particulates (PM$_{2.5}$) remain airborne for long periods and are carried into rural areas. Several respiratory and cardiac problems are exacerbated by these very small particles.

The World Health Organization (WHO) global air-quality guidelines suggest 24-hour values of <25 μg/m$^3$ for PM$_{2.5}$ for the short term and 10 μg/m$^3$ in the long term. In Europe, 70% of the particulates present in urban air result from the combustion of diesel fuel, providing a background concentration of 3–5 μg/m$^3$.

Deaths from respiratory and cardiovascular disease occur mainly in older populations; air pollution mainly causes bronchitis in children. Pollution from motor vehicles has been linked to increased hospital admissions, reduced lung function in children and younger adults, and an increase in lung cancer (polyaromatic hydrocarbons). Although it has been proposed that air pollution may cause asthma and other allergic diseases, there is no current evidence for this (Box 41.1). However, air pollution does adversely affect lung development in teenagers, while both NO$_2$ and ozone enhance the nasal and lung airway responses to inhaled allergens in people with established allergic disease.

Management

When air quality is poor, patients with asthma are advised to avoid exercising outdoors and to increase their anti-inflammatory medication (i.e. inhaled corticosteroids). Short- and long-term measures...

are required to reduce air pollution, particularly diesel particulates (which are predicted to increase as more diesel engines are used). Such measures include increased motor engine efficiency, catalytic converters, diesel particulate traps and decreased reliance on cars and trucks.

Further reading

HEAT INJURY

Body core temperature (T<sub>Core</sub>) is maintained at 37°C by the thermoregulatory centre in the hypothalamus, which integrates information from skin temperature sensors with core temperatures from receptors in the brain and in the walls of large blood vessels.

Heat is produced by cellular metabolism and is dissipated through the skin by both vasodilation and sweating, and in expired air via the alveoli. When the environmental temperature (T<sub>Env</sub>) is higher than 32.5°C, profuse sweating occurs. The elderly, whose ability to adjust physiologically to heat is reduced due to diminished thermoregulatory capacity, and the chronically ill are more easily affected. The rising global temperature has given rise to heat waves and increased mortality particularly in these groups.

**Sweat evaporation** is the principal mechanism for controlling T<sub>Core</sub> following exercise or in response to an increase in T<sub>Env</sub>. Heat acclimatization takes place over several weeks. The sweat volume increases and the sweat salt content falls. Increased evaporation of sweat reduces T<sub>Core</sub>.

**Heat cramps**

Painful muscle cramps, usually in the legs, often occur in fit people when they exercise excessively, especially in hot weather. Cramps are probably due to low extracellular sodium caused by excess intake of water over salt. They can be prevented by increasing dietary salt. They respond to combined salt and water replacement, and in the acute stage to stretching and muscle massage. T<sub>Core</sub> remains normal.

**Heat exhaustion**

At any environmental temperature (especially with T<sub>Env</sub> of >25°C), and with a high humidity, strenuous exercise in clothing that inhibits sweating, such as a wetsuit or military uniform, can cause an elevation in T<sub>Core</sub> in less than 15 minutes. Weakness/exhaustion, cramps, dizziness and syncope, with T<sub>Core</sub> higher than 37°C, define heat exhaustion. Elevation of T<sub>Core</sub> is more critical than water and sodium loss. Heat exhaustion may progress to heat stroke, a serious emergency (see below).

**Management**

Reduce (T<sub>Env</sub>) if possible and cool the patient with sponging and fans. Give O₂ by mask.

Other causes of high T<sub>Core</sub>, such as malaria, should be ruled out and appropriately treated.

Oral rehydration with both salt and water (25 g of salt per 5 L of water/day) is given in the first instance, with adequate replacement thereafter. In severe heat exhaustion, intravenous fluids are needed. Monitor serum sodium and correct secondary potassium loss.

**Heat stroke**

Heat stroke is an acute life-threatening situation in which T<sub>Core</sub> rises above 41°C. The diagnosis is based on a triad of hyperthermia, neurological symptoms and heat exposure or strenuous exercise. There is headache, nausea, vomiting and weakness, progressing to confusion, seizures, coma and death. The skin feels intensely hot to the touch. Sweating is often absent but not invariably so.

Heat stroke can develop in acclimatized people in hot, humid, windless conditions, even without exercise. Sweating may be limited by prickly heat (plugging or rupture of the sweat ducts, leading to a pruritic, papular, erythematous rash).

Excessive exercise in inappropriate clothing, such as exercising on land in a wetsuit, can lead to heat injury in temperate climates. Diabetes, alcohol and drugs, such as antimuscarinics, diuretics and phenothiazines, can contribute. Heat stroke can lead to a fall in cardiac output, lactic acidosis and intravascular coagulation.

