Foreword to the Tenth Edition

After 35 years and nine editions of Kumar and Clark’s *Clinical Medicine*, we felt it was time for the younger generation to continue with this 10th edition. The book has been described as the ‘gold standard, thorough guide to clinical medicine’, and is used by the majority of medical schools around the world. This would not have been possible without the dedication of our expert authors and specialists, who have written many chapters over the years. This 10th edition certainly maintains the high standard of its predecessors.

When we started those many years ago, our aim was to produce a comprehensive book of medicine which had a sound grounding in the basic sciences for understanding the mechanisms of diseases. This has proven to be a valuable concept for young students, doctors and practising health professionals. It contains sufficient knowledge and detail to be of great value in the day-to-day care of patients in hospitals and clinics, and in the field. It is used not only by the medical profession but also by all professions related to medicine. Pharmacists and consultant nurses are now taking a bigger role in patient care, and *Clinical Medicine* is the book used by many of these professionals as a source of evidence-based medical information.

Over the years, to keep up to date and advance with the times, we have travelled widely across the world, visiting many countries and developing lifelong friendships. This has enabled us to see different styles of education, along with different ways in which medicine is practised. The result has been the production of a textbook designed for a ‘doctor of the world’. This is essential, as with the swiftness of travel, diseases spread with ease and rapidity, as seen with the recent epidemics. Our International Advisory Board members have provided much useful advice and written articles for the online version to help us with this task.

We have taken much advice, as well as criticisms (!) and suggestions, from our readers so that *Clinical Medicine* remains a comprehensive reference book, as well as being practical and user-friendly.

We are delighted to welcome the new editors for this edition, who are all in current clinical posts with research activities. They have produced a book with a slightly different approach but still maintaining the high standards of previous editions.

We would like to give our warm thanks to all our readers and friends across the world. They should take credit for the way that this book has developed over the years, and no doubt will continue to help over future editions.

Lastly, on a personal note, we have both enormously enjoyed our time as authors and editors of *Clinical Medicine*. It is hard to believe that, 35 years ago, a few of us sat down to think and design a new textbook of medicine. We endeavoured to produce a new book with colour, tables and algorithms, changing the old, staid texts into a lively, easy-to-learn and user-friendly book. It has been very hard work but also a huge responsibility to assemble the correct medical facts to inspire the next generation of young doctors. We would like to thank all those with whom we have had the pleasure to work over the years, particularly the many dedicated staff at Elsevier, who have worked tirelessly with us to come up with the final products.

**Parveen Kumar and Michael Clark**

2020

---

Dr Michael L Clark and Professor Dame Parveen J Kumar on the occasion of the publication of the first edition of *Clinical Medicine* in 1987.
Preface to the Tenth Edition

‘There must be a good reason to write a new textbook of medicine when there are already a good number on the market.’ So began the preface to the First Edition of Clinical Medicine, published 33 years ago this year. Edited by Professor Dame Parveen Kumar and Dr Michael Clark, ‘Kumar and Clark’ has become synonymous not just with a medical textbook, but with the combination of excellence and accessibility they sought to provide. Their desire to empower clinical students and doctors has been the driving ambition behind the book ever since – ‘to strike a balance between exciting new developments in medical research and the vast quantity of established fact that needs to be absorbed... so that the management of disease can be based on sound physiological concepts’.

The book they produced has become an international medical best-seller, and has played a crucial part in the education of a generation of doctors – among them a new team of editors, humbled to be standing on the shoulders of these medical giants. Taking over is an honour and a great responsibility, and we are grateful for the legacy they have left, as well as for their continued support and input as we have brought this current edition to production.

Clinical Medicine has always attempted to bridge the gap between basic introductory texts and larger reference works: to be as comprehensible as it is comprehensive. The pace at which medical science continues to develop is astounding. The present generation of junior doctors and undergraduates must provide high-quality, patient-centred care in the context of a burgeoning body of medical research, patients presenting with multimorbidity and resulting polypharmacy, continuing inequalities in society and across the world, and a medical culture that expects doctors to work within teams, bridging traditional specialty and professional divides.

For this reason, we have introduced into this edition a number of new chapters to equip readers to address these new challenges: Evidence-based practice (Ch. 4), Surgery (Ch. 11), Public health (Ch. 14), Geriatric medicine, frailty and multimorbidity (Ch. 15), Haematological oncology (Ch. 17) and Men’s health (Ch. 40). In some cases, we have divided up larger chapters to highlight conditions that straddle traditional subspecialty boundaries but require a joined-up approach: Sepsis and the treatment of bacterial infection, (Ch. 8), Venous thromboembolic disease (Ch. 29), Hypertension (Ch. 31) and Obstetric medicine (Ch. 38).

We have included new clinical skills content at the beginning of most of the chapters to try to fulfil the historic aims of this book: bringing the clinical sciences to bear on the problems experienced by patients in day-to-day medical practice. We hope readers will learn not just to take generic histories and perform routine physical examinations, but to tailor their approach according to the presentation of the individual patient in front of them. We offer our own take on the clinical method and the importance of building a therapeutic relationship with patients in a new first chapter, describing what we believe remains key to the art of medicine: diagnosis (Ch. 1).

Online, readers will find a range of additional resources, including self-assessment questions, bite-sized overview topic pages covering major conditions, clinical skills videos and expanded coverage of subjects with particular international or regional relevance.

We hope you will find this edition helpful in your efforts to learn and practise medicine. Any suggestions you may wish to make are warmly welcomed and will help us to ensure that this book continues to meet the needs of its readers.

Adam Feather, David Randall and Mona Waterhouse
2020
HOW TO USE THIS BOOK

There is a broad movement through the book from early chapters which focus on general principles of clinical practice, to later chapters that deal with individual organ systems and clinical subspecialties.

These later chapters, based around individual subspecialties, begin by offering a tailored approach to basic clinical skills such as history-taking and examination. We have tried to encourage generic skills to be applied thoughtfully to the specialty in question: to encourage learners to adopt the approach taken by experts in the field, so that relevant questions are asked and key physical signs are carefully sought.

Most chapters then cover basic sciences, including the anatomy and physiology of the relevant organs in question, before dealing with individual conditions in order. Within the text:

- Pink subheadings introduce individual conditions,
- Green subheadings introduce the scientific background to the condition (e.g. ‘Aetiology’ or ‘Clinical features’), and
- Orange subheadings introduce clinical material, such as ‘Investigations’ or ‘Management’.

Boxes have been classified by the type of information they provide and have the following symbols:

- Emergency management
- Clinical information
- Differential diagnosis
- Practical procedures

‘Emergency’ boxes are in red.

E-Book extras

Clinical Overviews, Special Topics, Clinical Cases and more in the Learning Resources, Videos and Assessments chapters online, accessible via the PIN page in the front of this book.

Prescribing

We have used the Recommended International Non-proprietary Names (rINNs) for all drugs. In some diseases where a particular formulation of a drug is required, the proprietary name is used. Drugs spellings follow international usage, e.g. bendroflumethiazide and not bendrofluazide, and amfetamine and not amphetamine.

For adrenaline and noradrenaline, we have added epinephrine and norepinephrine in brackets, as these names are often used in emergency guidelines across the world.

Dosages have been given where appropriate but we recommend that all readers check with their national formularies for the exact dosages.

Units of measurement

We have used the International System of Units (SI units) throughout the book. On occasion, if there is a possibility for confusion, we have also used non-SI units and given a conversion factor.

Also in the Kumar & Clark family of books:

- Essentials of Kumar & Clark’s Clinical Medicine, 6e
- Kumar & Clark’s Cases in Clinical Medicine, 3e
- Clinical Surgery, 3e
- Essentials of Paediatrics, 2E
Online Clinical Overviews

Acid–base disorders
Anaemia: investigations
Arrhythmias: supraventricular tachycardia (SVT) and atrial fibrillation (AF)
Arrhythmias: bradycardia and heart block
Asthma

As always, this book is made what it is by the diligence and expertise of the individual chapter authors, who have worked hard to ensure that the content they provided is up to date, well presented and reflective of modern practice. We are grateful to them for their efforts.

The process of editing has been made much easier by the high standards and clear priorities set out by Parveen Kumar and Mike Clark through their careful editorial work on an astonishing previous nine editions of this book. We are now in a better position than many to appreciate the sheer amount of hard work this involved, and on behalf of the medical profession – our thanks.

We would like to acknowledge and offer grateful thanks for the input of all previous editions’ contributors, without whom this new edition would not have been possible. As well as welcoming a number of new contributors to this edition, we would like to thank various others who have stepped down this time around – especially those who have had a long association with the book. Much of their work is reflected in the text of this edition, and so we thank them for their input:

- John V Anderson (Diabetes mellitus and metabolic disorders)
- Rachel Buxton-Thomas (Respiratory medicine)
- Sarah R Doffman (Respiratory medicine)
- Gail E Eva (Palliative medicine)
- Anthony J Frew (Respiratory medicine)
- Edwin AM Gale (Diabetes mellitus and metabolic disorders)
- Christopher J Gallagher (Malignant disease)
- Charles J Hinds (Critical care medicine)
- Katharine Hurt (Respiratory medicine)

We were saddened to hear of the untimely death of Anthony J Frew (Respiratory medicine), who made a major contribution to this book but also to the wider practice of medicine.

We are grateful to the International Advisory Board, who have supplied a significant amount of online material that helps to ensure this book maintains the global relevance it has always striven to enjoy.

We would like to thank Dr Robert Stephenson and Dr Joseph Davies for their radiological input and figures.

The team at Elsevier have worked extremely hard in bringing this project to fruition. We are particularly grateful to Pauline Graham and Helen Leng, the commissioning and development editors, who did so much to drive this project forward before they left Elsevier. We owe them much gratitude and wish them every success in their future ventures. Pauline in particular has worked on a number of previous editions of this book and the recent success of Clinical Medicine owes much to her oversight.

Thanks to Alex Mortimer, who took over as commissioning editor relatively late in the project, and from a standing start provided helpful guidance and direction in the final stages of production. Thanks to Louise Cook, who completed various aspects of development with a close eye for detail. Thanks to our copy-editors, Wendy Lee and Lynn Watt, who checked thoroughly, detected error and redundancy, and acted pre-emptively to offer helpful suggestions. Julie Taylor and Anne Collett acted as production managers and we are grateful to them for their experience and efficiency in bringing a large and spreading project together into a finished piece of work. Thanks to Kim Benson for her work in putting together the online content in a way that will maximize its usefulness to readers around the world.

Finally, thanks to our long-suffering families, who have endured much absence and distraction as we have worked at antisocial hours on manuscripts at various stages of development. This would not have been possible without your patience and support, and we are most grateful.
In many patient interactions, the forming of a diagnosis stands as a turning point in the therapeutic journey: the focus shifts from the gathering of information and the performance of tests to planning of treatment and discussion of outcomes. Forming a diagnosis is a complex process, which always starts with taking a history. The initial patient story is first developed into a set of problems, which in turn becomes a list of differential diagnoses. Data-gathering, further information, initial treatment and the passage of time help to form and confirm a definitive diagnosis.

Fig. 1.1 shows how diagnosis is often an iterative process, in which information is gathered, interpreted and integrated to form a working diagnosis, and then communicated and acted on through treatment; all the time the working diagnosis is refined or revised using newly gathered information, including the patient’s response to treatment.

Being a doctor is a privilege; our patients allow us to share in their troubles and triumphs, and place their faith in our judgement and skill.

In the 21st century, professional roles and responsibilities are rapidly changing, and so defining what it means to be a doctor is difficult. Healthcare is provided by teams, not individuals, and other healthcare professionals now perform tasks in assessing and managing patients that were previously carried out exclusively by doctors. The use of artificial intelligence, which applies vast, unsorted clinical and academic datasets to produce algorithms that can inform diagnostic and management questions, provides a fundamental challenge to the historically crucial role of doctors in these areas.

While the process of diagnosis will be increasingly augmented by artificial intelligence, it is unlikely ever to be replaced by it because at the centre of any diagnostic conundrum is a human being. Working out what is wrong with a patient involves not just technical skills, such as the assimilation of information, interpretation of data and use of clinical reasoning to reach a diagnosis. It also requires compassion, empathy, trust, respect and humour: the stuff that makes up a relationship between human beings. And it brings into play an ethical code developed to ensure that the great power of medical knowledge is used for the good of individual patients and of society as a whole.

Once a diagnosis is made, the human tasks continue. Doctors tailor their explanations to the needs and understanding of their patients. They negotiate a management strategy and share clinical decision-making with the person under their care. However medicine evolves in the future, at the centre of everything we do must remain the huge privilege and pleasure of caring for, supporting, empowering and helping people so that their health and social needs are optimally met.
Box 1.2

Information-gathering

Once a rapport has been established, the consultation is generally divided into three parts: history, examination and investigations/management. Depending on the context and the acuity of the situation, these may occur in isolation, follow on from one another or, in severely ill patients, happen synchronously.

The history

In the construction of an accurate diagnosis, nothing is more important than taking a full history from the patient. It is estimated that up to 80% of the diagnosis can be made on the basis of a careful history alone. In addition to information-gathering, eliciting the history is key to the therapeutic relationship. If it goes well, the patient knows they have been listened to, has had an opportunity to convey all of their concerns, and knows that the clinician cares for them and will act as their advocate. This builds mutual trust and respect, and helps the patient to undergo invasive or intimate procedures and adhere to therapeutic interventions in the future.

A meeting of two experts

It has been said that a medical consultation is a meeting of two experts. A good consultation is based on mutual respect, rejecting a traditional paternalistic view of medicine (‘doctor knows best’), and assisting joint exploration of the biomedical and the patient perspectives on the problem. This will lead to shared understanding, where clinician and patient jointly grasp what is wrong, what impact it is having on the patient’s life, what the patient expects from medical intervention, and which options would be best for investigating and treating the problem (see Fig. 5.1).

The golden minute

At the start of the consultation the clinician should avoid interrupting the patient for as long as possible. Patients often mentally rehearse a script relating to the symptoms or problems they wish to describe. An early interruption may throw them off course and cause them to forget key points, leaving them feeling dissatisfied with the interaction. The term ‘the golden minute’ has been coined to encourage clinicians to allow patients to tell their story uninterrupted for at least 1 minute. This gives them time to describe their symptoms as they have experienced them, including information that might be missed if the clinician jumps in too soon with closed, focused questions.

Information-gathering

Once a rapport has been established, the consultation is generally divided into three parts: history, examination and investigations/management. Depending on the context and the acuity of the situation, these may occur in isolation, follow on from one another or, in severely ill patients, happen synchronously.

If it goes well, the patient knows they have been listened to, has had an opportunity to convey all of their concerns, and knows that the clinician cares for them and will act as their advocate. This builds mutual trust and respect, and helps the patient to undergo invasive or intimate procedures and adhere to therapeutic interventions in the future.

In 2011, geriatrician Dr Kate Granger was diagnosed with metastatic sarcoma, from which she eventually died in 2016. Noticing that many of the healthcare staff treating her during her illness failed to introduce themselves, she created the ‘Hello, my name is …’ campaign. Describing why an initial introduction is so important, she said, ‘I firmly believe it is not just about common courtesy, but it runs much deeper. Introductions are about making a human connection between one human being who is suffering and vulnerable, and another human being who wishes to help. They begin therapeutic relationships and can instantly build trust in difficult circumstances.’

The campaign encourages healthcare staff to greet and introduce themselves to patients and encourages the wearing of easy-to-read name badges like this one.

Box 1.2 Good practice for using the medical history to build a therapeutic relationship

- Allow the patient to tell their story, without jumping in prematurely with questions.
- Ask the patient specifically about their ideas, concerns and expectations (ICE);
  - Ideas: What do they think might be going on? Have they done any reading about their symptoms or asked anyone they know?
  - Concerns: Are they feeling anxious or worried about their symptoms? What is causing them concern? Are there any particular areas where their symptoms might be making life difficult?
  - Expectations: What are they hoping for from this consultation?
- Try to develop an understanding of who the patient is as a person. Where, and with whom, do they live? What is their occupation? What things do they enjoy? Moments of human connection, such as a shared interest in a place or activity, can be powerful in building a relationship between clinician and patient.
- Try to convey empathy and concern, reinforcing to the patient that you are their advocate and will do your best to help them.

Box 1.3 Strategies in history-taking

- Begin with open questions (‘Could you tell me more about the pain?’): do this before moving to closed questions to help rule certain key problems in or out (‘Did the pain get worse after eating?’).
- Emphasize your active listening; maintain eye contact, nod, acknowledge key points, and respond to comments the patient might make that are humorous or sad.
- Respond to the patient’s body language; note whether the patient becomes distressed or embarrassed. If so, acknowledge this and look for ways to address it.
- Empathize: try to show the patient that you care about what they are going through. Put yourself in their shoes: how might they be feeling? Communicate this: ‘Thanks for sharing this – it must be difficult not knowing what is going on.’
- Summarize: run through what the patient has told you, to make sure nothing has been missed out.
- Signpost: explain what you have just covered and what you are now going on to explore, and why.
- Use plain English: avoid medical jargon or complicated vocabulary, unless it is clear that the patient is able to understand this.

Box 1.4 A structured approach to information-gathering in the medical history

- Presenting complaint: why has the patient sought medical advice?
- History of the presenting complaint: further information about the patient’s main problem
- Past medical and surgical history
- Drug history and allergies
- Family history
- Social history: information on the patient’s present living arrangements and relevant risk factors

have given a lot of thought to their symptoms and come with a well-thought-through story; others may not have reflected much on what has been going on, and key information may need to be drawn out by sensitive questioning.

Structuring the medical history

Over the last 150 years a formal structure for the recording of the patient’s history has evolved. This has several subsections (Box 1.4). While facts may be recorded in this very stylized manner, the patient will rarely, if ever, present them in this structure. It is up to the interviewing clinician to assimilate and interpret the information fully and to form a considered diagnostic narrative, so that when it is presented to others, either verbally or in written form, sense can be made of the diagnostic reasoning and conclusions.

History of the presenting complaint

The aim is to provide a thorough account of the symptoms that led the patient to seek medical attention. It is vital to listen closely to how the symptoms are described and not to miss any clues that can be followed up with direct questioning. For each symptom the patient presents with, additional questioning should be used to identify:

- Time course: When did the problem begin? Does it come and go? Is there anything that triggers it? Is there any variation in the symptoms during the day or night? Has the patient ever had anything like this in the past? Establishing the pattern in which symptoms have developed is often one of the most helpful parts of the history in helping to form a diagnosis (Box 1.5).

Box 1.5 Using the time course of symptoms to suggest an underlying cause

<table>
<thead>
<tr>
<th>Time course</th>
<th>Possible causes</th>
</tr>
</thead>
<tbody>
<tr>
<td>Onset of symptoms</td>
<td>Vascular – thrombotic or embolic</td>
</tr>
<tr>
<td>Immediate (seconds to minutes)</td>
<td>Anatomical – e.g. perforation of a viscus</td>
</tr>
<tr>
<td></td>
<td>Electrical – e.g. dysrhythmias, seizures</td>
</tr>
<tr>
<td>Hours to days</td>
<td>Bacterial or viral infections</td>
</tr>
<tr>

<td>Degenerative conditions</td>
</tr>
<tr>
<td></td>
<td>Fibrotic diseases</td>
</tr>
</tbody>
</table>

- Associated symptoms: What else has the patient noticed? Begin with an open question, and then proceed to asking about the presence or absence of relevant symptoms that may help to determine the cause of the problem.
- Severity, site, radiation and character of any pain: How would the patient rate it on a scale from 1 to 10? Do they describe it as tight, dull, electric or burning? Is it getting worse, staying the same or starting to improve?
- Responses: What has the patient done about the symptoms? Have they sought medical advice or used medication that they have at home?

The ‘Clinical skills’ sections at the beginning of many of the chapters in this book present additional questioning techniques relevant to particular medical specialties. At this point in the history, asking questions to form a review of systems can be valuable in eliciting further symptoms that the patient may not have mentioned or not thought relevant (Box 1.6).

Past medical and surgical history

This should include all significant medical conditions, including hospital admissions, long-term conditions, life-threatening or life-changing conditions, and important investigations, procedures and therapeutic interventions (operations, endoscopies, biopsies and significant courses of treatment such as chemo- or radiotherapy).
Conducting a brief but comprehensive ‘review of systems’ may be a particularly useful schema when the patient has non-specific symptoms, e.g. weight loss, tiredness and weakness, or when someone reports ‘I just don’t feel right, doctor’. 

**Respiratory**
Cough, sputum (volume, frequency, consistency, colour, offensive taste or smell), haemoptysis (volume, frequency, consistency, colour, freshness, altered nature, clots), shortness of breath, exercise tolerance, orthopnoea, wheeze, chest pain

**Cardiovascular**
Chest pain, shortness of breath, cough, sputum, orthopnoea, swelling of ankles (peripheral oedema) or abdomen (ascites), paroxysmal nocturnal dyspnoea, palpitations

**Gastrointestinal**

- **General** – normal and present weight, appetite, oral intake
- **Upper** – dysphagia (level: high – base of neck, mid and lower chest), consistency of food tolerated/not tolerated, dyspepsia, odynophagia, upper abdominal pain, early satiety, nausea/vomiting (volume, frequency, consistency – unaltered food (regurgitation), altered food, blood), haematemesis (volume, frequency, consistency, colour, freshness, altered nature, clots)
- **Lower** – lower abdominal pain, altered bowel habit, constipation, diarrhoea (volume, frequency, consistency, colour), blood per rectum, mucus per rectum, anal pain

**Hepatobiliary and pancreatic**
Jaundice, associated pain, pruritus, symptoms of encephalopathy, abdominal swelling (ascites)

**Renal**
Urine (frequency, volume, colour, offensive odour), dysuria, haematuria (volume, frequency, colour, freshness, clots), symptoms of bladder outflow tract obstruction (hesitancy, frequency, small volume, terminal dribbling)

**Musculoskeletal**
Bone pains, back pain and stiffness, joint stiffness, swelling, pain, erythema, patterns of joints involved, muscular pain, weakness, acute pain suggesting pathological or fragility fractures

**Dermatological**
Rashes, blisters, ulcers

**Endocrine**
Diabetic symptoms and complications, sexual function, menstruation, symptoms of thyroid dysfunction

**Neurological**
Seizures, muscle weakness, involuntary movements, loss of sensation, altered gait, speech and swallowing dysfunction

**Ophthalmic**
Eye pain, redness, dryness or grittiness, changes in vision, flashing lights

**Ear, nose and throat**
Changes in smell, taste or hearing, pain in ears, nose, throat or sinuses, nasal discharge or crusting

**Haematological**
Easy bleeding or bruising, tiredness, lymph node swelling, abdominal fullness (splenomegaly)

**Mental health**
Mood (suicidality when relevant), anxiety, altered perceptions (hallucinations), abnormal beliefs (delusions)

**Genitourinary**
Urethral or vaginal discharge, pain or itching, pain during sexual intercourse, sexual function, in women – menstrual cycle, use of contraception, history of pregnancies and childbirth

### Box 1.7 Five questions for the patient with a long-term condition

1. **Diagnosis** – HOW, WHY, WHERE and WHEN was your condition first diagnosed?
2. **Progression** – How has it progressed since?
3. **Control** – How do you monitor your condition? Which healthcare professionals are involved with your care? When did you last have a check-up? What medications do you take? What are your biggest challenges in controlling your condition?
4. **The good and the bad** – What is the BEST and WORST your condition has ever been? How does it have an impact on your life?
5. **Today/recently** – How have you been? If unwell, have you ever been this unwell before? What happened when you were last this unwell?

If the patient has had any surgical interventions a comprehensive anaesthetic history should be sought and recorded. Five good questions to ask about chronic conditions are listed in Box 1.7.

**Drug history**
Document all medications the patient has been taking, including prescribed, over-the-counter and herbal or traditional treatments. Record when each was started, along with the dosing regimen; ask about side-effects and adherence to treatment. When you are unsure or ignorant of a drug, it is essential to research and record the class, common side-effects and interactions. Medication error is a common cause of morbidity and mortality, and ignorance is no defence. Ask about and record drug allergies, including the timing and nature of any reactions.

**Family history**
This is particularly relevant when assessing younger patients or when the differential diagnosis includes possible genetic conditions. It is essential to record the structure of the patient’s family in detail, including the patient’s and parents’ siblings, any ‘half-siblings’ (genetically related to only one of the patient’s parents), and where relevant, a history of consanguinity. Once this is completed, confirm which of these relatives have been affected by a given condition or by premature death (see p. 13).

**Social history**
The social history has two key purposes:

- **Establishing whether there are any environmental factors** that may be causative or exacerbating the patient’s symptoms. Always ask about housing, occupation, tobacco smoking, alcohol intake, and use of recreational and illicit drugs. Where relevant, draw up a travel history, including animal and insect bites, a sexual history (if a sexually transmitted disease, including HIV infection, is suspected), and hobbies, leisure activities and pets.

- **Understanding more about the lifestyle** of the patient. Where do they live? How active are they? Are they limited in any daily activities by physical or mental health problems? Do they have informal or formal carers? If so, how often do the carers attend and what do they do for the patient?

**Physical examination**
The physical examination, including any objective observations, should be used to confirm or refute the initial diagnosis/diagnoses made from the history. It is a key part of all medical interactions but its duration and extent will be guided by the patient’s history and the acuity of the presentation.

Even in the era of complex technological investigations a careful physical examination performs a number of key functions, including:

- Providing objective evidence (physical signs) to complement subjective evidence (symptoms) from the history. Sometimes a
The medical consultation

firm diagnosis can be made almost solely on the basis of examination findings, such as in a number of skin disorders.

- Assessing the severity or extent of problems.
- Identifying unexpected findings that patients themselves have not noticed.
- Building rapport with patients. The value of performing a physical examination can be significant in reinforcing to patients that they have been dealt with thoroughly and compassionately.

Typically a general assessment will be made as the history is being elicited (is the patient well or unwell? Why? distant symptoms? Current symptoms? Past medical history? Family history? Medication history? Social history?). This will be aided by a set of formal observations (blood pressure, heart rate, oxygen saturation, respiratory rate, level of consciousness, capillary blood glucose and temperature).

A more detailed assessment is then carried out, including a ‘general examination’ (hands, upper limbs, face and neck), examination of the likely affected system(s) as suggested by the history, and finally a wider examination of other organ systems.

**Fig. 1.2** A basic approach to clinical examination.

**1. Initial impressions** on approaching the patient, or as they come into the consultation area – the ‘end of the bed’:
- Establish whether the patient is well or unwell. Why?
- Perform observations (temperature, heart rate, blood pressure, respiratory rate, oxygen saturations, Glasgow Coma Scale (GCS) or ACVPU score – combined into the National Early Warning Score (NEWS-2, see p. 204)
- Carry out a feel-to-face examination – spend 30 seconds looking the patient up and down, noting any striking abnormalities – facial asymmetry, scars, deformities, skin lesions, amputations, sweating, breathlessness, discomfort
- Look for clinical clues around the bed – oxygen, intravenous fluids, sputum pot, urinary catheter

**2. Hands:**
- Look for peripheral signs of serious conditions like infective endocarditis or chronic liver disease
- Feel the temperature of the hands and the volume of the pulse to begin to assess the patient’s volume status

**3. Face:**
- Assess for signs of systemic conditions, including pallor and cyanosis
- Inspect the mouth and standards of dental care
- Consider the need for examination of some or all cranial nerves

**4. Neck:**
- Assess the jugular venous pressure (see p. 1031)
- Ensure that the trachea is central
- Palpate for cervical and supraventricular lymphadenopathy or other masses

**5. Heart:**
- Palpate the apex beat and examine for heaves and thrills
- Auscultate for heart sounds, performing additional manoeuvres as necessary

**6. Chest:**
- Examine for chest expansion and abnormal movement
- Auscultate throughout both lung fields; consider other manoeuvres such as percussion note or vocal fremitus if necessary

**7. Abdomen:**
- Inspect for obvious masses, distension or asymmetry, and for signs of medical intervention such as operative scars or a stoma bag
- Palpate gently for tenderness and masses
- Assess for organomegaly; assess other features (e.g. pulses, bruits, ascites) as necessary

**8. Limbs:**
- Inspect for skin changes and deformity; assess the joints
- Assess for peripheral oedema
- Check peripheral pulses
- Consider the need for formal examination of the peripheral nervous system

**9. Functional assessment:**
- Note any difficulty the patient may have with:
  1. Speech and language; swallowing problems
  2. Undressing and dressing during the examination
  3. Sit to stand, transfers and mobility – note any mobility aids or assistance required

**Discussion and negotiation around investigations**

In the modern era, there are a huge number of investigations available to the clinician, ranging from simple bedside tests such as spirometry or urine dipstick analysis, through to complex radiological
Diagnosis: the art of being a doctor

Imaging and invasive procedures such as endoscopy or angiography. Some tests may combine both diagnostic and therapeutic potential. Choosing appropriate and cost-effective interventions that maximize diagnostic yield, while minimizing the burden on the patient and the cost to providers, can be challenging, and each chapter in this book will provide guidance in specific contexts.

For any test that is being considered, a number of questions are relevant:

- **What question will this test help to answer?** Only the most basic of tests should be performed routinely. For all others, it is helpful to have clear diagnostic questions in mind, and often specialists, such as diagnostic radiologists, can help with choosing the most appropriate investigation to answer the relevant question in a particular patient context.

- **What is the sensitivity and specificity of the test?** A highly sensitive test will correctly identify a high proportion of patients with a given disease (true positives); a highly specific test will correctly identify a high proportion of those who do not have the disease (true negatives). For example, in the diagnosis of venous thromboembolism (VTE), see Ch. 29, measurement of serum D-dimer has a high sensitivity (a positive result picks out almost all patients with VTE) but a low specificity (many of those with a positive D-dimer do not have VTE). Since D-dimer measurement is cheap, it is a useful screening test (because a negative test effectively rules out VTE); a positive test is followed up by a high-sensitivity test, such as venous Doppler ultrasound or computed tomography pulmonary angiography (CTPA).

- **What are the risks of the test to the patient?** All ionizing radiation carries a small risk of future malignant disease, and invasive procedures may cause bleeding, infection or injury to internal organs. These dangers, along with the benefits of the investigation result, need to be discussed with patients to help them make a good decision.

- **How much certainty is needed?** Where highly burdensome treatment is contemplated (such as surgery or chemotherapy for cancer), it is usually necessary to obtain a formal histological diagnosis by tissue biopsy before starting treatment. If such treatment would not be appropriate, then undergoing invasive diagnostic procedures may not be appropriate either.

**CLINICAL DIAGNOSTIC REASONING**

Forming a diagnosis involves a complex process of reasoning. Large amounts of information gathered from the history, examination and available investigation results need to be assimilated and synthesized into a working diagnosis. Each piece of evidence should be weighed according to the degree of confidence you have in its accuracy, and no significant findings should remain unexplained.

If you, as the treating clinician, are unable to make sense of the information presented to you, you should be humble and insightful enough to seek help from others.

**Models of diagnosis**

A traditional model of medical diagnosis suggests that a clinician should begin by considering all possible causes of a particular presenting symptom, and use information gathered from the diagnostic process to include and exclude likely causes gradually, using probabilistic reasoning, until only one remains (Fig. 1.3A). According to the insights of the Nobel Prize-winning psychologist and economist Daniel Kahneman, this is ‘type 2 thinking’, and the kind of thinking we like to imagine that we carry out all the time: logical, deductive and rational.

An alternative model suggests that diagnosis proceeds instead primarily by pattern recognition, the kind of ‘type 1 thinking’ that allows humans to make quick judgements of new situations by comparing them with similar situations encountered in the past. In this form of diagnostic reasoning, clinicians rapidly compare the patient presenting to them with many other patients they have seen previously, subconsciously drawing on similarities and differences to form an initial impression that is then tested as further information becomes available (Fig. 1.3B).

In reality, a combination of these two approaches generally occurs: an initial rapid impression is formed, chiefly by type 1 thinking, which is subsequently revised by the slower, more reason-based type 2 thinking where the initial diagnosis proves inadequate. This ‘back to the drawing board’ approach, which draws on the strengths of both types of thinking, has been suggested as the best model for safe diagnosis – where a working diagnosis is continually re-evaluated as new evidence becomes available (Fig. 1.3C).

Type 1 thinking is prone to bias (see later), where it is assumed that everything new must be similar to things seen before. It is crucial for doctors to re-evaluate an initial diagnosis actively in situations where things ‘don’t quite fit’ rather than persisting with a hastily formed assumption that may prove incorrect.

**Diagnostic error and patient safety**

It has been estimated that 10–15% of medical diagnoses are wrong. Misdiagnosis or delayed diagnosis can be the cause of significant patient harm, including adverse effects from unnecessary treatment or failure to receive an appropriate timely intervention. While misdiagnosis may occur as a result of inadequate clinical knowledge or (particularly in resource-poor settings) through a lack of diagnostic resources, it also arises as a direct result of one or more cognitive biases. Box 1.8 lists a number of common cognitive biases, applied to the field of diagnostic reasoning, which together form a key avoidable source of medical harm, termed ‘human error’.

**Strategies for avoiding bias**

Various strategies can be employed in order to reduce the chances of making an incorrect diagnosis:

- **Adopting an iterative approach**, in which all previous diagnoses are subjected to appropriate re-evaluation, especially if evidence appears that brings them into question.
- **Team discussions**, where all team members are empowered to challenge the reasoning of more senior clinicians. Multidisciplinary team meetings bring clinicians from different specialties together with allied healthcare professionals to ensure that all relevant
Leaders of healthcare teams have a particular responsibility to ‘flatten the authority gradient’ and empower more junior members to contribute knowledge and ideas to team discussions.

- **Diagnostic criteria and guidelines**, where robust standards are outlined to ensure that potential diagnoses are correctly assigned and similar conditions are differentiated from each other.

- **Considering patient problems in language devoid of assumption**, as far as possible, seeking to describe a patient’s problems succinctly and objectively without recourse to previous diagnostic reasoning.

- **Using lists of disease classes to avoid jumping to conclusions**: simple *aides-mémoire* encourage clinicians to consider, for example, malignant, infectious, vascular, metabolic, inflammatory and degenerative causes of a particular problem.

---

### Levels of diagnostic depth

A clinical impression is formed by taking a comprehensive history and undertaking a relevant physical examination. Drawing on the information gathered, clinicians may typically assign a widely understood umbrella term to categorize a collection of signs and symptoms into a clinical entity: for example, ‘acute coronary syndrome’, ‘delirium’, ‘upper respiratory tract infection’ or ‘sepsis’. Some patient presentations do not fall neatly into boxes, and so sticking with a narrative description of the patient’s problems is appropriate in some cases. However, naming a clinical impression in a few simple words is often vital in moving towards a final diagnosis.

An impression formed at the end of a clinical consultation can often be refined by simple, quick and relatively non-invasive tests; but it might require complex, expensive or potentially hazardous investigations to produce a definitive diagnosis. Likewise, additional tests might be needed in order to demonstrate the extent, severity or treatment-responsiveness of the condition (Fig. 1.4).

Often, it is appropriate to stop at the level of a syndrome or clinical impression rather than continuing with investigations to demonstrate a precise histopathological cause. This might be the case if:

- the patient is satisfied with this level of explanation and declines further diagnostic work-up
- the problem is mild or self-limiting
- further investigation is unlikely to yield a specific cause, e.g. where a patient with acute but resolving diarrhoea or vomiting is diagnosed with likely viral gastroenteritis without a specified pathogen
- further investigation is unlikely to influence management, e.g. if none of the specific pathological processes that cause the condition is amenable to active management
- treatment is possible, but the patient is very frail and the proposed investigations or treatments are felt, after discussion with the patient, to be inappropriate.

---

### The role of watchful waiting

All diseases have a natural history. Some progress inexorably, some are self-limiting and some relapse and remit. Where there is diagnostic uncertainty, there can be a role for waiting to see how events develop before reaching for a diagnostic label. Indeed, this is sometimes
necessary, as the diagnostic criteria for some diseases stipulate that symptoms must have been present for a certain length of time before a diagnostic label can be assigned. For instance, in multiple sclerosis, where an initial presentation with symptoms suggestive of a demyelinating illness is usually termed a ‘clinically isolated syndrome’, some patients will suffer no further episodes while others will progress to multiple sclerosis. In other cases, it is wise to defer risky or burden-some investigations until the clinical course of the disease makes it clear that such investigations are justified. Watching and waiting can be a valid approach only if, firstly, the patient’s clinical condition allows it; and secondly, it does not involve withholding treatment that would otherwise be of benefit (Box 1.9). Discussion with the patient is crucial.

When not to investigate

Decisions about whether and how to pursue a formal diagnosis are often complex and should be made in conjunction with the patient. Everyone is different and individuals differ in their willingness to tolerate uncertainty, with some wanting to seek a firm diagnosis at all costs, and others happy to accept a presumed diagnosis and run the risk that this may be wrong. Clinicians can guide patients in making complex decisions by helping them understand the likely or possible outcomes of different decisions; often, offering ‘best- and worst-case scenarios’ for different potential courses of action is helpful. In general, investigations should be avoided where:

- the patient is too frail to derive any benefit from confirming a diagnosis
- the patient agrees to have an initial investigation, but will not accept intervention if the result is positive, e.g. the patient agrees to a myocardial perfusion scan but would not want to undergo subsequent coronary angiography or stenting
- the treating clinician feels that investigation is not deemed to be in the patient’s best interests – patients can refuse investigation or intervention, but cannot demand it.

Box 1.8 Cognitive biases leading to misdiagnosis

- **Anchoring**: Relying too heavily on a piece of information offered early as a potential explanation. For example, an elderly patient is sent to hospital by their GP with a ‘suspected chest infection’ and the doctor in the emergency department fails to consider other possible causes of breathlessness, such as heart failure or pulmonary embolus.
- **Availability**: Assuming that because certain explanations spring easily to mind, they are likely to be correct. For example, a doctor assumes that a patient presenting with acute kidney injury is dehydrated and administers intravenous fluids, even in the absence of evidence to support this, because of unfamiliarity with less common causes of this presentation, such as renal parenchymal disease.
- **Framing**: Making decisions in different ways, depending on whether a choice is presented in positive or negative terms. For example, a doctor may respond differently to a radiology report of an incidentally discovered adrenal mass that is reported as ‘probably benign’, compared to the same mass if the report reads ‘unable to exclude malignancy’.
- **Optimism**: Assuming that negative outcomes will occur at a lower rate than they really do. For example, a junior doctor may fail to call for senior help with a clearly deteriorating patient because of an unrealistically positive expectation that the interventions they have instituted will improve the situation.
- **Recency bias**: Remembering most easily things that have happened most recently. For example, a doctor may be distracted away from a common diagnosis by a much rarer one, which was covered in a recent teaching session they attended.
- **Substitution**: An easier (and related) question is solved in place of a more difficult one. For example, a patient with a history of intravenous drug use presents with worsening headache, although a CT scan of their head is normal. Rather than address a computationally difficult question (why does this patient still have a headache?), a simpler question is solved (might they simply be seeking opiate analgesia?).
- **The sunk-cost fallacy**: Continuing to invest in a failing idea because of significant prior investment. For example, a cardiologist recommends that a patient undergo high-risk elective valve replacement, despite colleagues suggesting conservative management because of the patient’s co-morbidities. The procedure is unsuccessful and the patient suffers significant complications, but the doctor subsequently recommends a second procedure rather than conservative management, in order to try to salvage something from the situation.

Diagnosis criteria

Some conditions are diagnosed with a single pathognomonic investigation result: for example, the presence of urate crystals on microscopic examination of synovial fluid is diagnostic of gout. In other situations, confirming the diagnosis is far more complex and may require a combination of symptoms, physical signs and investigation results. For example, according to the 2018 diagnostic criteria for systemic lupus erythematosus, published jointly by the American College of Rheumatology and European League Against Rheumatism, patients need to score ten or more points from different domains, including symptoms, signs, haematological and immunological blood tests, and histology (see p. 440).

Diagnostic criteria have a range of functions beyond treating individual patients, including a role in public health (in the compilation of statistics for monitoring trends in the incidence and distribution of diseases), research (to allow study of diseases and treatments in well-defined disease populations), and remuneration or reimbursement (in many health systems, payment to healthcare providers is on the basis of diagnostic codes assigned to patients receiving care). The International Statistical Classification of Diseases (ICD), now in its 11th edition, is produced by the World Health Organization in order to provide a standardized set of coding and diagnostic criteria across the world. Although useful at a population level, and for the research and administrative purposes described, these criteria are rarely used in routine clinical practice.

Overdiagnosis

Overdiagnosis refers to a diagnosis that is correctly assigned on the basis of a screening programme, but is inappropriate because it is unlikely ever to cause harm to the patient in question. It is the inevitable result of population health screening and poses risks to patients because of the potential for unnecessary further diagnostic procedures, therapy, or insurance charges.

For example, a frail 93-year-old man with dementia is visited at home by his GP at the request of his daughter. A routine check reveals a heart rate of 66 bpm and a blood pressure of 168/96 mmHg. A diagnosis of hypertension is made and the elderly man is started on an antihypertensive. This diagnosis may be considered inappropriate on a number of grounds:

- While blood pressure rises with age, ‘normal’ blood pressure in a 93-year-old is not clearly defined; neither is an acceptable target blood pressure to guide intervention.
Communicating a diagnosis

Box 1.9 The role of watchful waiting in diagnosis

- A 77-year-old woman is undergoing CT scanning of the coronary arteries after an episode of chest pain. A small (<10 mm) pulmonary nodule is incidentally noted. She is at high risk for lung cancer because of a long smoking history. In accordance with the British Thoracic Society’s ‘Guidelines for the Investigation and Management of Pulmonary Nodules’, she is offered computed tomography screening at 3 months and 1 year. These reveal stable appearances with no increase in size, so she is reassured and discharged from further follow-up of this nodule.
- A 34-year-old man is found to have abnormal liver function tests and is referred to a hepatology clinic. A set of blood tests screening for common causes of liver disease, including viral hepatitis antibodies, are all normal. A liver biopsy is discussed with the patient, but because his liver function tests are not rapidly deteriorating, a decision is made in favour of watchful waiting. Two months later, his liver function tests return to normal ranges and remain normal after another 6 months. He is discharged from clinic without a diagnosis for his transient liver injury.
- An 18-year-old woman with a history of presumed minimal change disease as a child presents to the renal outpatient department with recurrent nephrotic syndrome. She is commenced on a loop diuretic and high-dose corticosteroids, but after 2 months remission has not been achieved. Because it is atypical for minimal change disease to fail to remit by this point, and because the diagnosis had never before been histologically proven, a renal biopsy is carried out. This revealed a different but related renal disorder: focal segmental glomerulosclerosis.

COMMUNICATING A DIAGNOSIS

Towards the end of a clinical consultation, the clinician will need to explain their diagnostic reasoning to the patient, along with their plans for further investigation and intervention. Explaining and teaching is a key part of working in medicine, and this part of the consultation is crucial in laying the foundation on which decisions for the future can be made.

Explaining diagnoses to patients

Some patients will have little difficulty in understanding complex medical explanations; this should never be assumed, however. While it is wise to avoid patronizing patients with a good understanding, it is generally worth assuming that patients understand less rather than more about their condition, and explaining all parts of the reasoning process, at least in brief. Using a phrase like ‘I know you understand lots about this already, but I’m just going to go over things right from the beginning so we both understand each other’ can be a good way of giving simple explanations without causing embarrassment.