**Prevention**

Acclimatization, fluids, avoidance of inappropriate clothing and common sense are required.

**Management**

The major aim of treatment is to reduce the temperature below 40.5° as soon as possible. Delay only for essential cardiopulmonary action.
resuscitation. No pharmacological agents are effective in lowering core temperature.  
- Reduce T_{Env} if possible.  
- Arrange cold water immersion if facilities are available. Otherwise, cool the patient with sponging, icepacks or fanning.  
- Give O_2 by mask.  
- Move the patient to a medical facility. Manage in intensive care: monitor cardiac output and respiration; measure biochemistry, clotting and muscle enzymes.  
- Give fluids intravenously so the intravascular volume remains normal.

Prompt treatment is essential and can be curative, even with a T_{Core} higher than 40.5°C. Morbidity and mortality are directly related to the duration of the high T_{Core}.

Complications are hypovolaemia, intravascular coagulation, cerebral oedema, rhabdomyolysis, and renal and hepatic failure.

COLD INJURY

Cold injury may be divided into hypothermia, which is whole-body cooling, and peripheral cold injury (Box 41.2).

Hypothermia

Hypothermia occurs in many settings.

At home. Hypothermia can occur when T_{Env} is less than 8°C, if there is poor heating, inadequate clothing and poor nutrition. Depressant drugs, such as hypnotics, as well as alcohol, hypothyroidism or intercurrent illness also contribute. Hypothermia is commonly seen in the poor, frail and elderly. The elderly have a relatively large surface area in proportion to subcutaneous fat. Neonates and infants become hypothermic rapidly because of a diminished ability to sense cold and may have little insulating fat.

Outdoors on land. Hypothermia is a prominent cause of death in climbers, skiers and polar travellers, and in wartime. Wet, cold conditions with wind chill, physical exhaustion, injuries and inadequate clothing are contributory. Babies and children are at risk because they cannot take action to warm themselves.

Cold water immersion. Dangerous hypothermia can develop following immersion for more than 30 minutes to 1 hour in water temperatures of 15–20°C. In T_{Water} below 12°C, limbs rapidly become numb and weak. Recovery takes place gradually, over several hours following rescue.

Clinical features
Mild hypothermia (T_{Core} <32°C) causes shivering and initially intense discomfort. However, the hypothermic subject, though alert, may not act appropriately to rewarming: for example, by huddling, wearing extra clothing or exercising. As the T_{Core} falls below 32°C, severe hypothermia causes impaired judgement – including lack of awareness of cold – and drowsiness and coma. Death follows, usually from ventricular fibrillation.

Diagnosis
Diagnosis is straightforward, if a low-reading thermometer is available. If not, rapid clinical assessment is reliable. Someone who feels icy to the touch – abdomen, groin, axillae – is probably substantially hypothermic. If the person is clammy, uncooperative or sleepy, T_{Core} is almost certainly below 32°C.

Sequelae
Pulse rate and systemic blood pressure falls. Cardiac output and cerebral blood flow are low in hypothermia and can fall further if the upright position is maintained or the thorax restrained by a harness, or by hauling during evacuation. This is why helicopter and lifeboat winch rescues are often carried out with a stretcher rather than a chest harness.

Respiration becomes shallow and slow. Muscle stiffness develops; tendon reflexes become sluggish, then absent. As coma ensues, pupillary and other brainstem reflexes are lost; pupils are fixed and may be dilated in severe hypothermia. Metabolic changes are variable, with either metabolic acidosis or alkalosis. Arterial PO_2 may appear normal: that is, falsely high.

There is shift of the oxygen dissociation curve (see p. 206) to the left because of the reduction in temperature of haemoglobin. Thus, if an arterial blood sample from a hypothermic patient is analysed at 37°C, the PO_2 will be falsely high. Within the range 37–33°C, this factor is around 7% per degree centigrade. Many blood gas machines also calculate the arterial saturation; this too will be falsely high. When a patient is monitored using a pulse oximeter, the level of arterial oxygen saturation (S_\text{O}_2) will, however, be correct, but if S_\text{O}_2 is then converted by calculation to P_\text{O}_2, a downward correction must be applied – simply due to hypothermia.

Bradydary with ‘J’ waves (above the isoelectric line at the junction of the QRS complex and ST segment; Fig. 41.1) are pathognomonic of hypothermia. Prolongation of PR and QT intervals and the QRS complex also occurs. Ventricular dysrhythmia (tachycardia/fibrillation) or asystole is the usual cause of death.

Box 41.2 Cold injury

- **Hypothermia** – classification by temperature (T_{Core}):
  - Mild: 32–35°C
  - Moderate: 28–32°C. Risk of arrhythmias and cardiac arrest
  - Severe: <28°C. Frequently lethal

- **Peripheral cold injury** includes:
  - Frostbite: the local cold injury that follows freezing of tissue
  - Non-freezing cold injury: the damage – usually to feet – following prolonged exposure to a T_{Env} between 0°C and 5°C, usually in damp conditions

![Fig. 41.1 Electrocardiogram showing J waves in hypothermia.](image)
Management

- Maintain the patient horizontal or slightly head-down.
- Rewarm gradually.
- Correct metabolic abnormalities.
- Anticipate and treat dysrhythmias.
- Check for hypothyroidism (see p. 611).

If the patient is awake, with a core temperature of more than 32°C, place in a warm room, use a foil wrap and give warm fluids orally. Outdoors, add extra dry clothing, huddle together and use a warmed sleeping bag. Rewarming may take several hours. Avoid alcohol: this adds to confusion, boosts confidence factitiously, causes peripheral vasodilation and further heat loss, and can precipitate hypoglycaemia.

Severe hypothermia

In severe hypothermia (<28°C), people look dead. Always exclude hypothermia before diagnosing brainstem death (see p. 236). Warm gradually, aiming at a 1°C/hour increase in T<sub>core</sub>. Direct mild surface heat from an electric blanket can be helpful. Treat any underlying condition promptly, such as sepsis. Monitor all vital functions. Correct dysrhythmias. Check for sedative drugs.

Give warm intravenous fluids slowly. Correct metabolic abnormalities. Hypothyroidism, if present, should be treated with liothyronine. Various methods of artificial rewarming exist: inhaled warm humidified air, gastric or peritoneal lavage, and haemodialysis. These are rarely used. Extracorporeal membrane oxygenation (ECMO) is used in specialized centres with improved survival. Hypothermia is frequently lethal when T<sub>core</sub> falls below 30°C. Survival with full recovery has, however, been recorded with a T<sub>core</sub> of <16°C.

Prevention

Hypothermia in the field can often be prevented by forethought and action. For the elderly, improved home heating and insulation, central heating in bedrooms and electric blankets are helpful in cold spells. This can be expensive and unaffordable for some people, so supplemental finance is required.

Peripheral cold injury

Frostbite

Ice crystals form within skin and superficial tissues when the temperature of the tissue (T<sub>tissue</sub>) falls to −3°C; T<sub>env</sub> generally must be below −6°C. Wind chill is frequently a factor. Typically, fingers, toes, nose and ears become frostbitten.

Frostbitten tissue is pale, greyish and initially doughy to the touch. Later, tissue freezes hard, looking like meat from a freezer. Frostbite can easily occur when working or exercising in low temperatures and typically develops without the patient’s knowledge. Hands or feet that have lost their feeling are at risk of cold injury.

Management

Transport the patient – or if this is impossible, make them walk, even on frostbitten feet – to a place of safety before commencing warming. Warm the frozen part by immersion in hand-hot water at 39–42°C, if feasible. Assess hypothermia. Continue warming until obvious thawing occurs; this can be painful. Vasodilator drugs have no part in management. Blisters form in a few days and, depending on the depth of frostbite, a blackened shell – the carapace – develops as blisters regress or burst. Dry, non-adherent dressings and aseptic precautions are essential, though hard to achieve.

Frostbitten tissues are anaesthetic and at risk from further trauma and infection. Recovery takes place over many weeks and may be incomplete. Surgery may be needed, but should be avoided in the early stages.

Chilblains

These are small, purplish itchy inflammatory lesions, occurring on toes and fingers. They occur in cold, wet conditions. They are more common in women and heal in 7–14 days. Prevention is by keeping warm and wearing gloves and warm footwear.

Non-freezing cold injury

Non-freezing cold injury (NFCI; trench foot) describes tissue damage following prolonged exposure, usually for several hours or more, at T<sub>env</sub> around or slightly above freezing, but without frostbite. Wet socks and boots are the usual cause. There is severe vasoconstriction, and blotchiness of the lower limbs, with pain and oedema on rewarming. Recovery usually follows over several weeks. There may be a prolonged late susceptibility to cold. NFCI is a prominent cause of morbidity in troops operating in low temperatures and is a subsequent cause of litigation.

Prevention of frostbite and NFCI is largely by education and common sense: avoid damp feet and wet boots. Always carry spare dry socks, gloves and headgear.