Explaining a patient’s diagnosis is best done in chunks, waiting between each chunk to ensure they have understood (Box 1.10). It is wise to work chronologically through the symptoms, employing
10 Diagnosis: the art of being a doctor

Box 1.10 ‘Chunking’ the diagnostic process

Beginning with a summary of the clinical presentation, the clinician explains their diagnostic reasoning before suggesting what should happen next, ensuring after each chunk that the patient understands and agrees.

- ‘So you came in to see me because over the past month you’ve noticed pain, swelling and stiffness in your hands …’
- ‘When I examined your hands, I found that lots of the small joints in your fingers were hot, red and swollen, and I also noticed these new swellings behind your elbows you hadn’t seen before …’
- ‘Now I don’t know exactly what is going on, but when joints get red and hot like this, it often means there is inflammation in the joints – often the body’s immune system is attacking something in the joint …’

- ‘I’d like to do some blood tests to look for evidence that the immune system is causing this, and also get an X-ray of your hands …’
- ‘Once the results are back, I’m going to talk to a specialist rheumatologist at the hospital …’
- ‘It might be that they suggest starting anti-inflammatory medication over the next few days to try to reduce the swelling and stop it causing any damage to the joints …’
- ‘In the meantime, let me prescribe you some painkillers to try to make things more comfortable.’

Box 1.11 Breaking bad news

- Choose a setting that is private, quiet and comfortable – perhaps a relatives’ room or a main ward, after ensuring that you will not be disturbed.
- Ask the patient who they would like with them to discuss their test results – encourage them to bring along a trusted friend or relative. Try to have at least two members of clinical staff present, e.g. a senior treating doctor and a nurse caring for the patient.
- Set aside time – ideally, at least 20 minutes – to ensure that the discussion is not rushed and that questions can be dealt with.
- Introduce yourself and others present and explain the purpose of the meeting, e.g. to go through recent test results.
- Ask how the patient has been since the last time you spoke with them.
- Briefly (in not more than two or three sentences) recap their history – what symptoms they presented with and why certain tests were done.
- Fire a warning shot: explain that things are looking more serious than first thought.
- Pause.
- Clearly, briefly and in plain English, describe the findings, e.g. ‘I’m afraid that the CT scan revealed there is a lump in your left lung, and the doctor reporting the scan thinks that this could be lung cancer.’
- Pause.
- Be prepared for any reaction from the patient – they might break down in tears, or argue with you, or become angry, or simply deny that what you have said is true. Avoid giving too much more information until they indicate they are ready.
- Briefly outline the likely diagnosis, any areas of uncertainty and the next steps (e.g. further investigations or referral to a specialist).
- Pause.
- Invite questions.
- Be ready to answer the question ‘How long have I got?’ It is often impossible to say at this stage, and it is generally misleading and inappropriate to give specific figures. It can sometimes be helpful to outline whether a condition is survivable, or to give best- and worst-case scenarios.
- Give hope: explain what can be done, even if it is simply a matter of care, support and symptom control. Try to help patients to maintain some control over their life, but never make false promises.
- Empathize: e.g. some patients like to be touched, with a reassuring hand placed on theirs, while others do not. Always try to convey concern and support explicitly.
- Outline a brief plan: what happens now? What should they do if they think of questions over the next few hours?

Breaking bad news

Sometimes, clinicians have to tell patients that they have a severe, chronic or life-limiting disease. This might be expected news for the patient or it might come as a complete surprise. This is one of the most difficult things a clinician has to do. It is never a pleasant task but having a good structure enables a clinician to be sensitive and kind, and leaves the patient knowing that they are not on their own (Box 1.11).

Traditionally, it was commonplace to withhold bad news from patients, telling it only to their families. Such an approach will often cause far greater distress to the patient (as a result of being deceived) and is now considered unacceptable. Where patients do not wish to be told about their diagnosis, this should be respected, and information can be given to family members instead if the patient consents; often, in such cases, the patient may understand that the news is not good and may wish to be spared the full details. If major treatment decisions need to be made and the patient has mental capacity to make them, clinicians should do their best to persuade patients of the importance of understanding what is wrong with them.

Box 1.12 Example of a ‘problem list’ in an elderly patient admitted to hospital

1. Right lower lobe pneumonia (presumed aspiration pneumonia, no positive microbiology)
2. Impaired swallow, awaiting speech and language therapy assessment
3. Previous stroke, right-sided hemiparesis, bedbound
4. Acute kidney injury probably secondary to sepsis and hypotension – resolving
5. Previously struggling to cope at home despite four-times-daily care package; may require residential nursing care

Team communication

Communication of a diagnosis between members of the healthcare team should be succinct and accurate. Technical terms are appropriate, alongside abbreviations, as long as they are widely understood. Often, patients with complex medical histories may present with multiple problems, and so clinicians treating them may compile a ‘problem list’ outlining currently unresolved issues (Box 1.12). This can help to highlight issues that need to be resolved, guide investigations and management, and be used in communicating a patient’s needs between members of the healthcare team.
The SBAR tool

Reviews of serious incidents occurring in hospital often highlight poor communication between team members as playing a key role in subsequent patient harm. For example, a member of the nursing staff may notice a deteriorating patient and summon the on-call doctor, who may fail to appreciate the severity of the situation and therefore not respond in a timely manner.

To address this problem, the SBAR tool has been developed to help formalize such communication. Staff members are encouraged to use this to structure their communication, in order to emphasize the need for full attention and an adequate response from the professional receiving the call.

- **Situation**: who is making the call, which patient does it relate to and where are they in the hospital?
- **Background**: why was the patient admitted and what have been the recent events?
- **Assessment**: why are you calling, what are the patient’s current problems and what assessment have you made of them?
- **Response**: what do you need the person receiving the call to do?

### Shared decision-making

Generally a diagnosis will be reached that incorporates information from the history, physical examination and relevant investigations. This will be communicated to the patient by the clinician treating them, who should check their understanding and discuss the implications. As with history-taking, the patient must be regarded and treated as an equal partner. The concept of shared decision-making has been developed to emphasize just how important joint involvement is, with benefits for both the healthcare provider and the patient (Box 1.13).

For patients to participate as equal partners, it is crucial for them to be provided with all the necessary information about their condition and the various treatment options available, presented in language that is easily understood. Information leaflets and online materials, often produced by patient support groups and charities, are available to help achieve this.

### Managing uncertainty

Sometimes, it is not possible to make a definitive, corroborated diagnosis. This may be because:

- the investigations available are unable to provide definitive proof, for example if medicine is being delivered in a resource-poor setting
- definitive investigation is avoided because of the dangers or burdens involved
- the patient declines investigation
- investigations have commenced but will not reach a conclusion for some time.

This can be very difficult for both patients and clinicians. Without a confirmed diagnosis, it is impossible to produce a confident prognosis, and this can be profoundly challenging for patients. It can also be unnerving to clinicians to be taken to the point at which science can offer nothing more and they are forced to acknowledge their limitations. At this point, the clinician should help the patient deal with this lack of closure and uncertainty. It might be relevant to establish what gives the patient’s life meaning, to enquire about their religious or spiritual beliefs, or to ask what most concerns them about facing their current illness.

In the meantime, plans can be built on the available evidence relating to the patient’s underlying illness, guided by key concerns expressed by the patient:

- Symptomatic treatment (such as pain relief or anti-sickness drugs) is always appropriate when required, and may be a way of restoring a sense of control in an uncertain situation (see Ch. 7).
- Empirical treatment can be instituted on the basis of a suspected underlying pathology, even if a firm diagnosis is not possible. However, this needs clear discussion with the patient about the likelihood that the proposed treatment may cause side-effects, and may be ineffective or even harmful if the suspected diagnosis is incorrect.
- If a rapidly life-limiting condition, such as advanced malignancy, is suspected, then discussions should begin early about end-of-life care. What is important to the patient? Where would they like to be cared for in their final months or weeks?
- Help from psychologists or chaplains can be of great benefit and is often readily available.

### DIAGNOSIS, ARTIFICIAL INTELLIGENCE AND THE FUTURE OF MEDICINE

Artificial intelligence (AI) describes the ability of machines to perform tasks traditionally believed to require higher cognitive skills. Examples include natural language processing, learning, executive planning and pattern recognition. Although multiple predictions are made about the future powers of self-conscious computers and ‘super-intelligences’, all the AI technology available currently, and in the near future, may be described as ‘narrow AI’ or ‘weak AI’; that is, systems designed to augment specified tasks within limited and well-defined fields of activity. The basis of all AI systems lies in the ability of high-capacity computer systems to analyse and utilize trends in large datasets that correlate with predefined outputs, ‘seeing’ patterns in data that possess predictive significance but are invisible to human observers. AI systems are ‘fed’ data and use this to develop and refine rules that predict the outputs they are designed to detect.
AI systems in healthcare

A number of such narrow AI systems have been trialled with encouraging results in different areas of medical practice:

- ‘Computer vision’. These AI systems review large numbers of medical images with appropriate diagnostic labels supplied by experts, and build diagnostic algorithms based on features of the image that correlate with the assigned diagnosis. Such systems have been shown to perform as well as, or better than, human experts in a number of clinical settings, including the interpretation of electrocardiograms, the diagnosis of skin cancers, the recognition of abnormalities on retinal screening photographs, and the reporting of chest X-rays and other radiological images.

- Risk prediction. These AI systems consider large sets of patient data (age, sex, ethnicity, environmental risk factors, physiological observations, results of blood tests and other investigations, administered medications) and correlate these with patient outcomes to form powerful predictive tools. Patterns are detected that may have previously been overlooked by human researchers, such as beat-to-beat heart rate variation, which correlates strongly with mortality and development of sepsis in patients in critical care settings. Similar algorithms have been shown to be effective in predicting in-hospital complications and mortality, out-of-hospital events (such as 10-year cardiovascular mortality) and even less obvious outcomes (such as suicide risk).

- Individualized treatment. No two patients suffer exactly the same disease and yet patients with the same diagnosis are generally, at present, offered the same treatment options. AI systems have been developed that analyse a large volume of patient data (relating, for example, to patients’ whole-genome sequences or samples from tumours), allowing genetic variants to be identified that predict the likely responses to different types of treatment. These allow treatment regimens to be tailored to individual patients, maximizing efficacy and minimizing toxicity.

Future uses of AI

All of the currently and imminently available AI systems simply present clinicians with suggestions: probabilities that might suggest a diagnosis, or quantify a set of risks, or identify treatments most likely to be of benefit. As such, these AI systems provide doctors with a helpful ‘second opinion’, from a unique, non-human perspective. The key ethical issue of deciding what to do next falls to the patient and doctor, working collaboratively.

However, other AI technologies are being developed that pose far greater ethical questions about the role that machines should play in healthcare. Although these are presently far off, some developers envisage robotic systems that would almost completely replace human doctors: patients would tell a computer system their symptoms, undergo whatever investigations were required, and receive an automated, algorithm-driven diagnosis and management plan. These systems would use natural language processing to review all relevant medical literature, and make use of this data to identify exactly which treatment would be most appropriate for the patient in question.

In the social care sector, robotic systems are already being designed that provide ‘care’ and ‘companionship’ for elderly, disabled or cognitively impaired people. Other systems administer talking-based therapy to patients with mood disorders such as depression. Does this represent a good use of technology, reducing the cost and improving the quality of care? Or is there something fundamental about caring for people that requires a human to do it?

The role and goals of medicine

Predictions about the future implications of technology are notoriously difficult to make and prone to embarrassingly high degrees of error. It is right for doctors to welcome rigorously tested narrow AI as it is currently available, and to appraise future developments critically to ensure that they maintain the safety and dignity of the patients they are designed to help.

However, technology can never replace the human-to-human interaction at the heart of every medical consultation. While we strive to use all available technology to refine diagnosis and improve management, this must never be at the expense of the relationship that has always formed the cornerstone of effective medical care. We are increasingly able to provide our patients with the most incredible therapeutic interventions that deliver invaluable improvements in quality and quantity of life. But we are also always able to give them our attention, comfort, compassion and care. There can be no greater privilege than having a patient trust you with their life and health, and we shoulder a heavy responsibility when seeking to act as their doctors.

CORE SKILLS AND KNOWLEDGE

The clinical practice of diagnosing and managing genetic disease is an expanding and evolving field. Increasingly, this is carried out by experts in organ-based subspecialties (e.g. neurologists and dermatologists), in partnership with clinical genetics teams. Hence, a working knowledge of skills such as documenting a family history and understanding basic genetic investigations is relevant across a range of disciplines. Typically, clinical geneticists are qualified adult or paediatric physicians who undertake postgraduate training in the specialty, often including a period of laboratory-based research. Genetics services are usually delivered in specialist centres in the outpatient setting.

Key skills in clinical genetics include:
- Obtaining a comprehensive history. A careful family history is essential.
- Drawing and interpreting a family tree.
- Estimating the risk of a future pregnancy being affected or carrying a disorder, based on common patterns of inheritance.
- Understanding the principles of genetic testing, and the ethical challenges this may entail.

Exposure to genetics multidisciplinary team meetings and genetics clinics represent opportunities for medical students and training clinicians to gain insights into how to ask relevant questions when taking a history from a patient with genetic disease. This has to be coupled with thorough clinical examination, which may lead to the selection of appropriate radiological imaging tests and invasive tests such as tissue biopsies.
Taking a genetic family history

A genetic family history consists of information describing how family members are related to each other (their biological relationships) and any medical conditions they may have.

Establishing such a family history can:
- reveal patterns of inheritance
- help make or refine a diagnosis
- help assess the likelihood of genetic disease in relatives
- affect testing, treatment and management strategies
- highlight the need for referral to specialist services
- help in building rapport with patients.

Information is usually gathered by asking a series of questions about each member of the family in a systematic order (Box 2.1) and recording the information pictorially as a family tree (a pedigree; see opposite). Family history can be an important risk factor for cancer and a wide range of conditions with monogenic or complex polygenic aetiology. Some national clinical guidelines therefore highlight the importance of taking and recording a genetic family history.

Immediate family

In adult patients, information is typically obtained first on which members of the immediate family are affected by a disorder. Begin drawing a pedigree with the patient towards the bottom of the page (allowing space below for any children).
- Ask about their spouse or partner.
- Ask about any children the patient may have.
- Enquire sensitively about stillbirths and miscarriages.
  Where any individual is affected, try to determine the age at which they were diagnosed and the severity of their disease.

Patient's siblings and parents

Siblings are drawn alongside the patient and the parents are placed above, with lines indicating family relationships (which can be complex):
- Ask whether the patient’s parents are alive, and about any illnesses they have at present or have been diagnosed with in the past. If the parents are deceased, record the stated cause of death and the age at which this happened.
- Ask how many siblings and half-siblings the patient has, and their ages. Enquire about their health.
  Sometimes, patients may not know the family members’ cause of death, which may, in some cases, reflect medical uncertainty (e.g. in conditions that cause sudden death); this uncertainty should be recorded.

Father's side of the family

Typically, these family members will be drawn above and to the left of the patient, and include the father’s siblings and parents. Information on a minimum of three generations should be obtained.

Mother's side of the family

Typically, these family members will be drawn above and to the right of the patient, and include the mother’s siblings and parents. Information on a minimum of three generations should be obtained.

Family history questionnaire

Sometimes, patients may find it difficult to recall information in a clinical consultation. A family history questionnaire can aid information-gathering, as the patient can fill this in at home, with the help of family. These questionnaires can be verified against cancer registry data, which is important as patients sometimes may not know which specific cancers affected their relatives. Increasingly, online forms are being piloted, which can be filled in electronically.

Drawing a pedigree

A set of agreed symbols is used when drawing a pedigree (Fig. 2.1). In order to show how individuals are related to each other, lines are drawn between symbols. The correct placement of these lines is a key skill to ensure that the pedigree gives an accurate picture of family relationships.

A dominantly inherited example is presented in Fig. 2.2. Affected males and females are filled in with black, and unaffected are left white. Males and females are equally affected, and both can transmit the disease to their offspring, who carry a 50% chance of inheriting the ‘faulty’ gene. More examples of patterns of inheritance are shown on page 28.

16 Human genetics

INTRODUCTION

The genetic code that forms the instruction manual for humans can now be sequenced in less than a day. From a clinical perspective, this brings an enormous range of new possibilities and challenges to the practice of medicine. In this chapter, we aim to provide an overview of key concepts in DNA, when we can use it to predict with confidence, and the caveats that apply.

DNA is an efficient means of storing information. Three billion base-pairs (bp) sit in the nucleus of each cell and carry the instructions to make all the parts of any cell in the human body. When a cell divides, all of this information is duplicated, with systems designed to prevent mistakes from occurring during this process. Nonetheless, errors do arise, which can either be harmless or cause disease, depending on the nature and the timing of the change. The discovery that the genetic code could be ‘read’ or sequenced allowed changes in parts of this instruction manual to be sought as an explanation for inherited diseases. In addition, the study of how the genetic code is altered in malignant cells has provided new insights into cancer biology (see Ch. 6). Progressive advances in deoxyribonucleic acid (DNA) sequencing technology have meant that we are able to look at the human genome of an individual at multiple time points from conception to the grave (Fig. 2.3). This information can have a range of implications, from pre-implantation genetic diagnosis to predicting and stratifying disease, selecting treatments and assessing drug response and the risk of adverse side-effects. An understanding of how this new information fits into clinical medicine is immensely relevant for patient care. As the cost of DNA sequencing drops, adoption of this technology is likely to become more widespread. In the UK, the 100,000 Genomes Project aims to study patients with rare diseases and cancer. Commercially available testing is accessible simply by supplying a saliva sample in the post.

However, while we are able to sequence DNA rapidly, much bigger challenges lie ahead. For example, it can be difficult to interpret changes in DNA found in apparently healthy individuals. Until recently, genetic changes in rare diseases were studied in the context of affected individuals and their families. A genetic change that can cause disease within such families may not have the same effect in other people. This is thought to be due to the genetic context in which the change presents. It is hoped that when careful phenotyping and long-term follow-up are combined with genomics, we can advise appropriately on the implications of a broad range of such genetic changes. Currently, in some areas there is consensus on ‘actionable’ incidental findings in genomics: such as when preventative mastectomy should be discussed with patients when a genetic change is found that may predict early-onset breast cancer. But work remains to be done to capture how the human genotype predicts phenotype, and large consortia efforts such as the Human Phenotype Ontology project aim to achieve this across all diseases.

Gene editing

In addition to reading the human genome, we can now also edit and change the genetic code, using very precise molecular tools such as CRISPR (see Fig. 2.18). By 2018, reports had been verified of gene editing in humans, which can be transmitted to the next generation. There is much discussion about how gene-editing technologies should and should not be used.

Here we aim to highlight selected genetic advances that exemplify concepts of genetic disease and to describe cases where genetic information has been clinically relevant to patients, either in routine care or in the context of clinical trials. The ability to interpret and contextualize genetic information in clinical care is becoming increasingly relevant as genomics is mainstreamed across clinical specialties.

CLINICAL GENETICS

Genetic disorders pose considerable health and economic problems and early diagnosis is crucial. While individual diseases are rare, it is estimated that almost 6000 genetic disorders are recognized, and as a collective, 1 in 25 children may be affected with a genetic disorder. In any pregnancy, the risk of a serious developmental abnormality is approximately 1 in 50 pregnancies, and around 15% of
paediatric inpatients have a multifactorial disorder with a predominantly genetic element. In addition, 50% of clinical genetics referrals are adults with late-onset disease, including neurological, endocrine and gastrointestinal conditions, along with cancer.

Approach to the patient with a suspected genetic disease

Genetic services routinely coordinate clinical diagnosis, genetic testing, information-giving, family planning and targeted screening for a range of genetic disorders. Clinicians assessing a patient with a genetic disorder should keep in mind the following aims:

- **Obtaining a full history.** The pregnancy history, drug and alcohol ingestion during pregnancy, and maternal illnesses (e.g. diabetes) should be detailed.
- **Establishing an accurate diagnosis.** Examination may help in diagnosing a genetically abnormal child with characteristic features (e.g. trisomy 21) or ascertaining whether a genetically normal fetus was damaged in utero.
- **Drawing a family tree.** This is essential. Questions should be asked about abortions, stillbirths, deaths, marriages, consanguinity, and medical history of family members. Diagnoses may need verification from other hospital reports.
- **Estimating the risk of a future pregnancy being affected or carrying a disorder.** Estimation of risk should be based on the pattern of inheritance. Disorders caused by mutations in single genes carry a high risk; chromosomal abnormalities other than translocations typically carry a low risk. Empirical risks may be obtained from population or family studies.
- **Information-giving.** Information on prognosis and management should be supplied, with adequate time allowed for it to be discussed openly and freely, and repeated as necessary.
- **Continued support and follow-up.** An explanation should be provided of the implications for other siblings and family members.
- **Genetic screening.** This includes prenatal diagnosis or pre-implantation genetic diagnosis (in vitro fertilization followed by testing of embryos before implantation) and, if requested, carrier detection. A large number of molecular genetic tests are available.

Genetic counselling should be non-directive, with the couple making their own decisions on the basis of an accurate presentation of the facts and risks in a way they can understand.

Further details on taking a genetic history and drawing a family tree can be found on pages 2–3.

Ethical considerations

Ethical considerations must be taken into account in any discussion of clinical genetics. For example, prenatal diagnosis with the option of termination may be unacceptable on moral or religious grounds. In the case of diseases for which there is no cure and currently no treatment (e.g. Huntington’s chorea), genetic tests can accurately predict which family members will be affected; many people, however, would rather not have this information. One very serious outcome of new genetic information is that disease susceptibility may be predictable – for example, in Alzheimer’s disease – and so medical insurance companies can decline to issue policies for individuals at high risk. In some countries, a moratorium is in place to prevent insurers from using such data against patients in this way. It remains to be decided who should have access to an individual’s genetic information and to what extent privacy should be preserved.

Testing for genetic disease

Genetic testing is extremely powerful, as it can reveal changes in DNA that explain why a patient has a clinical disease. Once such information is acquired, it can, for example, guide the selection of screening tests, aid prognostication and influence treatment. In some instances, it can elegantly replace the multiple radiological tests that were previously required to make a diagnosis of a genetic disease. In some situations, where the diagnosis is unknown and a strong clinical suspicion of genetic disease exists, genetic tests can provide the necessary clues to exclude certain differentials and aid the process of making and refining a diagnosis.

There will increasingly be a temptation simply to order whole-genome sequencing (see p. 33) for any genetic disease but this may have negative outcomes. For example, it may reveal unexpected findings that patients may not necessarily have wanted to know, such as a predisposition to early-onset dementia or cancer. Changes in disease genes may also be detected and cause anxiety, yet the genetic changes may not give rise to the expected disease in that patient. In some situations, incomplete knowledge may make any form of prognostication or reassurance impossible. The individual responses of each patient to such uncertainty can be difficult to predict, and more dialogue is needed to understand how to make better decisions for comprehensive testing in partnership with patients.

The importance of taking a comprehensive personal and family history and performing a clinical examination should be highlighted. This information may identify a single gene that needs to be tested if a particular disorder is suspected. In some conditions, where a selection of genes may account for a phenotype, a panel of 10–20 relevant genes can be tested. Some genomic centres favour this approach, in which only clinically relevant genes are studied in a tiered manner, with further comprehensive testing carried out only in cases that are negative.

From a technical perspective, this increasingly involves a single test (such as whole-exome or genome sequencing) with reporting on relevant genes only. Genetic testing is a rapidly changing field and exposure to clinical genetics clinics and multidisciplinary meetings will be crucial in training clinicians to select and implement the ‘right’ test.

THE CELLULAR BASIS OF GENETICS

DNA and the genetic code

Hereditary information is contained in the sequence of the building blocks of double-stranded DNA (Fig. 2.4). Each strand of DNA is made up of a deoxyribose–phosphate backbone and a series of purine (adenine (A) and guanine (G)) and pyrimidine (thymine (T) and cytosine (C)) bases. Because of the way in which the sugar–phosphate backbone is chemically coupled, each strand has a polarity, with a phosphate at one end (the 5′-end) and a hydroxyl at the other (the 3′-end). The two strands of DNA are held together by hydrogen bonds between the bases. T can pair only with A, and G can pair only with C; therefore, each strand is the antiparallel complement of the other (see Fig. 2.4). This is key to DNA replication because each strand can be used as a template to synthesize the other.
Chromosomes are complex structures consisting of one linear molecule of DNA that is wound around histone proteins into small units called nucleosomes, and these are further wound to make up the structure of the chromosome itself.

Diploid human cells have 46 chromosomes, 23 inherited from each parent; thus there are 23 ‘homologous’ pairs of chromosomes (22 pairs of ‘autosomes’ and two ‘sex chromosomes’). The sex chromosomes, called X and Y, are not homologous but are different in size and shape. Males have an X and a Y chromosome; females have two X chromosomes. (Primary male sexual characteristics are determined by the SRY gene – sex-determining region on the Y chromosome.)

The chromosomes are classified according to their size and shape, the largest being chromosome 1. The constriction in the chromosome is the centromere, which can be in the middle of the chromosome (metacentric) or at one extreme end (acrocentric). The centromere divides the chromosome into a short arm and a long arm, referred to as the p arm and the q arm, respectively (see Fig. 2.4).

Chromosomes can be seen when they are in the metaphase stage of the cell cycle and are very condensed. The stain gives a different pattern of light and dark bands that is diagnostic for each chromosome. Each band is given a number, and gene-mapping techniques allow genes to be positioned within a band within an arm of a chromosome. For example, the CFTR gene (a defect in which gives rise to cystic fibrosis) maps to 7q21: that is, on chromosome 7 in the long arm in band 21.

During cell division (mitosis), each chromosome divides into two so that each daughter nucleus has the same number of chromosomes as its parent cell. During gametogenesis, however, the number of chromosomes is halved by meiosis, so that, after conception, the number of chromosomes remains the same and is not doubled. In the female each ovum contains one or other X chromosome, but in the male the sperm bears either an X or a Y chromosome.

Chromosomes can be seen easily only in actively dividing cells. Typically, lymphocytes from the peripheral blood are stimulated to divide and are processed to allow the chromosomes to be examined. Cells from other tissues can also be used for chromosomal analysis: for example, amniotic fluid, placental cells from chorionic villus sampling, or bone marrow and skin cells (Box 2.2).

The mitochondrial chromosome

In addition to the 23 pairs of chromosomes in the nucleus of every diploid cell, the mitochondria in the cytoplasm of the cell also have
The cellular basis of genetics

2

19

their own genome. The mitochondrial chromosome is a circular DNA (mtDNA) molecule of approximately 16500 bp, and every base-pair makes up part of the coding sequence. These genes principally encode proteins or RNA molecules involved in mitochondrial function. These proteins are components of the mitochondrial respiratory chain involved in oxidative phosphorylation, producing adenosine triphosphate (ATP). They also have a critical role in apoptotic cell death. Every cell contains several hundred mitochondria, and therefore several hundred mitochondrial chromosomes.

Virtually all mitochondria are inherited from the mother, as the sperm head contains no (or very few) mitochondria. Disorders mapped to the mitochondrial chromosome are shown in Fig. 2.5.

DNA transcription

To express the information in the genome, cells transcribe the code into the single-stranded ribonucleic acid (RNA). RNA is similar to
DNA in that it comprises four bases – A, G and C but with uracil (U) instead of T – and a sugar-phosphate backbone with ribose instead of deoxyribose. Several types of RNA are made by the cell. Messenger RNA (mRNA) codes for proteins that are translated on ribosomes. Ribosomal RNA (rRNA) is a key catalytic component of the ribosome, and amino acids are delivered to the nascent peptide chain on transfer RNA (tRNA) molecules.

A gene is usually 20–40 kilobases of DNA that contains the code for a polypeptide sequence (but lengths vary – the muscle protein dystrophin is 2.4 megabases long). Three adjacent nucleotides (a codon) specify a particular amino acid, such as AGA for arginine. There are only 20 common amino acids, but 64 possible codon combinations make up the genetic code (see Fig. 2.7). This redundancy means that most amino acids are encoded by more than one codon, and additional codons are used to signal initiation or termination of polypeptide-chain synthesis.

RNA is transcribed from the DNA template by an enzyme complex of more than 100 proteins, including RNA polymerase, transcription factors and enhancer proteins. Promoter regions upstream of the gene dictate the start point and direction of transcription. The complex binds to the promoter region, the nucleosomes are remodelled to allow access, and a DNA helicase unwinds the double helix. RNA, like DNA, is synthesized in the 5′ to 3′ direction as ribonucleotides are added to the growing 3′ end of a nascent transcript. RNA polymerase does this by base-pairing the ribonucleotides to the DNA template strand it is reading in the 3′ to 5′ direction. Messenger RNA is modified as it is synthesized (Fig. 2.6). It is capped at the 5′ end with a modified guanine that is required for efficient processing of the mRNA and translation. The 3′ end of the mRNA is modified with up to 200 A nucleotides by the enzyme poly-A polymerase. This 3′ poly-A tail is essential for nuclear export (through the nuclear pores), stability and efficient translation into protein by the ribosome. Human protein coding sequences (exons) are interrupted by intervening sequences that are non-coding (introns) at multiple positions (see Fig. 2.6). These are spliced from the nascent message in the nucleus by an RNA/protein complex called a spliceosome. Differential splicing can cause exons to be spliced alongside their intervening introns. This contributes significantly to the complexity of the human transcriptome, as proteins translated from these messages lack particular domains and therefore have different activity.

There are also a variety of RNAs that regulate gene expression or RNA processing. The non-coding RNAs (ncRNAs) include a group that regulate gene expression. These include microRNA (miRNA) and small interfering RNA (siRNA), which typically bind to a subset of mRNAs and inhibit their translation and/or initiate their degradation (siRNA only initiates degradation). Micro RNAs and siRNAs are short ncRNAs (19–29 bp) that together regulate expression of approximately 30% of genes by degradation of transcripts or repression of protein synthesis. A growing range of additional regulatory ncRNA classes are being identified, many of which control gene expression by epigenetic mechanisms (see later).

Control of gene expression

The genome of all cells in the body encodes the same genetic information, yet different cell types express very different subsets of proteins. Gene expression is controlled at many steps from transcription to protein degradation. However, for many genes, transcription is the key point of regulation. This is controlled primarily by proteins, which bind to short sequences within the promoter regions that either repress or activate transcription, or to more distant sequences where proteins bind to enhance expression. These transcription factors and enhancers are often the end-points of signalling pathways that transduce extracellular signals to change gene expression. This level of regulation often involves the translocation of an activated factor from the cytoplasm to the nucleus. In the nucleus, these DNA-binding proteins recognize the shape and position of hydrogen bond acceptor and donor groups within the major and minor grooves of the double helix (i.e. the double helix does not need to unwind). There are several classes of DNA-binding protein that differ in the protein structural motif that allows them to interact with the double helix. More permanent control of gene expression patterns can be achieved epigenetically.
Epigenetics

Although the importance of the genetic code has been emphasized, normal function and disease can occur, despite a particular DNA sequence being exactly the same. The term ‘epigenetics’ is used to explain changes that arise due to differing gene expression but do not involve changes in the underlying DNA sequence. Despite not altering the genetic sequence, the effects of epigenetic changes are stable over rounds of cell division. A number of systems initiate and sustain these changes:

- **Modifications to DNA’s surface structure** but not its base-pair sequence: DNA methylation. Enzymes called methyltransferases modify cytosine to 5-methylcytosine. This “tag” occurs mainly in sites where a cytosine molecule is next to a guanine nucleotide, a CpG site. When CpG islands (groups of CpG sites) in the promoter region are methylated, gene expression is repressed.

- **Modification of chromatin proteins** (in particular, acetylation of histones), which not only support DNA but also bind it so tightly as to regulate gene expression. At the extreme, such binding can permanently prevent the DNA sequences being exposed to, let alone acted on by, gene transcription (DNA-binding) proteins.

Some epigenetic modifications are also ‘transmissible’, meaning that a dividing liver cell, for example, can give rise to two daughter cells with the same epigenetic signals, such that they express the appropriate transcriptome for a liver cell. Epigenetic change forms the basis of genomic imprinting (see p. 29).

Epigenetic changes in gene expression also occur in cancer. An example is DNA methylation repressing tumour suppressor genes. Targeted therapy is already playing a big role in the control of malignant disease.

The X chromosome and inactivation

Although females have two X chromosomes (XX), they do not have two doses of X-linked genes (compared with just one dose for a male XY) because of the phenomenon of X inactivation or lyonization (after its discoverer, Dr Mary Lyon). In this process, one of the two X chromosomes in the cells of females is epigenetically (see earlier) silenced through the action of a regulatory ncRNA, so the cell has only one dose of the X-linked genes. Inactivation is random and can affect either X chromosome.

Protein synthesis and secretion

While the instructions are essentially the same in every cell, in different tissues the regions that are transcribed are cell-specific, and so are the ensuing proteins. For example, in skeletal muscle, the RNA transcripts involve the generation of proteins that are needed for muscle, such as myosin. Conversely, in the cells of the cornea, specific keratins that are transparent are expressed. The actual working parts of the cell are protein, and the translation of the nucleic acid sequence to protein involves the ribosome.

Protein translation

Mature mRNA is transported through the nuclear pore into the cytoplasm for translation into protein by ribosomes (Fig. 2.7A).

- The two subunits of ribosomes (40S and 60S) are formed in the nucleolus from multiple proteins and several rRNAs, before transport to the cytoplasm.

- In the cytoplasm, the two ribosomal subunits interact on an mRNA molecule, usually via ribosome-binding sites encoded in the untranslated 5′ region of the message. The mRNA is then pulled through the ribosome until a translation initiation codon is encountered (usually an AUG).

Protein structure

The amino acid sequence of a polypeptide chain (its primary structure) ultimately determines its shape. The weak bonds (hydrogen bonds, electrostatic and van der Waals interactions) formed between the side-chains of the different amino acids and/or the peptide backbone provide the secondary structure (α-helices, β-strands, loops). These, in turn, are folded into a three-dimensional, tertiary structure to provide functional protein domains of 40–350 amino acids. The modular nature of domains allows their functionality to be combined in protein complexes of different proteins. This final level of organization is the quaternary structure.

The folding of polypeptides into fully functional proteins is facilitated by an assortment of molecular chaperones, which bind to partially folded polypeptides and prevent the formation of inappropriate bonds.

Genetics and the cell
The nucleus is the most prominent cellular organelle (Fig. 2.8) and has a double membrane enclosing the human genome (the outer membrane is continuous with the endoplasmic reticulum). The double membrane contains nuclear pores, through which gene regulatory proteins, transcription factors and mRNA that has been transcribed from DNA are transported. The nuclear matrix is highly organized. Microscopically dense regions of heterochromatin represent highly compacted chromosomal DNA, which tends to be transcriptionally repressed. Lighter regions of euchromatin contain extended chromosomes, which tend to be transcriptionally active. Outside the nucleus, mRNA is translated into amino acid chains in the endoplasmic reticulum (see p. 20 for how the trinucleotide code is converted to the corresponding amino acids that are the building blocks of proteins).

Embryonic development and stem cells
It is critical to recognize that all of the estimated 37 trillion cells that form a person are derived from a single cell. Genetic changes that involve this first cell, whether due to natural variation or artificial manipulation via gene-editing techniques like CRISPR (clusters of regularly interspaced short palindromic repeats), are carried forward to every subsequent cell. These changes are also passed on to future generations. The gravity of intervening at this moment is captured in the ethical debates around interventions such as pre-implantation genetic diagnosis and mitochondrial replacement therapy (see p. 36).

Following fertilization, the newly formed zygote and the cells it forms following the first few divisions are totipotent, meaning that they can differentiate into any cell type in the adult body (Fig. 2.9A). At the blastula stage of embryonic development, these cells undergo a primary differentiation event to become either the trophoderm or the inner cell mass (ICM) (see Fig. 2.9A). The trophoderm gives rise to the fetal cells of the placenta, while the ICM cells are pluripotent and give rise to all other cell types of the body (except

Fig. 2.9 Cell division, embryogenesis and fetal development. (A) Early stages of cell division leading to the formation of the blastocyst. (B) Stages of fetal development.
Stem cells have great therapeutic potential and can be obtained from blood from the umbilical cord, which contains embryo-like cells, IPSC). They are stimulated by growth factors to leave non-cycle G0 to enter G1 phase. During G1, transcription of the DNA synthesis molecules occurs. Rb is a “checkpoint” (inhibition molecule) between G1 and S phases and must be removed for the cycle to continue. This is achieved by the action of the cyclin-dependent kinase produced during G1. During the S phase, any DNA defects will be detected and p53 will halt the cycle (see p. 24). Following DNA synthesis (S phase), cells enter G2, a preparation phase for cell division. Mitosis takes place in the M phase. The new daughter cells can now either enter G0 and differentiate into specialized cells, or re-enter the cell cycle.

**Further reading**

**Control of cell division**

The division of cells is central to the development, growth and maintenance of humans. At each division, a duplication of the entire genetic code occurs and is passed to the next generation of daughter cells. When this process goes awry, cancer can follow. The cell duplication cycle has four phases called G1, S, G2 and mitosis (Fig. 2.10), and takes about 20–24 hours to complete for a rapidly dividing adult cell. G1, S and G2 are collectively known as interphase, during which the cell doubles in mass (the two gap phases are for growth) and duplicates its 46 chromosomes (S phase). Mitosis describes, in four subphases (prophase, metaphase, anaphase and telophase; see Fig. 2.10), the process of chromosome separation and nuclear division before cytokinesis (division of the cytoplasm into two daughter cells).

**G1 – S – G2 – synthesis phase: DNA replication**

To undergo duplication of the genetic code, a robust mechanism for DNA duplication is initiated. DNA synthesis by a multi-enzyme complex is initiated simultaneously at multiple foci across the genome known as replication forks. The key components of the replication machinery are DNA helicase, DNA primase, DNA polymerase and single-stranded DNA binding proteins.

DNA helicase unwinds the double helix and exposes each strand as a template for replication. The two strands are antiparallel, and DNA is extended by addition of nucleotide triphosphates to the end of the growing chain. DNA primase synthesizes a short (approximately ten-nucleotide) RNA molecule annealed to the DNA template, which acts as a primer for DNA polymerase. DNA polymerase extends the primer by adding nucleotides to the 3’ end.

**The phases of mitosis (M)**

Once a copy of the entire genetic code has been made, there is careful separation of these two copies, such that one copy goes into each daughter cell. With a light microscope, it is possible to see that two copies have been made by counting chromosomal bodies, which rise from 46 to 92. The next steps are described at the level of a single chromosome pair (or sister chromatids) for simplicity (Fig. 2.11).

**Prophase**

The two sister chromatids condense in the nucleus. The two centromeres, at the centre of each chromatid, are the sites between which the microtubules of the mitotic spindle will form; they then move apart in the cytoplasm. At the end of prophase, the nuclear membrane breaks down. A protein complex called the kinetochore then orchestrates the movement of these chromosomes.

**Metaphase**

The chromosomes are aligned on a central plane, with the two centromeres at opposite poles. The sister chromatids are attached to microtubules from different centrosomes via the kinetochore.
Anaphase
The sister chromatids are pulled in opposite directions as the microtubules shorten towards their respective spindle poles.

Telophase
Each set of daughter chromosomes is held at a spindle pole and the nuclear envelope reforms around the genome of each new daughter cell.

Cytokinesis
Splitting of the cytoplasm begins in telophase, before the completion of mitosis, with the appearance of a ring of actin and myosin filaments around the equator of the cell. Cytokinesis is completed as the ring contracts to create a cleavage furrow and separate the two daughter cells.

When to divide? Control of the cell cycle and checkpoints
Cells can exit the cell cycle and become quiescent. Indeed, most terminally differentiated adult cells are in a phase termed G0, in which the cycling machinery is switched off. In some cell types, the switch is irreversible (e.g. in neurones), but others, like hepatocytes, retain the ability to re-enter the cell cycle and proliferate. This gives the liver a significant ability to regenerate following damage.

Cyclin-dependent kinases
Progression through the cell cycle is tightly controlled and punctuated by three key checkpoints, where the cell interprets environmental and cellular signals to determine whether it is appropriate or safe to proceed (see Fig. 2.11). The switches that allow progression beyond these checkpoints are a family of small protein complexes called cyclin-dependent kinases (Cdks), which phosphorylate serines or threonines in key target proteins at each stage.

Checkpoints, retinoblastoma protein and p53

Restriction point (G1 checkpoint)
The restriction point works to ensure that the cell cycle does not progress into S phase unless growth conditions are favourable and the genomic DNA is undamaged. The cyclin-Cdk complexes active early in S phase are denoted S-Cdk (cyclin A with Cdk1 or Cdk2).

S-Cdks have two roles:
• to phosphorylate their target proteins to initiate helix unwinding of the DNA at origins of replication, allowing the replication complex to begin DNA synthesis
• to prevent re-initiation at the same origin during the same cell cycle (because it would be deleterious to copy parts of the genome more than once).

S-Cdks are themselves subject to regulation by G1-Cdk (cyclin D1–3 with Cdk4 or Cdk5) and G1/S-Cdk (cyclin E with Cdk2), both of which can stimulate cyclin A synthesis. Two major cancer pathways converge on this checkpoint via the cyclin-Cdks:
• G1-Cdk responds positively to mitogenic (pro-growth) environmental signals like platelet-derived growth factor (PDGF) or epidermal growth factor (EGF). Activated G1-Cdk phosphorylates and inactivates the retinoblastoma protein (Rb), which releases the transcription factor E2F to stimulate the G1/S-Cdk and S-Cdk synthesis that is necessary for progression.
• G1/S-Cdk and S-Cdk also respond to DNA damage via the p53 pathway. On DNA damage, the transcription factor p53 is phosphorylated and stimulates transcription of the p21 gene. p21 protein is an inhibitor of both G1/S-Cdk and S-Cdk. Both Rb and p53 are regulators of the restriction point. Loss of function of either disables aspects of the negative control pathways. RB and p53 are commonly mutated in cancer and both are therefore considered ‘tumour suppressor genes’ (see p. 38).

G2/M checkpoint
The G2/M checkpoint prevents entry into mitosis in the presence of DNA damage or non-replicated DNA. M-Cdk (cyclin B with Cdk1) accumulates towards the end of G2 and is activated following dephosphorylation by the phosphatase Cdc25. Activated M-Cdk has three roles at the G2/M checkpoint:
• to initiate chromosome condensation
• to promote breakdown of the nuclear membrane
• to initiate assembly of the mitotic spindle.

DNA damage and the presence of non-replicated DNA negatively regulate M-Cdk and prevent entry into mitosis. The kinases that phosphorylate p53 in response to DNA damage and block progression through the restriction point can also phosphorylate and inhibit Cdc25, inactivating M-Cdk. Thus DNA damage also blocks cell cycle progression at this checkpoint.

Met/Ana checkpoint
The metaphase to anaphase checkpoint is regulated by protein degradation. The anaphase-promoting complex APC/C is a ubiquitin ligase that transfers a small protein, ubiquitin, to other proteins, marking them for degradation. The primary targets are securin, and the S- and M-cyclins of the cyclin-Cdks present at the start of mitosis. The degradation of securin results in the digestion of cohesin, which holds the two sister chromatids together, allowing them to be pulled apart by the mitotic spindle.