Further reading

HIGH ALTITUDE

The partial pressure of atmospheric oxygen – and hence alveolar and arterial oxygen – falls in a near-linear relationship as barometric pressure drops with increasing altitude (Fig. 41.2).

Commercial aircraft are pressurized to around 2400 m (lowering the oxygen saturation by 3–4%). This trivial reduction is not noticed by healthy individuals.

On land, below 3000 m there are few clinical effects. The resulting hypoxaemia causes breathlessness only in those with severe cardiorespiratory disease. Above 3000–3500 m, hypoxia causes a spectrum of related syndromes that affect high-altitude visitors, principally climbers, trekkers, skiers and troops (Box 41.3), especially when they exercise. These conditions occur largely during acclimatization, a process that takes several weeks; once completed, this can enable humans to live – permanently, if necessary – up to about 5600 m. At greater heights, although people can survive for days or weeks, deterioration due to chronic hypoxia is inevitable.

The world’s highest railway runs to Lhasa in Tibet, reaching altitudes of over 5000 m. Emergency oxygen is provided in the carriages. Roads at similar altitudes in Central Asia are used extensively but since road passengers do not exercise, serious altitude-related illnesses are unusual. Climbing the world’s highest summits is just possible without supplementary oxygen, though it is often used on peaks above 7500 m. At the summit of Mount Everest (8848 m), the barometric pressure is 34 kPa (253 mmHg). An acclimatized mountaineer has an alveolar PO<sub>2</sub> of 4.0–4.7 kPa (30–35 mmHg) – near
humans’ absolute physiological limit. In 2007, arterial blood samples from acclimatized doctors on Everest at altitude 8400 m, breathing air, showed an average $P_{O_2}$ of 24.6 mmHg (3.3 kPa).

### Acute mountain sickness

Acute mountain sickness (AMS) describes malaise, nausea, headache and lassitude that affect the majority of people for a few days, above 3500 m. Following arrival at this altitude, there is usually a latent interval of 6–36 hours before symptoms begin. Treatment is rest, with analgesics if necessary. Recovery is usually spontaneous over several days.

Prophylactic treatment with acetazolamide, a carbonic anhydrase inhibitor and respiratory stimulant, is of some value in preventing AMS. Acclimatizing – that is, ascending gradually – provides better and more natural prophylaxis.

In the minority, more serious sequelae – high-altitude pulmonary oedema and high-altitude cerebral oedema – develop.

### High-altitude pulmonary oedema

Predisposing factors include youth, rapidity of ascent, heavy exertion and severe AMS. Breathlessness, occasionally with frothy blood-stained sputum, indicates established oedema. Unless treated rapidly, this leads to cardiorespiratory failure and death. Milder forms are common. Breathlessness at rest should raise the suspicion of pulmonary oedema.

### High-altitude cerebral oedema

Cerebral oedema is the result of an abrupt increase in cerebral blood flow that occurs even at modest altitudes of 3500–4000 m.

It is unusual below 4500 m, and occurs typically in the first 2 weeks, during acclimatization. Cerebral oedema can also develop suddenly in well-acclimatized climbers above 7000 m. Headache is followed by drowsiness, ataxia and papilloedema, with coma and death if brain oedema progresses.

### Management

Any but the milder forms of AMS require urgent treatment. Oxygen should be given by mask if available, and descent should take place as quickly as possible. Nifedipine reduces pulmonary hypertension and is used in pulmonary oedema. Dexamethasone is effective in reducing brain oedema. Portable pressure bags inflated by a foot pump are widely used; the patient is enclosed in the bag.

### Retinal haemorrhage

Small flame haemorrhages within the retinal nerve fibre layer are common above 5000 m and usually symptomless. Rarely, a haemorrhage will cover the macula, causing painless loss of central vision. Recovery is usual.

### Deterioration

Prolonged residence between 6000 and 7000 m leads to weight loss, anorexia and listlessness after several weeks. Above 7500 m, the effects of deterioration become apparent over several days, although it is possible to survive for a week or more at altitudes near 8000 m without supplementary oxygen.

### Chronic mountain sickness

Chronic mountain sickness occurs in long-term residents at high altitudes, usually after several decades, and is seen in the Andes and in Central Asia.

Headache, polycythaemia, lassitude, cyanosis, finger clubbing, congested cheeks and ear lobes, and right ventricular enlargement develop. Chronic mountain sickness is gradually progressive.

Coronary artery disease and hypertension are rare in high-altitude native populations.

### Diving

Free diving by breath-holding is possible to around 5 m, or with practice to greater depths. Air can be supplied to divers by various methods. A snorkel provides air to a depth of about 0.5 m; inspiratory effort is the limiting factor. At depths of more than 0.5 m – that is, with a longer snorkel tube, forced negative-pressure ventilation can cause pulmonary capillary damage with haemorrhagic alveolar oedema. Scuba divers – recreational sports divers descending to 30 m – carry bottled compressed air or a nitrogen–oxygen mixture. Commercial divers who work at great depths breathe helium–oxygen or nitrogen–oxygen mixtures, delivered by hose from the surface.

Ambient pressures at various depths are shown in Box 41.4.
Decompression sickness

Decompression sickness (the bends) is caused by the release of bubbles of nitrogen or helium and follows too rapid a return to the surface. Decompression tables indicate the duration for safe return from a given depth to the surface. In general, no decompression is necessary for diving above 30 m; at 30–60 m, decompression is necessary.

Bends can be mild (type 1, non-neurological bends), with skin irritation and mottling and/or joint pain. Type 2, neurological bends, are more serious and involve the development of cortical blindness, hemiparesis, sensory disturbances or cord lesions.

If bubbles form in pulmonary vessels, divers experience retrosternal discomfort, breathlessness and cough, known as the chokes. These develop within minutes or hours of a dive. Decompression problems do not only occur immediately on reaching the surface; they may take some hours to become apparent. Over the subsequent 24 hours, further ascent, such as air travel, can occasionally provoke the bends.

Other problems during ascent include paranasal sinus pain and nosebleeds – medically minor but dramatic, with exsanguinating pain and a mask full of bloody fluid. Toothache can be caused by gas bubbles within rotten fillings.

Management

All but the mildest forms of decompression sickness, such as skin mottling alone, require recompression in a pressure chamber, following strict guidelines. Recovery is usual. A long-term problem is aseptic necrosis of the hip due to nitrogen bubbles causing infarction. Focal neurological damage may persist, but complaints of fatigue and poor concentration are issues compounded by litigation that commonly follows diving accidents. Objective, evidence-based assessments are essential.

Lung rupture, pneumothorax and surgical emphysema

These emergencies occur when divers breath-hold during emergency ascents after gas supplies become exhausted. There is dyspnoea, cough and haemoptysis. Pneumothorax and surgical emphysema resolve with 100% oxygen. Air embolism can also occur and is treated with recompression.

Further reading

DROWNING

Drowning is defined as a process resulting in primary respiratory impairment from submersion or immersion in a liquid medium. Terms such as ‘near-drowning’ and ‘wet drowning’ should not be used.

Drowning is a common cause of accidental death worldwide. In the UK, some 40% of drownings occur in children under 5 years of age. Drowning can also follow a seizure or a myocardial infarct. Exhaustion, alcohol, drugs and hypothermia all contribute to deaths following submersion.

Fresh or seawater aspiration destroys pulmonary surfactant, leading to alveolar collapse, ventilation/perfusion mismatch and hypoxaemia. Aspiration of hypertonic seawater (5% NaCl) pulls additional fluid into the alveoli with further ventilation/perfusion mismatch. In practice, there is little difference between saltwater and freshwater aspiration. In both, severe hypoxaemia develops rapidly. Severe metabolic acidosis develops in the majority of survivors.

Management and prognosis

Clearance of the airway and ventilation are the major requirements for submerged people, and bystanders should start resuscitation immediately once the person is stable on land. Rescue breaths and chest compression come before the initiation of standard support.
cardiopulmonary resuscitation as used in cardiac arrest (see p. 1045). Patients have survived for up to 30 minutes under water without suffering brain damage – and sometimes for longer periods if $T_{\text{water}}$ is near 10°C. Survival is probably related to the protective role of the diving reflex; submersion causes bradycardia and vasoconstriction. Oxygen consumption is also decreased by hypothermia.

Resuscitation should always be attempted, even with absent pulse and fixed dilated pupils. Patients frequently make a dramatic recovery. All survivors should be admitted to hospital for intensive monitoring, as acute respiratory distress syndrome (ARDS) can develop during the subsequent 48 hours.

Recovery is frequently complete if consciousness is regained within several minutes of commencing resuscitation but poor if a patient remains stuporose or in coma at 30 minutes.

**Prevention**

This includes making sure that all people can swim, particularly young children. Any water can be dangerous, and swimming should only be undertaken in supervised areas.

**Further reading**

---

**IONIZING RADIATION**

Ionizing radiation is either penetrating (X-rays, γ-rays or neutrons) or non-penetrating (α- or β-particles). Penetrating radiation affects the skin and deeper tissues, while non-penetrating radiation affects the skin alone. All radiation effects depend on the type of radiation, the distribution of dose and the dose rate.