Review of cellular genetics
According to the fundamental paradigm in genetics, information to create a human is stored in the genetic code in a cell. This code is identically replicated in every cell from conception onwards. In different cells, different parts of the code are needed, specific to that cell type, to make proteins required for the functioning of that cell; this control of gene expression is achieved through a number of mechanisms affecting gene transcription, processing of RNA and translation of mRNA into protein.

In the next section, we describe examples of what happens when there are specific changes in the genetic code that have been associated with the presentation of specific genetic disorders.
**GENETIC DISORDERS**

Inherited genetic disorders occur due to mutations in genetic code; their prevalence is indicated in Box 2.3. They can arise because of new mutations in sperm or ova, as a result of an inherited mutation passed down a family line. These disorders can stem from a single base-pair change, alteration of a region of a chromosome, or even duplication or omission of an entire chromosome (Box 2.4). The pattern of inheritance in a family tree depends on which chromosome the mutation occurs in, and whether both copies need to be affected to cause the disease. Somatic mutations typically occurring after birth can be responsible for benign and malignant tumours, and are discussed on page 37.

To start, we will consider conditions for which chromosomal changes are responsible. These were among the first to be studied, as the technique known as karyotyping allowed for visualization of differences in chromosomes using a light microscope.

**Chromosomal disorders**

Chromosomal abnormalities are much more common than is generally appreciated (see Box 2.3). Over half of spontaneous abortions have chromosomal abnormalities, compared with only 4–6 abnormalities per 1000 live births. Specific chromosomal abnormalities can lead to well-recognized and severe clinical syndromes; autosomal aneuploidy (a differing from the normal diploid number) is usually more severe than the sex chromosome aneuploides (Box 2.5). Abnormalities may occur in either the number or the structure of the chromosomes.

**Abnormal chromosome numbers**

If a chromosome or chromatids fail to separate (‘non-disjunction’) in either meiosis or mitosis, one daughter cell will receive two copies of that chromosome and one daughter cell will receive no copies of the chromosome. If this non-disjunction occurs during meiosis, it can lead to an ovum or sperm having:

- **an extra chromosome**, resulting in a fetus that is ‘trisomic’ and has three instead of two copies of the chromosome
- **no chromosome**, resulting in a fetus that is ‘monosomic’ and has one instead of two copies of the chromosome.

Non-disjunction can occur with autosomes or sex chromosomes. However, only individuals with trisomy 13, 18 and 21 survive to birth, and most children with trisomy 13 and trisomy 18 die in early childhood. **Trisomy 21 (Down’s syndrome)** is observed with a frequency of 1 in 650 live births, regardless of geography or ethnic background. This rate is reduced with widespread screening and selective termination of pregnancy (see p. 27). Full **autosomal monosomies** are extremely rare and generally incompatible with survival to full gestation. **Sex chromosome trisomies** (e.g. Klinefelter’s syndrome, XXX) are relatively common. The **sex chromosome monosomy** in which the individual has one X chromosome only and no second X or Y chromosome (i.e. X0) is known as Turner’s syndrome and is estimated to occur in 1 in 2500 live-born girls.

Occasionally, non-disjunction can occur during mitosis shortly after two gametes have fused. It will then result in the formation of two cell lines, each with a different chromosome complement; the person is termed a ‘mosaic’ as only some of his or her cells carry an incorrect number of chromosomes (see p. 29).

Very rarely, the entire chromosome set will be present in more than two copies, so the individual may be triploid rather than diploid and have a chromosome number of 69. Triplody and tetraploidy (four sets) is not usually compatible with life and results in spontaneous abortion.

**Abnormal chromosome structures**

As well as abnormal numbers of chromosomes, chromosomes can have abnormal structures, and the disruption to the DNA and gene sequences may give rise to a genetic disease.

- **Deletions** of a portion of a chromosome may give rise to a disease syndrome if two copies of the genes in the deleted region are necessary, and with just the one normal copy remaining on the non-deleted homologous chromosome the individual will not be normal. Many deletion syndromes have been well described. For example, **Prader–Willi syndrome** is

the result of deletion of part of the long arm of chromosome 15; Wilms’ tumour is characterized by deletion of part of the short arm of chromosome 11; and microdeletions in the long arm of chromosome 22 give rise to DiGeorge’s syndrome (see p. 60).

- **Duplications** occur when a portion of the chromosome is present on the chromosome in two copies, so the genes in that chromosome portion are present in an extra dose. A form of neuropathy, Charcot–Marie–Tooth disease (see p. 891), is due to a small duplication of a region of chromosome 17.

- **Inversions** involve an end-to-end reversal of a segment within a chromosome, e.g. ‘abcdefg’ becomes ‘abcfedgh’, as in haemophila (see p. 375).

- **Translocations** occur if two chromosome regions join together, when they would not do so normally. Chromosome translocations in somatic cells may be associated with tumorigenesis (see p. 38 and Fig. 2.23).

  Translocations can be very complex, involving more than two chromosomes, but most are simple and fall into one of two categories:

  - **Reciprocal translocations** occur when any two non-homologous chromosomes break simultaneously and rejoin, swapping ends. In this case, the cell still has 46 chromosomes but two of them are rearranged. Someone with a balanced translocation is likely to be normal (unless a translocation breakpoint interrupts a gene); however, at meiosis, when the chromosomes separate into different daughter cells, the translocated chromosomes will enter the gametes, and any resulting fetus may inherit one abnormal chromosome and have an unbalanced translocation with physical manifestations.

- **Robertsonian translocations** occur when two acrocentric chromosomes join and the short arm is lost, leaving only 45 chromosomes. This translocation is balanced, as no genetic material is lost and the individual is healthy. However, any offspring have a risk of inheriting an unbalanced arrangement. This risk depends on which acrocentric chromosome is involved. The 14/21 Robertsonian translocation is clinically relevant. A woman with this karyotype has a 1 in 8 risk of having a baby with Down’s syndrome (a male carrier has a 1 in 50 risk). However, they have a 50% risk of producing a carrier like themselves; hence the necessity for genetic family studies. Relatives should be alerted to the increased risk of Down’s syndrome in their offspring, and should have their chromosomes checked.

**Mitochondrial chromosome disorders**

The mitochondrial chromosome (see Fig. 2.5) carries its genetic information in a very compact form; for example, there are no introns in the genes. Therefore, any mutation has a high chance of having an effect. However, as every cell contains hundreds of mitochondria, a single altered mitochondrial genome will not be noticed. As mitochondria divide, there is a statistical likelihood that there will be more mutated mitochondria and, at some point, this will give rise to a mitochondrial disease.

Most mitochondrial diseases are myopathies and neuropathies with a maternal pattern of inheritance. Other abnormalities include retinal degeneration, diabetes mellitus and hearing loss. Myopathies include chronic progressive external ophthalmoplegia (CPEO); encephalomyopathies include myoclonic epilepsy with ragged-red fibres (MERRF) and mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes (MELAS) (see p. 897).
• *Kearns–Sayre syndrome* includes ophthalmoplegia, heart block, cerebellar ataxia, deafness and learning difficulties due to long deletions and rearrangements.

• **Leber's hereditary optic neuropathy** (LHON) is the most common cause of blindness in young men, with bilateral loss of central vision and cardiac arrhythmias, and is an example of a mitochondrial disease caused by a point mutation in one gene.

• **Multisystem disorders** include *Pearson's syndrome* (sideroblastic anemia, pancytopenia, exocrine pancreatic failure, subtotal villous atrophy, diabetes mellitus and renal tubular dysfunction). In some families, hearing loss is the only symptom, and one of the mitochondrial genes implicated may predispose patients to aminoglycoside cytotoxicity.

### Analysis of chromosomal disorders

Historically, karyotyping involved growing cells from patient samples and studying the chromosomes. The cell cycle can be arrested at mitosis with the use of colchicine and, following staining, the chromosomes with their characteristic banding can be seen and any abnormalities identified. This is an automated process with computer scanning software searching for metaphase spreads and then automatic binning of each chromosome to allow easy scoring of chromosome number and banding patterns.

Current approaches utilize genome-wide array-based platforms (called single nucleotide polymorphism (SNP) arrays) to identify changes in chromosome copy number and can identify very small interstitial deletions and insertions. The presence of translocations cannot be detected using SNP arrays, but instead is studied in a targeted way using fluorescence *in situ* hybridization (FISH). Large, region-specific probes are labelled with fluorescently tagged nucleotides and used to allow rapid identification of metaphase chromosomes. As whole-genome sequencing is becoming more accessible and coverage increases, it will increasingly be used to identify deletions, insertions and translocation breakpoints.

### Point mutations, insertions and deletions

The advent of Sanger sequencing rapidly accelerated the discovery of base-pair level changes. These mutations can have various effects on the expression of the gene and many cause a dysfunction of the protein product. In contrast to the previous section, where changes were described that affect millions of base-pairs in a cell, point mutations can involve just one critical base-pair. These are small but important changes.

### Mutations

Although DNA replication is a very accurate process, mistakes occasionally occur and produce changes or mutations. These changes can also arise because of other factors, such as radiation, ultraviolet light or chemicals. Mutations in gene sequences or in the sequences that regulate gene expression (transcription and translation) may alter the amino acid sequence in the protein encoded by that gene. In some cases, protein function will be maintained; in other cases, it will change or cease, perhaps producing a clinical disorder. Many different types of mutation occur.

### Point mutation

This is the simplest type of change and involves the substitution of one nucleotide for another, so changing the codon in a coding sequence and leading to an amino acid substitution (assuming the new sequence is non-synonymous with the former). For example, in the *sickle cell disease*, a mutation within the globin gene changes one codon from GAG to GTG so that, instead of glutamic acid, valine is incorporated into the polypeptide chain, which radically alters its properties. However, substitutions may have no effect on the function or stability of the proteins produced, as several codons code for the same amino acid (synonymous – see Fig. 2.7).

### Insertion or deletion

Insertion or deletion of one or more bases is a more serious change, particularly if the inserted or deleted DNA is not a multiple of three bases, as this will cause the following sequence to be out of the reading frame and can result in a premature stop codon.

### Splicing mutations

If the DNA sequences that direct the splicing of introns from mRNA are mutated, then abnormal splicing may occur. In this case, the processed mRNA that is translated into protein by the ribosomes may carry intron sequences or miss exons, so altering amino acid sequence and affecting protein function.

### Nonsense mutations

A nonsense mutation is a point mutation in a sequence of DNA that results in a premature stop codon.

### Prenatal diagnosis of congenital anomalies

Prenatal screening should be offered to all pregnant women. In England, screening for the three most common trisomies (Down’s, Edwards’ and Patau’s) is offered to all pregnant women. The risk increases disproportionately for children born to mothers older than 35 years. Infants born to mothers with a history or family history of other conditions due to chromosomal abnormalities may also be at increased risk.

### Personal choice

There should be a detailed discussion with all mothers about the possible consequences of each screening test before they are offered it. In particular, they should have an understanding of the failure rates, detection rates, and false-positive and false-negative rates of each test so that they can exercise choice properly.

### Investigations

The choice of investigation depends on gestational age:

**7–11 weeks (vaginal ultrasound)**

Ultrasound is used to confirm viability, fetal number and gestation by crown-rump measurement. This scan is not a screening test for aneuploidy.

**10–13 weeks and 6 days (combined test)**

The combined test comprises:

- ultrasound for nuchal translucency measurement; nuchal translucency is also increased in Turner’s syndrome)
- testing of maternal serum for pregnancy-associated plasma protein-A (PAPP-A from the syncytiotrophoblast) and β-human chorionic gonadotrophin for trisomy 21.

All serum marker measurements are corrected for gestational ages, a multiple of the mean (MOM) value for the appropriate week of gestation. If abnormalities are detected, it is necessary to continue to discuss whether further investigation is desired or not. The next option is chorionic villus sampling (CVS) at 11–13 weeks under ultrasound guidance.
to sample the placental site, or amniocentesis at 15 weeks to sample amniotic fluid and obtain the fetal cells necessary for cytogenetic testing. The combined test is more accurate than the triple test alone at 16 weeks.

14–20 weeks (serum triple or quadruple test)
A serum triple or quadruple test is done if the pregnancy is too advanced for the earlier tests or if the combined test was not offered. The triple test for chromosomal abnormalities consists of testing maternal serum for levels of:
- α-fetoprotein (low)
- unconjugated oestriol (low)
- human chorionic gonadotrophin (high) for Down’s syndrome and for neural tube defects.

The α-fetoprotein is high for neural tube defects. The quadruple test also measures inhibin A (high in Down’s syndrome).

18–20 weeks
Ultrasound detects structural abnormalities (e.g. neural tube defects and congenital heart defects).

Reported detection rates for congenital anomalies varies: for example, from 14–61% for hypoplastic ventricle to 97–100% for anencephaly.

Non-invasive prenatal testing
It is possible to sequence fetal DNA in the maternal bloodstream to measure the copies of chromosomes that inform the risk of the child having a chromosomal disorder. Known as non-invasive prenatal testing (NIPT), it is more accurate than standard combined or quadruple testing. NIPT has been evaluated in the UK’s National Health Service and there is a plan to introduce it as a follow-on screening test in some women.

Patterns of inheritance of single-gene diseases
Monogenetic disorders involving single genes can be inherited in a dominant, recessive or sex-linked manner.

Autosomal dominant disorders
Each diploid cell contains two copies of all the autosomes. An autosomal dominant disorder (Fig. 2.12A) occurs when one of the two copies has a mutation and the protein produced by the normal form of the gene cannot compensate. In this case, a heterozygous individual who has two different forms (or alleles) of the same gene will manifest the disease. The offspring of heterozygotes have a 50% chance of inheriting the chromosome carrying the disease allele, and therefore also of having the disease. However, estimation of risk to offspring for counselling families can be difficult because of three factors:
- Some disorders have a great variability in their manifestation. ‘Incomplete penetrance’ may occur if patients have a dominant
disorder but it does not manifest itself clinically in them. This gives the appearance of the gene having ‘skipped’ a generation.

- Dominant traits are extremely variable in severity (variable expression) and a mildly affected parent may have a severely affected child.
- New cases in a previously unaffected family may be the result of a new mutation. In this case the risk of a further affected child is negligible. Most cases of achondroplasia, for example, are due to new mutations.

**Autosomal recessive disorders**

These disorders (Fig. 2.12B) manifest themselves only when an individual is homozygous or a compound heterozygote for the disease allele: that is, both chromosomes carry the same gene mutation (homozygous) or two different mutations in the same gene (compound heterozygote). The parents are unaffected carriers (heterozygous for the disease allele). If carriers marry, the offspring have a 1 in 4 chance of carrying both mutant copies of the gene and being affected, a 1 in 2 chance of being a carrier, and a 1 in 4 chance of being genetically normal. Parental relatedness increases the risk.

**Sex-linked disorders**

Genes carried on the X chromosome are said to be ‘X-linked’ and can be dominant or recessive in the same way as autosomal genes (Fig. 2.12C,D).

**X-linked recessive disorders**

These disorders present in males and only in homozygous females (usually rare). X-linked recessive diseases are transmitted by healthy female carriers or affected males if they survive to reproduce. An example of an X-linked recessive disorder is haemophilia A (see p. 375), which is caused by a mutation in the X-linked gene for factor VIII. It has been shown that in 50% of cases there is an intrachromosomal rearrangement (inversion) of the tip of the long arm of the X chromosome (one breakpoint being within intron 22 of the factor VIII gene).

- Of the offspring from a carrier female and a normal male:
  - 50% of the girls will be carriers, as they inherit a mutant allele from their mother and the normal allele from their father; the other 50% of the girls inherit two normal alleles and are themselves normal
  - 50% of the boys will have haemophilia, as they inherit the mutant allele from their mother (and the Y chromosome from their father); the other 50% of the boys will be normal, as they inherit the normal allele from their mother (and the Y chromosome from their father).

The male offspring of a male with haemophilia and a normal female will not have the disease, as they do not inherit his X chromosome. However, all the female offspring will be carriers, as they all inherit his X chromosome.

**X-linked dominant disorders**

These are rare. Females who are heterozygous for the mutant gene and males who have one copy of the mutant gene on their single X chromosome will manifest the disease. Half the male or female offspring of an affected mother and all the female offspring of an affected male will have the disease. Affected males tend to have the disease more severely than the heterozygous female.

**Mitochondrial inheritance**

The pattern of inheritance associated with alterations in the mtDNA involves both males and females, but always with the condition passed on through the female line (maternal inheritance). Since many mitochondria are passed into the egg from the cells in the ovary, all the offspring of an affected woman would be expected to inherit the condition. An affected male does not pass his mitochondria on to his children, so his children will be unaffected (see Fig. 2.12E). Note that not all mitochondrial diseases will show this pattern of inheritance. As these conditions arise due to incorrectly functioning mitochondria, they may also be caused by an alteration in the nuclear DNA that has an impact on mitochondrial function, and not just be caused directly by a mitochondrial mutation. Hence, some mitochondrial diseases may demonstrate dominant patterns of inheritance.

**Special presentations of genetic disease**

These are disorders that may be due to mutations in single genes but which do not manifest as simple monogenetic disorders. They can arise from a variety of mechanisms.

**Mosaicism**

Genetic mosaicism arises when a mutation occurs in a cell during embryonic development. This cell and its progeny are then genetically distinct from the rest of the fetus. This can give rise to a less severe form of recognized genetic disease, sometimes referred to historically as a ‘forme fruste’. Equally, some mutations are not compatible with life if every cell in the fetus is affected, but may be rescued if the fetus is mosaic. Schimmpelenning’s syndrome is an example, where patients carry a mosaic HRAS gene mutation.

**Triplet repeat mutations and genetic anticipation**

In the gene responsible for myotonic dystrophy (see p. 896), the mutated allele was found to have an expanded 3’ UTR region in which three nucleotides, CTG, were repeated up to about 200 times. In families with myotonic dystrophy, people with the late-onset form of the disease had 20–40 copies of the repeat, but their children and grandchildren who presented with the disease from birth had vast increases in the number of repeats – up to 2000 copies. It is thought that some mechanism during meiosis causes this ‘triplet repeat expansion’ so that the offspring inherit an increased number of triplets. The number of triplets affects mRNA and protein function, and patients with more repeats present earlier (Box 2.6). The phenomenon has also been recognized with Huntington’s chorea, where patients with more repeats present earlier and with progressively worse symptoms. This ‘anticipation’ is due to unstable mutations occurring within the disease gene. Trinucleotide repeats, such as CTG (dystrophia myotonica) and CAG (Huntington’s disease), expand within the disease gene with each generation, and somatic expansion with cellular replication is also observed. This type of genetic mutation can occur within the translated region or untranslated (and presumably regulatory) regions of the target genes. This genetic distinction has been used to subclassify a number of genetic diseases that have now been shown to be caused by trinucleotide repeat expansion and display phenotypic ‘anticipation’ (see Box 2.6).

**Imprinting**

It is known that normal humans need a diploid number of chromosomes: that is, 46. However, the maternal and paternal contributions can be different. The mechanism that regulates the differential expression of two alleles of the same gene is termed genetic imprinting. Imprinting is relevant to human genetic disease because different phenotypes may result, depending on whether the mutant chromosome is maternally or paternally inherited. A deletion of part of the long

</tbody>
</table>

AD, autosomal dominant; AR, autosomal recessive.

**Fig. 2.13 CYLD cutaneous syndrome.** Distinct phenotypes seen with identical genetic mutations reflect the impact of the genetic background on disease presentation. (A) Scalp cylindromas. (B) Trichoepitheliomas around the nasal fold.

Arm of chromosome 15 (15q11–q13) will give rise to Prader–Willi syndrome, if it is paternally inherited. A deletion of a similar region of the chromosome gives rise to Angelman’s syndrome if it is maternally inherited. The affected gene has been identified as ubiquitin (UBE3A).

**Different genes that cause the same disease**

Although classically divided into autosomal dominant, recessive or X-linked disorders, many syndromes show multiple forms of inheritance pattern. For example, in Ehlers–Danlos syndrome, there is autosomal dominant, recessive and X-linked inheritance. This has now been explained by the finding that mutations in different genes that contribute to a common function can have the same clinical presentation. In addition, in some recessive disorders, even having just one defective allele gives a mild form of the disease (semidominant), while having both alleles with the mutation results in a more severe form of the syndrome.

**Different diseases caused by the same gene**

The following are two examples of how different mutations in a gene can cause different diseases, referred to as genotype–phenotype correlation.

**CYLD**

In patients with germline mutations in CYLD, two strikingly different phenotypes are seen. Patients can develop tumours on the head or on the face, previously categorized as two separate diseases. It is now known that these different presentations can occur within a family where the same pathogenic variant has been documented, so genetic changes may manifest differently based on the genetic background in which they arise (Fig. 2.13).

**STAT3**

The transcription factor signal transducer and activator of transcription 3 (STAT3) is a critical regulator of multiple and diverse cellular processes. Heterozygous, germline, loss-of-function mutations in STAT3 lead to the primary immune deficiency hyper-IgE syndrome. Recently, germline, heterozygous mutations in STAT3 that confer a gain of function have been discovered and result in early-onset, multiorgan autoimmunity.

**Complex traits: multifactorial and polygenic inheritance**

Characteristics resulting from a combination of genetic and environmental factors are said to be multifactorial; those involving multiple genes are said to be polygenic. There has been an explosion in genetic discoveries about these complex traits with the development of high-throughput genome-wide SNP arrays, which has allowed cost-effective and unbiased screening of large case–control cohorts (in excess of 1000 cases). These studies are known as genome-wide association studies (GWAS) and are discussed later. They have permitted unequivocal identification of SNPs associated with a variety of traits and diseases. For
example, over 30 SNPs in immune-related gene loci have been associated with coeliac disease, with over half also associated with other immune-mediated or inflammatory diseases. This indicates that there are many low-risk genetic risk factors associated with complex traits, and common pathways are implicated in different diseases.

Most human diseases, such as heart disease, diabetes and common mental disorders, are multifactorial traits (Box 2.7).

### Techniques for studying the genetic code

#### Polymerase chain reaction

Polymerase chain reaction (PCR) is a core technique in genetics, which has revolutionized genetic research because small regions of interest in a sample of DNA – for example, the *BRCA1* gene – can be amplified over a million times within a few hours. The DNA is amplified between two short (generally 17–25 bases) single-stranded DNA fragments (‘oligonucleotide primers’) that are complementary to the sequences on different strands at each end of the DNA of interest (Fig. 2.14). These short lengths of amplified DNA can then be sequenced to obtain identification of the exact nucleotide sequence using Sanger sequencing (named after its inventor).

#### Sanger sequencing

This involves a chemical process known as dideoxy-sequencing. Once the sequence of interest is amplified, this is used as a template for the Sanger sequencing reaction. An oligonucleotide primer is designed to anneal adjacent to the region of interest. This primer acts as the starting point for a DNA polymerase to build a new DNA chain that is complementary to the sequence under investigation. Chain extension is prematurely interrupted when a fluorescently labelled dideoxynucleotide becomes incorporated (this happens because it lacks the necessary 3’-hydroxyl group needed for extension). Each base dideoxynucleotide (G, C, T, A) has a different fluorochrome attached, and thus each termination base can be identified by its fluorescent colour. As each strand can be separated efficiently by capillary electrophoresis according to its size or length, simply monitoring the fluorescence as the reaction products elute from the capillary tube will give the gene sequence (Fig. 2.15). This is a widely used but relatively low-throughput method, which is increasingly being replaced with high-throughput methods.

#### Next-generation sequencing

Sequencing technology has developed such that it is now possible to sequence DNA molecules in a high-throughput manner (‘next-generation sequencing’, NGS) and new, faster and cheaper methods are being developed. For under £200 (2019 price), it is possible to sequence all the coding genes in an individual’s human genome (termed the ‘exome’) to catalogue all possible disease-associated and non-disease-associate variants in every human gene. If necessary, whole genomes (including non-coding regions) can also be sequenced in this way, although this involves a greater cost.

---

**Fig. 2.14** Polymerase chain reaction. The technique is based on thermal cycling and has three basic steps. (a) The double-stranded genomic DNA is heat-denatured into single-stranded DNA. (b) The sample is cooled to favour annealing of the primers to their target DNA. (c) A thermostable DNA polymerase extends the primers over the target DNA. After one cycle, there are two copies of double-stranded DNA, after two cycles there are four copies, and so on.
sequences are typically generated as short runs of sequences between 75 and 200 bp long, known as reads, which are aligned to the reference human genome (Fig. 2.16).

Differences from the reference genome are called ‘variants’ and are catalogued for each sample. The computational requirements for processing data from NGS experiments are significant and are usually performed on dedicated computer clusters. Whole-genome sequencing has the advantage over whole-exome sequencing of being able to detect intronic changes, structural variants and changes in DNA copy number.

**Hybridization arrays**

This technique employs a fundamental property of DNA: when two strands are separated – for example, by heating – they will always reassociate and stick together again because of their complementary base sequences. The presence or position of a particular gene can therefore be identified using a gene ‘probe’ consisting of DNA or RNA, with a base sequence that is complementary to that of the sequence of interest. A DNA probe is thus a piece of single-stranded DNA that can locate and bind to its complementary sequence. Almost 1 million
such probes can be placed on a chip in an array, and can be used to interrogate samples to obtain clinically relevant information such as SNP data for GWAS studies (see below) at a low cost per sample.

Transcriptomics

As well as sequencing genomic DNA, NGS technology can be used to sequence RNA (termed ‘RNAseq’) to assess gene expression levels accurately, in addition to determining all splice variations and allelic copy number. Analysis of all the RNA transcripts in a sample, or ‘transcriptomics’, allows for the comprehensive study of disease states. A limitation of this approach is that there may be a difference between levels of RNA transcripts and corresponding proteins that are encoded, warranting validation using additional techniques. Note that, in addition to carrying out such work on whole-tissue samples, such as liver or skin, it is now possible to sequence single cells. This represents an opportunity to investigate disease states at unprecedented resolution; the Human Cell Atlas is one such project that aims to capture representative transcriptomes of human cells from all tissues.

Epigenetic techniques

NGS can also be used to study epigenetic changes. Changes in methylation can be studied using a technique that converts the unmethylated cytosines across the whole genome using a chemical process called bisulphite conversion, allowing for the absence and presence of methylation to be comprehensively detected. In addition to methylation, it is possible to determine the accessibility of chromatin using additional techniques such as assay for transposase-accessible chromatin sequencing (ATAC-seq).

Genome databases

Information arising from human genome sequencing is publicly available, providing biological information on every gene in the human genome. Information on any gene describing its protein product, function, tissue-specific expression, disease association and sequence variation/mutation can be easily obtained by searching and manipulating computer databases. In addition to genotype, it is necessary to consider databases that couple genotype with phenotype, such as DECIPHER. Phenotyping is difficult to do, although frameworks to aid this have been developed, such as the Human Phenotype Ontology (HPO).

Research techniques

Discovery of disease-causing genes

Sequencing trios using whole-exome and whole-genome sequencing (WES/WGS)

The ability to study whole genomes is being used in work such as the 100,000 Genomes Project to discover new disease-causing genes. The aims of gene discovery include diagnosis, genetic counselling and targeted screening. Typically, affected and unaffected individuals are studied, and variants that segregate with the disease are filtered. The DNA from both parents and the affected individual, known as a ‘trio’, is the minimum, and usually the suspected gene in the affected individual will be found in other families with the same disease, strengthening the association. These advances have made it possible to find novel disease-causing genes in smaller pedigrees.

Genetic polymorphisms and linkage studies

Linkage analysis has provided many breakthroughs in mapping the positions of genes that cause genetic diseases, such as the gene for cystic fibrosis, which was found to be tightly linked to a marker on chromosome 7.

These studies relied on finding markers that segregate with the disease in large families and are typically used in rare monogenic disease. Techniques that identify and quantitate genetic polymorphisms, such as SNPs (see p. 30), microsatellites and copy number variants (CNVs), are essential, as these serve as markers. Polymorphisms that are closer together are more likely to have alleles that move together in a block during meiosis than those further apart. This phenomenon is called ‘linkage disequilibrium’ and enables, for example, one SNP variant (tag SNP) in this block to act as a marker for the presence of other SNP variants.

Genome-wide association studies (GWAS)

Breakthroughs in complex polygenic disease are increasingly being achieved by studying large numbers (typically several thousands) of affected and unaffected patients. Many of these studies use SNP arrays, which provide informative data on hundreds of thousands of SNPs across the entire genome of an individual. Using these markers, statistical testing of association is applied and changes that are linked with disease are typically plotted on a Manhattan plot (so called because the graph can look like the skyline of Manhattan: Fig. 2.17). This plot has genomic coordinates on the x-axis, and a measure of the statistical likelihood that the association detected has occurred by chance on the y-axis. SNPs that are likely to be associated with the disease have a low p-value, and as the y-axis values are plotted as negative logarithmic transformations of these p-values, a peak is displayed for such changes. These SNPs may not necessarily sit within in the causative gene but may, for example, lie nearby, such as in the promoter of the gene affecting expression. GWAS can highlight regions of interest for polygenic diseases, which can then be studied in more detail, with the aim of gaining genetic insights into disease pathogenesis.

Identification of gene function

Following the finding of genes of interest in either rare or common disease, the challenge is to understand the function of these protein-coding genes. To gain insights into gene function, the genetic changes found in disease can be modelled in cells or in animals. Most studies rely on the comparison of a cell’s or an animal’s phenotype in the presence or absence of the genetic change in question. Each approach has its respective merits and faults.

Cell culture models

DNA transfection

Human cells can be grown in cell culture flasks in the laboratory and their behaviour (growth rate, morphology, motility, gene expression profile and biochemistry) characterized. A specific gene can then be
introduced in a small plasmid (a circle of DNA from which the gene of interest can be expressed) or incorporated into a virus, and the change in cell behaviour assessed to provide an indication of gene function.

A recent advance is the use of CRISPR (clusters of regularly interspaced short palindromic repeats) gene editing to introduce the genetic change found in humans into cell lines (Fig. 2.18). This has the advantage of achieving physiological levels of gene expression over plasmids, where genes may be expressed at higher levels due to the presence of viral promoters in plasmid DNA. CRISPR can be used to introduce patient mutations into cells or to knock out genes completely to study their function.

RNA interference
Alternatively, if the cell line in question already expresses the gene of interest, its expression can be knocked down by RNA interference (RNAi). RNAi takes advantage of the cellular machinery that allows microRNAs encoded by the genome to regulate the expression of many genes at the level of mRNA stability and translation (see p. 20). This phenomenon has been exploited in the laboratory to study the function of a gene of interest or, on a much larger scale, the function of each gene in the genome. In such an RNAi screen, an siRNA specific for each gene in the genome is introduced into cells grown in vitro, in effect knocking down expression of each gene in approximately 20,000 separate experiments. The phenotype of the cells in each experiment is then monitored to test the effect of loss of gene expression.

Animal models
The effect of a gene at organism level can also be tested by mis-expression/over-expression or knockout of a particular gene in a model animal. Nematode worms (Caenorhabditis), fruit flies (Drosophila), zebrafish and rodents have all been genetically engineered to identify the function of a gene of interest. Knockout models of the higher organisms can be particularly helpful for medical research in providing a model of disease for exploration of therapeutic intervention. Large-scale mutagenesis programmes are knocking out every gene or regulatory element in the mouse genome. However, note that the physiology of rodents and humans can differ.

GENOMIC MEDICINE
Gene therapy
A clinical aim of genetics has been to correct the disease-causing mutation and to treat the disease.

There are many technical problems to overcome in gene therapy, particularly in finding delivery systems to introduce DNA into a mammalian cell. Very careful control and supervision of gene manipulation is necessary because of its potential hazards and the attendant ethical issues.

Two major factors are involved in gene therapy:
• the introduction of the functional gene sequence into target cells
• the expression and permanent integration of the transfected gene into the host cell genome.

Haemophilia
These approaches have been gaining ground with conditions such as haemophilia, where recent trials of gene therapy have meant that some patients no longer need transfusions to maintain normal clotting function. This approach has involved using a virus to deliver a DNA construct with a normal sequence of factor VIII (haemophilia A) or factor IX (haemophilia B) to cells in the patient, administered as an infusion. Due to the design of this DNA construct, liver cells selectively express and produce functional clotting factors, with clinical improvement measured as reduction of bleeding episodes in the absence of regular transfusions of coagulation factors (Fig. 2.19).

Cystic fibrosis
Restoring function in diseases affecting solid organs rather than blood poses different challenges. In cystic fibrosis (CF), rather than trying to restore the altered sequence of the gene in every affected cell, a different approach is used. CFTR, the cystic fibrosis transmembrane regulator (see also p. 984), is an unusual ABC transporter in that it does not function as a primary active transporter but as a ligand-gated chloride channel (Fig. 2.20). The common CF mutation is a 3bp deletion in exon 10 that results in the removal of a codon specifying pherylalanine (F508del). In this mutation, the CFTR protein is misfolded,
Haemophilia A
Coagulation factor VIII deficiency
Liver-specific promoter
Truncated factor VIII variant
AAV construct (AAV5 capsid)
Single i.v. infusion
Increase in factor VIII activity levels
↓ Reduction in bleeding episodes

Haemophilia B
Coagulation factor IX deficiency
Liver-specific promoter
Highly active factor IX
AAV construct (AAV-Spark100 capsid)
Single i.v. infusion
↑ Sustained high factor IX activity levels
↓ Reduction in bleeding episodes

Fig. 2.18 Gene editing using technologies such as CRISPR (clusters of regularly interspaced short palindromic repeats).

thereby causing ineffective biosynthesis and consequently disrupting the delivery of the protein to the cell surface. This mutation has recently been targeted with a combination of therapies (lumacaftor–ivacaftor) in phase 3 clinical trials, and is now approved for clinical use. Lumacaftor brings more mutant CF channel proteins to the cell surface, and ivacaftor aids by prolonging the opening of the chloride ion channel, which restores partial function to the mutated protein. Early clinical results are encouraging, with patients demonstrating increased pulmonary function as measured by improved forced expiratory volume. More recent trials are being carried out to determine whether early intervention in childhood may modify the course of the disease.

**Mitochondrial replacement therapy**

In mitochondrial diseases arising due to mutations in the mitochondrial DNA, it is possible to avoid transmission of these maternally transmitted mitochondria using a technique known as pro-nuclear transfer. This involves transferring the nucleus from a fertilized cell from an affected patient with mitochondrial disease to a fertilized cell from a healthy donor, from which the nucleus has been removed. By doing this, the developing embryo will have mitochondria only from the healthy donor, while retaining nuclear DNA from the biological parents. In the UK, this process is under way in a small number of families (Fig. 2.21).

**Stem cell therapy**

Stem cell therapy has the potential to change the treatment of human disease radically (see p. 23). A number of adult stem cell therapies already exist, particularly bone marrow transplants in immune deficiencies. In this context, a patient with a genetic immune deficiency receives a transplant from a healthy donor, and these normally functioning cells confer immunity. It is currently anticipated that technologies derived from stem cell research can be used to treat a wider variety of diseases in which replacement of destroyed specialist tissues is required, such as in Parkinson’s disease, spinal cord injuries and muscle damage.

In the era of gene editing, the possibility of restoring genetically corrected cells has become a reality in some genetic blistering skin disorders. A boy with junctional epidermolysis bullosa developed blisters, with epidermal loss affecting 80% of his total body surface area. Skin cells were taken from this patient and transduced with a DNA construct that resulted in the production of the necessary protein, laminin 332. These corrected stem cells were grown in the laboratory before being transplanted back on to the patient’s skin. Therapy resulted in complete coverage of the patient’s skin, with genetic testing of the skin confirming the presence of the corrected cells.

These examples are indicative of the potential for using genetic information for clinical benefit, and also of the length of time it takes to achieve meaningful outcomes.
**The genetic basis of cancer**

The preceding sections have given an outline of how the genetic code gives rise to human health and disease. Cancers are genetic diseases and involve changes to the genetic code that result in abnormal function of cellular genes. The Cancer Genome Project set out to map the variety of mutations seen across human cancers, and these changes are detailed in online repositories (the Catalogue of Somatic Mutations in Cancer, COSMIC). Multiple gene mutations interact during oncogenesis and a progression of genetic defects gives a cancer cell a survival advantage over surrounding normal cells, famously termed the ‘hallmarks of cancer’ (see Fig. 6.2). These hallmarks include processes like increased proliferation, avoidance of control mechanisms such as apoptosis (programmed cell death) and the ability to evade immune detection. In the vast majority of cancer cases (especially those arising later in life), the multiple genetic changes that occur are somatic: that is, they occur de novo and are not inherited. In the next section, the impact of inheriting mutations in cancer predisposition genes, such as early-onset and multiple cancers, is exemplified.

### Inherited cancer syndromes

In some cancers (normally those that occur at an earlier age), an inherited single-gene defect can give rise to an almost Mendelian trend with lifetime risks of nearly 90%.

#### Autosomal dominant inheritance of cancer syndromes

The development of cancers at an earlier age and the occurrence of multiple tumours in these individuals highlight how genetic mutations facilitate the development of cancer. The following are examples of cancer syndromes (see Box 6.1) that exhibit dominant inheritance:

- **Retinoblastoma.** This eye tumour is found in young children. It occurs in both hereditary (40%) and non-hereditary (60%) forms. In the hereditary form, there is a germline mutation in the retina-
blasto...ma (RB1) and people are also at risk of developing other tumours, particularly osteosarcoma. Knudson studied these patients and this led to the ‘two-hit hypothesis’ (see p. 39).

- **Breast and ovarian cancer.** Two major genes have been identified: BRCA1 and BRCA2. A strong family history along with germline mutation of these genes accounts for most cases of familial breast cancer and over half of familial ovarian cancers. BRCA1 and 2 proteins bind to the DNA repair enzyme Rad51 to make it functional in repairing DNA breaks. Mutations in the BRCA genes will lead to accumulation of unrepaired mutations in tumour suppressor genes and crucial oncogenes. Recently, treatments that block the remaining repair mechanism of double-stranded breaks in these cells, a process called ‘non-homologous end joining’, have been used to treat BRCA-deficient cancers. This paradoxically increases the mutational load in these cells, resulting in cell death. The process is described as synthetic lethality and, in the case of BRCA-deficient tumours, is achieved by inhibitors of an enzyme called poly-ADP ribose polymerase (PARP).

- **Neurofibromatosis.** Inactivation of the NF1 gene will lead to constitutive activation of Ras proteins and the development of multiple tumours in the nervous system (see p. 886).

- **Lynch’s syndrome** (see p. 1215). Patients with defects in a group of genes that encode proteins involved in DNA mismatch repair are at increased risk of colorectal cancer. This syndrome has recently been highlighted as one instance where chemoprevention with aspirin can reduce the development of colorectal cancer by as much as 63%.

**Autosomal recessive inheritance of cancer syndromes**

Some relatively rare autosomal recessive diseases associated with abnormalities of DNA repair predispose to the development of cancer:

- **Xeroderma pigmentosum.** There is an inability to repair DNA damage caused by ultraviolet light and by some chemicals, leading to a high incidence of skin cancer.

- **Ataxia telangiectasia.** Mutation results in an increased sensitivity to ionizing radiation and a higher incidence of lymphoid tumours.

- **Bloom’s syndrome and Fanconi’s anaemia.** An increased susceptibility to lymphoid malignancy is seen. The majority of individuals who develop cancer do not have a genetic predisposition. In these people, somatic changes in DNA drive cancer. Studies of cancer where such changes are amplified have led to the discovery of selected genes that repeatedly cause cancer when mutated. These include oncogenes and tumour suppressor genes.

**Oncogenes**

The genes coding for growth factors, growth factor receptors, secondary messengers or even DNA-binding proteins would act as promoters of abnormal cell growth if mutated. This concept was verified when viruses were found to carry genes that promoted oncogenesis when integrated into the host cell. These were originally termed viral or ‘v-oncogenes’; later, their normal cellular counterparts, c-oncogenes, were found. Thus, oncogenes encode proteins that are known to participate in the regulation of normal cellular proliferation: for example, erb-A on chromosome 17q11–q12 encodes for the thyroid hormone receptor.

**Activation of oncogenes**

Non-activated oncogenes, which are functioning normally, have been referred to as ‘proto-oncogenes’ (Box 2.8). Their transformation to oncogenes can occur by mutation. A range of patterns of genetic mutations have been shown to cause cancer, and additional mechanisms such as ‘chromothripsis’, or chromosomal shattering, have been recently described.

**Mutation**

Carcinogens, such as those found in cigarette smoke, ionizing radiation and ultraviolet light, can cause point mutations in genomic DNA encoding tumour suppressor genes or oncogenes.

**Chromosomal translocation**

If an error occurs during cell division and two chromosomes translocate, so that a portion swaps over, the translocation breakpoint may occur in the middle of two genes, resulting in a mutation. If this happens, then the end of one gene is translocated onto the beginning of another gene, giving rise to a ‘fusion gene’. Therefore, sequences of one part of the fusion gene are inappropriately expressed because they are under the control of the other part of the gene. An example of such a fusion gene (the Philadelphia chromosome) occurs in chronic myeloid leukaemia (Fig. 2.23).

**Viral activation**

There are different ways in which viruses can cause cancer. When viral RNA is transcribed by reverse transcriptase into viral cDNA and, in turn, is spliced into the cellular DNA, the viral DNA may integrate within an oncogene and activate it. Alternatively, the virus may pick up cellular oncogene DNA and incorporate it into its own viral genome. Subsequent infection of another host cell might result in expression of this viral oncogene. For example, the Rous sarcoma virus of chickens was found to induce cancer because it carried the Ras oncogene.

**Tumour suppressor genes**

These genes restrict undue cell proliferation (in contrast to oncogenes), and induce the repair or self-destruction (apoptosis) of cells containing damaged DNA. Therefore, mutations in these genes, which disable their function, lead to uncontrolled cell growth in cells with active oncogenes.

The **RB gene** was the first tumour suppressor gene to be described. In inherited retinoblastoma, the first mutation in the RB gene is inherited; by chance, a second somatic mutation in the remaining normal

CORE SKILLS AND KNOWLEDGE

Aspects of immunity have an impact on all areas of medicine, from diagnosis and treatment through to diseases that arise when the immune system goes wrong. There are more than 80 different autoimmune diseases, which affect 1 in 20 individuals at some point in their life; allergic disease is even more common, affecting 1 in 10.

The role of a clinical immunologist is to manage immune-mediated diseases and provide specialist advice and guidance to primary care physicians and hospital practitioners on diagnostic testing, interpretation and treatment. Clinical immunologists run clinics for severe or complex allergy, and patients with inborn errors of immunity (IEI) that can lead to severe immunodeficiency.

Key skills in clinical immunology include:
- recognizing the possibility of an immunodeficiency syndrome in patients presenting with recurrent or severe infections such as meningitis or pneumonia, and understanding appropriate ways to investigate and manage this
- assessing patients with complex allergy, including food and drug allergy, and undertaking provocation testing and desensitization when appropriate.

Opportunities to learn clinical immunology in general medical contexts include seeking to apply basic immunological principles to understand patients with autoimmune conditions or those receiving immunosuppressant medications. Attending specialist immunology clinics gives insight into how patients live with chronic disease, how parenteral therapies such as immunoglobulins are administered, and how immunologically mediated conditions, including urticaria, angioedema, allergic rhinitis and anaphylaxis, can be managed.