**Dosage** is measured in joules per kilogram (J/kg): 1 J/kg = 1 gray (1 Gy) = 100 rads.

**Radioactivity** is measured in becquerels (Bq): 1 Bq is defined as the activity of a quantity of radioactive material in which one nucleus decays per second; $3.7 \times 10^{10}$ Bq = 1 curie (Ci), the older, non-SI unit.

Radiation differs in the density of ionization it causes. Therefore, a dose-equivalent called a sievert (Sv) is used. This is the absorbed dose weighted for the damaging effect of the radiation. The annual background radiation is approximately 2.5 mSv. A chest X-ray delivers 0.02 mSv and CT of the abdomen/pelvis about 10 mSv (see Box 6.5).

A cumulative risk of cancer following repeated imaging procedures has been established and X-ray exposures should be reduced if possible.

Excessive exposure to ionizing radiation follows accidents in industry, nuclear power plants and hospitals, and deliberate nuclear explosions designed to eliminate populations – and exceptionally, by poisoning, with polonium, for example.

**Mild acute radiation sickness**

Nausea, vomiting and malaise follow doses of approximately 1 Gy. Lymphopenia occurs within several days, followed 2–3 weeks later by a fall in all white cells and platelets.

**Acute radiation sickness**

Many systems are affected; the extent depends on the dose of radiation (Box 41.5).

---

**Haemopoietic syndrome**

Absorption of 2–10 Gy is followed by transient vomiting in some individuals, followed by a period of improvement. Lymphocytes are particularly sensitive to radiation damage; severe lymphopenia develops over several days. A decrease in granulocytes and platelets follows 2–3 weeks later, since no new cells are formed in the marrow. Thrombocytopenia develops with bleeding and frequent overwhelming infections; there is a high mortality.

**Gastrointestinal syndrome**

Doses higher than 6 Gy cause vomiting several hours after exposure. This then stops, only to recur some 4 days later, accompanied by diarrhoea. The villous lining of the intestine becomes denuded. Intractable bloody diarrhoea follows, with dehydration, secondary infection and sometimes death.

**CNS syndrome**

Exposures of more than 30 Gy are followed rapidly by nausea, vomiting, disorientation and coma. Death due to cerebral oedema can follow, usually within 36 hours.

**Radiation dermatitis**

Skin erythema, purpura, blistering and secondary infection occur. Total loss of body hair is a bad prognostic sign and usually follows an exposure of more than 5 Gy.

**Late effects of radiation exposure**

Survivors of the nuclear bombings of Hiroshima and Nagasaki in 1945 provided data on long-term radiation effects. Risks of acute myeloid leukaemia and cancer, particularly of skin, thyroid and salivary glands, increase. Infertility, teratogenesis and cataract are also late sequelae, developing years after exposure.

**Major nuclear power plant accidents**

Two high-level nuclear accidents have occurred: the first in 1986 in Chernobyl in the Ukraine (part of the Soviet Union at the time), and the second in 2011 in Fukushima in Japan.

In Chernobyl, 30 people died in the first 3 months due to radiation and other factors. The majority of the people in the area received variable doses of radiation and the long-term consequences are still occurring, including the high incidence of cancer, particularly of the thyroid. However, the long-term effects on mortality are said to be enormously higher than originally thought and will keep increasing.

In the Fukushima disaster, which occurred following an earthquake that generated tsunamis along the east coast of Japan, radiation release was 10–30% of that released in Chernobyl. There were no immediate deaths due to radiation and the long-term effect of radiation is thought likely to be small.
The major problems caused by both disasters relate to psychological and social effects, as a result of the populations’ evacuation and removal from their homes for years following the accidents, as well as a general concern about the effects of radiation on themselves and their children.  

Fig. 41.3 shows the measures needed in a nuclear disaster.

Therapeutic radiation

The sequelae of therapeutic radiation – early, early-delayed and late-delayed radiation effects – are discussed on page 116. Focusing techniques are used to target radiation towards the field being treated, so that radiosensitive structures, such as the ovaries, are protected by shielding.

Management

Acute radiation sickness is an emergency. Absorption of the initial radiation dose can be reduced by removing contaminated clothing.

Management is largely supportive: prevention and treatment of infection, haemorrhage and fluid loss. Harvesting of blood products is sometimes carried out.

Accidental ingestion of, or exposure to, bone-seeking radioisotopes (e.g. $^{90}$strontium and $^{137}$caesium) is treated with chelating agents, such as EDTA and massive doses of oral calcium.

Radio-iodine contamination should be treated immediately with potassium iodide to block radio-iodine absorption by the thyroid.

ELECTRIC SHOCK

Electric shock can produce:

- **Pain and psychological sequelae.** The common domestic electric shock is typically painful, but rarely fatal or followed by serious sequelae. Nevertheless, it is an unpleasant and intensely frightening experience. A brief, immediate jerking episode can occur, which is not an epileptic seizure. There is usually no lasting neurological, cardiac or skin damage.

- **More serious effects.** These are distinctly rare following accidents in the home or in industry, but claims by survivors following industrial accidents are frequently made.
Inhaled smoke

- **Cardiac, neurological and muscle damage.** Ventricular fibrillation, muscular contraction and spinal cord damage can follow a major shock.
- **Electrical burns.** These are commonly restricted to the skin. Muscle necrosis and spinal cord damage can also occur.
- **Electrocution.** This means death following ventricular fibrillation, either accidentally, or deliberately as a method of execution. In the USA, at executions, an initial voltage of more than 2000 volts was applied for some 15 seconds in the electric chair, causing loss of consciousness and ventricular fibrillation, before the voltage was lowered. The $T_{core}$ during the execution process would sometimes reach higher than 50°C, leading to severe damage to internal organs.

**LIGHTNING STRIKE**

This describes cloud-to-ground lightning originating in thunderstorms. Human tissues are directly damaged by the high-voltage DC current of more than 10 million volts that lasts only for a few milliseconds. The result is cardiac arrest due to asystole.

Fern-shaped burns are seen on the skin. The victim’s clothes explode off the body and the person is pulseless, not breathing and in coma. The only chance of survival at this stage is bystander cardiopulmonary resuscitation. The mortality is high and those who survive are left with variable CNS damage.

**INHALED SMOKE**

Smoke is air containing toxic and/or irritant gases and carbon particles, coated with organic acids, aldehydes and synthetic materials. Carbon monoxide, sulphur dioxide, sulphuric and hydrochloric acids, and other toxins may also be present. The highly toxic polyvinyl chloride is no longer used in household goods. Air pollution is discussed on page 1487.

On smoke inhalation, patients become breathless and tachypnoeic immediately. Choking and stridor may require intubation. Pulmonary oedema and hypoxia can be fatal.

Breathing through a wet towel or clothing is the best emergency treatment. Remove the victim from the scene as rapidly as possible. Give oxygen and arrange intensive therapy unit (ITU) support. **Prevention.** Smoke alarms, regularly checked, should be installed in every household.

**NORMAL VALUES** *(These vary: please check with your local laboratory.)*

### Haematology

- **Haemoglobin**
  - Male: 135–177 g/L
  - Female: 115–155 g/L

- **Mean corpuscular haemoglobin (MCH)**: 27–32 pg

- **Mean corpuscular haemoglobin concentration (MCHC)**: 320–360 g/L

- **Mean corpuscular volume (MCV)**: 80–96 fL

- **Packed cell volume (PCV) or haematocrit**
  - Male: 0.40–0.54 L/L
  - Female: 0.37–0.47 L/L

- **White blood count (WBC)**: 4–11 × 10⁹/L
  - Basophil granulocytes: 0.01–0.1 × 10⁹/L
  - Eosinophil granulocytes: 0.04–0.4 × 10⁹/L
  - Lymphocytes: 1.5–4.0 × 10⁹/L
  - Monocytes: 0.2–0.8 × 10⁹/L
  - Neutrophil granulocytes: 2.0–7.5 × 10⁹/L

- **Platelet count**: 150–400 × 10⁹/L

- **Serum B₁₂**: 12160–925 ng/L (150–675 pmol/L)

- **Serum folate**: 4–18 μg/L (5–63 nmol/L)

- **Red cell folate**: 160–640 μg/L

- **Reticulocyte count**: 50–100 × 10⁹/L

- **Erythrocyte sedimentation rate (ESR)**: <15 mm in 1 h

- **Plasma viscosity**: 1.5–1.72 mPa.s

### Coagulation

- **Activated partial thromboplastin time (APTT)**: 26–37 s

- **Prothrombin time**: 11.5–13.5 s

- **International Normalized Ratio (INR)**: 1.0–1.3

- **D-dimer**: <500 μg/L pulmonary embolism unlikely

### Biochemistry

* (Serum/plasma in alphabetical order)