INTRODUCING THE TISSUES, CELLS AND MOLECULES OF THE IMMUNE SYSTEM

Immunity can be defined as protection from infection, whether this is bacterial, viral, fungal or due to multicellular parasites. The immune system is composed of cells and molecules organized into specialized tissues and acts in concert to orchestrate an immune response (Fig. 3.1).

The primary lymphoid organs (thymus and bone marrow) are where the cells originate. Cells and molecules of the immune system circulate in the blood; immune responses do not take place there but are initiated at the site of infection (typically the mucosa or skin). Immunity is then propagated and refined in the secondary lymphoid organs (e.g. lymph nodes). Following resolution of the infection, immunological memory specific for the pathogen is generated and resides in cells (lymphocytes) in the spleen and lymph nodes, as well as being widely secreted in a molecular form (antibodies). Secondary lymphoid organs also include adenoids, tonsils, spleen, Peyer’s patches in the small intestine, peripheral lymph nodes (cervical, axillary, inguinal) and the thoracic duct, which drains the lymph (containing immune cells) into the right subclavian vein.
Immune response: location and dynamics

1. Initial encounter with pathogen: local defences engage and innate cells and molecules enter from blood

2. Cells and pathogen debris travel via lymphatics to lymph node

3. Adaptive immune response generated in lymph node

4. Specialized immune cells and antibodies travel via lymph then blood to tissues

Fig. 3.1 Overview of the cells, molecules and tissues of the immune system. Lymphocytes are generated as precursors in the bone marrow and differentiate into T (thymus) or B (bone marrow) lymphocytes in the primary lymphoid tissue. Once differentiated, 98% of lymphocytes reside in the secondary lymphoid tissue, where the adaptive immune response takes place. Other types of immune cells originate in the bone marrow (left-hand box). Non-immune host defence mechanisms (right-hand box) are occasionally insufficient and an immune response is initiated by infection in the tissues (1). There are rapid local responses that include ingress of cells (e.g. neutrophils) from the blood. Immune cells and pathogen debris migrate via lymphatics to the local lymph node (2), where an adaptive immune response is generated (3). Effector cells travel by lymph and then blood to the infected tissue (4).
Cells involved in immune responses: origin and function

All immune cells derive from pluripotent stem cells generated in the bone marrow. They have diverse functions (see Fig. 3.1). T lymphocytes undergo ‘education’ in the thymus to avoid self-recognition, and populate the peripheral lymphoid tissue, where B lymphocytes also reside. Both sets of lymphocytes undergo activation in the peripheral tissue, to become mature effector cells. B lymphocytes may further differentiate into antibody-secreting plasma cells. Lymphoid tissue is frequently found at mucosal surfaces in non-encapsulated patches, termed mucosa-associated lymphoid tissue (MALT).

The immune system

Cells and molecules involved in immune responses are classified into innate and adaptive systems:

- The innate immune system is inborn and operates throughout life (see p. 43).
- The adaptive immune system changes in response to the pathogens it encounters (see p. 48).

There are also non-immunological barriers that are involved in host protection, and lowering of these may allow a pathogen to gain a foothold (see Fig. 3.1).

The immune system is immensely powerful, in terms of its ability to inflame, damage and kill, and it has a capacity to recognize a myriad of molecular patterns in the microbial world. However, immune responses are not always beneficial. They can give rise to a range of autoimmune and inflammatory diseases, known as immunopathologies. Conversely, the immune system may fail, giving rise to immune deficiency states. These conditions are grouped under the umbrella of clinical immunology.

A major feature of the immune system is the complexity of its surface-bound, intracellular and soluble mediators. In particular, it is necessary to be aware of the clusters of differentiation (CD) classification (Box 3.1) and the functions of cytokines and chemokines. The CD classification is like a barcode for defining a cell.

Cytokines

Cytokines are small polypeptides released by a cell in order to change the function of the same or another cell. These chemical messengers are found in many organ systems but especially the immune system. Cytokines have become markers in the investigation of disease pathogenesis; they are also therapeutic agents in their own right, as well as the targets of therapeutic agents (see p. 67). The key features of a cytokine are:

- pleiotropy: has different effects on different cells
- autocrine function: modulates the cell secreting it
- paracrine function: modulates adjacent cells
- endocrine effects: modulates cells and organs at remote sites
- synergistic activity: acts in concert with other cytokines to achieve effects greater than the summation of their individual actions.

The main immune cytokines are the interferons (IFNs) and the interleukins (ILs). The IFNs are limited to a few major types (α, β and γ), whereas there are 40 interleukins.

Chemokines

The defining feature of chemokines is their function as chemotactic molecules: that is, they attract cells along a gradient of low to high chemical concentration, particularly from the blood into the tissues, and from the tissues into lymphatics. They also have the ability to activate immune cells. All chemokines have a similar structure relating to the configuration of cysteine residues, which gives rise to four families (Box 3.2).

Cell-surface receptors for chemokines are denoted by ‘R’. CCR5 is a co-receptor for the human immunodeficiency virus (HIV; see p. 1441), and drugs to block this and other chemokine receptors are under active development to combat inflammation.

INNATE IMMUNE SYSTEM

Innate immunity provides immediate, first-line host defence. The key features of this system (as well as the adaptive system, p. 48) are shown in Box 3.3. It is present at birth and remains operative at comparable intensity into old age. Innate immunity

| Box 3.2 Features of chemokine mediators and receptors |

<sup>a</sup>Opsonization means coat bacteria to enhance phagocytosis by granulocytes and monocytes/macrophages. <sup>b</sup>C-reactive protein (CRP) is an acute phase protein. Blood level rises 10–100-fold within hours of the start of an infective or inflammatory process, making it extremely useful in monitoring infective or inflammatory diseases and their response to treatment.

Activation of innate immune responses is mediated by a variety of cells and molecules (Box 3.4). Activation of innate immune responses is mediated through interaction between:

- the pathogen side, comprising a relatively limited array of molecules (pathogen-associated molecular patterns, PAMPs)
- the host side, comprising a limited portfolio of receptors (pattern recognition receptors, PRRs).

Activation of certain cells in the innate immune system leads in turn to activation of the adaptive immune response (see p. 48).

The dendritic cell is especially involved in this process, and forms a bridge between innate and adaptive systems.

**Complement**

Complement proteins are produced in the liver and circulate in an inactive form. When triggered, complement molecules become enzymatically active and trigger several molecules of the next stage in a series. This complement cascade is initiated via three distinct pathways: alternative, classical and lectin (Fig. 3.2). Each pathway culminates in the cleavage of C3 and C5. Cleavage of C3 has a number of biological consequences; breakdown of C5 achieves the same and, in addition, provides the triggering stimulus to the final common (‘membrane attack’) pathway, which provides most of the biological activity (see Fig. 3.2).

The main functions of complement activation are to:

- promote inflammation (e.g. through the actions of the anaphylatoxins C3a, C4a and C5a)
- recruit cells (e.g. through chemoattractants)
- kill targeted cells, such as bacteria
- solubilize antigen-antibody (‘immune’) complexes and remove them from the circulation.

During an immune response, removal of immune complexes protects unaffected tissues from the deposition of these large, insoluble composites, which could result in unwanted inflammation. Failure of this protective mechanism can result in immunopathology: for example, in the joints, kidney and eye.

**Neutrophils**

Neutrophils (see also p. 363) phagocytose and kill microorganisms by releasing antimicrobial compounds (e.g. defensins). They are derived from the bone marrow, which can produce between $10^{11}$ (healthy state) and $10^{12}$ (during infection) new cells per day. In health, neutrophils are rarely seen in the tissues.

Neutrophil phagocytosis is activated by interaction with bacteria, either directly or after bacteria have been coated (opsonized)
Innate immune system

To make them more ingestible (Fig. 3.3), the contents of neutrophil granules are released both intracellularly (predominantly azurophilic granules) and extracellularly (specific granules) following fusion with the plasma membrane. Approximately 100 different molecules in neutrophil granules (Box 3.5) kill and digest microorganisms, for example:

- **Myeloperoxidase** and **cytochrome b\textsubscript{558}** are key components of major oxygen-dependent bactericidal systems.
- **Cathepsins, proteinase-3 and elastase** are deadly to Gram-positive and Gram-negative organisms, as well as some Candida species.
- **Defensins** are naturally occurring cysteine-rich antibacterial and antifungal polypeptides (29–35 amino acids).
- **Collagenase and elastase** break down fibrous structures in the extracellular matrix, facilitating progress of the neutrophil through the tissues.

Granule release is initiated by the products of bacterial cell walls, certain complement proteins, leukotrienes (LTB\textsubscript{4}) and chemokines (e.g. CXCL8), and cytokines such as tumour necrosis factor-alpha (TNF-\alpha). A further defence mechanism is the formation of **neutrophil extracellular traps (NETs)** from DNA, which bind pathogens to facilitate killing.

**Eosinophils**

Eosinophils release pro-inflammatory mediators to provide immunity against parasites. In contrast to neutrophils, several hundred times more eosinophils are present in the tissues than in the blood, particularly at epithelial surfaces, where they survive for several weeks. The main role of eosinophils is protection against multicellular parasites such as worms (helminths). This is achieved by the release of pro-inflammatory mediators, which are toxic, cationic proteins. In populations and societies in which such parasites are rare, eosinophils contribute mainly to allergic disease, particularly asthma (see p. 949). Eosinophils have two types of granule:

- **Specific granules** (95%) contain the cationic proteins, of which there are four main types: major basic protein (MBP), eosinophil cationic protein (ECP) and eosinophil peroxidase, similar to neutrophil myeloperoxidase.
- **Primary granules** (5%) synthesize and release leukotrienes C\textsubscript{4} and D\textsubscript{4} and platelet-activating factor (PAF), which alter airway smooth muscle and vasculature.

Eosinophils are activated and recruited by a variety of mediators via specific surface receptors, including complement factors and LTB\textsubscript{4}. In addition, the chemokines eotaxin-1 (CCL11) and eotaxin-2 (CCL24) are highly selective in eosinophil recruitment. There are surface receptors for the cytokines IL-3 and IL-5, which promote the development and differentiation of eosinophils.

**Mast cells and basophils**

Mast cells release pro-inflammatory and vasoactive mediators, and have a role in allergy. Mast cells and basophils share features in common, especially in that they contain:

- histamine-containing granules
- high-affinity receptors for immunoglobulin E (IgE, an antibody type that is involved in allergic disease, see Box 3.10).

Mast cells are found in tissues (especially skin and mucosae) and basophils in the blood. Both mast cells and basophils release pro-inflammatory mediators, which are either pre-formed or synthesized de novo (Box 3.6).

Histamine is a low-molecular-weight amine (111Da) with a blood half-life of less than 5 minutes; it constitutes 10% of the mast cell's
Monocytes and macrophages

Monocytes (in blood) and macrophages (in tissue) ingest and kill bacteria, release pro-inflammatory molecules, present antigen to T lymphocytes, and are necessary in immunity to intracellular pathogens such as mycobacteria.

Cells of the monocyte/macrophage lineage are highly sophisticated phagocytes. Monocytes are the blood form of a cell that spends a few days in the circulation before entering into the tissues to differentiate into macrophages, and some types of dendritic cell. Blood monocytes can be divided into subsets according to expression of CD14 (a receptor for lipopolysaccharide, a bacterial cell wall component) and CD16 (a receptor for IgG antibodies).

A key role of tissue macrophages is the maintenance of tissue homeostasis through clearance of cellular debris, especially following infection or inflammation. They are responsive to a range of pro-inflammatory stimuli, using their PRRs to recognize PAMPs. Once activated, they engulf and kill microorganisms, especially bacteria and fungi, and release a range of pro-inflammatory cytokines. Evidence suggests that evolutionarily conserved molecular patterns in mitochondria (organelles that were originally derived from bacteria) can also activate macrophages. These damage-associated molecular patterns (DAMPs) could play a major role in the systemic inflammatory response that follows extensive tissue damage (e.g. following ischaemic injury).

It has been observed that some PAMPs induce the cytoplasmic assembly of large oligomeric structures of PRRs termed inflammasomes. There are numerous examples: members of the Nod-like receptor (NLR) family can be activated by stimuli such as viruses, bacterial toxins and, interestingly, crystallized endogenous molecules, including urate. Inflammasomes have potent effects in activating caspases, leading to processing and secretion of pro-inflammatory cytokines such as IL-1β and IL-18.

Macrophages have pro-inflammatory and microbicidal capabilities similar to those of neutrophils. Under activation conditions, macrophages present antigen to T lymphocytes (see p. 56) and secrete a range of cytokines, notably TNF-α, IL-1 and IFN-γ. These are necessary for the removal of certain pathogens that live within mononuclear phagocytes (e.g. mycobacteria). Macrophages and related cells may also undergo a process termed autophagy. Autophagy is a lysosomal degradative process that removes abnormal organelles, protein aggregates and intracellular pathogens. The autophagy machinery targets an autophagosome with the relevant material to fuse with lysosomes, which then causes degradation of the contents. This self-cannibalization is a critical property of many cell types under starvation conditions, but is used by the immune system to destroy intracellular pathogens such as Mycobacterium tuberculosis, which otherwise persist within cells and block normal antibacterial processes. Autophagy is also a means of enhancing antigen presentation pathways. Dysregulation of the autophagic pathway has been associated with a number of diseases, including cancer, inflammatory disease and infections.

Tissue macrophages involved in chronic inflammatory foci may undergo terminal differentiation into multinucleated giant cells, typically found at the site of the granulomata characteristic of tuberculosis and sarcoidosis (see pp. 968 and 985).

Dendritic cells

The function of dendritic cells is activation of naive T lymphocytes to initiate adaptive immune responses (see p. 48); they are the only cells capable of this. The definition of a dendritic cell is one that has:

- dendritic morphology (Fig. 3.4)
- machinery for sensing pathogens
- the ability to process and present antigens to CD4 and CD8 T lymphocytes, coupled with the ability to activate these T lymphocytes from a naïve state
- the ability to dictate the T lymphocyte’s future function and differentiation.

This is a powerful cell type that functions as a critical bridge between the innate and adaptive immune systems.

Types of dendritic cell

The major types are the conventional DC (cDC), the plasmacytoid DC (pDC) and a variety of specialized DCs found in tissues.
that resemble cDCs (e.g. the Langerhans cell in the skin; see Ch. 22). DCs have several distinctive cell surface molecules, some of which have pathogen-sensing activity (e.g. the antigen uptake receptor DEC205 on cDCs), while others are involved in interaction with T lymphocytes (Box 3.7). Immature cDCs and pDCs are present in the blood but at very low levels (<0.5% of lymphocyte/macrophage cells).

Pathogen-sensing is a key component of the function of immature DCs, as well as monocytes/macrophages, and is achieved through expression of a limited array of specialized PRR molecules capable of binding to structures common to pathogens, aided by long cell dendrites and pinocytosis (constant ingestion of soluble material).

PRRs include mannose-binding lectin, which initiates complement activity, inducing opsonization (see Fig. 3.3), and signal receptors, such as the PRR known as Toll-like receptor 4 (TLR4), which binds lipopolysaccharide, a molecular pattern found in the cell walls of many Gram-negative bacteria (Box 3.8). Other TLRs bind double-stranded and single-stranded RNA from viruses and other non-self antigens. Innate immunity critically depends on TLR signalling. The key principle at play is that the immune system has devised a means of identifying most types of invading microorganisms by using a limited number of PRRs recognizing common molecular patterns, or PAMPs. This recognition event has been termed a ‘danger signal’; it alerts the immune system to the presence of a pathogen. Sensing danger is a key role of the DC and a key first step towards activation of the adaptive immune system.

Dendritic cells and T-cell activation

In a sequence of events that spans 1–2 days, immature DCs are activated by PAMPs or DAMPs in the tissues binding to PRRs. The immature pDC is a small, rounded cell that develops dendrites on activation and secretes enormous quantities of IFN-α, a potent antiviral and pro-inflammatory cytokine; this seems to be the major role of pDCs. In contrast, the activated cDC migrates to the local lymph node with the engulfed pathogen. During migration, the cDC matures, changing its shape, gene and molecular profile and function within a matter of hours to take on a mature form, with altered capabilities (Box 3.9 and Fig. 3.5), the most important of which is upregulating the machinery required to activate T lymphocytes. Once in the lymph node, the mature cDC interacts with naive T lymphocytes (antigen presentation), resulting in two key outcomes:

- activation of T cells with the ability to recognize peptide fragments (termed epitopes) of the pathogen
- polarization of the T cell towards a functional phenotype (see below) that is tailored to the particular pathogen.

The mature cDC provides three major signals to naive T cells (see Fig. 3.5):

- signal 1: presentation of peptide fragments from the pathogen bound to surface human leucocyte antigen (HLA) molecules
- signal 2: co-stimulation through CD80 and CD86 interacting with CD28 on T cells
- signal 3: secretion of cytokines, notably IL-12.

**Natural killer cells**

Natural killer (NK) cells are described on page 53.

**Innate lymphoid cells**

Innate lymphoid cells (ILCs) were identified relatively recently as a lymphoid cell type that resembles T lymphocytes in terms of function...
but differs in that it lacks any form of specific receptor to recognize targets such as pathogens. The role of these cells in immunity and pathology is the subject of intense interest.

**Further reading**

**Fig. 3.5** Dendritic cell activation of T lymphocytes. (a) Immature dendritic cells (DCs) in the tissues are activated by pathogens through pathogen-associated molecular pattern–pattern recognition receptor (PAMP–PRR) interaction. (b) Multiple rapid changes in gene expression lead to migration to the lymph node as the DC takes on the mature phenotype. During migration, there is synthesis of the machinery required for activation of T lymphocytes, shown here in response to *signals 1–3*. CD, cluster of differentiation; HLA, human leucocyte antigen; IL-12, interleukin 12; TCR, T-cell receptor.

**ADAPTIVE IMMUNE SYSTEM**

The information gained by cDCs that interact with a pathogen is passed on, in the form of signals 1–3 (see *Fig. 3.5b*). These activate T lymphocytes in the adaptive immune system, which recognize the same pathogen. T lymphocytes may be involved in pathogen removal directly (e.g. by killing) or indirectly (e.g. by recruiting B lymphocytes to make specific antibody). Lymphocytes orchestrate immune responses via cell-to-cell interactions and cytokine release.

**Antigen receptors on T and B lymphocytes**

One of the key features of the adaptive immune system is specificity for antigen. For example, if a person is immunized against the measles virus, that person does not have immunity to hepatitis B, and vice versa. This specificity is conferred by two types of receptor: the T-cell receptor (TCR) on T lymphocytes and an equivalent on B lymphocytes, the B-cell receptor (BCR). BCRs are also termed surface immunoglobulin (sIg); they differ from TCRs in also being secreted in large quantities by end-stage B lymphocytes (plasma cells) as soluble immunoglobulins, also known as antibodies.

**Immunoglobulins**

In structural terms, antibodies have four chains: two identical heavy and two identical light chains (*Fig. 3.6*). Each chain contains both highly variable and essentially constant regions. The variable parts of the heavy and light chains pair to form the potentially diverse part of the antibody molecule that binds antigen. The constant region of the heavy chain dictates the function of the antibody and belongs to one of the classes M, G1–4, A1–2, D and E, giving rise to antibodies called IgM, IgG1–4, IgA1–2, IgD and IgE. The characteristics of these different isotypes are shown in *Box 3.10*. As it matures, and under the instruction of T lymphocytes, a B lymphocyte may change the class (class switching), but never the specificity, of the antibody it makes; minor changes in antibody gene sequence can take place (somatic mutation), potentially allowing antibodies with higher affinity to arise and be selected for the effector response (affinity maturation).
Antibody function
In host defence, antibodies target, neutralize and remove infectious organisms and toxins from the circulation and tissues, often through recruitment of innate host effector mechanisms such as complement, phagocytes and mast cells (by binding to specific surface receptors on these cells).

In clinical medicine, specific anti-pathogen antibody levels are used in diagnosing/monitoring infectious disease, and may also be administered as serum pools to provide host protection passively. Antibodies can be raised in animals to generate monoclonal antibodies, which are commonly used in diagnostic immunology tests and increasingly employed as therapeutics (immunotherapy; e.g. to target cancer cells, or to target immune cells and molecules to suppress or activate immune responses), often after ‘humanization’ (see later).

T-cell receptor genes and receptor diversity
The genomic organization of T-cell receptor (TCR) genes and principles of generation of receptor diversity are similar to those of immunoglobin genes. The TCR exists as a heterodimer, with a similar overall structure to that of the antibody molecule. There are two TCR types:
• **α and β chains** (αβ TCR). These are expressed on all CD4 T lymphocytes and approximately 90% of CD8 T lymphocytes; they play a role in adaptive immune responses.
• **γ and δ chains** (γδ TCR). These are fewer in number and are expressed mainly on intraepithelial lymphocytes; they are involved in epithelial defence.

The chains of each type of TCR are divided into variable and constant domains, each domain being encoded by separate gene pools. Like the B lymphocyte producing a single clone of immunoglobin molecules, the T lymphocyte expresses only one form of TCR once the genes have been rearranged. Unlike antibodies, TCRs do not undergo somatic hypermutation and are not secreted.

T lymphocyte development and activation
T lymphocytes are generated from precursors in the bone marrow, which migrate to the thymus (Fig. 3.7). Only 1% of the cells that enter the thymus will leave it as naive T lymphocytes to populate the lymph nodes. This process (termed thymic selection) leads to a cohort of cells (Box 3.11) with:
• functionally rearranged genes allowing surface expression of a receptor for antigen (the TCR) alongside the CD3 accessory molecule involved in transducing the antigen-specific signal.

- selection of a co-receptor, either CD4 or CD8, to stabilize the interaction between TCR and peptide-HLA:
  - CD4 T-cell responses require presentation of peptide antigens by self HLA class II molecules
  - CD8 T-cell responses require presentation of peptide antigens by self HLA class I molecules
- a reduced or absent tendency of the selected TCR to recognize self antigens (thus avoiding autoimmunity).

Thus, during thymic education, most TCRs are rejected for further use (negative selection), either because they are unable to bind self HLA molecules, or because they bind with too strong an affinity, which would run the risk of self-reactivity and autoimmune disease. The chosen TCRs (positive selection) have low/intermediate affinity for self HLA molecules. During post-thymic activation of T lymphocytes in the lymph node, TCR interaction with HLA has to be bolstered by additional signals (called co-stimulation) provided by cDCs. This ensures that T lymphocytes are activated by a mature cDC; this happens only in the presence of pathogens.

Co-stimulation of T cells is such a critical event in immune responses that it is tightly regulated. One level of control relies on molecular interactions that are termed immune checkpoints. An example is cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4), which is expressed shortly after T-cell activation and competes with CD80 and CD86 for CD28, at the same time providing a negative signal, reducing T-cell activation (Fig. 3.8). This immune checkpoint is exploited in a highly successful treatment for rheumatoid arthritis, in which the interaction between CD80/86 and CD28 is blocked using a drug called abatacept (also known as CTLA-4Ig, being a soluble form of CTLA-4 fused to the Fc portion of an antibody), leading to co-stimulation blockade and suppression of T-cell responses. A further example is the immune checkpoint involving programmed cell death protein-1 (PD-1) and its ligands (PD-L1/L2). Like CTLA-4, PD-1 is upregulated after T lymphocyte activation, and interaction with PD-L1/L2 leads to inhibition of T lymphocyte function. PD-L1/L2 may be expressed on a variety of cells, including cDCs but also many non-immune cells, most notably tumour cells. Immune checkpoint blockade (see Fig. 3.8) using monoclonal antibodies focused on to PD-1/PD-L interactions releases the brakes on the immune system and is at the heart of the recent revolution in cancer immunotherapy (see p. 112), the discovery of which was awarded the 2018 Nobel Prize for Medicine.

Most naive T lymphocytes are resident in the lymph nodes or spleen, while 2% are present in the blood, representing a recirculating pool. Naive T lymphocytes are activated for the first time in the lymph node by antigens presented to their TCRs as short peptides bound to major histocompatibility complex (MHC) molecules on the surface of DCs (see Fig. 3.5). Provision of signals 1–3 (see p. 47) sets off an intracellular cascade of signalling molecule activation, leading to induction of gene transcription in T lymphocytes.

The outcome is T lymphocyte activation, cell division and functional polarization, which is the acquired ability to promote a selected type of adaptive immune response. These processes take several days to achieve. The best-described polarities of T-cell responses (Box 3.12) are:

- CD4+ pro-inflammatory T lymphocytes; T helper 1 (Th1), Th2 and Th17
- CD8+ cytotoxic T lymphocytes (CTLs) (Box 3.13)
- CD4+ regulatory responses (Treg).

Through cell division, a proportion of the T lymphocytes that are activated in response to a pathogen undertake these effector or regulatory functions, while a proportion is assigned to a memory pool. Once established, effector and memory T lymphocytes have lesser requirements for subsequent activation, which can be mediated by monocytes, macrophages and B lymphocytes.

**CD4 T lymphocyte functions**

As the pivotal cell in immune responses, the CD4 T lymphocyte influences most aspects of immunity, either through the release of cytokines or via direct cell–cell interaction, a process often termed ‘licensing’. Licensing critically involves the pairing of CD40 on a specialized subset of cDC (cDC1) with CD40 ligand (CD40L, CD154) on the CD4 T lymphocyte; defects in this process result in antibody deficiency (see later).
Major functions of CD4 T lymphocytes are:

- **licensing of cDCs** during antigen presentation to activate CD8 T lymphocytes and generate cytotoxic cells
- **licensing of B lymphocytes** to initiate and mature antibody responses, leading to class switching, affinity maturation of antibodies, and generation of plasma cells or memory cells
- **secretion of cytokines** responsible for growth and differentiation of a range of cell types, especially other T lymphocytes, macrophages and eosinophils
- **regulation of immune reactions**.

### T helper 1 cells

T helper 1 cells (Th1) are the main effector subtype of CD4 T lymphocytes. In physiology, they drive activation of monocytes/macrophages and CTLs. In pathology, they have a key role in protection against intracellular pathogens such as viruses and mycobacteria. Th1 cells are recognized by secretion of the pro-inflammatory cytokines IFN-γ and TNF-α (Box 3.13).

### T helper 2 cells

In physiology, Th2 cells drive antibody responses, especially IgE, and also promote eosinophil granulocyte functions. In pathology, they have a key role in protection from extracellular parasites (helminths) and also in the immune responses that underlie allergic disease. Th2 cells are recognized by secretion of IL-4, IL-5 and IL-13.

### T helper 17 cells

In physiology, Th17 cells drive inflammatory responses, especially via recruitment of neutrophil granulocytes. In pathology, they are

necessary for protection from fungal infections, and are increasingly recognized as having a role in chronic inflammatory diseases such as multiple sclerosis, rheumatoid arthritis and inflammatory bowel disease. They are recognized by secretion of IL-17.

**T follicular helper cells**

T follicular helper cells (Thf) express CXCR5, the inducible T-cell co-stimulator molecule (ICOS), and secrete IL-21. They are responsible for licensing B lymphocytes for antibody production (see earlier).

**Regulatory T lymphocytes**

The generation of B and T lymphocytes provides a potentially vast array of rearranged antigen receptors. Although there are selection processes to remove lymphocytes with ‘dangerous’ avidity for ‘self’, these are not foolproof and the potential for autoreactivity remains. The fact that there is no self-destruction in the vast majority of people implies that the norm is a state of immunological self-tolerance: the controlled inability to respond to self. Several mechanisms operate to maintain this state, including CD4 T lymphocytes that respond to antigenic stimulation by suppressing ongoing immune responses. These regulatory T lymphocytes (Treg) express high levels of CD25, the receptor for IL-2; regulate other T lymphocytes by cell–cell contact; and also secrete the immune-suppressive cytokines IL-10 and TGF-β. They can be generated in the thymus or post-thymically in the periphery. Their key feature is high expression of the transcription factor Foxp3.

Evidence that Tregs are clinically relevant is provided by rare cases of genetic defects in the Foxp3 gene, leading to IPEX (immune dysregulation, polyendocrinopathy, enteropathy, X-linked) syndrome. Patients with this rare syndrome have defective Tregs and develop a range of conditions soon after birth, including organ-specific autoimmune disease such as type 1 diabetes. Much research effort is directed at harnessing this natural regulatory potential in new immunotherapies: for example, to control organ-specific autoimmune disease such as type 1 diabetes.

**CD8 T lymphocyte functions**

Cytotoxic CD8 T lymphocytes (CTLs) are involved in defence against viruses. CTLs kill virus-infected cells following recognition of viral peptide-HLA class I complexes. CTLs must be activated first in the lymph node by a specialized cDC subset (called cDC1) that cross-presents the same viral peptide that is seen on infected cells, and is licensed by a CD4 T lymphocyte recognizing viral peptide-HLA class II complexes. The same defence mechanism may also apply in tumour surveillance. This is a checkpoint that ensures that CTL responses, which have great destructive power, are activated only against a target for which there is also a CD4 T-cell response. CTLs kill via three mechanisms:

- cytotoxic granule proteins (cytolysins such as perforin, granzyme B)
- toxic cytokines (e.g. IFN-γ, TNF-α)
- death-inducing surface molecules (e.g. Fas ligand binds Fas on target cells mediating apoptosis via caspase activation, Fig. 3.9).

### Natural killer cells

Natural killer (NK) cells are bone marrow-derived, present in the blood and lymph nodes, and represent 5–10% of lymphoid cells. The name reflects two features. Unlike B and T lymphocytes, NK cells are able to:

- mediate their effector function spontaneously (i.e. killing of target cells through release of perforin, a pore-forming protein) in the absence of previous known sensitization to that target
- achieve this with a very limited repertoire of germline-encoded receptors that do not undergo somatic recombination.

For identification purposes, the main surface molecules associated with NK cells are CD16 (see later) and CD56 (note that NK cells are CD3- and TCR-negative). The role of NK cells is to kill ‘abnormal’ host cells, typically cells that are virus-infected, or tumour cells. Killing is achieved in similar ways to CTLs. NK cells also secrete copious amounts of IFN-γ and TNF-α, through which they can mediate cytotoxic effects and activate other components of the innate and adaptive immune systems. To become activated, NK cells integrate the signal from a potential target cell through a series of receptor–ligand pairings (Box 3.14). These pairings provide activating and inhibitory signals, and it is the overall balance of these that determines the outcome for the NK cell. The balance can be abnormal on a virus-infected or tumour cell, which might have altered expression of HLA molecules, for example, that mark them out for NK cytotoxicity.

In addition, through CD16, which is the low-affinity receptor for IgG (FcgRIIIA), NK cells can kill IgG-coated target cells in a process termed antibody-dependent cellular cytotoxicity (ADCC).

### Further reading

retain lymphocytes in the lymph nodes is balanced by the activity of sphingosine-1-phosphatase (S1P) and its receptors. High levels of S1P allow activated immune cells to recirculate back into the tissues. Modulation of S1P can be used to retain lymphocytes in the lymph node in the treatment of multiple sclerosis (see p. 867).

Migration into inflamed tissue requires:
- an affected organ or tissue to signal that there is a focus of injury/infection and
- responding immune cells to bind and adhere specifically to that tissue.

This process is highly organized and has a similar basis for all immune cells, involving three basic steps: rolling, adhesion and transmigration. Each of these is dependent on specialized adhesion molecules (Fig. 3.11).

The expression of these molecules (e.g. leucocyte function associated antigen-1, LFA-1) is upregulated on T lymphocytes after activation in the lymph node. Intercellular cell adhesion molecule 1 (ICAM-1) expression on tissue endothelium is sensitive to numerous pro-inflammatory molecules and allows immune cells to be guided from the blood into the tissues. Once there, cells move along a gradient of increasing concentration of mediators such as chemokines embedded within a physical groove at the extremity of the HLA molecule (Fig. 3.12).

The HLA genes are particularly interesting for clinicians and biologists. First, differences in HLA molecules between individuals are responsible for tissue and organ graft rejection (hence the name ‘histo’(tissue)-compatibility). Second, possession of certain HLA genes is linked to susceptibility to particular diseases (Box 3.15).

### The human major histocompatibility complex

The human MHC comprises three major classes (I, II and III) of genes involved in the immune response (Fig. 3.13).

#### HLA classes

##### Classical HLA class I genes

Classical HLA class I genes (also termed la) are designated HLA-A, HLA-B and HLA-C. Each encodes a class I α chain, which combines with a β chain to form the class I HLA molecule (see Fig. 3.12). While there are several types of α chain, there is only one type of β chain: β2 microglobulin. The HLA class I molecule has the role of presenting short (8–10 amino acid) antigenic peptides to the T-cell receptor on the subset of T lymphocytes that bear the co-receptor CD8. As an example of HLA polymorphism, there are nearly 200 allelic forms at the A gene locus. Class I HLA molecules are expressed on all nucleated cells.

##### Non-classical HLA class I genes

Non-classical HLA class I genes are less polymorphic, have a more restricted expression on specialized cell types, and present a restricted type of peptide or none at all. These are the HLA-E, F and G (lb genes) and HLA class I-related (MIC, or class Ic) genes, A and B. The products of these genes are predominantly found
HLA molecules and antigen presentation

HLA class II genes

The class II genes have three major subregions: DP, DQ and DR. In these subregions are genes encoding A and B genes that combine to form dimeric αβ molecules that present short (12–15 amino acid) peptides to T lymphocytes that bear the CD4 co-receptor. Class II HLA genes (apart from DRA) are highly polymorphic. Other genes in this region encode proteins with key roles in antigen presentation (e.g. TAP, HLA-DM, HLA-DO, proteasome subunits; see later). Class II HLA genes are expressed on a restricted cohort of cells that go by the general term of antigen presenting cells (APCs; DCs, monocyte/macrophages, B lymphocytes).

HLA class III genes

HLA class III genes encode proteins that can regulate or modify immune responses; they include tumour necrosis factor (TNF), heat shock protein (HSP) and complement protein (C2, C4).

HLA genotypes and the range of their protein products

HLA genotype is denoted first by the letters that designate the locus (e.g. HLA-A, HLA-DR, HLA-DQ). For class I alleles, this is followed by an asterisk and then a two- to four-digit number defining the allelic variant at that locus, often called the HLA type (e.g. HLA-A*02 is the 02 variant of the HLA-A gene). The class II nomenclature is the same, except that both A and B genes are named (although HLA-DR molecules require only the name of the B gene because the A gene is the same in all of us).

Some general principles apply to the HLA genes and their protein products:

- The presence of multiple genes on each chromosome, and the fact that both maternal and paternal genes are co-dominantly expressed, allow considerable breadth in the number of HLA molecules that an individual expresses.
Antigen presentation

HLA molecules bind short peptide fragments that are processed ('chopped up') from larger proteins (antigens) derived from pathogens. The peptide–HLA complex is presented on APCs for recognition by TCRs on T lymphocytes. There are three major routes to antigen processing and presentation:

- **The endogenous route** (Fig. 3.14) is a property of all nucleated cells; the internal milieu is sampled to generate peptide–HLA class I complexes for display ('presentation') on the cell surface. In a healthy cell, the peptides are derived from self proteins in the cytoplasm (see Fig. 3.14) and are ignored by the immune system. In a virus-infected cell, viral proteins are processed and presented. The resulting viral peptide–HLA class I complex is presented to CD8 T lymphocytes that have cytotoxic (killer) function. In an immune response against a virus infection, CD8 T lymphocytes recognizing viral peptide–HLA complexes on the surface of an infected cell will kill it as a means to limit and eradicate infection.

- **The exogenous route** (Fig. 3.15) is a property of APCs; the external milieu is sampled. Antigens are internalized, either in the process of phagocytosis of a pathogen, through pinocytosis, or through specialized surface receptors (e.g. for antigen/antibody/complement complexes). The antigen is broken down by a combination of low pH and proteolytic enzymes for 'loading' into HLA class II molecules. At the APC surface, the pathogen peptide–HLA class II complex is presented to, and able to interact with, CD4 T lymphocytes. Presentation by DCs can initiate an adaptive immune response by activating a naive, pathogen-specific CD4 T lymphocyte. Presentation by monocyte/macrophages and B lymphocytes can maintain and enhance this response by activating effector and memory pathogen-specific CD4 T lymphocytes.
**Fig. 3.15** The exogenous route of antigen presentation and cross-presentation. External material (e.g., virus particles) is taken into an antigen presenting cell and broken down into specialized compartments by a combination of low pH and proteolysis. Peptides are then loaded into human leucocyte antigen (HLA) class II molecules for presentation to CD4 T lymphocytes. Material may also be transferred across the cell so that it is loaded on to HLA class I molecules for presentation to CD8 T lymphocytes. This process of cross-presentation is restricted to specialized antigen presenting cells such as dendritic cells. ER, endoplasmic reticulum.

- **Cross-presentation** refers to the ability of some APCs (mainly cDC1s) to internalize exogenous antigens and process them through the endogenous route (see Fig. 3.14). This is an essential component in the activation of CD8 cytotoxic T-cell responses against a virus.

**THE IMMUNE SYSTEM IN CONCERT**

**Acute inflammation: events and symptoms**

This is the early and rapid host response to tissue injury. To take a bacterial infection as the classic example:

- Local expansion of pathogen numbers leads to direct activation of complement in the tissues, with ensuing degranulation of mast cells.

  - Inflammatory mediators (from mast cells and complement) change the blood flow and attract and activate granulocytes (neutrophils).

  - Concomitantly, there are the local symptoms of heat, pain, swelling and redness, and perhaps more systemic symptoms such as fever due to the effect of circulating cytokines (IL-1, IL-6, TNF-α) on the hypothalamus. Indeed, gene mutations that lead to excessive actions of IL-1 (e.g. mutation of the *IL1RN* gene, which encodes a natural IL-1 antagonist) give rise to rare disease with just these symptoms, as well as bone erosion and skin rashes, which are treatable with IL-1 blockade using soluble IL-1 receptor antagonist (anakinra) or monoclonal anti-IL-1β antibody.

  - Systemically active mediators (especially IL-6) also initiate the production of C-reactive protein (CRP) in the liver.

  - Bacterial lysis follows through the actions of complement and neutrophils, leading to formation of fluid in the tissue space containing dead and dying bacteria and host granulocytes (‘pus’).

  - At the site of pathogen entry, there is often relative tissue hypoxia. The low oxygen tension has the effect of amplifying the responses of innate immune cells and suppressing the response of adaptive immune cells. This is probably an effective means of preventing excessive immune activation, which can result in collateral damage (Fig. 3.16).

  - The inflammation may become organized and walled off through local fibrin deposition to protect the host.

  - Antigens from the pathogen travel via the lymphatics (which may become visible as red tracks in the superficial tissues—lymphangitis) in soluble form or are carried by DCs to establish an adaptive immune response, which, at the first host–pathogen encounter, takes approximately 7–14 days. DCs are activated via the PRR–PAMP system (see Fig. 3.5).

  - The adaptive immune response leads to activation of pathogen-specific T lymphocytes and of B lymphocytes, and production of pathogen-specific antibody, initially of the IgM class and of low to moderate affinity, and subsequently of the IgG class (or IgA if the infection is mucosal) and of high affinity.

  - Resolution of the infection is aided by the scavenging activity of tissue macrophages.

  - The common feature of these pathological processes is the difficulty of removing the inciting stimulus. For example, some viruses and mycobacteria remain hidden intracellularly. In many ways, the pathology that results is inadvertent: the immune system is caught between the repercussions of not dealing with the infection or insult and the tissue damage that is caused by chronic activation of lymphoid and mononuclear cells.

**Chronic inflammation: events and symptoms**

Inflammation arising in response to immunological insults that cannot be resolved in days or weeks gives rise to chronic inflammation. Examples include infectious agents (viruses that cause chronic infections such as hepatitis B and C, or intracellular bacteria such as mycobacteria) and environmental toxins (such as asbestos and silicon). At the intracellular level, key processes of inflammasome generation (see p. 46) and autophagy (see p. 46) serve to enhance the chronic inflammatory process. Chronic inflammation is also a hallmark of some forms of allergic disease, autoimmune disease and organ graft rejection.

The common feature of these pathological processes is the difficulty of removing the inciting stimulus. For example, some viruses and mycobacteria remain hidden intracellularly. In many ways, the pathology that results is inadvertent: the immune system is caught between the repercussions of not dealing with the infection or insult and the tissue damage that is caused by chronic activation of lymphoid and mononuclear cells.
**Mycobacterium leprae**

In *Mycobacterium leprae* infection (leprosy, p. 550) this feature is well demonstrated. With the same infecting organism, two very different forms of disease are seen: lepromatous or tuberculous. In the tuberculous form, there is a good immune response to chronic infection but the immune response causes nerve damage and numb patches of skin. In the lepromatous form, Th1 responses are less pronounced and infection is widespread but there is less nerve damage.

In both of these forms of mycobacterial disease, the chronic inflammation may lead to permanent organ damage or impaired vascular function, and can be fatal. If the inciting stimulus is removed, inflammation resolves. With leprosy, this is achieved with antibiotics. However, inflammation can return rapidly (24–48 hours) on re-exposure. This rapid recall response is the basis for patch testing to identify the cause of contact dermatitis, another form of chronic inflammation, and also for the Mantoux (skin) or the interferon gamma release (IGRA) blood test of tuberculosis immunity.

The main immunological event is the presence of a pro-inflammatory focus comprising T and B lymphocytes and APCs, especially macrophages. If antigen persists, inflammation becomes chronic and the macrophages in the lesion fuse to form giant cells and epitheliod cells. Both Th1 and Th2 reactivity is recognized but specific syndromes may be polarized towards one or the other (e.g. chronic mycobacterial or viral infection initiates Th1 responses, chronic allergic inflammation Th2).

When the inflammation is sufficiently chronic, it may take on the appearance of organized lymphoid tissue resembling a lymph node germinal centre (e.g. in the joints in rheumatoid arthritis, p. 456).

There is massive cytokine production by T lymphocytes and APCs, which contributes to local tissue damage. Granulomata, which ‘wall off’ the inciting stimulus, may also arise and result in fibrosis and calcification. Symptoms typically relate to the site of the inflammation and the type of pathology, but there may also be systemic effects such as fever and weight loss.

**Crohn’s disease**

Chronic inflammation is a hallmark of several immune-mediated and autoimmune diseases but it is often unclear what kick-starts or maintains the inflammatory process. Large-scale studies that identify the genetic basis for these disorders (genome-wide association studies (GWAS), p. 33) are beginning to provide some clues. A good example is Crohn’s disease (see p. 1198). Several of the polymorphisms associated with Crohn’s disease reside in genes known to be involved in inflammasome induction, such as *NOD2*. Cytokine regulation has also emerged as a critical disease pathway in GWAS studies on Crohn’s disease: most notably, *IL-23R* (the IL-23 receptor gene), which influences Th17 cell differentiation. Clues like these point to patients with Crohn’s disease having impaired ability to control or terminate inflammasome activity, as well as a predisposition to make polarized pro-inflammatory cytokine responses. This information can now be exploited to devise novel therapeutic approaches, such as monoclonal antibodies that target the key cytokines.

*Apart from AIDS, all the diseases shown here are primary immunodeficiencies.

**CLINICAL IMMUNODEFICIENCY**

**Secondary (acquired) versus primary immunodeficiency**

Most forms of immunodeficiency are secondary to infection (mainly HIV) or therapy (e.g. corticosteroids, monoclonal antibody therapy, cytotoxic anticancer drugs, bone marrow ablation pre-transplant).