- **Alanine aminotransferase (ALT)**: <40 U/L

- **Albumin**: 35–50 g/L

- **Alkaline phosphatase**: 39–117 U/L

- **Amylase**: 25–107 U/L

- **Angiotensin-converting enzymes**: 10–70 U/L

- **α₁-antitrypsin**: 2–4 g/L

- **Aspartate aminotransferase (AST)**: Male 12–40 U/L, Female 20–170 U/L

- **Bilirubin**: <17 μmol/L (0.3–1.5 mg/dL)

- **Brain natriuretic peptide (BNP)**: threshold 100 pg/mL

- **Caeruloplasmin**: 1.5–2.9 μmol/L

- **Calcium**: 2.20–2.67 mmol/L (8.5–10.5 mg/dL)

- **Chloride**: 98–106 mmol/L

- **Complement C₃**: 0.75–1.65 g/L

- **Copper**: 11–20 μmol/L (100–200 μg/dL)

- **Creatine kinase (CPK)**: Female 20–170 U/L, Male 30–200 U/L

- **C- reactive protein**: <5 mg/L

- **Creatinine**: 79–118 μmol/L (0.6–1.5 mg/dL)

- **Cystatin C**: <1.0 mg/L

- **Ferritin**: 15–200 μg/L

- **C-Reactive protein**: <0.2 mg/L

- **Fructosamine**: up to 285 μmol/L

- **Gamma-glutamyl transpeptidase (γ-GT)**
  - Male: 11–58 U/L
  - Female: 7–32 U/L

- **Glucose**: fasting 4.5–5.6 mmol/L (70–110 mg/dL)

- **Glycosylated (glycated) haemoglobin (HbA₁c)**: 20–40 mmol/mol (4–5.9%)

- **Immunoglobulins (11 years and over)**
  - IgA: 0.8–4 g/L
  - IgG: 5.5–16.5 g/L
  - IgM: 0.4–2.0 g/L

- **Iron**: 13–32 μmol/L (50–150 μg/dL)

- **Lactate dehydrogenase**: 240–480 U/L

- **Magnesium**: 0.7–1.1 mmol/L

- **β₂-microglobulin**: 1.0–3.0 mg/L

- **Osmolality**: 275–295 mOsm/kg

- **Phosphate**: 0.8–1.5 mmol/L

- **Potassium**: 3.5–5.0 mmol/L

- **Prostate-specific antigen (PSA)**: up to 4.0 μg/L

- **Protein**: total 62–77 g/L

- **Sodium**: 135–146 mmol/L

- **Tryptase**: <13 ng/mL

- **Uric acid**: 0.18–0.42 mmol/L (3.0–7.0 mg/dL)

- **Urea**: 2.5–6.7 mmol/L (8–25 mg/dL)

- **Vitamin A**: 0.5–2.0 μmol/L

- **Vitamin D (seasonal variation)**: 25-hydroxy 37–200 nmol/L (0.15–0.80 ng/L)

- **Zinc**: 11–24 μmol/L

### Lipids and lipoproteins

- **Cholesterol**: 3.5–6.5 mmol/L (ideal <5.2 mmol/L)

- **High-density (HDL)**
  - Male: 0.70–2.1 mmol/L
  - Female: 0.50–1.70 mmol/L

- **Low-density (LDL)**: 1.55–4.4 mmol/L

- **Phospholipids**: 2.9–5.2 mmol/L

- **Triglycerides**
  - Male: 0.70–2.1 mmol/L
  - Female: 0.50–1.70 mmol/L

### Thyroid function tests

- **Thyroxine (free T₄)**: 9–21 pmol/L

- **Tri-iodothyronine (free T₃)**: 0.9–2.4 nmol/L

- **Thyroid stimulating hormone**: 0.2–4.5 mU/L

### Blood gases (arterial)

- **PₐCO₂**: 4.8–6.1 kPa (36–46 mmHg)

- **PₐO₂**: 10.6–13.3 kPa (80–100 mmHg)

- **[H⁺]**: 35–45 mmol/L

- **pH**: 7.35–7.45

- **Bicarbonate**: 22–26 mmol/L

### Urine values

- **Calcium**: 7.5 mmol/24 h or less (<300 mg daily)

- **Copper**: 0.2–1.0 μmol/24 h (15–40 mg/24 h)

- **Creatinine**: 0.13–0.22 mmol/kg body weight per day

- **5-hydroxyindole acetic acid (5HIAA)**: <47 μmol daily; amounts lower in females than males

- **Protein (quantitative)**: <0.15 g/24 h

### Serum/urine values

- **Estimated glomerular filtration rate (eGFR)**
  - Male: 90–140 mL/min
  - Female: 80–125 mL/min

- **Albumin mg/Creatinine mmol (ACR)**
  - Female: <3.5
  - Male: <2.5