Examples of other secondary immunodeficiencies are:

- **Acquired neutropenias**, which are common (e.g. due to myelosuppression by disease or drugs, or the increased rate of destruction in hypersplenism or autoimmune neutropenia) and carry a high risk of infection once the neutrophil count falls below $0.5 \times 10^9/L$.

- **Acquired reductions in levels of immunoglobulins** (hypogammaglobulinaemia), which are seen in patients with myeloma and chronic lymphocytic leukaemia or lymphoma.

- **Impairment of defence against capsulated bacteria**, especially pneumococcus, following splenectomy; such patients should receive pneumococcal, meningococcal and Hib vaccinations as a matter of course (see Box 16.18).

Primary immunodeficiency is rare and arises at birth as the congenital effect of a developmental defect or as a result of genetic abnormalities (Box 3.17). Gene defects may not become...
manifest until later in infancy or childhood, and some forms of immunodeficiency typically present in adolescence or adulthood.

**Clinical features of immunodeficiency**

The infections associated with immunodeficiency have several typical features:

- They are often chronic, severe or recurrent.
- They resolve only partially with antibiotic therapy or return soon after cessation of therapy.
- The organisms involved are often unusual (‘opportunistic’ or ‘atypical’).

The pattern of infection, in terms of the type of organism involved, is indicative (**Box 3.18**):

- **‘Opportunistic’ organisms** are of low virulence but become invasive in immunodeficient states, e.g. atypical mycobacteria, *Pneumocystis jiroveci*, *Staphylococcus epidermidis*.
- **Phagocyte defects** cause deep skin infections, abscesses and osteomyelitis, for example.
- **Defective antibody** producers experience infections with pyogenic (‘pus-forming’) bacteria.
- **T lymphocyte deficiency** causes infection with fungi, protozoa and intracellular microorganisms.
- **Congenital deficiencies** of antibody production are not revealed for several months after birth, due to the 28-day half-life of maternal IgG.

The family history may reveal unexplained sibling death, the fact that only males of the family are affected (X-linked), or consanguinity; each of these makes a primary genetic syndrome more likely. Graft-versus-host disease (GVHD) may arise as a complication of primary or secondary T lymphocyte immunodeficiency. For GVHD to occur, there must be impaired T lymphocyte function in the recipient and the transfer of immunocompetent T lymphocytes from an HLA non-identical donor (see later). GVHD is usually caused by therapeutic interventions such as transfusions or transplantation, but may be due to transfer of maternal cells across the placenta, in which case it is called materno-fetal engraftment.

- *Toxoplasma gondii*
- *Herpes simplex*
- *Herpes zoster*
- *Cytomegalovirus*
- *Epstein–Barr virus*

**Primary immunodeficiency**

**T lymphocyte deficiency**

**Complete DiGeorge’s syndrome**

DiGeorge’s syndrome arises in 1–5 per 100 000 of the population due to deletions on the long arm of chromosome 22. It has a highly variable presentation, including cardiac abnormalities, abnormal facies, thymic dysfunction, cleft deformities and hypocalcaemia/hypoparathyroidism, remembered by the acronym ‘CATCH-22’. In those DiGeorge individuals born without a thymus, the lack of a location for T lymphocyte development means that they have reduced or absent T lymphocyte number and proliferation responses. Apart from calcium supplementation, correction of cardiac abnormalities and prophylactic antibiotics, cure has been reported with thymic transplantation using fetal tissue or stem cell transplant (SCT) from HLA identical siblings. Other athymic conditions include Foxn1 deficiency and CHARGE syndrome (coloboma, heart defects, choanal atresia, retardation of growth and development, ear abnormalities) caused by CHD7 mutations.

**Other T lymphocyte deficiencies**

Other T lymphocyte deficiencies caused by single-gene defects have been characterized and typically present from the age of 3 months with candidial infections of the mouth and skin, protracted diarrhoea, fever and failure to thrive. These disorders are similar in presentation and management to the combined (T and B lymphocyte) immunodeficiencies.

**T and B lymphocyte deficiency**

**Severe combined immunodeficiencies**

Severe combined immunodeficiencies (SCID) are a heterogeneous group of rare (1–2 live births per 100 000), genetically determined disorders resulting from impaired T, NK and B lymphocyte immunity. The most common form of SCID is an X-linked defect in the IL-2 receptor γ chain, interfering with the function not just of IL-2 but also of IL-4, IL-7, IL-9 and IL-15, which share
IgG has declined, while other syndromes may present variably throughout childhood and adult life. The clinical features of antibody deficiency are severe, recurrent sinopulmonary infection leading to bronchiectasis and persistence of gut pathogens (e.g. Giardia) with resultant chronic diarrhoea and malabsorption. Morbidity and mortality are high if the conditions are untreated, mainly due to chronic lung disease and central nervous system infections with enteroviruses.

**X-linked agammaglobulinaemia**

X-linked agammaglobulinaemia (XLA) is an intrinsic defect in B lymphocyte maturation. The cause is a loss-of-function mutation of Bruton’s tyrosine kinase, which is involved in cell activation and maturation. B lymphocyte development is arrested at the pre-B stage, and B lymphocytes are absent in the blood. Clinical presentation follows the fall in protective maternal IgG.

**Common variable immunodeficiencies**

Common variable immunodeficiencies (CVID) are a heterogeneous group of disorders arising during late childhood and early adulthood, with very low IgG levels. Although rare (1/50,000) it is the most common severe primary immune deficiency and carries a significant risk of morbidity and mortality. Autoimmunity and granulomatous disease are found in up to 15% of cases. Genetic defects underlying the condition have revealed mutations in multiple genes: in Europe the most common is haploinsufficiency of NFKB1. In most patients, the underlying defect remains unknown.

**Selective IgA deficiency**

Selective IgA deficiency (IgAD; serum IgA <0.05 g/L), with normal levels of IgG and IgM, is found in approximately 1/600 Northern Europeans. Most individuals are asymptomatic but numerically this is the most common primary immunodeficiency. The underlying defect is unknown. Patients may present at any age with recurrent infections caused by pyogenic organisms, particularly affecting mucosal sites.

**Treatment of antibody deficiencies**

Treatment of IgAD is not usually required; when it is, antibiotics are used. Some IgAD patients produce anti-IgA antibodies of the IgG and IgE classes, and so infusion of exogenous IgA (e.g. during a blood transfusion) could result in anaphylaxis. IgAD patients should therefore be screened for anti-IgA antibodies if there is a history of transfusion reaction, and transfused with appropriate precautions if positive.

For patients with XLA, CVID or another major antibody deficiency, treatment is with replacement immunoglobulins (intravenous or subcutaneous, IVIg or SCIg) to a level that controls infections. Trough IgG concentrations should remain well within normal limits (i.e. >6 g/L), and infections should be treated promptly and aggressively with antibiotics. Prognosis has improved in recent years as more patients survive into adulthood, but chronic lung disease and lymphomas remain life-threatening complications.

**Defects in antigen presenting cell function**

A series of rare genetic defects have been uncovered in which APCs demonstrate an inability to mount protective responses to intracellular bacteria, particularly low-virulence mycobacteria and salmonella. The axis affected is the interplay between CD4 T lymphocytes and APCs that drives Th1 responses, and therefore in turn activates mononuclear cells such as macrophages to kill and eradicate intracellular pathogens. Defective genes so far identified include those...
encoding a component chain of IL-12; a component chain of the IL-12 receptor; and IFN-γ receptor chains 1 or 2 or the intracellular signalling pathway (STAT 1).

**Neutrophil defects**

**Chronic granulomatous disease**

Chronic granulomatous disease (CGD) is a rare (1/250,000) immuno-deficiency that is caused by a defect in neutrophil killing; it is characterized by deep-seated infections. The functional defect is an inability to generate antibacterial metabolites through the respiratory burst (see Box 3.5). X-linked and autosomal forms are described. Typical onset is at toddler age. Neutrophil numbers are normal or increased. A simple respiratory burst test of neutrophil function is diagnostic. The dysfunctional neutrophils’ inability to clear infection adequately and frustrated apoptosis lead to granulomatous inflammation, and CGD may also present with a Crohn’s-like gut disease (see p. 1198).

Treatment of infections and prophylactic antibiotic and antifungal therapy are required. In many cases, SCT is necessary. For the X-linked form, gene therapy is a treatment option when a suitably matched donor cannot be found.

**Leucocyte adhesion deficiency**

Leucocyte adhesion deficiency (LAD) results from defects in integrins (see Fig. 3.11). Numerous underlying defects in the genes encoding one of the component chains, CD18, have been described in LAD-1. LAD-1 has an autosomal recessive inheritance, presenting almost immediately after birth with delayed umbilical cord separation. In later life, there is a characteristic failure to lose primary dentition and severe gingivitis. Recurrent infections appear during the first decade of life. Blood neutrophil levels are high but cells are absent from the sites of infection, which require aggressive antimicrobial and antifungal treatment, and SCT for cure.

**Hyper-IgE syndrome (Job’s syndrome)**

This is an autosomal dominant (occasionally sporadic) immune disorder with high serum IgE levels, dermatitis, boils, pneumonias with cyst formation, and bone and dental abnormalities. Mutations in STAT3, DOCK8 and ZNF341 have been found.

**Schwachman–Diamond syndrome**

This can resemble cystic fibrosis clinically, with exocrine pancreatic insufficiency and pyogenic infections. A mild neutropenia is associated with a defect of neutrophil migration.

**Chédiak–Higashi syndrome**

This rare recessive disorder is caused by a mutation in the lysosomal trafficking regulator gene (LYST) on chromosome 1q42–45. There are defects in neutrophil function with defective phagolysosome fusion, and large lysosome vesicles are seen in phagocytes. Patients have recurrent infections, neutropenia, anaemia and hepatomegaly. As with Schwachman–Diamond syndrome, tissue infiltration with histiocytes is usually seen, including in bone marrow, and Chédiak–Higashi syndrome is one of several genetic causes of primary haemophagocytic lymphohistiocytosis (HLH). Similar genetic abnormalities in melanocytes cause partial oculocutaneous albinism.

**Complement deficiency**

The consequences of deficiency of complement proteins can be predicted from their functions (see Fig. 3.2):

- Failure of the classical pathway results in a tendency towards infection and also towards diseases in which immune complex deposition causes inflammation, such as systemic lupus erythematosus (e.g. C1 and C4 deficiency), vasculitis and glomerulonephritis.
- Neisserian infections (e.g. meningitis due to *N. meningitidis*) are often encountered in patients with complement defects of the membrane attack complex (C6–9). Lectin pathway deficiency in isolation rarely causes major ill health.

**Complement regulatory proteins**

Deficiency of C1 inhibitor (*C1 esterase deficiency*; see also p. 668) is relatively rare. Since this enzyme is involved in regulation of several plasma enzyme systems (e.g. the kinin system) and is continuously consumed, a single parental chromosome defect resulting in 50% of normal production barely copes with the demand and fails under stress (hence has an autosomal dominant effect). As a result, uncontrolled activation of low-molecular-weight kinins may occur, leading to oedema of the deep tissues affecting the face, trunk, viscera and airway, and explaining the alternative name of hereditary angio-oedema (HAE). Treatment is with C1 inhibitor concentrate or a selective bradykinin-2 receptor antagonist (icatibant). Steroids and antihistamines are not useful in this form of angio-oedema. Prophylaxis may be with attenuated androgens or specific kallikrein inhibitors. A rarer acquired form (acquired angio-oedema, AAEd) may be seen in lymphoproliferative disease or complicating autoimmunity. The treatment is largely as for HAE.

**Further reading**

---

**ALLERGIC DISEASE (IMMEDIATE HYPERSENSITIVITY)**

Normally, host defence can cope with potentially harmful cells and molecules. Under some circumstances a harmless molecule can initiate an immune response that can lead to tissue damage and death. Such exaggerated, inappropriate responses are termed hypersensitivity reactions or allergic disease.

In **allergic hypersensitivity**, the binding of an antigen to specific IgE bound to its high-affinity receptor on a mast cell surface results in massive and rapid cell degranulation and the inflammatory response outlined on page 45. The antigens involved are typically inert molecules present in the environment (these are termed allergens, p. 949).

The immediate effects of allergen exposure are often very florid (early phase response). Allergic disorders also have a second phase, occurring a few hours after exposure and lasting up to several days. These *late phase responses* (LPRs) are mediated by Th2 cells recognizing peptide epitopes of the allergen. Recruitment of eosinophils is often a prominent feature.

From a pathological and therapeutic viewpoint, the LPR gives rise to chronic inflammation, which is difficult to control. In **asthma**, the LPR causes prolonged wheezing, which can be fatal. Immediate hypersensitivity is usually responsive to antihistamines but the LPR is not, requiring powerful immune modulators such as corticosteroids.
In immunopathological terms, in the LPR:

- Neutrophils and eosinophils are prominent in the first 6–18 hours and may persist for 2–3 days.
- Th2 cells accumulate around small blood vessels and persist for 1–2 days.
- Mediators responsible for the cellular infiltrate include platelet-activating factor and leukotrienes (Box 3.19).
- Th2 cytokines IL-4 and IL-5 and chemokines such as eotaxin act as growth and activation stimuli for eosinophils, which are capable of extensive tissue damage. Th2 cytokines are also responsible for the class switch of Ig production towards IgE, maintaining the cycle of immediate and late responses.

What makes an allergen so powerful?

Several allergens are proteolytic enzymes, allowing them to cross skin and mucosal barriers. They are often contained within small, aerodynamic particles (e.g. pollen grains) that gain access to nasal and bronchial mucosa.

Why do some people react and others do not?
The tendency to develop allergic responses (known as atopy) shows strong heritability. Between 20% and 30% of the UK population is atopic, and two, one or no atopic parents pass on the atopic trait to their children with a risk of 75%, 50% and 15%, respectively. In developing nations, the tendency to allergy is estimated at one-tenth of the rate in industrialized countries. Among the predisposing genes are those encoding the β chain of the high-affinity receptor for IgE and IL-4, both strongly associated with Th2 pathways. The presence of Th2 cells recognizing allergens is the pathological hallmark of allergy.

What environmental factors are involved?

Early exposure to allergens (even in utero) may be a factor in developing atopy. Over-zealous attention to cleanliness (the hygiene hypothesis) in developed societies (use of antibiotics, reduced exposure to pathogens that might favour a Th1-like environment) may favour a reduction in Treg activity. This environmental factor is demonstrated by the rapid increase of allergy in the eastern part of Germany following reunification in 1990.

In clinical terms, approximately two-thirds of atopic individuals (who can be identified as those with circulating allergen-specific IgE) have clinical allergic disease (equating to 15–20% of the UK population). Allergy accounts for up to one-third of school absences because of chronic illness. Allergic disorders include allergic rhinitis (hay fever), allergic eczema, bee and wasp venom allergy, some forms of food allergy, urticaria and angio-oedema.

Diagnosis

Diagnosis of allergic disease is usually made on the history and backed up by skin-prick testing (insertion of a tiny quantity of allergen under the skin and measurement of the size of the weal) and/or measurement of serum allergen-specific IgE. Mast cell tryptase serum levels peak 1–2 hours after an event, remaining high for 24 hours.

Treatment

Avoidance is the first line of therapy. Other measures are as follows:

- **Antihistamines** are effective for many immediate hypersensitivity reactions (but have no role in the treatment of asthma).
- **Corticosteroids** have several well-identified modifying actions in the allergic process: production of prostaglandin and leukotriene mediators is suppressed, inflammatory cell recruitment and migration are inhibited, and vasoconstriction leads to reduced cell and fluid leakage from the vasculature.
- **Cysteinyl leukotriene receptor antagonists (LTRA)**s inhibit leukotrienes (LTs) by blocking the type I receptor (e.g. montelukast, used in asthma, particularly the aspirin-induced type).
- **Omalizumab** is a monoclonal antibody that binds IgE. It is used in severe asthma (see p. 953) that cannot be controlled with a corticosteroid plus a long-acting β2 agonist. Treatment must be initiated in a specialist centre where staff have experience of treating severe, persistent asthma.
- **Dupilumab** is a monoclonal antibody that inhibits the biological activity of both IL-4 and IL-13. It has been shown to be beneficial in severe atopic eczema and asthma.
- **Desensitization (allergen immunotherapy)** works on the principle that allergy can be prevented by inoculation if the allergen is given in a controlled way. Desensitization is indicated for disorders in which the hypersensitivity is IgE-mediated, e.g. life-threatening allergy to insect stings, drug allergy and allergic rhinitis. An induction course of subcutaneous injections of increasing doses of the allergen extract, given once every 1–2 weeks, is followed by maintenance injections monthly for 2–3 years. A systematic review of 51 published randomized, placebo-controlled clinical trials, enrolling a total of nearly 3000 participants, showed a low risk of adverse events with consistent clinical benefit. From an immunological viewpoint, desensitization seems capable of modifying the allergic response at several levels (Box 3.20). Sublingual allergen

immunotherapy (using grass pollen extract tablets of Phl p 5 from timothy grass) is used in hay fever that has not responded to anti-allergic drugs (the first dose is given under medical supervision) (see p. 947).

Anaphylaxis

Anaphylaxis is a serious allergic reaction that is rapid in onset and may cause death. It arises as an acute, generalized IgE-mediated immune reaction involving specific antigen, mast cells and basophils. The reaction requires priming by the allergen, followed by re-exposure. To provoke anaphylaxis, the allergen must be systemically absorbed, after either ingestion or parenteral injection. A range of allergens that provoke anaphylaxis has been identified (Box 3.21).

Anaphylaxis is rare, but the symptom/sign constellation ranges from widespread urticaria to cardiovascular collapse, laryngeal oedema, airway obstruction and respiratory arrest leading to death:

- Fatal reactions to penicillin occur once every 7.5 million injections.
- Between 1 in 250 and 1 in 125 individuals have severe reactions to bee and wasp stings, and a death takes place every 6.5 million injections.

Central to the pathogenesis of anaphylaxis is the activation of mast cells and basophils, with systemic release of some mediators and generation of others. The initial symptoms may appear innocuous: tingling, warmth and itchiness. The ensuing effects on the vasculature lead to vasodilatation and oedema. The consequence of allergens that provoke anaphylaxis has been identified (Box 3.21).

Anaphylaxis is rare, but the symptom/sign constellation ranges from widespread urticaria to cardiovascular collapse, laryngeal oedema, airway obstruction and respiratory arrest leading to death:

- Fatal reactions to penicillin occur once every 7.5 million injections.
- Between 1 in 250 and 1 in 125 individuals have severe reactions to bee and wasp stings, and a death takes place every 6.5 million stings, with 60–80 deaths per year in North America and 5–10 in the UK.

Central to the pathogenesis of anaphylaxis is the activation of mast cells and basophils, with systemic release of some mediators and generation of others. The initial symptoms may appear innocuous: tingling, warmth and itchiness. The ensuing effects on the vasculature lead to vasodilatation and oedema. The consequence may be no more than a generalized flush, with urticaria and angio-oedema. More serious sequelae are hypotension, bronchospasm, laryngeal oedema and cardiac arrhythmia or infarction. Death may occur within minutes.

Serum platelet-activating factor (PAF) levels correlate directly with the severity of anaphylaxis, whereas PAF acetylhydrolase (the enzyme that inactivates PAF) correlates inversely and is significantly lower in peanut-sensitive patients with fatal anaphylactic reactions.

Management

Early recognition and treatment are essential (Box 3.22).

The best treatment is prevention. Avoidance of triggering foods, particularly nuts and shellfish, may require almost obsessive self-discipline. Patient education is necessary and many are instructed in the self-administration of adrenaline (epinephrine) and carry pre-loaded syringes. Desensitization has a well-established place in the management of this disorder, particularly if exposure is unavoidable or unpredictable, as in insect stings. In peanut allergy (see p. 1257), it has been shown that early introduction of peanuts in children modulates the response in later life, and this benefit extends to high-risk children with atopic eczema or allergy to another food. Further studies have shown that it is possible to give graded peanut exposure to those already sensitized and that oral desensitization can reduce the risk of anaphylaxis associated with inadvertent exposure in children with a history of peanut allergy. The addition of modified peanut peptides further enhances the success and tolerability of this approach.

AUTOIMMUNE DISEASE

Autoimmunity is when the immune response turns against self, i.e. recognizes ‘self’ antigens. The vast array of possible TCRs and antibodies that can be generated by the host make it highly probable that at least a small proportion can recognize self (i.e. are autoreactive). Moreover, a degree of autoreactivity is physiological: the TCR is designed to interact both with the peptide epitope in the HLA molecule binding groove and with the HLA molecule itself.

The critical event in the development of autoimmune disease is when T and B lymphocytes bearing these receptors for ‘self’ become activated: this leads to loss of immunological tolerance. The major checkpoints that the immune system has in place to prevent this are:

1. removal of TCRs with very strong affinity for ‘self’ in the thymus
2. the presence of naturally arising regulatory T lymphocytes (Tregs)
3. the requirement for a danger signal to license dendritic cells to activate CD4 T lymphocytes.

Failure of immune tolerance checkpoint 1: thymic education

During thymic education, TCRs with a dangerously high affinity for self are deleted. It has become apparent that this process relies on

**Box 3.21 Sources of allergens known to provoke anaphylaxis**

**Foods**
- Nuts: peanuts (protein – Arachis hypogaea Ara h 2), Brazil, cashew
- Shellfish: shrimp (allergen Met e 1), lobster
- Dairy products
- Egg
- More rarely: citrus fruits, mango, strawberry, tomato

**Venoms**
- Wasps, bees, yellow-jackets, hornets

**Medications**
- Antisera (tetanus, diphtheria), dextran, latex, some antibiotics

**Box 3.22 Treatment of acute anaphylaxis**

**Clinical features**
- Bronchospasm
- Facial and laryngeal oedema
- Hypotension
- Nausea, vomiting and diarrhoea

**Management**
- ABCDE (airway, breathing, circulation, disability, exposure)
- Position the patient lying flat with the feet raised
- Ensure the airway is free
- Give oxygen
- Monitor blood pressure
- Establish venous access
- Administer 0.5 mg intramuscular adrenaline (epinephrine) 0.5 mL of 1:1000 adrenaline, i.e. 1 mg/mL, and repeat after 5 min if shock persists (dose reduced for children or adults on beta-blockers)
- Administer intravenous antihistamine (e.g. 10–20 mg chlorphenamine) slowly
- Administer 100 mg intravenous hydrocortisone.
  - If hypotension persists, give 1–2 L of intravenous fluid
  - If hypoxia is severe, assisted ventilation may be required
  - Take blood for tryptase levels (aids diagnosis)
the thymic expression of self antigens. Situations that compromise the expression of a self protein would be expected to favour the development of autoimmunity. Indeed, in a rare group of patients who develop multiple autoimmune disorders affecting the adrenal and parathyroid glands (autoimmune polyglandular syndrome type 1, p. 648), there is a defect in the autoimmune regulator (AIRE) gene, which controls thymic expression of a host of self genes. When the gene malfunctions, there is reduced expression of self proteins in the thymus and autoimmune disease is a consequence.

**Failure of immune tolerance checkpoint 2: regulatory T lymphocytes**

An example of Treg failure is the defect in the gene encoding Foxp3, a critical transcription factor in Tregs, which leads to IPEX (see p. 52). IPEX is very rare but it serves to indicate how Treg defects can lead to autoimmune disease. Laboratory studies in this area are revealing subtle Treg defects in several autoimmune diseases (e.g. type 1 diabetes, multiple sclerosis, rheumatoid arthritis). The role of Foxp3 in regulating peripheral immune responses highlights the control of immune expansion and regulation of immunological ‘space’. Another component of this process is the contraction of an immune response once the infection has been dealt with. Autoimmune lymphoproliferative syndrome (ALPS) is a disorder with defects in either Fas, its ligand (Fasl or CD95) or the associated intracellular signalling pathway. Individuals develop multiple cytopenias, organ-specific autoimmunity, and lymphoproliferation that may mimic lymphoma. The common problem is the inability to ‘switch off’ activated T cells. Treatment is with haemopoietic SCT if the disorder is severe. Many patients with multiple cytopenias, including Evans’ syndrome (autoimmune thrombocytopenia and haemolytic anaemia), are revealed to have ALPS defects when appropriately tested.

**Failure of immune tolerance checkpoint 3: CD4 T lymphocyte activation against an autoantigen (or its mimic)**

For an autoimmune disease to develop, there must be presentation of autoantigens to a naive, potentially autoreactive CD4 T lymphocyte by activated cDCs. Several theories exist to explain this:

- Tissue damage due to infection leads to both the release of hidden self antigens and the provision of sufficient danger signals to activate cDCs, which in turn activate autoreactive CD4 T lymphocytes, as well as pathogen-specific ones. This is often termed ‘bystander activation’.
- A pathogen mimics a self antigen. In the process of mounting an entirely appropriate immune response against the pathogen, T or B lymphocytes are generated that also have the capacity to recognize self. This is termed molecular mimicry.
- Post-translational modification. Self proteins and peptides are modified in such a way that they appear foreign. A good example is an antibody found in patients with rheumatoid arthritis, which recognizes citrulline-modified forms of self peptides.

It is unlikely that, for the common autoimmune diseases (Box 3.23), there is a ‘single tolerance checkpoint’ explanation. Rather, it is likely that multiple subtle defects, at various checkpoints, are at play.

### Tissue damage via chronic inflammation

In a number of autoimmune diseases (e.g. type 1 diabetes, multiple sclerosis), autoreactive T lymphocytes are likely to be the main drivers of disease and tissue damage. Th1 cells, CTLs and Th17 cells induce chronic inflammation and release cytokines that recruit other effector cells (macrophages) or are directly toxic (e.g. insulin-producing β cells are susceptible to the combined effects of IL-1β, IFN-γ and IL-17 in type 1 diabetes).

**IgG4 disease**

IgG4 disease is a fibro-inflammatory condition with the formation of swellings at multiple sites infiltrated with IgG4-producing plasma cells and a tendency to high circulating levels of IgG4. Unlike many autoimmune disorders, IgG4-related disease is driven by Th2 T cells in association with high numbers of FoxP3+ T cells. The first recognized form of this disorder was autoimmune pancreatitis, but lesions in the biliary tree, salivary glands, periorbital tissues, kidneys, lungs, lymph nodes, meninges, aorta, breast, prostate, thyroid, pericardium and skin are recognized (Box 3.24). The current hypothesis is that Th2 cells drive the activation of macrophages and myofibroblasts, leading to fibrosis and IgG4 plasma cell proliferation.

### Tissue damage via autoantibodies

Examples of damage through direct binding to a target cell or structure, with recruitment of complement and other destructive processes, include:

- **myasthenia gravis** (autoantibodies against the acetylcholine receptor cause damage to the neuromuscular junction)
- **autoimmune haemolytic anaemia** (autoantibody targets red blood cell autoantigens, leading to lysis)

**Mechanisms of tissue damage in autoimmune disease**

Figure. 3.17 illustrates potential mechanisms of immune damage in autoimmune disease.
Goodpasture’s syndrome (anti-glomerular basement membrane autoantibodies damage glomerular integrity). Autoantibodies can also bind their antigen in the circulation to form immune complexes. When these are deposited in the tissues, complement- and cell-mediated immune reactions are initiated. Immune complexes preferentially deposit in sites such as the kidney glomerulus, leading to chronic kidney disease. This is a feature of systemic lupus erythematosus, in which the autoantigen within the immune complexes is DNA.

**Common autoimmune diseases**

Over 80 diseases are now classified as autoimmune. The autoimmune origin of some of these diseases is very clear-cut but that is not so for others, and both major and minor factors must be defined.

**Major criteria**
- There is evidence of autoreactivity (e.g. activated or memory autoreactive T lymphocytes or autoantibodies).
- A clinical response to immune suppression can be demonstrated.
- Passive transfer of the putative immune effector (e.g. autoreactive T lymphocyte or autoantibody) causes the disease (this is the hardest criterion to satisfy in humans but is the most stringent).

**Minor criteria**
- An animal model exists that resembles the human condition, and in which there is a similar loss of immunological tolerance to self.
- There is evidence that, in the animal model, passive transfer of the putative immune effectors reproduces the disease in a naive animal.
- There is an HLA association (a frequent indicator that a disease is autoimmune).

**Further reading**
ORGAN REJECTION IN CLINICAL TRANSPLANTATION

The outcome of an allograft (i.e. a graft between genetically non-identical members of the same species) in the absence of adequate immunosuppressive therapy is immunological rejection. Histological analysis of rejected organs shows a range of immunological processes in action (Box 3.25). With modern tissue-matching approaches, hyperacute rejection is rare and acute rejection can usually be prevented or treated with immunosuppression. The process of chronic rejection typically takes place over several years and is the main reason for organ graft failure.

The antigens recognized in acute and chronic graft responses are donor HLA molecules (alloantigens):

- In acute rejection, it is thought that the predominant response is against intact HLA molecules (direct allore cognition) and is mediated by CD4+ and CD8+ T lymphocytes.
- As the rejection process becomes more chronic, peptides from donor HLA molecules are processed and presented to T lymphocytes by host HLA molecules (indirect allore cognition).

IMMUNE-BASED THERAPIES

Manipulation of the immune response in a therapeutic setting has seen many successes, as evidenced by the control of organ rejection in clinical transplantation through targeted immunosuppression (Box 3.25). Monoclonal antibodies offer the opportunity to neutralize the unwanted effects of cytokines, or to direct immune responses, drugs, toxins or irradiation against a specific target, whether it be a tumour cell or an immune cell involved in a damaging autoimmune response. Natural antiviral mediators, such as the interferons, are already in the clinic as therapies for chronic viral infection, among other things. Genetic manipulation of T lymphocytes has generated a new class of cellular therapies.

Monoclonal antibody therapy (targeted therapy)

The combined power of monoclonal antibody (MAb) and recombinant DNA technology has led to a series of ‘designer’ drugs, which have been engineered so that they:

- are exquisitely targeted
- have optimal effector function
- do not carry antigenic segments that may incite a neutralizing response in the host.

In general, this has meant a process of ‘humanizing’ antibodies of mouse origin and selecting an appropriate effector function. For example, a MAb designed to remove a subpopulation of lymphocytes from the patient should have good complement-fixing ability or bind well to receptors on phagocytes, whereas a MAb designed to ‘modulate’ a cell without depletion should have these functions removed. Many examples of MAbs in current use are described in individual chapters. Therapeutic MAbs are potent modifiers of essential components of immune responses and therefore carry both predictable and unpredictable risks. For example, anti-TNF therapies increase the risk of invasive viral and mycobacterial infection. The new inhibitors of integrins, such as natalizumab, have been associated with JC virus reactivation in patients, leading to progressive multifocal leuкоencephalopathy (PML). Since integrins are essential for the migration of T cells into tissues, the blockade prevents egress into inflammatory sites but also reduces immune surveillance of infection.

Chimeric antigen receptor T-cell therapy

Chimeric antigen receptor (CAR) T-cell therapy is an exciting new approach to the treatment of haematological malignancy. In the first licensed product of its kind (tisagenlecleucel) for B lymphocyte leukaemia and lymphoma, blood is taken from the patient and T lymphocytes are separated out. Using a retrovirus, the T lymphocytes are modified to express the CAR (which comprises a receptor for CD19 coupled to a powerful intracellular co-stimulation molecule). The CD19 target is expressed on all B lymphocytes (including lymphomas and B-cell leukaemias). The CAR-modified T lymphocytes are infused back into the patient and will then kill all target B lymphocytes. The main risk of this therapy is massive cytokine release from CAR T lymphocyte activation. Since all B lymphocytes (and not just the tumour cells) are removed, the patients develop antibody deficiency and require life-long immunoglobulin replacement. Specific co-stimulation domains in the CAR T cells have been shown to aid long-term persistence, correlating with prolonged protection against disease relapse. Further targets and approaches are now in clinical trials.

Immunosuppressive drugs

- Glucocorticosteroids (cortisone, hydrocortisone, prednisone and prednisolone) are the most commonly used steroids and have a variety of effects on immune function, including:
  - potent effects on monocyte production of the pro-inflammatory cytokines IL-1 and TNF-α
Immunity

- blockade of T lymphocyte production of IL-2 and IFN-γ
- reduced activation and migration of a range of innate and adaptive immune cells.

- **Ciclosporin, tacrolimus and sirolimus (rapamycin)** have similar effects on T lymphocyte function. Ciclosporin and tacrolimus are calcineurin inhibitors and inhibit Ca\(^{2+}\)-dependent second messenger signals in T lymphocytes following activation via TCRs. By contrast, sirolimus achieves a similar effect but acts at the level of post-activation events in the nucleus.

- **Purine analogues** such as azathioprine are also frequently used as anti-inflammatory drugs in conjunction with steroids and act by inhibiting DNA synthesis in dividing adaptive immune cells. Similar in mode of action, but more powerful, is mycophenolate mofetil (MMF).

- **Alkylating agents** that interfere with DNA synthesis, such as cyclophosphamide, are also used for immunosuppression.

- **Kinase inhibitors** have profoundly improved the treatment of some malignancies with previously very poor outcomes. Tyrosine kinases (TYK) are ubiquitous regulators of cell activation, promoting cell division and proliferation in response to growth factors and cytokines. Inhibition of the signalling pathways can lead to immune suppression. In immune cells, the relevant kinases include the Janus kinases (JAK) that signal through the STAT pathway. Inherited mutations in JAK-STAT pathway molecules can lead to immunodeficiency or, if the mutation causes constant (constitutive) activation, can give rise to uncontrolled cell division independent of growth factors: that is, cancer. Specific inhibitors of TYK have been developed for a range of cancers and as T- and B-cell immune suppressants.

**Cytokines and anticytokines**

Cytokines are pleiotropic agents with powerful pro-inflammatory and immunosuppressive effects, and are attractive targets for therapies that inhibit or enhance their function. TNF-α targeting agents (cytokine modulators) have been tested in rheumatoid arthritis, as has the recombinant IL-1 receptor antagonist anakinra, although with much less success. None the less, the good safety profile of anakinra has prompted its use in other diseases, and a beneficial effect has been shown in type 2 diabetes, which may have an innate inflammatory component. IL-2 and its receptor (CD25) are also obvious candidates for immune therapies. Interferons are successfully used to boost pro-inflammatory immunity in chronic virus infection.

**Restoring tolerance in autoimmune diseases and allergy**

One of the goals of immune-based therapies for autoimmune disease is not simply to achieve immunosuppression, but also to restore immunological tolerance against the relevant autoantigens. In animal models, an effective means of achieving this is to administer the autoantigen itself, or key peptide epitopes from it. This is known as antigen-specific or peptide immunotherapy and is under trial for several autoimmune diseases, where it appears to induce Tregs. The diseases that have the most advanced clinical data are in the field of allergy. For example, administration of cocktails of peptides of the cat allergen Fel d 1 has led to a reduction in detectable skin-prick responses and improved clinical scores.

**Intravenous immunoglobulin**

Intravenous immunoglobulin (IVIg) is a preparation of polyspecific IgG chemically purified from the plasma of large numbers (>20 000) of healthy donors. IVIg is used as a replacement therapy in patients with primary and secondary antibody deficiencies. When it is used for inflammatory conditions, however, there is also a therapeutic benefit, although randomized, placebo-controlled studies are few. In the USA, IVIg is recommended only for a small number of diseases in addition to antibody deficiency. These include immune-mediated thrombocytopenia, Kawasaki’s disease, chronic inflammatory demyelinating polyneuropathy and post-transfusion purpura.

The mechanism of action is not known, but may include:

- blockade of Fc receptors to prevent pathogenic antibodies binding to phagocytes
- inhibition of autoantibody synthesis by B lymphocytes
- modulation of dendritic cell function
- inhibition of complement activation
- inhibition of specific cytokines
- induction of T-cell regulation.

**Further reading**

INTRODUCTION

The evidence-based medicine movement emerged over 30 years ago and is widely accepted as the gold standard for medical decision-making. It was defined in 1996 as ‘the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients’, with evidence in this case referring to peer-reviewed research literature. The focus has since expanded to include an emphasis on the importance of the patient and carer perspective in decision-making, alongside research evidence. We therefore refer in this chapter to evidence-based practice (EBP), which we define as ‘an approach to decision-making in which the clinician uses the best scientific evidence available, in consultation with the patient, to decide upon the option that suits the patient best’. This chapter will also embrace evidence-based public health practice, which applies evidence to wider populations, as well as individual patients.

The need for EBP

A number of factors have driven the rapid expansion of EBP. These include a growing awareness among health professionals of the gap between the large amount of good-quality research evidence available in the published literature and its often limited use in clinical practice. For example, thrombolysis using tissue plasminogen activator (tPA) is an evidence-based treatment that is effective in acute stroke. However, despite the potential benefits offered by thrombolysis, achieving and sustaining high rates of tPA delivery to eligible patients has proved problematic. EBP also has a role in ensuring that treatments offered by healthcare providers are of high value and accrue the most benefits for patients and the public – especially where escalating demands for care result in constrained resources.

Barriers to EBP

A multitude of barriers exist that lead to research evidence not being taken up into clinical practice, or to its being implemented in a delayed or patchy manner.

Knowledge barriers and the use of clinical guidelines

The most obvious barrier is lack of knowledge. It is estimated that general physicians would need to read 20 articles a day, all year round, to keep abreast of emerging knowledge in their specialist field. As research evidence continues to expand, clinical guidelines have become an important mechanism for informing day-to-day practice and helping clinicians keep up to date. Clinical guidelines identify, evaluate and summarize the best available research evidence relating to the management of specific conditions.
Consequently, they are a useful first port of call when seeking information on which to base decision-making. Guidelines are usually produced at national or international level by medical associations or government bodies. In the UK, the National Institute for Health and Care Excellence (NICE) provides recommendations about care for patients with specific conditions. In the USA, the National Guideline Clearing House maintains a catalogue of guidelines published by various health and medical associations, including the Agency for Healthcare Research and Quality.

While clinical guidelines are not legally binding, doctors are expected to take them into account, and yet the extent to which this happens in practice varies. For example, UK clinical guidelines recommend that patients with high blood pressure and raised cholesterol should receive antihypertensives, antiplatelet drugs and lipid-lowering drugs for the secondary prevention of ischaemic stroke. However, one study demonstrated that only 25.6% of men and 20.8% of women receive appropriate treatment, and the likelihood of 80–89-year-olds receiving secondary prevention is nearly half that of 50–59-year-olds.

Other factors limiting the implementation of EBP

These include:

- doubts about the accuracy of the research evidence being promoted
- national and local political values
- priorities and pressures from industry, patients, the public and clinicians
- cost.

These often interconnecting factors can lead to health policies being implemented despite the availability of contradictory evidence. For example, a programme of five-yearly preventative health checks for 40–74-year-olds is now mandatory across the National Health Service in England. It had been argued that the scheme would help prevent 1600 heart attacks yearly, saving at least 650 lives; prevent over 4000 people from developing diabetes; and detect at least 20 000 cases of diabetes or kidney disease earlier. However, the evidence suggests that general health checks:

- do not, in fact, reduce morbidity or mortality
- increase the number of diagnoses made, with consequent costs to the health service.

For example, although health checks lead to more diagnoses and more medical treatment for hypertension, this does not improve mortality or morbidity. Consequently, this intervention could be considered inappropriate, as the potential harms outweigh the expected benefits.

A framework for applying evidence to clinical problems

EBP offers a framework to assist clinicians in making efficient and appropriate use of the available literature and in reaching considered decisions about its application. The goal of this chapter is to promote ways in which evidence can be used wisely, with good understanding of its value and its limitations. In the following sections, we describe four essential steps:

- converting information needs into answerable questions
- locating the best available evidence
- appraising the evidence critically
- applying the evidence in practice.

**Further reading**

**ASKING ANSWERABLE QUESTIONS**

Every day, doctors make multiple decisions that involve asking implicit and explicit questions. Evidence-based care protocols, pathways and clinical guidelines are available that cover the management of a wide range of both common and rare conditions, and these should generally be a clinician’s first port of call.

Sometimes, however, a literature search is required – perhaps where a patient does not fit well into the categories dealt with by clinical guidelines, or where a condition is rare and not covered by good evidence-based summaries. The first step is to turn the information need into a focused question. This must be directly relevant to the patient at hand and incorporate the key issues that need to be present in research articles to inform the decision-making process. Identification of these key issues will allow formulation of a focused literature search strategy.

The *PICO approach* facilitates this process (Box 4.1), where patient, intervention, comparison and outcome (PICO) are considered the four most key parts of a well-built clinical question.

**SEARCHING FOR THE EVIDENCE**

The next step is to identify relevant research evidence that will provide an answer to the clinical question. There are two main sources of evidence available.

**Primary sources of evidence**

These are comprised of the thousands of original articles published every year in research journals. Research papers are catalogued in a variety of databases, which are searchable on the Internet.
For many medical queries, Medline is the best-known database of health-related literature and makes a good starting place. The size and breadth of databases mean that a systematic searching approach is required to identify the best evidence available.

**Secondary sources of evidence**

In order to deal with the growing volume of primary research, secondary sources of evidence are increasingly consulted. Secondary sources are summaries and analyses of evidence derived from and based on primary sources. The Cochrane Library (UK) was one of the first online collections of databases relevant to medicine and other healthcare specialties, and includes the Cochrane Database of Systematic Reviews. Other organizations producing systematic reviews and other evidence syntheses to inform practice and policy include the Joanna Briggs Institute and the Campbell Collaboration.

**How to conduct a search**

Although biomedical databases vary in terms of their structure, the principles of using them are largely the same. Using the PICO approach to generate a clinical question is helpful, as the components can then be employed to select search terms for conducting a search in Medline. Text-word searching involves seeking specific words or phrases, usually in the title or abstract of an article. The first step is to break the clinical question down into its individual components. **Box 4.2** contains a worked example, using the PICO approach.

Practical tips for searching databases include:
- Searching only for articles that include a full phrase, rather than individual words on their own, by putting double quotation marks around a group of words (e.g. “sore throat”).
- Narrowing the search and reducing the number of citations identified by using **AND** in the database search function.
- Avoiding narrowing too far. Using the example question in **Box 4.2**, entering “**sore throat**” **AND** antibiotics in the search function will identify articles that contain both terms, whereas including “**sore throat**” **AND** antibiotics **AND** “symptom duration”, theoretically yielding the highest concentration of relevant articles, may also miss others. Consequently, for routine clinical queries, using two terms in a search strategy is usually sufficient to focus the search.
- Engaging the help of expert health sciences librarians. This may be valuable in developing search strategies for more complex queries.
- Remembering the dangers of publication bias. Studies with negative results may not have made it as far as publication. On the other hand, studies may be in progress that could inform decision-making.

**APPRAISING THE EVIDENCE**

Once some potentially relevant research articles have been identified, the next step is to decide whether the studies described were undertaken in a way that makes their findings reliable and valid, and to consider the relevance of any articles to the clinical question identified. This process is known as critical appraisal.

**The hierarchy of evidence**

Ethically, patients should receive the best-evidenced treatment available, and the ‘hierarchy of evidence’ is a core principle of EBP that helps to ensure this. The hierarchy is formed by ranking study types based on the extent to which the reader can be confident that the results and estimates of a treatment effect are correct. In most hierarchies, meta-analyses and systematic reviews are at the top of the pyramid, followed by experimental and observational studies, with case reports or case series at the bottom (Fig. 4.1). The hierarchy encourages a top-down approach to locating the best evidence.
Evidence, which involves first searching for evidence at the top (e.g., a recent meta-analysis), and if that is not available, moving down to the next level of evidence.

Whatever the study design, when reading papers it is important to remain vigilant for poorly conducted research, as this diminishes the confidence that can be placed in the results.

Systematic reviews and meta-analyses

Systematic reviews

These synthesize the results of all available studies in a particular area, identified via comprehensive, systematic literature searches. They therefore provide a summary of current evidence about a topic, including an analysis of study results, strengths and weaknesses. Systematic reviews also highlight remaining gaps in knowledge or a lack of robust evidence. Data from all the included studies are combined to build up a broader picture of the evidence.

Systematic reviews aim to locate as much as possible of the research relevant to a particular research question. Explicit methods are then used to identify what can reliably be said about the topic, drawing on the findings of all the included studies. All study types can be included in a systematic review, including randomized controlled trials (RCTs) and observational studies, which are described later. A well-conducted review will assign a quality score to included studies so that the conclusions provide an overview of the status of the research field. For example, where there is a lot of robust evidence available to answer a question, clear recommendations can be made about patient care, or – in contrast – where there is a limited amount of low-quality evidence available, reliable recommendations cannot be made.

As systematic reviews draw together the findings of multiple studies, they lie at the top of the evidence hierarchy, though this position is not an absolute. For example, findings might quickly be superseded by evidence that is more recent. A large, well-conducted RCT may also provide more convincing evidence of effect than a systematic review of smaller RCTs.

Meta-analyses

These represent an extension of a systematic review. Data from each of the included studies are combined statistically to give a single estimate of effect. To conduct a meta-analysis, the included studies must address the same research question and make use of the same outcome measure. It can be carried out only when the relevant numerical data are presented in enough detail in the individual research papers.

An estimate of effect is calculated using weighted averages of all the results. The weighting given to individual studies is based on their sample size, with larger studies contributing more to the final meta-analysis than smaller ones. As meta-analyses pool findings from all the included studies, and therefore draw on data from a larger number of patients, they provide a stronger and more accurate estimate of a treatment effect than individual studies on their own.

Interventional studies

Randomized controlled trials (RCTs)

RCTs are generally considered to provide the most reliable evidence of whether an intervention is effective. A range of different types of intervention can be tested in an RCT, including therapeutic and prophylactic agents (e.g., drugs, vaccines), surgical and medical procedures, or health service and public health strategies.

Randomization

The strength of the RCT lies in the process of randomization, which is characteristic of this type of study design. Study participants are randomly assigned to one of two study groups: the experimental group who will receive the intervention being tested, and a comparison group (known as controls) who may receive:

- a conventional treatment (referred to as usual care)
- no intervention
- a placebo: a substance that resembles the intervention in all respects, except that it contains no active ingredients.

Every participant has an equal chance of being in the treatment group or the control group. The two groups are then followed up prospectively over time, to assess the effectiveness of the intervention compared with the conventional or placebo treatment.

The goal of randomization is to ensure that the two study groups are as similar as possible in all respects, apart from the treatment or intervention. Any other factors that might also have an impact on the outcome, known as confounders, should be distributed equally and randomly between the two groups. Consequently, any observed differences between the study groups are more likely to be due to differences in the treatment alone.

Those responsible for recruiting participants into a study must not influence the process of randomization. A common method of achieving this is randomization by telephone, where the investigator calls a central randomization service to obtain information about which study arm the participant should be allocated to.

Confounding factors

These are factors that could potentially influence both the exposure and the outcome in a study, leading to inaccurate results. For example, when the relationship between alcohol consumption (the exposure) and coronary heart disease (CHD; the outcome) is under examination, smoking may be a confounding factor. Smoking is correlated with alcohol consumption but is also associated with CHD, so may mask the true relationship between alcohol and CHD. Randomization is a way of trying to control for confounders, by ensuring that these factors are randomly (and, one hopes, fairly equally) divided between control and intervention groups.

Blinding

When a participant has been randomized, the investigator may or may not be aware of which group the participant has been allocated to. If they know which treatment the participant is receiving, this might influence (intentionally or unintentionally) the way in which they measure or interpret the outcome data, introducing bias into the study. For example, they may interpret information more favourably if it comes from participants who they know to be receiving the drug under investigation. Similarly, if a participant knows that they have been allocated to the placebo group, this may influence the way in which they participate in the trial. Therefore, blinding can be seen as a way to avoid potential bias.

- In a double-blind study, neither the patients nor the investigators know the study group allocation.
- In a single-blind study, patients do not know their study group allocation.

Blinding also involves ensuring that, as far as possible, the intervention and standard or placebo treatment both appear the same, although this may not be possible for non-drug interventions. For example, if the intervention involves physiotherapy exercises or a new way of delivering a service, it is often not feasible to conceal which group participants have been allocated to.

Intention-to-treat analysis

During an RCT, participants may be lost to follow-up for a range of reasons. Individuals may be unable to continue participating,
or may stop taking their allocated treatment – perhaps because of adverse side-effects or because they felt it was not working. If these individuals are subsequently excluded from the analysis of the results, the effectiveness of the drug may be overestimated. In the real world, patients do not always take their medication as prescribed, so RCT data are often examined using intention-to-treat analysis. The final results are analysed based on the treatment arm to which participants were initially allocated, and not on the treatment they actually received.

Limitations of RCTs
Although RCTs are considered to provide the most reliable evidence of effectiveness, by minimizing the possibility of bias, they are not without their limitations.

Patients to whom the results might subsequently be applied in real clinical practice may often be excluded from RCTs in order to minimize differences between experimental groups. For example, strict inclusion and exclusion criteria may mean that patients with co-morbidities are excluded, as this might affect their response to the intervention. However, many patients in the real world will have more than one condition. Patients recruited to trials are also more likely to be receiving care in teaching hospitals, where care may differ from that provided in district general hospitals. This reduces the external validity or generalizability of the trial, or the extent to which the findings can be applied in other settings.

Additionally, although RCTs are the gold standard for evaluating the effectiveness of interventions, randomization may not always be required. For example, an RCT may be unnecessary when the effect of an intervention is dramatic (e.g. vaccination for smallpox or penicillin for bacterial infections). In these cases, the likelihood of unknown confounding factors affecting the outcome is so small that they can be ignored.

An RCT may be unfeasible when the outcome of greatest interest occurs rarely (e.g. death), and may be too costly if the outcome of greatest interest occurs far in the future (e.g. loosening of artificial hip joints). Observational methods, such as cohort studies, may be the only practical means of obtaining such information in these cases.

Finally, the use of RCTs raises several ethical issues. RCTs are based on the premise that there is sufficient doubt about the particular intervention being tested to justify not giving it to half of the participants. At the same time, there must be sufficient belief in its potential benefit to justify exposing the remaining half of the patients. This is known as clinical equipoise, and requires careful consideration to be given to the intervention that is received by the control group. If an effective treatment already exists, participants in the control group should have this rather than a placebo, in order to make a transparent assessment of the novel intervention in comparison to usual care. Informed consent is required in all study designs but particularly so in RCTs. Participants need to understand that they are participating in an experiment and, consequently, may not receive the treatment under investigation.

Observational studies
Cohort studies
Cohort studies follow a group of individuals over a period of time (often years) to examine whether they benefit from a healthcare or public health intervention, or develop a disease or other outcome of interest. A cohort is a group of individuals who have a common characteristic. Cohorts are selected on the basis that individuals share similar, relevant characteristics, such as receiving cancer screening or being exposed to cigarette smoking. For example, the British Doctors Study, which ran from 1951 to 2001, was a cohort made up of doctors, including both smokers and non-smokers. It provided convincing proof of the association between smoking and lung cancer, and led to a dramatic decline in smoking from the 1970s onwards.

Cohort studies are a type of observational study, meaning that no adjustments are made to participants’ treatments or lifestyle. However, detailed information is collected about the interventions they receive, their sociodemographic characteristics, lifestyles and behaviours, and their outcomes, using questionnaires, interviews, physical examinations and investigations such as blood tests, and taking information from existing sources such as medical records. Cohort studies can therefore be prospective, involving the collection of new data, or retrospective, looking back in time and using existing data such as medical records. Retrospective studies are cheaper and faster to conduct because the data have already been collected and stored. However, because it was not collected for research purposes, information in patients’ medical records may be incomplete, inaccurate and inconsistently recorded.

Cohort studies can also vary significantly in terms of their size and complexity. At one extreme, a large population may be studied over decades. For example, the Millennium Cohort Study (MCS) follows the lives of around 19,000 young people born across England, Scotland, Wales and Northern Ireland in 2000-1. Families were first assessed when children were 9 months old and have been followed up at regular intervals. Interviews are carried out with the main parent and the child, and a range of information is collected, including employment and income; housing; family structure; ethnicity; parenting activities such as reading to the child; developmental indicators; and both parental and child mental health. At the other extreme, some cohort studies follow up relatively small groups for a few days or weeks.

Cohort studies are particularly valuable in situations where RCTs cannot be performed because randomization is either unethical or impractical. They also allow rare or long-term outcomes to be assessed: for example, in the UK, the National Joint Registry collects information on a nationwide cohort of patients who have undergone joint replacement operations. Implants that fail earlier than expected can be identified and the information acted on. External validity (also referred to as generalizability) will be higher in large cohort studies such as this because a broad range of patients, from different settings, are included, without the restricted inclusion criteria required in an RCT.

A limitation of the cohort method is losses to follow-up. Cohort members may decline to continue participation in the study or fail to maintain contact. Such events may (or may not) be related to the exposure, the outcome or both. For example, a study looking at the effect of high-impact exercise on risk factors for osteoporosis had greater loss to follow-up in the group assigned to exercise. Women who dropped out may have had inherently lower bone strength that made the exercise less tolerable for them. If so, this would have produced selective loss of women more likely to develop osteoporosis from the active treatment group, and this would cause a biased estimate: specifically, an overestimate of the benefit of exercise.

Case–control studies
In a case–control study, patients who have received a healthcare intervention or developed a disease are identified. Their past history is then compared with that of individuals – or controls – who did not receive the intervention or do not have the disease. For example, participants with a disease of interest (e.g. lung cancer) may be tracked back in time, sometimes for many years, to determine
Evidence-based practice

whether they were exposed to a risk factor of interest (e.g., second-hand tobacco smoke). In another example, a study used primary healthcare records to look at service use in the previous year, in order to identify factors associated with frequent attendance at hospital emergency departments.

Researchers try to ensure that the cases and controls are as similar as possible with respect to other factors. This can be done either on an individual basis (e.g., by pairing each case with a control of the same age and sex) or in groups (e.g., choosing a control group with an overall age and sex distribution similar to that of the cases). Unknown differences may still exist between the cases and controls, however, which could influence the results.

A particular limitation of case–control studies is the risk of recall bias. Case participants are usually keen to find out what caused their illness, or may ascribe their positive and adverse outcomes to an intervention. As a result, they may be better motivated to remember details of their past than controls with no special interest in the study question. Assessing the exposure of controls may therefore be challenging, especially if this relies only on their personal recall. This risk can be lessened by using data from electronic medical records.

Case–control studies are another form of observational study because no intervention takes place. Since the assessment is retrospective and the risk of recall bias is high, case–control studies lie towards the bottom of the EBP hierarchy. However, they can provide interesting insights. For example, case–control studies start with people who are known to have a disease of interest, rather than looking at a population free of disease and waiting to see who develops it. This approach therefore lends itself to studying groups of patients with rare conditions. For example, in 1955, Richard Doll published a case–control study demonstrating a significant excess of lung cancer and mesothelioma among asbestos workers. This study was the first to identify asbestos as one of the world’s most dangerous industrial carcinogens.

Cross-sectional surveys

These observational studies provide a snapshot of a particular group of patients or people at a single point in time, and can be used to assess the prevalence of illness or a risk factor, or the range of perceived symptoms in a given population. Examples include the proportion of patients with bladder cancer who smoke, or patient-reported outcomes on discharge from hospital.

As cross-sectional data describe only what is happening at a single moment in time, they cannot be used to answer questions about the causes of disease or the impact of treatment. They also do not provide information about changes over time, unless they are repeated. Consequently, they are ranked low in the EBP hierarchy of evidence.

Nevertheless, cross-sectional surveys can provide key information: for example, in planning services and ensuring that they are equipped to meet the needs of the local population. They may also be used to draw inferences about possible relationships between factors or outcomes, or to gather preliminary data to support further research and experimentation.

Case series or case reports

These describe a group of patients or a single individual with an outcome of interest, or novel and unusual features. Due to their descriptive nature, they provide little evidence about causality. Their small size and lack of representativeness also mean that they cannot be assumed to have relevance for the wider population of patients with the same condition. Therefore, they are regarded as the weakest form of evidence in the EBP hierarchy.

Nevertheless, they can still provide useful information, particularly in the very early stages of research into a disease area. For example, in 1985, the Centers for Disease Control in the USA published a report describing five cases of Pneumocystis pneumonia in previously healthy, gay men in Los Angeles. This was the first official reporting of what became known as the AIDS epidemic. However, case reports can also be misused: for example, the now discredited case series published in The Lancet in 1998, which posited a link between the measles, mumps and rubella vaccine, colitis and autism.

Problems with the ‘hierarchy of evidence’

Although the evidence hierarchy has become widely accepted, concerns have been raised about ranking evidence in this way. As has been outlined, study designs traditionally ranked lower down the hierarchy may be more appropriate if, for example, outcomes of interest are rare or occur far into the future. Observational studies also produce results with higher external validity because inclusion and exclusion criteria are usually less restrictive. Additional concerns, including the extent to which the findings of RCTs can be applied to patients in other settings, are explored in the final section of this chapter.

The hierarchy focuses only on research addressing the question of the effectiveness of interventions. Other questions are equally salient, however, such as:

- prognosis (what is likely to happen?)
- harm (is this substance likely to have adverse effects?)
- experience (what is it like to receive this intervention?)
- implications for services (staff workload, the need for additional monitoring and so on).

Different types of question require different study designs (Box 4.3):

- Determining the number of patients living with a condition at a given point in time (a prevalence question) may be best achieved using a cross-sectional survey. However, because it provides only a snapshot of that single point in time, it cannot explain the likely duration between diagnosis and death.
- The design needed for a prognosis question is a cohort study – a study that follows up recently diagnosed patients and records what happens to them.
- To answer experience questions (what it is like to live with a particular condition, or whether a certain intervention is acceptable to patients), qualitative approaches, such as interviews or focus groups, are often also needed.

Combined approaches

Although there are big differences between the underlying assumptions of quantitative and qualitative research, the most comprehensive, generalizable and useful research is that which brings the two approaches together. For example, qualitative approaches can helpfully be used within an RCT to explore how an intervention was implemented and what was actually delivered, compared with what was intended. This is known as a process evaluation, as it documents the process that took place. Process evaluation can explain discrepancies between expected and observed outcomes, help us to understand how local context influences outcomes, and provide insights to aid implementation in other settings.

Critical appraisal

Critical appraisal aims to:

- identify the methodological strengths and weaknesses of a piece of research
Box 4.3 Key messages about study design

Randomized controlled trials (RCTs)

- **Randomization** aims to ensure that the study groups are as similar as possible, apart from whether or not they receive the treatment being studied. Consequently, observed differences are more likely to be due to differences in the treatment alone.
- **Blinding** ensures that there are no differences in the way participants in each study arm are managed or their progress and outcome is measured. In a double-blind study, neither patients nor investigators know the study arm to which the participant has been allocated.
- In an **intention-to-treat analysis**, RCT findings are analysed based on the treatment arm to which participants were initially allocated, regardless of whether they dropped out of the study.
- Ensuring that RCT participants are as similar as possible enhances the **internal validity** of the results (i.e., their accuracy in the study context) but may reduce their **external validity** (i.e., their generalizability to the diverse range of patients with the condition under study).
- RCTs are a form of **experimental study**. The researcher manipulates exposure to the intervention (e.g., a new drug treatment) by allocating participants to the intervention or control group.

- assess whether the researchers used the right design for their study
- make informed decisions about the quality of the evidence being appraised
- establish how useful the piece of research is for wider decision-making.

A range of tools and checklists exist to help assess the quality of each design (see ‘Further reading’). However, these checklists should merely supplement the level of careful thought and judgement required whenever reading a paper. Regardless of the study type, critical appraisal involves some overarching questions (Box 4.4); the three main steps involved are described below.

**Question 1: Are the results of the study valid?**

Validity refers to the soundness or methodological rigour of a study. A study is considered valid if the way it has been designed and carried out means that the results provide a trustworthy estimate of clinical effectiveness. A study that is **sufficiently free from bias** has internal validity.

Bias is a consistently occurring error in a study that results in an incorrect estimate of the association between an exposure and an outcome. For example, in a case–control study, recall bias may occur because a patient with an outcome of interest (e.g., lung cancer) may report their exposure experience (e.g., smoking) differently to a control without the outcome. This would then lead to an incorrect assessment of the relationship between smoking and lung cancer.

No study is perfect and free from all bias. A systematic check should be carried out to ensure that the researchers have done all they can to minimize it. Different study designs are prone to different types of bias but observational studies (and especially case–control studies) are particularly susceptible. More than 50 types of research bias have been identified but, for simplicity, they can be broadly grouped into two categories:

- **Information bias**. This results from systematic differences in the way in which data are collected from the various study groups, including data relating to either the exposure (i.e., factors that may be associated with an outcome of interest, such as weight) or the outcome (e.g., type 2 diabetes). For example, has participants’ weight been recently recorded or does the study rely on information collected at the time they registered in primary care?

- **Selection bias**. This occurs when there is a systematic difference between either:
  - those who participate in the study and those who do not or
  - those in the treatment arm of a study and those in the control group.

Observational studies

- In an **observational study**, the researcher measures exposures (e.g., new surgical procedures) that the participants are already receiving. Outcomes (e.g., postoperative complications) are then observed as they occur.
- In a **cohort study**, a group of participants (the cohort) is followed over time. Researchers observe which individuals develop outcomes of interest (e.g., breast cancer), and collect information about factors that might be relevant to the development of the outcome (e.g., smoking, alcohol consumption). Cohort studies can provide valuable evidence when conducting an RCT is unfeasible. The findings may have greater generalizability because inclusion and exclusion criteria are usually less restrictive.
- In a **case–control study**, patients who have an outcome of interest are identified (i.e., cases). Their past history is then compared with that of individuals – or controls – who do not. Cases and controls should be as similar as possible with respect to other factors. A particular limitation of case–control studies is the risk of recall bias because cases may be better motivated to remember details of their past than controls.

Box 4.4 Key questions in critical appraisal

**Why was the study done?**

- A clearly focused question should address population, intervention and outcomes.

**What type of study was done?**

- The study design must match the question asked.

**What are the study characteristics?**

- Use the PICO question format to help answer this question.

**Are the results of the study valid?**

- Was the assignment of patients to treatments in a controlled trial (RCT) randomized? If another design was used, how were participants allocated?
- Were patients, health workers and study personnel ‘blind’ to treatment allocation?
- Were all the patients who entered the study properly accounted for at its conclusion? Look for follow-up tables and whether patients in an RCT were analysed in the groups to which they were randomized.
- Were the groups similar at the start of the study?
- Aside from the experimental intervention, were the groups treated equally?

**What were the results?**

- How large was the treatment effect? How precise was the estimate of the treatment effect?
- Look for confidence limits and p-values.

**Will the results help?**

- Can these results be applied locally? Are these findings applicable to other patients?
- Were all relevant outcomes considered, including those relevant to patients?
- Are the benefits worth the harms and costs?

In this case, information might be systematically more accurate for patients with diabetes than for patients without weight-related conditions, leading to an incorrect estimate of the association between exposure and outcome.
Patients and clinicians who have strong treatment preferences are often excluded from RCTs. While these steps increase the internal validity of an RCT, they often lead to selection bias and an over-estimation of the benefits of treatment, especially for patient-centred outcomes. For example, some women with early breast cancer have a strong preference for less invasive lumpectomy, whereas others prefer the reassurance of knowing that all potentially cancerous tissue has been removed by a mastectomy. In one series of RCTs, only women without a strong preference for a particular treatment were recruited. However, as few as 10% subsequently agreed to have their treatment chosen at random, significantly reducing the extent to which the findings could be generalized to the wider population.

Similarly, telehealth interventions are becoming a prominent part of healthcare delivery, with examples including online cognitive behavioural therapy or home monitoring of health parameters such as blood pressure. There is some evidence of their effectiveness from RCTs. However, in several trials a large number of eligible individuals (over 75% in some cases) have declined to take part. As well as compromising external validity, this may also indicate problems with the acceptability of the intervention, which may have a negative impact on uptake if it is later introduced into routine practice. In the case of telehealth, issues might include physical barriers in terms of accessing technology, as well as psychological barriers such as low confidence in using it.

**Question 2: What are the results?**

The second step of critical appraisal is to consider the results. A range of statistical methods are available to help determine whether an intervention is effective. Results are presented in many different ways but are typically expressed in terms of likely harms or benefits. In RCTs, cohort studies and case-control studies, two groups are compared and the results are often expressed as ratios. These are calculated by dividing the outcome in the intervention group by the outcome in the control group.

- If the outcome is measured as the *likelihood* or odds of an event occurring in a group (those with the event/those without the event), then this comparison is known as the odds ratio (OR).
- If the outcome is the *frequency* with which an event occurs in a group (those with the event/the total number in that group), then this is known as the relative risk or risk ratio (RR). A worked example is provided in Box 4.5.

When there is no difference between the groups, the OR and the RR are 1. A ratio of more than 1 means that the outcome occurred more frequently in the intervention group, compared with the control group. If this is a desired outcome, such as stopping smoking or using a new medicine, then the intervention worked. If the outcome is not desired – for example, death – then the control group performed better. Similarly, if the ratio is less than 1, then the outcome occurred less frequently in the intervention group.

Results may be more helpful when they are presented as absolute, rather than relative, numbers. For example, a relative risk reduction as large as 50% is likely to influence decision-making. However, decision-makers also need to understand whether this represents an absolute difference in risk of, say 0.1-0.2%, rather than 10-20%. To express a result in terms of absolute numbers, the proportion of events in the control group is subtracted from that in the intervention group. The risk difference can also be presented as the number needed to treat (NNT, Box 4.6).

**Confidence intervals and p-values**

The results of many tests that examine the relationship between an intervention and an outcome are expressed using confidence intervals and p-values (Box 4.7). There will always be some uncertainty about the true result because trials provide us with only a sample of possible results. However, the confidence interval (CI) gives the range of where the ‘true’ value in the population can be found. CIs are usually expressed for a given degree of certainty, usually 95%. This means that we can be 95% confident that the true value lies within those limits.

In contrast, p-values report the probability of seeing a result, such as the one obtained, if, in fact, the intervention had no real effect. In other words, how likely is the result to have occurred by chance? p-values can range from 0 (absolutely impossible) to 1 (absolutely certain). A p-value of less than 0.05 means that a result, such as the one seen, would occur by chance on less than 1 in 20 occasions. In this circumstance, a result is described as statistically significant. However, judgement should be applied to the p-value because a statistically significant result may not be clinically significant, if, for example, the effect size is too small to make a meaningful difference to patients.

CIs are more informative than p-values because they provide a range of values that are likely to include the true effect. Statistical non-significance may occur because the study sample size was too small. This is often indicated by very wide CIs. A bigger sample will result in small CIs and hence a more precise estimate of the effect of the intervention. As we have seen, however, statistical significance does not necessarily equal clinical significance. The best-quality studies first define and then examine evidence of an effect that is meaningful to patients and their clinicians.

**Question 3: Will the results help?**

The final step of critical appraisal is considering whether the study is applicable to the decision being made for a particular patient. There are three issues to consider here.

First, are there any important differences between the participants in the study and the patient in question? These must be identified, as they could have an impact on the effectiveness of an intervention. Check the study inclusion and exclusion criteria, which are usually reported in the methods section. Would the patient in your care have been eligible for inclusion in the study? Identify any characteristics that the patient has that were not considered in the study.

Second, many interventions and processes used in everyday clinical practice have both benefits and adverse consequences. and these should be weighed against each other. For example, breast cancer screening programmes in the UK currently invite women aged 50–70 years to undergo mammography every 3 years. Breast screening helps identify breast cancer early. The earlier the condition is found, the better the chances of surviving it, and the less likely patients are to need a mastectomy or adjuvant therapy (chemotherapy and/or radiotherapy). However, for each woman with breast cancer whose death is prevented by screening, three women will be over-diagnosed. Over-diagnosis refers to the detection of cancers through screening that would not have become clinically apparent in the woman’s lifetime. Although their cancer would not have caused their death, these women will undergo treatment, such as surgery, which may result in side-effects and complications, as well as psychological, social and financial consequences. Of the 307,000 UK women aged 50–52 years who are invited to begin screening every year, just over 1% will be over-diagnosed with cancer in the next 20 years. This risk of unnecessary treatment, and the potential associated harms, means that the appropriateness of breast cancer screening is hotly debated.
A randomized controlled trial was conducted to examine the benefits of prescribing the antiplatelet agent clopidogrel in addition to aspirin in patients with an ST-elevation myocardial infarction (MI). A total of 45,852 patients admitted to hospital within 24 h of suspected acute MI onset were randomly allocated to a group receiving clopidogrel 75 mg daily (n = 22,961) or a group receiving a matching placebo (n = 22,891). Both groups also received aspirin 162 mg daily. Treatment was continued until discharge or up to 4 weeks in hospital (mean 15 days in survivors). One of the pre-specified primary outcome measures was death from any cause during the scheduled treatment period. Some 1726 (7.5%) of the participants in the clopidogrel group died during the treatment period, compared with 1845 (8.1%) in the placebo arm. OR = 0.93 (95% CI 0.87–0.99, p = 0.03 (COMMIT Collaborative Group. Addition of clopidogrel to aspirin in 45,852 patients with acute myocardial infarction: randomised placebo-controlled trial. Lancet 2005; 366:1607–1621).

The findings of the trial can be summarised in a 2 × 2 table.

<table>
<thead>
<tr>
<th></th>
<th>Event from any cause</th>
<th>No event</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Intervention arm</strong></td>
<td></td>
<td></td>
<td></td>

<tr>
<td>Clopidogrel group</td>
<td>D_I</td>
<td>A_I</td>
<td>N_I</td>
</tr>
<tr>
<td><strong>Control arm</strong></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Placebo group</td>
<td>D_C</td>
<td>A_C</td>
<td>N_C</td>
</tr>
</tbody>
</table>

D_I, D_C, A_I and A_C are the numbers of participants with each outcome (‘D’ or ‘A’) in each group (‘I’ or ‘C’). Text in italics refers to the study described earlier.

**Odds ratios (OR)**

An odds ratio is a relative measure of effect, which allows comparison of the intervention group of a study to the comparison or placebo group.

The trial compared participants who had received clopidogrel (intervention arm) with participants who had received a placebo (control arm). The outcome – or event – of interest was mortality from any cause, and the findings were as follows:

Odds of all-cause mortality in clopidogrel group (intervention arm):

- Number of participants with an event/Number of participants with no event
- Number of participants who died/Number of participants who remained alive
- \( \frac{D_I}{A_I} \)
- \( \frac{D_I}{A_I} = \frac{1726}{21 235} = 0.0812 \) (4 decimal places)

Odds of all-cause mortality for placebo group (control arm):

- Number of participants with an event/Number of participants with no event
- Number of participants who died/Number of participants who remained alive
- \( \frac{D_C}{A_C} \)
- \( \frac{D_C}{A_C} = \frac{1845}{21 046} = 0.0877 \) (4 decimal places)

Odds ratio:

- Odds of event in intervention arm/Odds of event in control arm
- \( \frac{D_I/A_I}{D_C/A_C} \)
- \( \frac{0.0812}{0.0877} = 0.93 \)

An odds ratio of 0.93 means that the odds of death in the clopidogrel group (intervention arm) are 7% less than in the placebo group (control arm).

Here, the OR is <1, so the intervention is better than the control.

If the OR were >1, the control would be better than the intervention.

**Box 4.5 Interpreting odds ratios, relative risk, confidence intervals and p-values – worked example**

If the OR were = 1, there would be no difference between the two study groups, as the outcome is the same in both.

**Relative risk (RR)**

Risk of event in clopidogrel group (intervention arm):

- Number of participants with an event/Total number of participants
- \( \frac{D_I}{N_I} \)
- \( \frac{1726}{22 961} = 0.0752 \) (4 decimal places)

Risk of event in placebo group (control arm):

- Number of participants with an event/Total number of participants
- \( \frac{D_C}{N_C} \)
- \( \frac{1845}{22 891} = 0.0806 \) (4 decimal places)

Risk ratio:

- Risk of event in intervention group/Risk of event in control arm
- \( \frac{D_I/N_I}{D_C/N_C} \)
- \( \frac{0.0752}{0.0806} = 0.93 \)

A risk ratio, also known as the relative risk, of 0.93 means that the risk of death in the clopidogrel group (intervention arm) is 7% less than in the placebo group (control arm). The RR is <1, so again the intervention is better than the control.

**Confidence intervals (CI)**

The confidence interval indicates the level of uncertainty around a measure of effect (i.e. the precision of the effect estimate), which in this study was expressed as an odds ratio. Confidence intervals are used because a study recruits only a small sample of the overall population. By interpreting upper and lower confidence limits, we can infer that the true population effect lies between these two points. Most studies report the 95% confidence interval (95% CI).

If the confidence interval crosses 1 (e.g. 95% CI 0.9–1.1), this implies that there is no difference between the two arms of the study. If it does not (e.g. 95% CI 0.7–0.8), then a difference exists.

In the trial comparing clopidogrel to placebo, OR = 0.93 (95% CI 0.87–0.99). This can be interpreted as follows: the odds of death in the clopidogrel arm are 7% less than in the placebo arm, and we can be 95% confident that the true population effect lies between 13% and 1%.

**P-values**

The p-value in this study is 0.03. This means that if clopidogrel actually had no effect, compared to the placebo, there is a 3% of chance that the study result (i.e. the observed difference) occurred by chance.

A p-value of <0.05 indicates that there is a statistically significant difference between groups. A p-value of >0.05 indicates that the difference is not statistically significant.

**Conclusion**

The trial comparing clopidogrel to placebo stated OR = 0.93 (95% CI 0.87–0.99, p = 0.03). This means that the odds of death in the clopidogrel arm are 7% less than in the placebo arm, and we can be 95% confident that the true population effect lies between 13% and 1%. This result was statistically significant (https://ebm.bmj.com/content/ebmed/11/3/82.full.pdf).

Finally, cost-effectiveness is commonly not reported in the analysis of clinical trials. If a treatment is effective but provides only a small benefit and is very expensive, it may not be a good use of resources. Equally, even if a treatment is shown to be cost-effective, it may not be affordable. In the UK, NICE uses the cost per quality-adjusted life-year (QALY) to judge the cost-effectiveness of new technologies. This is the estimated cost of each additional year of life gained by a treatment or procedure, measured not just in terms of extra months or years of life, but in terms of the quality of that life. This is defined, for example, as freedom from or reduction in pain, or the ability to carry out the basic activities of daily living. Currently, NICE uses a threshold of £20 000–£30 000 per QALY. Treatments that come in at or below the threshold are usually approved. Those that come in above tend not to be judged cost-effective and so are not recommended for adoption by the NHS. Again, however, affordability to the healthcare system is not taken into account by this approach. For example, a treatment may result in significant quality of life gains, but be very expensive and applicable only to a small subset of patients with a particular condition.
Box 4.6 Relative risk, absolute risk and number needed to treat – worked example

A study compared the incidence of dyskinesia after treatment with either ropinirole (ROP) or levodopa (LD) in patients with early Parkinson’s disease.6 A total of 17 of 179 patients who took ROP (treatment group) and 23 of 89 who took LD (control group) developed dyskinesia. The risk of developing dyskinesia among patients who took ROP was 17/179 = 0.095, whereas the risk of developing dyskinesia among patients who took LD was 23/89 = 0.258.

The relative risk of a treatment equals the risk in the treated group divided by the risk in the control group (i.e., the risk ratio).

Absolute risk reduction (ARR) is the difference between the risk of an event in the treated group and the risk of an event in the control group (i.e., risk in treatment group minus risk in control group).

In the Parkinson’s trial, the relative risk was 0.095/0.258 = 0.368. This means that the risk of dyskinesia was 63.2% lower in the ROP group. However, the ARR was 0.258–0.095 = 0.163. This means that, by using ROP rather than LD, the risk of developing dyskinesia was reduced by 16%.

While the RR is useful for summarizing the trial findings, the ARR provides a better indication of the likely clinical benefit of using ROP rather than LD.

Based on the ARR, the number needed to treat (NNT) is the reciprocal of the absolute risk reduction (i.e., 1/ARR). This measure indicates the number of patients that need to be treated to achieve the desired outcome in 1 patient who would not have benefited otherwise.

In the trial, the number needed to treat = 1/ARR = 1/0.163 = 6.13. This means that at least 6 patients would need to be treated with ROP, rather than LD, to achieve the desired outcome in 1 patient who would not have benefited otherwise.

Box 4.7 Estimating confidence in research findings

95% confidence interval

We can be 95% confident that the true value lies within the limits given.

p-value

The likelihood that a given result has occurred by chance alone (e.g., if p < 0.001, then the result would occur only 1:1000 times by chance).

APPLYING THE EVIDENCE

The medical literature is continuously expanding, with new information published every day that could help to improve care for patients and population health. However, there are often major challenges involved in implementing the findings of research in clinical practice, with some estimates suggesting that the process takes an average of 17 years. The gap leads not only to the under-use of effective interventions, but also to the incorrect use of others, as well as the over-use of unhelpful or unproven interventions. All of this means negative outcomes for patients and for population health. It is also a waste of health service resources and of costly and time-consuming research. Consequently, considerable effort has been put into improving the routine use of research findings.

Challenges of implementing evidence

Trial design

RCTs are designed to minimize the possibility of bias in the results, so that any observed variation can be interpreted as a causal relationship. They may achieve this internal validity at the expense of external validity or generalizability. There are three reasons why RCTs in many areas of healthcare may have low external validity:

• The provider. The healthcare professionals who participate may be unrepresentative. They may have a particular interest in the topic or be enthusiasts and innovators.

• The setting. This also may be atypical: a teaching hospital, for example.

• The patients. All trials exclude certain categories of patients: for example, older patients or those with more than one illness. Often the exclusion criteria are so restrictive that the patients who are eligible for inclusion represent only a small proportion of the patients being treated in normal practice.

The outcome of drug treatment is likely to be unaffected by the characteristics of the prescribing doctor or the setting in which it is administered. On the other hand, the outcome of activities such as surgery and physiotherapy may be highly dependent on the characteristics of the provider, setting and patients. As a result, RCTs generally offer an indication of the efficacy of an intervention, rather than its actual effectiveness in everyday practice. For successful implementation, however, both external validity and effectiveness are required if the findings are to be generalized to different patients and different settings.

Pragmatic RCTs

In a conventional RCT, the principal aim is to establish whether a treatment works. As outlined, because of the emphasis placed on internal validity, these ‘explanatory’ RCTs generally provide evidence of efficacy, or what can be achieved in ideal circumstances.

However, the ultimate goal is to improve the health of real people in real settings, so it is crucial also to know whether an intervention is going to be effective in the real world. In contrast to explanatory trials, pragmatic RCTs place the emphasis on effectiveness rather than efficacy, and seek to measure the benefit that the treatment produces in routine clinical practice; they therefore provide better evidence for decision-making.

There are some key differences between explanatory and pragmatic trials:

• Explanatory trials recruit as homogeneous a population as possible. In contrast, the design of a pragmatic trial reflects variations between patients that occur in real clinical practice.

• It may not be possible to blind participants and investigators to the treatment that is being given. Such biases are not necessarily viewed as detrimental in a pragmatic trial.

• In pragmatic trials, outcome measures should represent the full range of health gains relevant to patients and clinicians, e.g. both a reduction in mortality after stroke and an improvement in quality of life.

• The two approaches to trial design will sometimes arrive at different conclusions about the benefit of a treatment because a treatment that works in an ideal setting may not work in real life.
The difference could also stem from the fact that improvement in a biomedical end-point does not produce the expected health gain. For example, although fluoride treatment for osteoporosis increases a commonly measured biomedical end-point (non-vertebral bone density), it actually raises fracture rates (an important clinical end-point) because it increases skeletal fragility. Consequently, it is not effective treatment for postmenopausal osteoporosis.

**Patient-centred outcome measures**

Research only has external validity if it reflects the wider priorities of patients and, for population health research, the public. For this reason, the outcomes of most relevance to patients must be included in trials. In one study, for example, patients with multiple sclerosis and their doctors were independently asked to select the three aspects of the disease that had the greatest effect on quality of life. Doctors focused mainly on the physical effects of the disease, whereas patients were more concerned about mental health, emotional wellbeing, general health and vitality, which are often not measured in RCTs. Similarly, in RCTs of anticonvulsants, individuals with epilepsy are much more interested in the proportion of patients rendered free of seizures than they are in changes in mean seizure frequency (a commonly used measure of benefit in RCTs).

**Barriers and facilitators to change**

Almost all healthcare interventions are complex and involve several interacting components. For example, a new drug therapy may superficially seem simple to implement and yet the process might actually require additional patient monitoring or allow management to move from an inpatient to a community setting, requiring a change in care pathways. Other new interventions may necessitate amendments to referral processes (e.g. by allowing direct access to hospital care) or involve care provision by different staff (e.g. allied health professionals rather than doctors). These changes may involve modification of working practices, equipment and care setting, and entail additional unforeseen costs. It is often not clear which of the specific components of these complex interventions represent the ‘active ingredient’ for bringing about the intervention’s effect.

If interventions are to be rolled out in other settings, careful consideration should be given to ensuring that interventions are designed in such a way as to be easily and successfully replicated. This involves trying to identify not only the key ‘ingredients’ that must be included, but also whether or not the intervention might be sensitive to particular features of the local setting.

**Intervention context**

Barriers to change can arise at different levels in the healthcare system: the patient, their carer and family, the individual care professional, the healthcare team, the healthcare organization (e.g. its resources, capabilities, structure, culture and politics) and wider society (e.g. the economic, social and political environment). Each of these components makes up the context of the intervention (Fig. 4.2). When a new intervention is being implemented, consideration should be given to what will happen when these individual contextual factors interact. Because of the complexity and diversity of each of these factors, the effect is likely to differ in different settings.

For example, reduction in hospital-acquired infections is a healthcare priority in many countries. Hand-washing plays a key role. However, concordance on the part of healthcare workers in general, and doctors in particular, is known to be poor. Doctors who are generally aware of the evidence but overestimate their own hand-washing practices. Most countries and many hospitals have guidelines on prevention of infections but they are frequently not followed. This means that, despite well-established evidence that has been properly disseminated, performance remains poor.

**What is the problem?**

Research has shown that a range of competing demands reduce the likelihood of doctors washing their hands. These include a high workload; organization of the ward and access to facilities; concerns about skin irritation; lack of knowledge of the evidence; a lack of leadership to encourage change and mutual accountability; and an absence of institutional policies. Even if doctors are aware of the evidence and are willing to change, altering well-established patterns of care is difficult, if the clinical environment is not conducive to change. These factors will be present to differing extents in different settings. The key ones should be identified in each location to ensure that change comes about.

**Leadership**

Local leadership has been identified as key to ensuring that evidence is used in practice. Leadership includes the actions taken by formal leaders in an organization to influence change. The attributes and qualities of leaders that appear to facilitate the use of research evidence to change practice include:

- valuing research
- being knowledgeable about research
- role-modelling evidence-based practice
- involving other staff in decision-making
- supporting changes in practice
- ensuring that policy and procedures are evidence-based and up-to-date.

Resistant leadership that fails to support change reduces the likelihood that evidence will be applied in practice.

**Improving the uptake of evidence**

There is a growing body of evidence relating to the effectiveness of different interventions to improve the uptake of evidence and change clinical and public health practice, which includes synthesizing and disseminating evidence in more accessible formats. For example, information graphics (or ‘infographics’) utilize images and data visualizations (pie charts, bar graphs, line graphs) to present research in an engaging way. Infographics add value by enhancing understanding and the reach of research. Information is more likely to be retained if it has been learned from an infographic than from text alone. However, although this may help ensure the uptake of...
Evidence-based practice

Some simple changes, it is insufficient for most innovations. Instead, multifaceted approaches are required, including a combination of:

- **Educational strategies.** Large conferences and courses have limited effects; small group interactive education sessions with active participation have more positive results. Educational outreach by experts may be especially effective for improving prescribing behaviour.

- **Audit and feedback.** These seem to be most effective when targeting diagnostic test ordering and prevention interventions. The effect size depends on the type of feedback, its source and format, and the frequency or intensity of presentation. Feedback is recommended in combination with education, outreach visits or reminders.

- **Use of reminders and computers.** Computer prompts, for example, may be one of the most effective interventions. They have been shown to be particularly effective for increasing the use of prevention interventions, e.g. vaccination and cancer screening reminders.

All of these interventions have the potential to help facilitate the effective transfer of evidence to practice, although the evidence base for them is still emerging. More than one approach may be needed. Further research is on-going to increase understanding of the processes and elements behind successful change.

SECTION 2: CRITICAL APPRAISAL

In this section, you should read and critically appraise the following papers:

CASP checklists can be downloaded at https://casp-uk.net/casp-tools-checklists/. Specimen answers are provided for your reference at https://coursewareobjects.elsevier.com/objects/elr/Kumar/clinicalmedicine10e/PDF/.
If tuberculosis treatment is not taken regularly, there may be risks to the patient and the public through generation of drug resistance, relapse and transmission of infection. Consequently, Directly Observed Treatment (DOT) is currently recommended by the World Health Organization for patients at high risk of poor adherence: for example, those with a history of homelessness, imprisonment, or drug use. Although DOT can be administered in clinic, community or home settings, it still entails substantial inconvenience to patients and service providers. Developments in video technology have raised the possibility of remote video-observed treatment (VOT) as an alternative approach.

This study was carried out to test whether or not levels of treatment observation were improved with VOT. Patients who were at least 16 years old, with active pulmonary or non-pulmonary tuberculosis and eligible for DOT, were identified from 22 clinics in England. Individuals were then randomly assigned to either VOT (daily remote observation using a smartphone app) or DOT (observations done three to five times per week in the home, community, or clinic settings). The primary outcome was completion of 80% or more scheduled treatment observations over the first 2 months following enrolment.

A total of 226 patients were randomly assigned: 112 to VOT and 114 to DOT. Some 78 (70%) of 112 patients on VOT successfully completed ≥80% scheduled observations during the first 2 months, compared with 35 (31%) of 114 on DOT. Adjusted odds ratio (OR) 5.48, 95% CI 3.10–9.68; p<0.0001.

Adapted from Story A et al. Smartphone-enabled video-observed versus directly observed treatment for tuberculosis: a multicentre, analyst-blinded, randomised, controlled superiority trial. Lancet 2019; 393(10177):1216–1224.

Q1: What type of study is this?
Answer
A randomized controlled trial. Participants were randomly assigned to receive either the intervention, VOT (daily remote observation using a smartphone app) or the usual treatment/control, DOT (observations done three to five times per week in the home, community, or clinic settings).

Q2: What is the odds ratio in this study?
Answer
5.18.

Q3: What does this mean in practice?
Answer
An odds ratio is a relative measure of the effectiveness of the intervention being studied, which allows the comparison of the intervention group of a study to the comparison or placebo group.

The trial above compared participants who had received Video Observed Therapy (VOT, intervention arm) with participants who had received Directly Observed Therapy (DOT, control arm). The outcome – or event – of interest was ≥80% scheduled observations successfully completed during the first 2 months.

An odds ratio of 5.18 means that patients in the VOT group (intervention arm) were more than 5 times as likely to successfully complete ≥80% scheduled treatment observations, compared with the DOT group (control arm).

Here, the outcome is a desirable one (successful completion of treatment).

The OR is >1, so the intervention is better than the control – the odds of the outcome occurring is greater in the intervention group.

If the OR were <1, the control would be better than the intervention – the odds of the outcome occurring is lower in the intervention group.

If the OR were = 1, there would be no difference between the two study groups, as the outcome is the same in both.

Q4: The authors report an adjusted odds ratio. What does this mean?
Answer
The authors used a statistical technique (logistic regression) to adjust for – or take into account – other factors, which might impact the likelihood of patients successfully completing ≥80% scheduled treatment observations. These factors are listed in the footnotes for Table 2, and include time since start of treatment, age, sex and social risk factors such as homelessness and imprisonment.

Q5: What is the confidence interval?
Answer
95% CI 3.10–9.68.

Q6: What does this mean in practice?
Answer
The confidence interval indicates the level of uncertainty around the measure of the effectiveness of the intervention being studied (i.e. how precise the effect estimate is), which in this study was expressed as an odds ratio. Confidence intervals are used because a study recruits only a small sample of the overall population. By interpreting upper and lower confidence limits, we can conclude that the true population effect lies between these two points. Most studies report the 95% confidence interval (95% CI).

If the confidence interval crosses 1 (e.g. 95% CI 0.9–1.1), this implies that there is no difference between the two arms of the study. If it does not (e.g. 95% CI 0.7–0.8), then a difference exists.

In the trial comparing VOT to DOT, the confidence interval is reported as 95% CI = 3.10–9.68. This can be interpreted as follows: we can be 95% confident that the true effect of VOT lies between 3.1 times and 9.68 times greater than the effect of DOT.

Q7: What is the p-value?
Answer
p<0.0001.

Q8: What does this mean in practice?
Answer
The p-value in this study is <0.0001. This means that, if VOT actually had no effect, compared to DOT, there is a 0.01% of chance that the study result (i.e. the observed difference) occurred by chance.

A p-value of <0.05 indicates that there is a statistically significant difference between groups. P-values of >0.05 indicate that the difference is not statistically significant.

Q9: How would you summarize the findings of this study?
Answer
This trial was carried out to examine whether or not levels of treatment observation were improved with Video Observed Therapy (VOT), compared with conventional Directly Observed Therapy (DOT). The results were presented as adjusted odds ratio = 5.48, 95% CI 3.10–9.68; p<0.0001. This means that the odds of patients successfully completing ≥80% scheduled treatment observations were more than 5 times greater in the VOT arm, compared with the DOT arm, and we can be 95% confident that the true population...
effect lies between 3.1 times and 9.68 times greater. This result was statistically significant.

As a consequence, the authors concluded that VOT was a more effective approach to observation of tuberculosis treatment than DOT. They note that VOT is likely to be preferable to DOT for many patients across a broad range of settings, providing a more acceptable, effective and cheaper option for supervision of daily and multiple daily doses than DOT.

**Paper 2**

When a meniscal tear is judged to be the cause of knee pain, surgical treatment to remove the unstable meniscal tissue – arthroscopic partial meniscectomy is frequently recommended, and is one of the most common orthopaedic surgical procedures worldwide. However, after the publication of the results of several randomized controlled clinical trials, the effectiveness of the procedure has been debated. A key concern is the occurrence of rare but serious complications.

In this trial, the researchers analysed national Hospital Episode Statistics data for all arthroscopic partial meniscectomies done in England between 1 April 1997, and 31 March 2017. They identified complications occurring in the 90 days post surgery. The primary outcome was the occurrence of at least one serious complication within 90 days, which was defined as either myocardial infarction, stroke, pulmonary embolism, infection requiring surgery, fasciotomy, neurovascular injury, or death. Logistic regression modelling was used to identify factors associated with complications.

During the study period 1,088,782 arthroscopic partial meniscectomies were done, 699,965 of which were eligible for analysis. Within 90 days, serious complications occurred in 2218 (0.317% [95% CI 0.304–0.330]) cases. The results included an adjusted odds ratio for increased age of 1.247 per decade (95% CI 1.208–1.288) and 0.640 (95% CI 0.580–0.705) for female sex.

**Q1: What type of study is this?**

Answer
A cohort study. The research examined outcomes in a group (i.e. cohort) of patients who underwent an arthroscopic partial meniscectomy in England between 1 April 1997 and 31 March 2017.

**Q2: What is the odds ratio for increasing age in this study?**

Answer
1.247 per decade.

**Q3: What does this mean in practice?**

Answer
In a cohort study, an odds ratio (OR) is a measure of association between an exposure and an outcome. This study sought to identify factors that are associated with serious postoperative complications in patients who underwent an arthroscopic partial meniscectomy. The primary outcome measure was the presence of at least one serious complication within 90 days. The authors identified a number of factors which could be associated with a lesser or greater risk of complications (i.e. exposures). These are listed in the Statistical Analysis section of the Methods, and include age group, sex and ethnicity.

The OR represents the odds that an outcome (i.e. serious postoperative complications) will occur given a particular exposure (e.g. age, sex and ethnicity), compared to the odds of the outcome occurring in the absence of that exposure. In the case of demographic variables, such as age and sex, the comparison usually made to a pre-specified baseline sub-group of participants (e.g. in this study, males or patients aged <20). A statistical technique known as logistic regression is then used to estimate the change in the likelihood of the outcome occurring, associated with a one-unit increase in the exposure.

To examine the effect of age, patients were allocated to one of five age groups (see Table 3). In this case the OR for the effect of increasing age was 1.247 per decade. This means that the odds of patients experiencing serious complications (outcome) increased by 24.7% with each decade of life (exposure).

Here, the outcome is an undesirable one (serious postoperative complications).

The OR is >1 so the exposure (increasing age) is associated with higher odds of outcome.

If the OR were <1, the exposure would be associated with lower odds of outcome.

If the OR = 1, there would be no difference between the two study groups, as the outcome is the same in both, so the exposure does not affect the odds of outcome.

**Q4: What is the confidence interval for increasing age?**

Answer
95% CI 1.208–1.288.

**Q5: What does this mean in practice?**

Answer
The confidence interval indicates the level of uncertainty around the measure of the effectiveness of the intervention being studied (i.e. the precision of the effect estimate), which in this study was expressed as an odds ratio. Confidence intervals are used because a study recruits only a sample of the overall population. By interpreting upper and lower confidence limits, we can infer that the true population effect lies between these two points. Most studies report the 95% confidence interval (95% CI).

In this study, the 95% confidence interval for the estimate of the effect of increasing age = 1.208–1.288. This can be interpreted as follows: we can be 95% confident that the true population effect lies between 20.8% and 28.8%.

In a cohort study, if the confidence interval crosses 1 (e.g. 95% CI 0.9–1.1), this implies that the exposure does not affect the odds of the outcome. If it does not (e.g. 95% CI 0.7–0.8, or 1.05–1.23) then the exposure has a true effect.

**Q6: What is the odds ratio for female sex in this study?**

Answer
0.640.

**Q7: What does this mean in practice?**

Answer
See Q5 above for a detailed explanation of how to interpret odds ratios calculated for cohort studies.

In this case, the researchers compared the odds of serious complications (outcome) in male and female patients compared to males (i.e. the exposure is female sex). The odds ratio in female patients was 0.640. This means that, compared with males, the odds of women experiencing serious complications are around a third lower (36%).

Here, the outcome is an undesirable one (serious postoperative complications).

The OR is <1 so the exposure (female sex) is associated with lower odds of outcome.
If the OR were $>$1, the exposure would be associated with higher odds of outcome.
If the OR $=$ 1, there would be no difference between the two study groups, as the outcome is the same in both, so the exposure does not affect the odds of outcome.

Q8: What is the confidence interval for female sex?
Answer
95% CI 0.580–0.705.

Q9: What does this mean in practice?
Answer
See above for a detailed explanation of how to interpret odds ratios calculated for cohort studies.

In this study, the 95% confidence interval for the estimate of the effect of female sex $= 0.580–0.705$. This can be interpreted as follows: we can be 95% confident that the true odds in females is between 29.5% and 42% lower than the true odds in males.

Q10: How would you summarize the findings of this study?
Answer
This study was carried out to examine the factors that are associated with serious complications in patients who have undergone an arthroscopic partial meniscectomy. The results included an adjusted odds ratio for increased age of 1.247 per decade (95% CI 1.208–1.288) and 0.640 (95% CI 0.580–0.705) for female sex. This means that the odds of serious complications increased by 24.7% with every decade of life, and we can be confident that the true population effect lies between 20.8% and 28.8%. The adjusted odds ratio for female sex was 0.640 (95% CI 0.580–0.705). This means that compared with males, the odds of women experiencing serious complications are around a third lower (36%). The true population effect lies between 29.5% and 42%.

Increasing age was associated with an increased risk of serious complications, whilst female sex was associated with a reduced risk of serious complications.

Paper 3

Children with persistent hearing loss due to otitis media with effusion, also known as ‘glue ear’, are commonly managed by surgical intervention. Previous poor-quality trials have found short-term benefit from oral steroids. The aim of this study was to investigate whether a short course of oral steroids would achieve acceptable hearing in children with persistent otitis media with effusion and hearing loss.

Participants were children aged 2–8 years with symptoms attributable to otitis media with effusion for at least 3 months and with confirmed bilateral hearing loss. Individuals were allocated to receive either prednisolone (an oral steroid) or an identical placebo. The primary outcome was audiometry-confirmed acceptable hearing at 5 weeks. A total of 200 individuals were assigned to receive oral steroids and 189 to receive placebo. Hearing at 5 weeks was assessed in 183 children in the oral steroid group and in 180 in the placebo group. Acceptable hearing was observed in 73 (40%) children in the oral steroid group and in 59 (33%) in the placebo group. Adjusted odds ratio 1.36 ([95% CI 0.88–2.11]; p = 0.16).

Q1: What type of study is this?
Answer
A randomized controlled trial. Participants were randomly assigned to receive either prednisolone (the intervention) or an identical placebo.

Q2: What is the odds ratio in this study?
Answer
1.36.

Q3: What does this mean in practice?
Answer
An odds ratio is a relative measure of the effectiveness of the intervention being studied, which allows the comparison of the intervention group of a study to the comparison or placebo group.

The trial above compared participants who had received prednisolone (the intervention) with participants who had received an identical placebo (the control group). The outcome of interest was audiometry-confirmed acceptable hearing at 5 weeks.

An odds ratio of 1.36 means that patients in the prednisolone group (intervention group) were 36% more to have audiometry-confirmed acceptable hearing at 5 weeks, compared with the placebo group (control group).

Here, the outcome is a desirable one (audiometry-confirmed acceptable hearing).

The OR is $>$1, so the intervention is better than the control – the odds of the outcome occurring is greater in the intervention group.

If the OR were $<$1, the control would be better than the intervention – the odds of the outcome occurring is lower in the intervention group.

If the OR were $=$ 1, there would be no difference between the two study groups, as the outcome is the same in both.

Q4: The authors report an adjusted odds ratio. What does this mean?
Answer
The authors used a statistical technique (logistic regression) to adjust for – or take into account – other factors, which might impact the likelihood of patients having audiometry-confirmed acceptable hearing at 5 weeks. These factors are listed in the footnotes.

Q5: What is the confidence interval?
Answer
95% CI 0.88–2.11.

Q6: What does this mean in practice?
Answer
The confidence interval indicates the level of uncertainty around the measure of the effectiveness of the intervention being studied (i.e. how precise the effect estimate is), which in this study was expressed as an odds ratio. Confidence intervals are used because a study recruits only a small sample of the overall population. By interpreting upper and lower confidence limits, we can conclude that the true population effect lies between these two points. Most studies report the 95% confidence interval (95% CI).

If the confidence interval crosses 1 (e.g. 95% CI 0.9–1.1), this implies that there is no difference between the two arms of the study. If it does not (e.g. 95% CI 0.7–0.8), then a difference exists.
In this study comparing prednisolone to placebo, the confidence interval is reported as 95% CI = 0.88–2.11. As the confidence interval crosses 1, this implies that there is no difference between the two treatments. We can be 95% confident that, on the one hand, individuals who took prednisolone may be 12% less likely to achieve acceptable hearing, or – on the other – up to 2.11 times more likely, compared to those who took the placebo.

**Q7: What is the p-value?**

**Answer**
p=0.16.

**Q8: What does this mean in practice?**

**Answer**
The p-value in this study is 0.16. This means that, if prednisolone actually had no effect, compared to the placebo, there is a 16% chance that the study result (i.e. the observed difference) occurred by chance.

A p-value of <0.05 indicates that there is a statistically significant difference between groups. P-values of >0.05 (such as this one) indicate that the difference is not statistically significant.

**Q9: How would you summarize the findings of this study?**

**Answer**
This trial was carried out to examine whether a short course of oral steroids would achieve acceptable hearing in children with persistent otitis media with effusion and hearing loss. The results were presented as an adjusted odds ratio = 1.36 (95% CI 0.88–2.11); p=0.16. This means that the likelihood of patients achieving acceptable hearing was 36% higher in the prednisolone group, compared with the placebo group. However, the confidence interval crosses 1, so there is no real difference between the two arms of the study. The p-value is also >0.05, which indicates that the result is not statistically significant.

As a consequence, the authors concluded that a short course of oral prednisolone is not an effective treatment for most children aged 2–8 years with persistent otitis media with effusion.

### SECTION 4: MULTIPLE CHOICE QUESTIONS

**Questions**

Correct answers are indicated in **bold**

1. Which of the following is a primary source of evidence?
   a. Medline
   b. Cochrane Database of Systematic Reviews
   c. Research papers

2. Which of the following is not a component in the PICO approach to developing structured clinical questions?
   a. Patient
   b. Comparison
   c. Observations

3. Which of these three study types is regarded as the strongest form of evidence in the “hierarchy of evidence”?
   a. Randomized controlled trials
   b. Case series
   c. Observational studies

4. What is the goal of randomization in an RCT?
   a. To ensure that study groups are as similar as possible
   b. To ensure that allocation to the intervention or control arm is fair
   c. To ensure that similar numbers of participants are allocated to each study arm

5. Which of the following is not true of pragmatic RCTs?
   a. Outcome measures are chosen represent the full range of health gains relevant to patients and clinicians
   b. Pragmatic trials should represent the spectrum of patients to whom the treatment will be applied
   c. Patients and clinicians must be blinded to the intervention that is being delivered

6. Which of the following statements is true of cohort studies?
   a. No adjustments are made to participants’ treatments or lifestyle
   b. Cohort studies are always retrospective (i.e. looking back in time)
   c. Cohort studies cannot be used to study rare outcomes

7. Which of the following statements is true of case-control studies?
   a. There is a high risk of recall bias affecting the results
   b. Careful matching of cases and controls eliminates the risk of unknown confounding factors affecting the results
   c. Information is usually gathered from cases and controls via focus groups

8. Qualitative research methods (e.g. interviews and focus groups) can be useful to explore which of the following type of question?
   a. The number of patients living with a condition
   b. Whether or not a new intervention is acceptable to patients
   c. The likely length of time between diagnosis of a condition and death

9. In a study with high internal validity, which of the following is correct?
   a. The study findings are relevant to patients in other settings
   b. The study is sufficiently free from bias
   c. The study team is reputable

10. In a study with high external validity, which of the following is correct?
    a. The study findings are relevant to patients in other settings
    b. The study is sufficiently free from bias
    c. The study team is reputable

11. Which of the following is an example of potential information bias?
    a. Participants in a cohort study are all patients at a major teaching hospital
    b. Participants in a case-control study are more likely to remember relevant past history if they have the disease of interest
    c. The average age of participants in the intervention arm of an RCT is ten years younger than that in the control group

12. An odds ratio describes:
    a. The likelihood of an event occurring in the intervention group versus the control group
    b. The frequency with which an event occurs in the intervention group versus the control group
    c. The probability of seeing a result, such as the one obtained if in fact the intervention had no real effect

13. A risk ratio describes:
    a. The number of people to whom the treatment would have to be given to see an effect
    b. A comparison of the frequency with which an event occurs in a group who received an intervention versus a group who did not
    c. The likelihood that an intervention will have no effect versus the control
14. In a study comparing all-cause mortality in patients who have received a novel cancer drug, compared with conventional medication, the odds ratio is 1.14. This means that:
   a. There is no difference between the intervention and the control
   b. The control performs better than the intervention
   c. The intervention performs better than the control

15. What does a confidence interval tell us?
   a. We can be 95% certain that the true value lies within the confidence interval limits
   b. The results are 95% correct, which is sufficient for us to be confident in their validity
   c. The study has involved 95% of the possible participants in the population and therefore we can confidently report that the results are true for this group

16. The p-value reported for an RCT is 0.01. What does this tell us?
   a. There is a 1% chance that the study result (i.e. the observed difference) occurred by chance
   b. The intervention is not effective
   c. The intervention should be used in routine clinical practice

**Answers**

Correct answers are indicated in bold

1. Which of the following is a primary source of evidence?
   a. Medline
   b. Cochrane Database of Systematic Reviews
   c. Research papers

2. Which of the following is not a component in the PICO approach to developing structured clinical questions?

8. Qualitative research methods (e.g. interviews and focus groups) can be useful to explore which of the following type of question?
   a. The number of patients living with a condition
   b. Whether or not a new intervention is acceptable to patients
   c. The likely length of time between diagnosis of a condition and death

9. In a study with high internal validity, which of the following is correct?
   a. The study findings are relevant to patients in other settings
   b. The study is sufficiently free from bias
   c. The study team is reputable

10. In a study with high external validity, which of the following is correct?
    a. The study findings are relevant to patients in other settings
    b. The study is sufficiently free from bias
    c. The study team is reputable

11. Which of the following is an example of potential information bias?
    a. Participants in a cohort study are all patients at a major teaching hospital
    b. Participants in a case-control study are more likely to remember relevant past history if they have the disease of interest
    c. The average age of participants in the intervention arm of an RCT is ten years younger than that in the control group

12. An odds ratio describes:
    a. The likelihood of an event occurring in the intervention group versus the control group
    b. The frequency with which an event occurs in the intervention group versus the control group
    c. The probability of seeing a result, such as the one obtained if in fact the intervention had no real effect

13. A risk ratio describes:
    a. The number of people to whom the treatment would have to be given to see an effect
    b. A comparison of the frequency with which an event occurs in a group who received an intervention versus a group who did not receive the intervention
    c. The likelihood that an intervention will have no effect versus the control

14. In a study comparing all-cause mortality in patients who have received a novel cancer drug, compared with conventional medication, the odds ratio is 1.14. This means that:
    a. There is no difference between the intervention and the control
    b. The control performs better than the intervention
    c. The intervention performs better than the control

15. What does a confidence interval tell us?
    a. We can be 95% certain that the true value lies within the confidence interval limits
    b. The results are 95% correct, which is sufficient for us to be confident in their validity
    c. The study has involved 95% of the possible participants in the population and therefore we can confidently report that the results are true for this group

16. The p-value reported for an RCT is 0.01. What does this tell us?
    a. There is a 1% chance that the study result (i.e. the observed difference) occurred by chance
    b. The intervention is not effective
    c. The intervention should be used in routine clinical practice
At its heart, the practice of medicine is a human endeavour concerned with forming therapeutic relationships with patients. It is crucial for everyone practising medicine to understand the moral and legal framework that underlies and regulates their work. Likewise, effective communication is fundamental to achieving optimal patient-centred care, maintaining safety and ensuring optimal health outcomes. Patients expect humanity and empathy from their doctors, as well as competence.

In routine practice, ethical and legal decisions are made on a daily basis by clinical teams working with patients and, where appropriate, involving their families. Sometimes an ethics committee’s view or a legal opinion may be sought. If situations are contested and disagreement seems intractable, the courts will occasionally make a decision. Many clinicians have qualifications in ethics and law, and further study can lead to academic, policy, legal, ethical and leadership roles.

Communication ability is not just innate. There is an evidence base for effective skills that can be developed by training and experience. Reflect carefully about your practice and seek feedback. Remain informed about changes in the law, ethical guidance and professional standards. University departments, specialist sections in general medical journals and, in the UK, the General Medical Council, the British Medical Association’s ethics team and the Institute of Medical Ethics are good starting points for further exploration.

**CORE SKILLS AND KNOWLEDGE**

At its heart, the practice of medicine is a human endeavour concerned with forming therapeutic relationships with patients. It is crucial for everyone practising medicine to understand the moral and legal framework that underlies and regulates their work. Likewise, effective communication is fundamental to achieving optimal patient-centred care, maintaining safety and ensuring optimal health outcomes. Patients expect humanity and empathy from their doctors, as well as competence.

In routine practice, ethical and legal decisions are made on a daily basis by clinical teams working with patients and, where appropriate, involving their families. Sometimes an ethics committee’s view or a legal opinion may be sought. If situations are contested and disagreement seems intractable, the courts will occasionally make a decision. Many clinicians have qualifications in ethics and law, and further study can lead to academic, policy, legal, ethical and leadership roles.

**ETHICS AND THE LAW**

**Ethics: what it includes and why it matters**

The subject of ethics incorporates knowledge, cognitive skills such as reasoning, critique and logical analysis, and skills for integrating abstract ethical learning with other clinical learning and applying it appropriately. Unless students and clinicians are able to draw on learning in ethics to enhance daily practice and better serve their patients, ethics education has ultimately failed.

The practice of medicine is inherently moral:

- Biomedical expertise and clinical science have to be applied by and to people.
- Medical decisions are underpinned by values and principles.
- Potential courses of action will have implications that are often uncertain.
- Technological advancements sometimes have unintended or unforeseen consequences.

All doctors should develop:

- an awareness of key moral theories and ethical tools
- an understanding of legal concepts and principles
- the cognitive skills necessary for reasoning, critiquing and communicating ethical decisions
- a range of advanced communications skills for listening and speaking to all types of people in a range of different settings.

Communication ability is not just innate. There is an evidence base for effective skills that can be developed by training and experience. Reflect carefully about your practice and seek feedback. Remain informed about changes in the law, ethical guidance and professional standards. University departments, specialist sections in general medical journals and, in the UK, the General Medical Council, the British Medical Association’s ethics team and the Institute of Medical Ethics are good starting points for further exploration.

The profession has to agree on its collective purpose, aims and standards. People are much more than a collection of symptoms and signs – they have preferences, priorities, fears and hopes. Doctors, too, are much more than interpreters of symptoms and signs – they also have preferences, priorities, fears and hopes. Ethics is part of practice; it is a practical pursuit.

**Ethical reasoning** may sound grand or even off-putting but it is simply thinking through the available options and weighing the relative merits logically and thoroughly. Becoming, and practising as, a doctor demands an awareness of, and reflection on, our ethical attitudes. All of us have personal values and moral intuitions. In the field of ethics, a necessary part of learning is becoming aware of the assumptions on which these personal values are based, reflecting on them critically, and listening and responding to challenging or opposing beliefs.

A frequently heard complaint about ethics is that there is ‘no right answer’. While ethics often incorporates diverse analyses, leading sometimes to a number of different conclusions, there are ways of approaching an ethical issue that are dependent on an accurate
Ethical practice and clinical communication

understanding of the relevant law, professional guidance and clear elucidation of the relevant moral questions. In other words, there is information to learn and there are ways of expressing views that provide structure and rigour. Personal views are important, but need to acknowledge other perspectives, be supported by reasoning and be located in an accurate understanding of the current law and relevant professional guidance.

Ethics is commonly characterized as the consideration of big moral questions that preoccupy the media. Questions about cloning, stem cells and euthanasia are what many immediately think of when the words 'medical ethics' are used. However, ethics pervades all of medicine. The daily and routine workload is rife with ethical questions, choices and dilemmas; introductions to patients, dignity on the wards, the use of resources in clinic, the choice of antibiotic; knowing whether and when to challenge a colleague, how to balance one's own wellbeing in a demanding clinical practice, or whether to provide a medical report for a third party – all of these are as central to ethics as the issues that pervade the common representation of this area.

Ethics and law are a core part of most medical curricula and postgraduate training programmes. Formal teaching ranges from didactic lectures to small group discussions, and from sessions led by specialists in ethics to those led by patients. There are plenty of specialist books, journals and online resources to provide additional material to supplement the core curriculum. Much of what is learned in ethics will, like other areas of clinical practice, develop by watching others. Role models, both positive and less so, are influential, and most students and doctors will be exposed to a wide range of approaches, ethical engagement and practice. Noting when you admire or are discomfited by someone will teach you much about what you value and what kind of a practitioner you want to be (and remain).

Ethical practice: sources, resources and approaches

Engaging with an ethical issue in clinical practice depends on:

• discerning the relevant moral question(s)
• looking at the relevant ethical theories and/or tools
• identifying applicable guidance (e.g. from a professional body)
• integrating the ethical analysis with an accurate account of the law (both national and international).

Personal views must be taken into account, but other perspectives should also be acknowledged and supported by reasoning, and reflect an accurate understanding of the current law and relevant professional guidance.

Key ethical theories that you might encounter are summarized in Box 5.1.

Many people find that frameworks and tools that focus on the application of ethical theory to clinical problems are useful. Perhaps the best known is the 'Four Principles' approach:

• autonomy: allowing 'self-rule', i.e. letting patients make their own choices and decide what happens to them
• beneficence: doing good, i.e. acting in a patient's best interests
• non-maleficence: avoiding harm
• justice: treating people equitably and fairly.

For others, a consistent process, almost like a checklist, that incorporates the best of each theoretical approach works well. For example, whatever the ethical question, one should:

• analyze with reference to ethical principles, consequences, professional guidance and the law
• acknowledge other approaches and state the preferred one with explanation.

Do not be afraid to experiment with ways of thinking about and approaching ethics. Whatever approach you favour, the steps set out at the beginning of this section provide a structure. What this means in practice is shown in the scenario in Box 5.2.

Box 5.1 Key ethical theories

- **Deontology**: a universally applicable rule or duty-based approach to morality, e.g. a deontologist would argue that one should always tell the truth, irrespective of the consequences.
- **Consequentialism**: an approach that argues that morality is located in consequences. Such an approach will focus on likely risks and benefits.
- **Virtue ethics**: an approach in which particular traits or behaviours are identified as desirable.
- **Rights theory**: an assessment of morality with reference to the justified claims of others. Rights are either 'natural' and arise from being human, or legal and therefore enforceable in court. Positive rights impose a duty on another to act, while negative rights prohibit interference by others.
- **Narrative ethics**: an approach that argues that morality is embedded in the stories shared between patient and clinician, and allows for multiple perspectives.

Professional guidance and codes of practice

As well as ethical theories and frameworks, there are codes of practice and professional guidelines. For example, in the UK, the standards set out by the General Medical Council (GMC) inform doctors’ regulation; if a doctor falls below the expectations of the GMC, disciplinary procedures may follow, irrespective of the harm caused or whether legal action ensues. In other countries, similar professional bodies license doctors and regulate healthcare. All clinicians should be aware of the regulatory framework and professional standards in the country within which they practise.

Ethical practice and professionalism are significant from the earliest days of medical study and training. In the UK, the GMC defines the standards expected of medical students, and all medical schools are required to have ‘fitness to practise’ procedures. Students should be aware of their professional obligations from the beginning. All medical schools are effectively vouching for a student’s suitability for provisional registration at graduation. Medical students commonly work with patients from the earliest days of their training and are privileged in the access they have to vulnerable people, confidential information and sensitive situations. As such, medical schools have particular responsibilities to ensure that students behave professionally and are fit to study, and eventually to practise, medicine.

The Hippocratic Oath, although well known, is outdated and rarely, if ever, sworn. The symbolic value of taking an oath remains, however, and many medical schools expect students to make a formal commitment to maintain ethical standards.

Further reading

Box 5.2 Vignette 1

Malik is a junior doctor who works on a busy ward where junior doctors frequently care for large numbers of patients. He regularly stays on to complete tasks after his shift was due to end and this evening is no exception. As he is leaving, Malik is approached by a patient’s son, who is concerned that his father, Mr Homa, who has dementia and was admitted following a fall, is ‘in unacceptable distress’. Specifically, he tells Malik that his father is ‘too often in pain’ and ‘the staff seem too busy to respond’.

Commentary
Discerning the moral question(s)

There are several moral problems or questions that arise, even from this short vignette. They include:

• What is Malik’s responsibility, given that he is already working beyond his contracted hours on the ward?
• Are there considerations of confidentiality in talking to the patient’s son?
• What particular characteristics and considerations apply to Mr Homa and what might that mean for a clinician’s duty of care?
• Does Mr Homa have capacity? If not, on what basis is care being provided, both in general and in relation to the administration of medication?
• What systemic factors might contribute to the situation described by the patient’s son? What is Malik’s role, as an individual within a complex system, in terms of raising and addressing those factors?
• Is Mr Homa vulnerable in ways that potentially mean he is being, or should be, treated differently?

Looking at the relevant ethical theories and/or tools

• What duties does Malik have and to whom?
• What might be the consequences of his options and choices, and for whom?
• What would a virtuous doctor do in this situation? Which virtues are most relevant and why?
• What would it look like for Malik to demonstrate values-based practice in responding to this situation?
• Does Malik need to think about using an ethical decision-making tool or approach to inform and structure his approach?

Identifying applicable professional guidance

• What does national and professional guidance on consent, prescribing and confidentiality say that might be relevant?
• Is there other relevant guidance, e.g. from the hospital or an appropriate health organization, on responding to complaints?
• Are there any safeguarding considerations and, if so, which guidance is relevant?

Integrating the ethical analysis with an accurate account of the law

• What does the law relating to mental capacity and decision-making say about working with patients who may lack capacity?
• What criteria should Malik use to evaluate Mr Homa’s capacity, and have they been used appropriately here?
• What limits are there to sharing confidential information, even with a family member?
• Might the patient’s son be Mr Homa’s legal proxy? How would Malik know, and what might it mean?
• What legal obligations apply to individual clinicians working for a large NHS organization, and what does this mean for Malik’s responsibilities in this case?
• If Malik had concerns about Mr Homa’s care, how would he raise those lawfully and effectively?
• How might Malik’s response relate to the law concerning medical negligence?

Malik is unlikely to think about all of these things at the same time, and, depending on where he is working and who is available to support him, some areas will be more relevant or constitute greater priorities than others. Of course, Malik is also a busy junior doctor who needs to make a decision and get home! With an ethical disposition and an internal capacity to think about a situation from different perspectives and perhaps make time to reflect on it afterwards, Malik is well placed to make a considered choice that is grounded in both principle and the practicalities of a demanding clinical service. He can also, if asked, explain why he responded as he did, which, as a junior doctor, is an essential skill.

The law

As it pertains to medicine, the law establishes boundaries for what is deemed to be acceptable professional practice. The law that applies to medicine is both national and international: for example, the European Convention on Human Rights (Box 5.3). In the UK, along with other jurisdictions, both statutes and common law apply to the practice of medicine (Box 5.4). There are legal differences between England and Wales, Scotland and Northern Ireland.

The majority of cases involving healthcare arise in the civil system. Occasionally, a case is subject to criminal law: for example, when a patient dies in circumstances that could constitute manslaughter.

Respect for autonomy: capacity and consent

Capacity

Capacity is central to ethical decision-making because it is the gateway to self-determination (Box 5.5). People can make choices only if they have the capacity to do so. The presumption is that adult patients have capacity to make their own decisions. Assessing capacity is a significant ethical undertaking: a patient’s freedom to choose depends on it. In England and Wales, the Mental Capacity Act 2005 sets out the criteria for evaluating whether a person has the capacity to make a decision (see p. 800). In Scotland, the Adults with Incapacity (Scotland) Act 2000 applies. In Northern Ireland, there is no statute but common law applies.

Evaluating capacity is not a one-off judgement. Capacity can fluctuate and assessments should be regularly reviewed. Capacity should be understood as decision- and time-specific, and task-oriented. People may have capacity to make some choices but not others, and capacity is not precluded by specific diagnoses or impairments such as dementia. How a doctor communicates can enhance or diminish a patient’s capacity, as can pain, fatigue and the environment.

Consent

Consent is integral to ethical and lawful practice. To act without, or in opposition to, a patient’s valid consent is, in many jurisdictions, to commit an assault or battery. Obtaining consent fosters choice and gives meaning to autonomy. Valid consent is:

• given by a patient with capacity
• voluntary, i.e. free from undue pressure, coercion or persuasion
• sufficiently informed
• continuing, i.e. patients should know that they can change their mind at any time.

The basis of consent

Those seeking consent for a particular intervention must be competent in applying the procedure or treatment and be familiar with its problems. While it is good practice for written information to be
Ethical practice and clinical communication

Box 5.3 European Convention on Human Rights: substantive rights that apply to evaluating good medical practice

- Right to life (Article 2)
- Prohibition of torture, inhuman or degrading treatment or punishment (Article 3)
- Prohibition of slavery and forced labour (Article 4)
- Right to liberty and security (Article 5)
- Right to a fair trial (Article 6)
- No punishment without law (Article 7)
- Right to respect for private and family life (Article 8)
- Freedom of thought, conscience and religion (Article 9)
- Freedom of expression (Article 10)
- Right to marry (Article 12)
- Prohibition of discrimination (Article 14)

Box 5.4 Statutes and common law

Statutes
- Primary legislation made by the state, e.g. Acts of Parliament in the UK, such as the Mental Capacity Act 2005
- Secondary (or delegated) legislation: supplementary law made by an authority given the power to do so by the primary legislation
- Implementation (or statutory) guidance, e.g. the Mental Health Act Code of Practice

Common law
- Judicial decisions made in cases: these establish precedents, which are then applied to future cases
- Precedent: whether a decision constitutes a precedent depends on which court made the decision – higher-level courts have authority over lower-level courts

Box 5.5 Principles of self-determination

- Every adult has the right to make their own decisions and to be assumed to have capacity unless proved otherwise.
- Everyone should be encouraged and enabled to make their own decisions, or to participate as fully as possible in decision-making.
- Individuals have the right to make eccentric or unwise decisions.
- Proxy decisions should consider best interests, prioritizing what the patient would have wanted, and should be the "least restrictive of basic rights and freedoms".

Consent in educational settings

Medical education and training often take place in clinical environments. Future doctors have to learn new skills and apply their knowledge to real patients. However, patients must be given a choice as to whether they wish to participate in educational activities. The principles of seeking consent for education are identical to those applied to clinical situations.

Advance decisions

Many countries have laws that allow people to make decisions about their future care. In the UK, these are called advance decisions (sometimes colloquially described as ‘living wills’ or, more formally, as ‘advance decisions to refuse treatment’). An advance decision enables someone to express their wishes about future care. Advance decisions are made in anticipation of someone losing capacity. An advance decision may refuse treatment but cannot request specific treatment. Where the treatment is life-saving, the advance decision must be made in a specific way. Countries have differing approaches to advance decision-making and the relevant law where medicine is being practised must be understood. In the UK, legislation governs advance decisions. For example, the Mental Capacity Act 2005 applies in England and Wales, where a legally valid advance decision must be:
- made by someone with capacity
- made voluntarily
- based on appropriate information
- specific and applicable to the situation in which it is being considered.

In practice, it is often the specificity requirement that is difficult to satisfy because inevitable uncertainty surrounds future illness and potential treatments or interventions. For some people, the difficulty in anticipating the future and how they are likely to feel about that future informs an ethical objection to advance decision-making.

Format

Advance decisions can be made orally or in writing. However, decisions about withdrawing or withholding life-sustaining treatment must be in writing and witnessed. The decision should state explicitly that it is intended to include life-saving situations. The more informal and non-specific an advance decision is, the more likely it is to be challenged or disregarded. If working in a country where advance decisions are recognized, clinicians should make reasonable attempts to establish whether a valid advance decision exists. The presumption is to save life where there is ambiguity about either the existence or the content of an advance decision. Advance decisions should be periodically reviewed; amendments, revocations or additions are possible, provided an individual still has capacity.

Ethical and practical rationale

The ethical rationale for advance decisions is usually said to be respect for patient autonomy and extension of the right to make choices about healthcare to the future. Respect for autonomy necessarily involves supporting people to make choices that others might consider misguided. Some suggest that advance decisions foster trust and effective clinical relationships. However, others argue that none of us can have the capacity to make decisions about our future care because the person we become when ill differs from who we are when we are healthy.

Advance statements

Advance statements are broader than advance decisions and allow patients to express preferences and priorities without specifically provided, offering leaflets and using a consent form do not remove the responsibility to talk to the patient. The information that is given should be that which a reasonable person in the patient’s situation would require and doctors must be alert to the particular priorities and concerns of individuals. Information shared should:
- cover potential harms and benefits, considering how these might be perceived by the individual patient, e.g. whether some elements matter more than others
- explain possible consequences of treatment and non-treatment
- explain options
- disclose uncertainty; this should be as much part of the discussion as sharing what is well understood.

Patients should be encouraged to ask questions and express their concerns, values and preferences. Since it is the health and lives of patients that are at stake, the moral focus of such disclosure should be on what is acceptable to patients rather than to the professionals.
Box 5.6 Vignette 2

Malik visits Mr Homa. He finds signs of infection, including a high temperature, and notes that Mr Homa appears to be in distress. Malik talks to Mr Homa about his symptoms and what he believes is happening. He notes that Mr Homa is not able to understand or remember information, and he shows no ability to weigh things up when Malik explains that he wants to begin treatment with antibiotics and do further investigations. Malik recognizes that Mr Homa’s confusion might be related to his acute symptoms or his dementia but is clear that he should continue to evaluate his capacity, irrespective of the diagnosis. Malik concludes that Mr Homa lacks capacity and asks to speak to the patient’s concerned son. Malik asks him whether his father has a legal proxy or whether Mr Homa made an advance statement or decision before he became unwell. Mr Homa’s son says that neither applies. Malik explains that he would like to investigate and treat Mr Homa in his best interests. Mr Homa’s son is relieved and asks when his father is likely to be more comfortable. Malik obtains a chest X-ray, blood cultures and blood tests, and starts Mr Homa on a broad-spectrum antibiotic pending further information. He also checks with his consultant whether Mr Homa’s medication and care plan should be reviewed following his new symptoms. Malik asks Mr Homa’s son to let him know if there is anything else that might be comforting or supportive for his father while he is in hospital. Malik arranges for Mr Homa to be reviewed regularly and for that to include consideration of his capacity.

Commentary
Malik follows the steps to manage Mr Homa’s care ethically and lawfully. He evaluates his capacity using the criteria set out in the Mental Capacity Act and records his findings in a timely way and relating to the specific decision. Malik does not assume that Mr Homa lacks capacity because he has dementia, and he recognizes that he must assess function and review that assessment. Malik asks whether Mr Homa has a lasting power of attorney or has made an advance decision about future care. On learning that neither is applicable, Malik proceeds on the basis of Mr Homa’s best interests. His question about Mr Homa’s on-going comfort and wellbeing after he has arranged investigations and begun treatment show that he is alert to best interests beyond the merely medical. Finally, he arranges for the evaluation of capacity to be revisited as part of reviewing the patient.

Provision or cessation of life-sustaining treatment

For a patient who lacks capacity and has neither an advance decision nor an LPA, it is considered acceptable not to use medical means to prolong life where:

- the team believes, based on good evidence, that further treatment will not save the patient’s life
- the patient is already imminently and irrevocably close to death
- the patient is so permanently or irreversibly brain-damaged that they will always be incapable of any future self-directed activity or intentional social interaction.

Moral beliefs vary and, in general, decisions not to provide or continue life-sustaining treatment should be made with as much consensus as possible among the clinical team and those close to the patient. Where there is unresolvable conflict, a court should be consulted. In the UK, judges are available in the relevant court, even in emergencies.

Where clinicians decide not to prolong the lives of imminently dying and/or extremely brain-damaged patients, the legal conceptualization is that they are acting in the patient’s best interests by seeking to minimize suffering rather than intending to kill. Ethically, the significance of intention, along with the moral status of acts and omissions, is integral to debates about assisted dying and euthanasia.

Assisted dying

The language surrounding assisted dying can be confusing and disputed. Assisted dying is a term that describes what happens when someone helps another person to die. Other terms that are used include euthanasia, which can be categorized as ‘active’ or ‘passive’, and ‘voluntary’ or ‘involuntary’. Active and passive refer to the distinction sometimes drawn between ‘killing’ and ‘letting die’. The terms ‘active’ and ‘passive’ are used infrequently in contemporary medical practice. Voluntary and involuntary euthanasia refer to whether an individual has requested or sought an assisted death. Assisted dying is the term that is more commonly used. Physician-assisted dying is where a doctor helps an individual to die; it is a subcategory of ‘assisted dying’.

In many countries, such as the UK, assisted dying is illegal. In contrast, some jurisdictions, including the Netherlands, Switzerland, Belgium and certain US states, allow assisted dying. Where
assisted dying is not lawful, withholding and withdrawing treatment are usually acceptable in strictly defined circumstances, where the intention of the clinician is to minimize suffering, not to cause death. The doctrine of double effect remains in law, but its clinical application is limited because of improved practice and understanding in palliative and supportive care. Double effect is the legal doctrine that allows clinicians to prescribe medication that has, as its principal aim, the reduction of suffering but which may have side-effects that potentially shorten someone’s life. Such prescribing is legally justifiable because the intention is benign and the side-effects, while foreseen, are not the primary aim. End-of-life care pathways are discussed in Chapter 7.

Although assisted dying is unlawful in the UK, the Director of Public Prosecutions (DPP) provides guidance on how prosecution decisions are made following an action brought by right-to-die campaigner Debbie Purdy. Those guidelines indicate what circumstances are likely to weigh either in favour of, or against, a prosecution and make reference to an individual who has a professional role, such as a doctor or nurse. Nevertheless, the law itself is clear: for a clinician to end a patient’s life is a criminal offence.

The legalization of assisted dying remains a matter of debate in the UK, including among doctors and the organizations that represent them, such as the Royal Colleges and medical associations. Those who support a change in the law emphasize patient autonomy and choice, arguing that it is morally right that people can determine the extent to which they can tolerate illness and suffering. Those who oppose assisted dying express concerns about vulnerability, the potential for a slippery slope whereby regulation is unable to prevent abuse, and arguments that such legislative change undermines what they believe to be the inherent sanctity of life. For some doctors, there is a question about whether assisting another to die is contrary to the medical role as they perceive it. When someone does help a patient to die – for example, by supporting their travel to a jurisdiction where assisted dying is lawful – the DPP will use guidance to determine whether there should be a prosecution. There have been a number of cases where relatives have been interviewed by the police as part of a formal investigation but no prosecutions have yet followed.

How the legal and ethical framework apply in practice is shown in Box 5.7.

Mental health and consent

The majority of people being treated for psychiatric illness have capacity. However, mental illness sometimes compromises an individual’s capacity to make his or her own decisions. Many countries have specific legislation that enables people to be treated without consent on the basis that they pose a risk to themselves and/or to others.

People who have, or are suspected of having, a mental disorder may be detained for assessment and treatment in England and Wales under the Mental Health Act 2007. The Act was reviewed in 2018, but at the time of writing, no changes to the law have yet been made. The law defines a mental disorder as ‘any disorder or disability of the mind’. Addiction to drugs and alcohol is excluded. Appropriate medical treatment should be available to those admitted under the Mental Health Act. In addition, the legislation provides for Supervised Community Treatment Orders. The law sets out multiple checks and limitations that are essential, given the ethical implications of detaining and treating someone against their will.

In situations in which it is lawful to give a detained patient psychiatric treatment compulsorily, consent should be sought and obtained if possible. For concurrent physical illness, capacity should be evaluated as usual. If the patient has capacity, consent should be obtained for treatment of the physical illness. If a patient lacks capacity because of the severity of a psychiatric illness, treatment for physical illness should be given on the basis of best interests or with reference to a proxy or advance decision. If treatment can be postponed without compromising the patient’s interests, consent should be sought when the patient has capacity.

Consent and children

Where a child does not have the capacity to make decisions, treatment will usually depend upon obtaining proxy consent. In the UK, consent is sought on behalf of the child from someone with ‘parental responsibility’. In the absence of someone with parental responsibility – for example, in emergencies, where urgent treatment is indicated – clinicians proceed on the basis of the child’s best interests.

Sometimes parents and doctors disagree about the care of a child who is too young to make their own decisions. Both national and European case law demonstrate that the courts are prepared to override parental beliefs if they are perceived to compromise the child’s best interests. However, the courts have also emphasized that a child’s best medical interests are not necessarily the same as a child’s best overall interests or welfare. Whenever the patient is a child, clinicians interact with a family unit. Sharing decisions and attending to the child as a member of a family are the most effective and ethical ways of practising.
As children mature, whether a young person has capacity to make his or her own decisions is evaluated using principles derived from a case called *Gillick v. West Norfolk and Wisbech Area Health Authority*, which determined that a young person can make a choice about their own health where:

- the patient, although under 16, can understand medical information sufficiently
- the doctor cannot persuade the patient to inform, or give permission for the doctor to inform, the parents
- a young person is seeking contraception and is likely to have sexual intercourse with or without adequate contraception
- the patient’s mental or physical health (or both) is likely to suffer if treatment is not provided
- it is in the patient’s best interests for the doctor to treat without parental consent.

The *Gillick* case recognized that young people differ in their abilities to make decisions and established that function, not age, matters when considering whether a child can give consent. Situations should be approached on a case-by-case basis, taking into account the individual young person’s level of understanding of a particular treatment. It is possible (and perhaps likely) that someone may be considered to have capacity to consent to one treatment but not another. Even where a child does not have capacity to make their own decision, clinicians should respect the child’s dignity by discussing the proposed treatment with the child, even if the consent of the parents also has to be obtained.

In the UK, once a child reaches the age of 16, the Mental Capacity Act 2005 states that they should be treated as an adult, except for the purposes of advance decision-making and appointing an LPA.

### Confidentiality

Confidentiality is essential to therapeutic relationships. If clinicians violate the privacy of their patients, they risk harm, disrespect autonomy, undermine trust and call the medical profession into disrepute. The diminution of trust is significant ethically, with potentially serious consequences. Within the UK, confidentiality is protected by common and statutory law. Some jurisdictions make legal provision for privacy. Doctors who breach the confidentiality of patients may face professional and legal sanctions.

### Respecting confidentiality in practice

Patients should understand that information about them will be shared with other professionals involved in their treatment. Usually, by giving consent for investigations or treatment, patients are deemed to give their implied consent for information to be shared within the clinical team. Rarely, patients might object to information being shared, even within a team. In such situations, the advice is that the patient’s wish should be respected, unless it compromises treatment. In almost all clinical circumstances, therefore, the confidentiality of patients must be respected. Confidentiality can be breached inadvertently. For example, clinical conversations take place in lifts, corridors and cafés. Even on wards, confidentiality may be compromised by the proximity of beds and the visibility of whiteboards containing medical information. Everyone should be alert to incidental breaches of confidentiality and seek to minimize their role in unwittingly revealing sensitive information.

---

**Box 5.8 Examples of circumstances in which a doctor is required to share confidential information**

- Notifiable diseases, which, by virtue of public health legislation, must be notified to the relevant consultant in communicable disease control
- Court orders
- Road traffic accidents that lead to requests from the police
- Actual or suspected terrorist activity

### When confidentiality must or may be breached

The duty of confidence is not absolute. Sometimes, the law requires that clinicians must reveal information about patients to others, even if they wish it were otherwise (Box 5.8). There are also circumstances in which a doctor has the discretion to share confidential information within defined terms. Such circumstances highlight the ethical tension between the rights of individuals and the public interest.

Aside from legal obligations, there are three situations in which information may be shared, namely:

- The patient has given consent.
- It is in the patient’s best interests to share the information, but it is impracticable or unreasonable to seek consent.
- It is in the public interest.

These three categories are a useful framework within which to think about the duty of confidentiality. They also require ethical judgement, particularly where sharing confidential information might be in the ‘public interest’. In England and Wales, there is legal guidance on what constitutes sufficient ‘public interest’ to justify sharing confidential information, which is derived from the case of *W v. Egdell*. In that case, the Court of Appeal held that the ‘most compelling circumstances’ could justify a doctor acting contrary to the patient’s perceived interest in the absence of consent. The court stated that it would be in the public interest to share confidential information where:

- there is a real and serious risk of harm
- the risk is of physical harm
- there is a risk to an identifiable individual or individuals.

Consent should be sought wherever possible, and disclosure on the basis of the ‘public interest’ should be a last resort. Each case must be weighed on its own merits and a clinician who discloses confidential information on the grounds of ‘public interest’ must be prepared to justify the decision. Even where disclosure is justified, confidential information must be shared only with those who need to know.

If there is a perceived risk to the public interest, does a doctor have a duty to warn others of potential risk? In some jurisdictions there is a duty to warn, but in England and Wales there is no professional duty to do so. The judgement in *W v. Egdell* provides a justification for breaches of confidence in the public interest but it does not impose an obligation on clinicians to warn third parties about potential risks posed by their patients.

### Resource allocation

Resources encompass all aspects of clinical care: that is, they include time, knowledge, skills and space, as well as treatment. In
circumstances of scarcity, waste and inefficiency of any resource are of ethical concern.

Access to healthcare is considered to be a fundamental right and has been captured in international law since it was included in the Universal Declaration of Human Rights. However, the question of how to allocate limited resources is a perennial ethical question. Within the UK, the courts have made it clear that they will not force National Health Service (NHS) Trusts to provide treatments that are beyond their means. Nevertheless, the courts also demand that decisions about resources must be made on reasonable grounds.

**Fairness**

Both ethically and legally, prejudice or favouritism is unacceptable. Methods for allocating resources should be fair and just. In practice, this means that scarce resources should be allocated to patients on the basis of need and the time at which they sought treatment. It is respect on the part of clinicians for these principles of equality – equal need and equal chance – that fosters fairness and justice in the delivery of healthcare. For example, a well-run emergency department will draw on the principles of equality of need and chance to:

- decide who to treat first and how
- offer treatment that has been shown to deliver optimal results for minimal expense
- use triage to determine which patients are most in need and ensure that they are seen first, the queue (or waiting list) being based on need and time of presentation.

People should not be denied potentially beneficial treatments on the basis of their lifestyles. Such decisions are almost always prejudicial. For example, why single out smokers or the obese for blame, as opposed to those who engage in dangerous sports? Patients are not equal in their abilities to lead healthy lives and to make wise healthcare choices. Education, information, economic worth, confidence and support are all variables that contribute to, and socially determine, health and wellbeing. As such, to regard all people as equal competitors and to reward those who, in many ways, are already better off is unjust and unfair.

**Global perspectives**

Increasingly, resource allocation is being considered from an international or global perspective. Beyond the boundaries of the NHS and the borders of the UK, moral questions about the availability of, and access to, effective healthcare are rightly attracting the attention of ethicists and clinicians. Anyone who is training for, or working in, medicine in the 21st century should consider fundamental moral questions about resource allocation, in particular those being raised by issues such as:

- the role and work of pharmaceutical companies
- the mobility of trained clinicians
- the preoccupation of funded and commercial biomedical research with diseases that are prevalent in developed countries
- notions of rights to health and life
- the status of those seeking asylum
- persistent inequalities in health.

In practice, there is often overlap and interaction between the categories: for example, a doctor may be both a defendant in a negligence action and the subject of fitness to practise procedures. Professional bodies are established by, and work within, a legal framework and, in order to implement policy, legislation is required and interpretative case law will often follow.

**Standards and the law**

In most countries, the law provides the statutory framework within which the medical profession is regulated. For example, in the UK, it is the function of the GMC to maintain the register of medical practitioners, provide ethical guidance, guide and quality-assure medical education and training, and conduct fitness-to-practise procedures. It is the GMC that defines standards of professional practice and has responsibility for investigation when a doctor’s standard of practice is questioned.

Clinicians have a responsibility not only to reflect on their own practice, but also to be aware of and, if necessary, respond to the practice of colleagues, even in the absence of formal ‘line management’ responsibilities.

**Conscientious objection**

Doctors are human beings who will have their own views about what is and is not acceptable ethically. Any student or doctor should feel able to express concerns, raise questions and challenge constructively. However, the GMC is clear that doctors must not allow their own beliefs or judgements to compromise clinical care or discriminate against patients.

In the UK (apart from Northern Ireland), there is one situation in which the law provides for a right of conscientious objection: namely, in the provision of terminations of pregnancy and some reproductive medicine involving embryos. The right of conscientious objection allows doctors to choose not to be involved in providing terminations, including making referrals to specialist services. However, doctors must not convey their beliefs in a judgemental way to a patient and should arrange for colleague to see the patient without delay. In an emergency, which is likely to be extremely rare in contemporary Western practice, a doctor would have to act if no one else was available.

The law is silent on whether the provision applies to medical students, although most medical schools will offer guidance and accommodate students who have a conscientious objection to terminations.

**Clinical negligence**

*Negligence* is a civil claim where damage or loss has arisen as a result of an alleged breach of professional duty, such that the standard of care was not, on the balance of probabilities, that which could be reasonably expected.

Of the components of negligence, duty is the simplest: all doctors have a duty of care to their patients. Whether a doctor has discharged their professional duty adequately is determined by expert opinion on the standards that can reasonably be expected and an individual’s conduct in relation to those standards. If doctors have acted in a way that is consistent with a reasonable body of their peers and their actions or omissions withstand logical analysis, they are likely to meet the expected standards of care. Lack of experience is not taken into account in legal determinations of negligence.

The most common reason for a clinical negligence action to fail is causation. For example, the alleged harm may have occurred against the background of a complex medical condition or course of treatment, making it difficult to establish the actual cause.

**Professional competence and mistakes**

Doctors must practise to an acceptable professional standard. There are essentially three sources that inform what it means to be a ‘competent’ doctor, namely:

- the law
- professional guidance from bodies such as the GMC
- local policy.
Clinical negligence remains relatively rare and undue fear of litigation can lead to defensive and poor practice. All doctors make mistakes and these do not necessarily constitute negligence or indicate incompetence. Inherent in the definition of incompetence is time; that is, on-going review of a doctor’s practice to see whether there are patterns of error or repeated failure to learn from error. Regulatory bodies and medical defence organizations require doctors to be honest about their mistakes and to apologize, remembering that to do so is not necessarily an admission of negligence. Such honesty and humility, aside from its inherent moral value, have been shown to reduce the prospect of patient complaints or litigation. Being open is recognized as good practice internationally, and examples of an open approach in the USA, Australia and Singapore have actually reduced the costs of complaints.

Professional bodies

Professional bodies have diverse but often overlapping roles in developing, defining and revising standards and obligations relating to competence and performance are Duties of a Doctor and Good Medical Practice.

Policy

There have been an exponential number of policy reforms that have shaped the ways in which the medical competence and accountability agendas have evolved. One of the most notable is the increase in the number of organizations concerned broadly with ‘quality’ and performance. The increased scrutiny of doctors’ competence has found further policy translation in the development of appraisal schemes and the revalidation process. There have been other policy initiatives that adopt the rhetoric of ‘quality’, such as increased use of clinical and administrative targets and the development of specialist facilities.

Professional accountability is a hot topic. The law, professional guidance and policy documentation provide a starting point for clinicians. Complaints and possible litigation are often brought by patients who feel aggrieved for reasons that may be unconnected with the clinical care that they have received. When patients are asked about their decisions to complain or to sue doctors, it is common for poor communication, insensitivity, administrative errors and lack of responsiveness to be cited as motivation. Doctors should offer an apology and explain fully and promptly what has happened, along with the likely short-term and long-term effects of any harm. Reluctance to say ‘sorry’ comes from a fear that it is an admission of fault, which later implies liability, but guidelines from medical defence organizations emphasize that this is not so. There is less to fear than doctors sometimes believe. The courts and professional bodies are concerned neither with best practice, nor with unfeasibly high standards of care. What is expected is that doctors behave in a way that accords with the practice of a reasonable doctor – and the reasonable doctor is not perfect. As long as clinicians adhere to some basic principles, it is possible to practise defensible rather than defensive medicine. Good habits begin in medical school. In particular, effective communication is a potent weapon in preventing complaints and, ultimately, encounters with the legal and regulatory systems. Having a clear framework helps resolve complaints, reduces clinicians’ stress and develops their professional reputation for handling difficult situations properly (Box 5.9).

Further reading

Box 5.9 Responding to complaints

- Remember that the complainant is still a patient, to whom there is a duty of care.
- Do not delay.
- Listen and express regret for distress.
- Acknowledge when things have gone wrong – be objective, not resentful or defensive.
- Apologize for actual or perceived shortcomings.
- Provide easily understood information or explanations.
- Explain what has happened and the likely short-term and long-term effects of any harm.
- Offer appropriate redress.
- Explain how things will improve.
- Leave medical records strictly unaltered.

COMMUNICATION IN MEDICINE

Worldwide changes in society, together with evidence relating to improved health outcomes, are the forces driving expectations of patient partnership in care. While ethics and law underpin the context of healthcare, it is through communication processes that evidence-based and patient-centred care is delivered. Doctors conduct around 200,000 consultations during their careers. Specific skills contribute to a consulting style that fosters trust and demonstrates flexibility, openness, partnership, respect for autonomy and collaboration with the patient. Medical schools all over the world now include the learning skills of communication as a core part of the curriculum.

What is patient-centred communication?

Patient-centred care aims to reach a common understanding with the patient about the illness, its treatment, and the roles that the clinician and the patient will assume (Fig. 5.1). Both the biomedical facts relating to the patient’s illness and the patient’s ideas, concerns, expectations and feelings are needed in order to diagnose what is the matter with the patient and to discover what matters to them (see Ch. 1).

This requires a good balance between:
- clinicians asking all the questions needed to include or exclude diagnoses
- patients being asked to express their thoughts, ideas, concerns and expectations
- clinicians explaining and advising in ways that patients can understand so that they can be involved in decisions about their care.

This does not mean that clinicians totally abdicate power but rather that they share it. Patients want their doctors’ expert opinions and, in some cases, may still prefer to leave matters to the clinician.

Understanding patient concerns and expectations is always important because clinicians can offer practical help; even when they cannot, they can always listen supportively. Empathy has been described as ‘imagination for others’. It is different from sympathy.
Ethical practice and clinical communication

Fig. 5.1 The patient-centred clinical interview: content and skills. (Adapted from McWhinney IR, Levenstein JH. In: Stewart M, Roter D, eds. Communicating with Medical Patients. Thousand Oaks, CA: Sage; 1989.)

(Feeling the same as the patient), which rarely helps and can lead to clinician burnout. Empathy is a key skill in building the patient-clinician relationship and is itself highly therapeutic. The essential starting point is attentive listening and observation of patients to try to understand their particular predicament and respond in a supportive way. Empathy can be developed with practice, but it has to be genuine and cannot be counterfeited by a repertoire of routine mannerisms.

The majority of health problems in industrialized countries are long-term conditions that cannot be cured. In 2018 in the UK, people with long-term conditions accounted for about 50% of all GP appointments, 64% of all outpatient appointments and over 70% of all inpatient bed days. To manage their conditions well on a daily basis, patients have to become experts in self-care and try to reduce their risks from lifestyle habits. All of these factors support the need for person-centred communication.

Patient-centredness has evolved in the West and English-speaking countries, and may not align well with societies where cultural norms prioritize collectivism over individualism. In the latter, people are seen as part of their wider social group (family-oriented), and harmony, obedience and respect for seniors are valued over open expression of difference in opinion and egalitarianism. In recent years, research on professional–patient communication in parts of East Asia and India has revealed complexity and variability of clinical encounters and patient preferences due to such culturally specific influences. Nevertheless, there are increasing signs that patient and professional preferences in these societies are moving towards active patient involvement in discussions about treatment. A more participatory style of healthcare is likely to grow with worldwide access to the Web and societal expectations.

What are the effects of communication?

Communication can have an effect on health outcomes in a variety of ways (Fig. 5.2). Decades of research evidence show which aspects of communication improve diagnostic accuracy and efficiency, patients’ ability to follow treatment advice, patient and clinician satisfaction and, ultimately, health outcomes. Poor communication results in missed problems and concerns, strained relationships, distress for patients, complaints and litigation. In the USA, surgeons exhibiting an authoritarian style and tone of communication are more likely to be sued.

Some patients may not understand or remember what doctors said, while others actively decide not to follow advice and commonly do not tell their doctors, resulting in poor management. Skillful communicators routinely check patients’ understanding as they explain and ask what patients think of the advice they are given (Box 5.10). Errors in use of medications are costly and risk patient safety.

Improved time management and costs

Integrating patient-centred communication into all interviews actually saves time in the long term and reduces non-essential investigations and referrals, which waste resources. Patients given the latest evidence of benefits and risks in treatment options commonly choose more conservative management, without detriment to health. This has potential for considerable savings for health budgets.

Barriers and difficulties in communication

Communication is not straightforward. Time constraints can prevent both doctors and patients from feeling that they have each other’s attention and that they fully understand the problem from each other’s perspective. Under-estimation of the influence of psychosocial issues on illness and their costs to healthcare means clinicians may resort to avoidance strategies, such as switching topic, premature reassurance or jollying patients along when they fear the discussion will unleash emotions that are too difficult to handle, upset the patient or take too much time. Patients, for their part, may not disclose concerns if they are anxious and embarrassed, or sense that the clinician is not interested or thinks that their complaints are trivial.

Oral and written information is often so complex that it exceeds many people’s functional skills in language and numeracy. Health literacy is the ability to understand health information well enough to access and use information and services in order to make decisions. Many patients have poor knowledge of how their body works and struggle to understand new information provided by doctors. Some concepts may be too unfamiliar to make sense of, even if...
Breaking bad news about a serious medical condition presents particular challenges (see p. 10). The way that news is broken has an immediate and long-term effect. When skillfully performed, it helps the patient and family to understand, cope and make the best of even very bad circumstances. These interviews are difficult because biomedical measures are sometimes of limited help, and patients are upset and can react unpredictably. The clinician may also feel upset – more so if there is an element of medical mishap. The two most difficult things that clinicians report are how to be honest with the patient while not destroying hope, and how to deal with the patient’s emotions. Guidelines on communicating bad news provide help to do these well.

Managing uncertainty is part of medical practice (see p. 11). Around 20% of GP consultations in the UK are for persistent bodily complaints where adequate examination does not reveal a structural or pathological explanation. In secondary care, 50% of outpatients fulfill criteria for such medically unexplained symptoms. Guidelines and training are available for doctors on how best to communicate and manage this difficult situation for patients in order to reduce futile and costly investigations or interventions and help patients cope with symptoms.

Anxiety and emotions are major blocks to communication. Breaking bad news about a serious medical condition presents particular challenges (see p. 10). The way that news is broken has an immediate and long-term effect. When skillfully performed, it helps the patient and family to understand, cope and make the best of even very bad circumstances. These interviews are difficult because biomedical measures are sometimes of limited help, and patients are upset and can react unpredictably. The clinician may also feel upset – more so if there is an element of medical mishap. The two most difficult things that clinicians report are how to be honest with
Clinicians are human and are often rushed and stressed. They work against the clock and infallible systems. However, as professionals, they, together with healthcare managers, bear the responsibility for addressing communication difficulties.

Teamwork
Modern healthcare is complex, with patients being looked after by multiple healthcare professionals working in shifts. Problems arise when information is not transmitted, is misunderstood or is not recorded. A shared sense of ethical endeavour and effective communication are essential, especially when people are busy or a patient is critically ill.

Most complaints in teams relate to communication. Communication styles vary. Some people are indirect and more elaborate in their speech, while others come straight to the point, leaving out detail and their own rationale. Each type can feel irritated, offended or puzzled by the other. Hierarchies make it harder for people to speak up. The multidisciplinary team meeting is a space to establish norms, model inclusivity and enact ethical practice by listening, valuing and involving all members of the team. A functional team is an ethical team that recognizes that good care begins with the way colleagues treat each other. Poor communication and inattention to ethical norms can be dangerous if, for example, someone feels unable to point out an error, offer information or ask a question. Hinting and hoping is not good communication. Team leaders who ‘flatten’ the hierarchy by knowing and using people’s names, routinely having briefings and debriefings, do not let their own self-image override doing the right thing, and positively encourage colleagues to speak up reduce the number of adverse events. Teamwork requires collaboration, open sharing of ideas and a readiness to discuss weaknesses and errors. Lessons from industries such as aviation have been used to show how to reduce errors caused by poor communication.

Contexts for team communication include ward handovers, requests for help, acceptance of referrals and communication in the operating theatre.

Handover between teams is helped when everyone adopts a clear system. Frameworks such as SBAR (situation – background – assessment – recommendation) use standardized prompt questions in four sections to ensure team members share concise and focused information at the correct level of detail (see p. 11). This increases patient safety.

Communication on discharge is just as essential, and primary care physicians need sufficient information, including details of medication, to continue care safely. Patients in some countries now receive copies of letters sent to their doctors to ensure that information is shared. This requires some skill to enable meaning to be clear to all parties.

Clinical records
All medical interviews should be well documented. Good records are vital in providing best care, reducing error and ensuring patient safety. They are the responsibility of everyone in the healthcare team (Box 5.12).

In many countries, patients have the right to see their records, which provide essential information when a complaint or claim for negligence is made. They are also valuable as part of audit to improve standards of healthcare.

Electronic patient records are increasingly replacing written ones. They include more information, overcome problems of legibility, and reduce prescription error by 66% compared to handwritten ones. With adequate data protection, they offer immense potential for unifying record systems and allowing access across the healthcare team in primary, secondary and tertiary care sectors. Increasingly, patients will have access and even contribute to their records.

Culture, diversity and communication
Culture is a broad term that extends beyond language and includes values, beliefs, behaviours, practices, institutions and the way people communicate. Clinicians commonly express anxiety and uncertainty about how to respond to cultural diversity, how to work with interpreters and how to avoid causing offence. Doctors strive to treat all patients equally; however, research reveals that those

Box 5.12 Essentials of record-keeping
What records should include
• Relevant clinical and psychosocial information – history and examination
• Relevant findings, both positive and negative
• Diagnosis, including uncertainties
• Test results
• Correspondence, including e-mails and text messages
• Decisions made, actions agreed and identification of who is making and agreeing decisions
• Information given to patients

Criteria for good records
• Clear, accurate, legible and contemporaneous
• Dated and signed with printed name
• Original – never altered (using a signed, dated additional note alongside any mistake)
• Kept secure

from minority cultures receive poorer healthcare, even when they speak the same language as the clinician. They experience fewer expressions of empathy, shorter consultations and less inclusion in shared decision-making. They also tend to say less in consultations.

Beliefs
We all take our culture for granted but it can profoundly affect ideas about symptoms, causes of illness, and appropriate behaviour and treatment. Beliefs influence when a patient seeks medical assistance, what patients and doctors expect of the consultation, and how they communicate. In some cultures, for example, it is very difficult for a woman to be seen by a male doctor. Talking about death is strongly taboo in others, thus inhibiting discussions about end-of-life care. Some cultures regard it as the family members’ duty to speak for the patient, while the doctor, respecting patient autonomy, will expect to talk directly with the patient. Sensitive topics may be more difficult but avoidance could jeopardize care. It helps to apologize if inadvertent offence occurs and explain why such questions are required. Clinicians vary too. Those from traditional cultures may have a more paternalistic style than some patients want.

Language
Patients sometimes bring a family member or friend to interpret. The latter may not understand medical questions and may be censoring sensitive matters or expressing their own views rather than those of the patient. Confidentiality cannot be guaranteed and patients may feel restricted in what they can say. On the other hand, patients may want a trusted family member to translate. Children should not be used to interpret.

For these reasons a trained interpreter who follows best practice guidelines should be used. Ask for the correct pronunciation of a patient’s name and about any beliefs and concerns that are relevant in the patient’s culture, as well as cultural differences in body language. Patients may be more or less culturally traditional, so check out assumptions.

Arrange seating to see both the patient and the interpreter but always look and speak directly to the patient. Speak in short phrases, avoid jargon and find out the patient’s ideas, concerns and expectations. Watch for non-verbal communication and check that the patient understands.

Clinicians sometimes worry that interpreters are editing when long exchanges are followed by only a short summary back to them. It helps to ask interpreters to translate exactly what has been said. The interpreter can stand outside the curtain during examination. If professional interpreters are not available, telephone language lines can be used. Advocates are more than just language interpreters in that they understand cultural beliefs and practices. They also help patients to understand the workings of the healthcare system.

Non-verbal communication
Awareness of cultural taboos is helpful in maintaining dignity and respect. For example, hand-shaking, eye contact, personal space and sensitive subjects vary across cultures.

*Paraverbal* communication – the way things are said rather than what is said – also differs and influences rapport and relationships. We infer things from tone of voice, stress on words and phrases, silence, pace and the politeness conventions that are used. Some cultures are more open, direct and assertive than others. Some languages do not differentiate gender in common nouns and pronouns, so ‘he’ and ‘she’ may be used interchangeably. It is hardly surprising that misunderstandings occur and it can be much harder to create a rapport. It is worth remembering that smiling is a universal expression of kindness and warmth.

**Patients with impaired communication faculties**

All healthcare professionals need patience, ingenuity and willingness to learn to be able to communicate effectively with patients who have impaired communication faculties.

**Impaired hearing**
Some 55% of people over 60 are deaf or hard of hearing. Patients may be accompanied by a signer but fewer than 1% of hearing-impaired people sign. Many hard-of-hearing people lip-read and some common-sense tips are listed in *Box 5.13*. Clinicians who mumble, speak fast or have strong accents have a responsibility to make particular efforts to be understood. Conversation aids may be available or patients can be asked how best to communicate with them.

**Impaired vision**
Patients who have visual impairment can miss non-verbal cues in communication. It may sound obvious but it helps to make more conscious efforts to use patients’ names so they know they are being spoken to. Clinicians should avoid sudden touch, explain what they are about to do, and say what they are doing as they go along. Large-print information sheets should be available. Email and SMS text communication is increasingly used by blind and partially sighted people who have a smartphone, tablet or computer equipped with assistive technology.

**Patients with limited understanding or speech**
*Aphasia* is a communication disorder following strokes. Even though hearing and thought processes are unaffected, patients find it hard to understand, or they know what they want to say but cannot find the words; they are literally ‘lost for words’. This also affects their ability to write, gesture, draw or mime their thoughts.

Patients may have a strength in one area – for example, ability to understand – with a weakness in another other area – for example, expression – or vice versa. It helps to find a quiet place without distractions, to make eye contact and attract the person’s attention. Speak slowly and clearly, use simple phrases, try different words, and leave plenty of time between sentences to allow for extra processing time. Make it obvious when changing the subject.

*Box 5.13 Communicating with people who are deaf or hard of hearing*

- Ask if they need to lip-read when you are speaking
- Position yourself on the better-hearing side
- Smile and use eye contact
- Face the light
- Do not cover your face or mouth
- Use plain language
- Speak clearly but not too slowly
- Do not shout
- If stuck, write it down
- Check for understanding
- Never say ‘Forget it’!

Closed questions requiring ‘yes’ or ‘no’ answers are easier. Write down key words or headings, to which both the patient and the clinician can refer. This helps because the auditory memory needed to ‘hold on to’ the spoken word taxes the patient’s language system. Use pictures and have pen and paper to hand if the patient can use them. Gestures, pointing and more facial expression can help. Do not interrupt or pretend to understand. Seek advice from carers and speech and language therapists.

**Technology**

**The Internet**

The Internet has revolutionized ready access to information. Research reveals that people feel more able to ask informed questions and have less fear of the unknown. Most doctors support Internet use in enhancing consultations, especially post diagnosis, when it helps patients understand and manage their illness. They also worry that patients access poor-quality information. Directing patients to trustworthy, reputable Internet sites is recommended. Telemedicine and artificial intelligence are growing areas within healthcare. They call for adaptation of communication and the need for research on its impact on health outcomes.

**Decision aids**

Weighing up treatment benefits and risks where both may be substantial but not guaranteed is very hard for patients. Decision aids that are evidence-based, are written in non-technical language and include visual representations help people digest complex statistical information. They are available in a variety of media (online, print, video). Decision aids from reliable and independent sources help people think through what is important to them, so that they can make choices from the evidence that reflect their own values and preferences.

These aids can improve communication between doctors and patients, and support patient autonomy in decisions over management. If they are to become part of routine clinical practice, they need to be embraced by the clinical community, established as part of the clinical workflow, and included in education, training and development programmes for healthcare professionals.

**Training in communication skills**

This chapter has covered principles and some practical advice on communication in healthcare. There is clear evidence that communication ability is not just innate. It is a professional skill and responsibility that can be learned. Skills cannot be learned from books, and the opportunity to practise and receive constructive feedback on performance is essential.

In developed countries, more than one-third of the population will develop cancer at some time during their life, and it is second only to cardiovascular disease as a cause of death. Many advances have been made in recent years, in terms of both the molecular understanding and the targeted treatment of different cancers.

Patients are diagnosed with cancer in a number of different settings: by screening, via the GP, as an emergency admission, or in a routine hospital outpatient or inpatient encounter. Many professionals are involved in the care of patients with cancer, and management decisions are made at multidisciplinary team meetings (usually tumour site-specific), with input from surgeons, oncologists, radiologists, pathologists, palliative care physicians, clinical nurse specialists and allied health professionals.

Oncologists are trained to deliver radiotherapy and/or systemic therapy. They must combine clinical skill and knowledge with empathy and excellent communication skills, as they often see patients when they are at their most vulnerable.

Key learning outcomes in malignant disease include:
- understanding the biology of cancer, including its presentation and natural history
- understanding the goals of treatment – cure, active management and palliation – and the principles underlying the main classes of cancer intervention: surgery, chemotherapy, radiotherapy, hormonal therapy, targeted therapy and immunotherapy
- being able to assess a patient with a malignant disease, understanding where they are in the course of their disease and treatment, and communicating likely outcomes
- managing emergencies caused by the cancers themselves (such as spinal cord compression) or by anti-cancer treatment (such as neutropenic sepsis).

Opportunities for learning about malignant disease include reviewing patients undergoing urgent investigation for malignant disease (e.g. in urgent referral outpatient clinics), attending cancer multidisciplinary team meetings, visiting chemotherapy and radiotherapy day units, attending clinics with the treating clinicians, and shadowing clinical nurse specialists.
This needs to be tailored to the clinical setting: in a patient being investigated for malignant disease the diagnostic questions will be crucial, as will the patient’s performance status. In a patient already undergoing active therapy, questions about treatment-related symptoms and general fitness will be more relevant. At all stages, it is necessary to consider how the patient is coping with the emotional challenges of confirmed or suspected malignancy, and to adopt an empathetic and caring approach.

The questions in Box 6.1 are grouped into different sections that can be brought together according to the clinical setting. Patients often present with non-specific systemic symptoms such as weight loss, malaise and lethargy, pains all over, ‘not feeling great’ – for these patients it can be worth using ‘review of systems’ questions to slowly tease out specific system-based problems.

### Investigations

Cancers require both radiological and histological evaluation for a complete diagnosis (Box 6.2 and see pp. 102 and 107). The findings are used to establish histological grade and radiological staging, according to internationally agreed systems specific to each type of malignancy.

#### Formulating a management plan

A diagnosis of cancer can have different implications for a patient. After seeing patients with a confirmed or suspected malignancy, it is crucial to establish where they are in the disease process. Are they previously fit and well but recently diagnosed with a potentially curable disease? Or are they into their third cycle of chemotherapy for metastatic malignancy, with few additional treatment options left? Asking the questions in Box 6.3 will shed light on the patient’s perspective, and the answers can then be supplemented by reviewing medical records for investigation results and details of multidisciplinary team discussions.

---

### Box 6.1 Taking a history in malignant disease

#### General symptoms of malignancy
- Weight loss
- Anorexia/loss of appetite
- Malaise, weakness and tiredness
- Paraneoplastic syndromes

#### Common site-specific symptoms
- **Brain:** seizures, any focal neurological symptoms, personality change
- **Lung:** cough, haemoptysis, chest wall pain (if invasive), breathlessness
- **Oesophagus and stomach:** mechanical dysphagia, early satiety, regurgitation, symptoms of anaemia due to occult blood loss
- **Hepatobiliary tract:** upper abdominal pain and heaviness, jaundice
- **Colon and rectum:** altered bowel habit, rectal bleeding, tenesmus, symptoms of anaemia from blood loss
- **Breast:** breast lump, skin changes, nipple discharge
- **Prostate:** obstructive lower urinary tract symptoms (see p. 1477)
- **Ovary:** abdominal discomfort and bloating
- **Cervix and endometrium:** postmenopausal, intramural or postcoital bleeding
- **Thyroid:** neck swelling, thyrotoxicosis
- **Urinary tract:** painless haematuria
- **Bone:** dull bony pain, pathological fractures, back pain

#### Risk factors
- Smoking
- Obesity
- Air pollution
- Industrial exposure: asbestos, chemicals, dyes, dusts
- Viral infection: hepatitis viruses, human immunodeficiency virus, HPV, Epstein–Barr virus
- Lack of engagement with screening: breast, cervix, bowel

#### Common chemotherapy related side-effects
- Nausea and vomiting
- Oral mucositis
- Anorexia/loss of appetite
- Diarrhoea
- Peripheral neuropathy
- Fever: if present, always consider neutropenic sepsis, which is a medical emergency
Box 6.3 Implications of a cancer diagnosis for the patient

- When was the patient diagnosed?
- What do they understand about the condition?
- Have they been offered surgery, chemotherapy, radiotherapy or other forms of treatment?
- What do they understand about the aims of the treatment – cure or palliation?
- What do they understand about the likely outcomes of their disease?
- How do they feel about further courses of treatment?
- Who is supporting them through their disease, and what other sources of support (social networks, religious faith etc.) do they have?
- Do they have late effects from their curative treatment?
INTRODUCTION

Cancer is on the rise globally, driven by a range of factors including obesity, urbanization, air pollution, tobacco smoking and increasing life expectancy in the developing world. The Global Cancer Observatory predicts that the worldwide incidence of cancer will rise by 62% between 2018 and 2040. In England, the number of new cases of cancer continues to increase, with over 300,000 new cancers registered in 2016, equivalent to 828 new cases a day. Of these, over 50% were accounted for by breast (15.3%), prostate (13.4%), lung (12.7%) and colorectal (11.5%) malignancies, although globally there is significant variation in the pattern of malignant disease, reflecting differences in environmental risk factors. The global burden of different types of cancer is shown in Fig. 6.1. Cancer is a disease of older people, with those over 65 years accounting for 65.3% of total registered cancers.

Data from the UK suggests that whilst most patients with cancer are diagnosed after presenting to primary care with symptoms of malignancy, around a quarter are diagnosed in the context of an emergency presentation requiring hospital attendance or admission. Patients diagnosed in an emergency situation tend to have a worse outcome, as the cancer is more aggressive or is more advanced at presentation.

An appreciation of the genetic and biological basis of cancer is crucial in understanding how the disease progresses and how different modalities of treatment work.

THE BIOLOGY OF CANCER

Most human neoplasms are clonal in origin: that is, they arise from a single population of precursor or cancer stem cells. This process is typically initiated by genetic aberrations within this precursor cell that may be inherited (germline) or acquired (somatic). Cancer becomes increasingly common with increasing age, and can be related to a time-dependent accumulation of DNA damage that is not repaired by the normal mechanisms of genome maintenance, damage tolerance and by checkpoint pathways. The hallmark areas of loss or gain in function in developing cancer are shown in Fig. 6.2.
Whole-genome sequencing experiments are now identifying significant clonal genetic heterogeneity within tumours, including ‘passenger’ (inactive) and ‘driver’ (active) mutations. This heterogeneity is a potential source of treatment-resistant clones and is temporally variable, so that, at relapse, the predominant founder clone that has not been eradicated is seen to have acquired new mutations on its return; alternatively, a subclone, selected out by treatment pressure, has gained further mutations and led to a recurrence. A fuller description of the genetic basis of cancer is found in Chapter 2.

**Evading growth suppression**

Tumour cells are usually not recognized and killed by the immune system, for two main reasons:

- There is a failure to express molecules such as human leucocyte antigen (HLA) and co-stimulatory B7 molecules that are required for activation of cytotoxic, or ‘killer’, T lymphocytes.
- Tumours may also actively secrete immunosuppressive cytokines and cause a generalized immunosuppression.

Successful strategies for tumour vaccines that overcome these obstacles are developing in renal cancer and prostate cancer. The monoclonal antibody (MAb) ipilimumab, which works against the inhibitory cytotoxic T lymphocyte-associated antigen 4 (CTLA4) molecule expressed after T-cell activation, is used in melanoma (see p. 113). There is increasing interest in the programmed death pathway (PD/PD-ligand), a checkpoint inhibitor (see p. 50) that negatively affects the immune response. Blocking of either PD-1 (on T cells) or its ligand, PDL-1, which is present in some tumours, has recently been associated with an immune response capable of producing tumour shrinkages that may be durable. Common tumours, such as squamous lung cancer and transitional cell carcinomas, have responded, as have those tumours expected to be susceptible to immunological therapies (melanoma and renal cancer).

**Inducing angiogenesis**

There is a progressive slowing of the rate of growth as many tumours become larger. This occurs for many reasons but outgrowing the blood supply to the tumour is a crucial factor. New vessel formation (angiogenesis) is stimulated by a variety of peptides produced both by tumour cells and by host inflammatory cells, such as basic fibroblast growth factor (bFGF), angiopoietin 2 and vascular endothelial growth factors (VEGFs), which are stimulated by hypoxia. The anti-VEGF-receptor MAb, bevacizumab, has had some success in the treatment of colorectal and ovarian cancer. Alternatively, small molecules that target post-receptor response (tyrosine kinase inhibitors, TKIs) may be used; examples include sunitinib and pazopanib.

**Invasion and metastasis**

Solid cancers spread by both local invasion and distant metastasis (Fig. 6.3), through the vessels of the blood and lymphatic systems. Infiltration into surrounding tissues is associated with loss
of cell–cell cohesion, which is mediated by active homotypic cell adhesion molecules (CAMs). Epithelial cadherin (E-cadherin) is expressed by many carcinomas and mutated in some, such as familial gastric carcinoma (see p. 1178).

Invasion is also determined by the balance of activators and inhibitors of proteolysis. The matrix metalloproteinases (MMPs) and their tissue inhibitors (TIMPs) are involved in tumour growth, invasion, metastasis and angiogenesis, and are being targeted by new therapeutic drugs for cancer treatment.

Dissemination of tumour cells occurs through intravasation into the vascular and lymphatic vessels and dissemination to distant sites, partly by chance, but also because of specific interactions between receptors and cytokines found on stromal and tumour cells, such as tumour necrosis factor (TNF), interleukin 6 (IL-6) and chemokines.

**Further reading**

**AETIOLOGY AND EPIDEMIOLOGY**

In most patients the cause of cancer is unknown, probably representing a multifactorial interaction between individual genetic predispositions and environmental factors.

**Aetiology**

**Genetic factors**

These are outlined on pages 37–8.

**Environmental factors**

A wide range of environmental factors has been identified as being associated with the development of malignancy (Box 6.4) and may be amenable to preventative action, such as smoking cessation, dietary modification and antiviral immunization (Box 5.5). Environmental factors interact with genetic predisposition. For example, subsequent generations of people moving from countries with a low incidence of breast or colon cancer to those with a high incidence acquire the cancer incidence of the country to which they have moved, while Northern Europeans exposed to strong ultraviolet radiation have the highest risk of developing melanoma.

**Tobacco**

Since the mid-1990s the incidence of lung cancer, in both men and women, has increased dramatically worldwide but is falling in many high-income countries. The association of smoking with lung cancer is indisputable and causative mechanisms have been identified; cigarette tobacco is responsible for one-third of all deaths from cancer in the UK. Smoking not only causes lung cancer, but also is associated with cancer of the mouth, larynx, oesophagus and bladder. Smoking is discussed on page 963.

**Alcohol**

Alcohol is associated with cancers of the upper respiratory and gastrointestinal tracts, and also interacts with tobacco in the aetiology of these tumours. It may be associated with an increased risk of breast cancer.
Box 6.5 Key messages for a healthy lifestyle and the prevention of cancer

- Stop smoking
- Moderate alcohol consumption
- Maintain a healthy weight
- Take moderate exercise
- Eat healthily (fruit and vegetables, high fibre, low fat/salt/sugar)
- Limit sun exposure
- Minimize occupational risk
- Minimize radiation exposure
- Vaccinate against hepatitis B and human papillomavirus

Diet

One-third of cancer deaths have been attributed to dietary factors, although it is often difficult to differentiate these from other epidemiological causes. For example, the incidence of stomach cancer is particularly high in the Far East, while breast and colon cancers are more common in Western, high income countries. Many associations have been observed, without a causative link being identified, between the incidence of cancer and the consumption of dietary fibre, red meat, saturated fats, salted fish, vitamin E, vitamin A and many others. Food and its role in the causation of gastrointestinal cancer are discussed on in Chapter 33. Higher levels of obesity in the developed world have been linked with increases in cancers associated with oestrogenic stimulation of the breast and endometrium in women.

Ultraviolet light

Ultraviolet (UV) light is known to increase the risk of skin cancer (basal cell, squamous cell and melanoma). The incidence of melanoma is therefore particularly high in the white Anglo-Celtic population of Australia, New Zealand and South Africa, where exposure to UV light is combined with a genetically predisposed population.

Arsenic contamination

Arsenic contamination of water supplies has been linked to a high incidence of lung and colon cancers in South-east Asia, particularly where boreholes are the main water source.

Occupational factors

In 1775, Percival Pott described the association between carcinogenic hydrocarbons in soot and the development of scrotal epitheliomas in chimney sweeps. The principal causes nowadays are asbestos (lung and mesothelial cancer) and polycyclic hydrocarbons from fossil fuel combustion (skin, lung and bladder cancers). Organic chemicals, such as benzene, may cause the development of bone marrow conditions, such as myelodysplastic syndrome or acute myeloid leukaemia.

Infectious agents

The geographical distribution of some rare malignancies suggests that they might be caused by, or associated with, an infective agent. Chronic persistent infection provides growth stimulation, while many viruses contain transforming viral oncogenes.

T-cell leukaemia, seen almost exclusively in residents of the southern island of Japan and in the West Indies, is caused by infection with the locally endemic retrovirus human T-cell leukaemia (or lymphotropic) virus type 1 (HTLV-1) and integration of the oncogene, TAX, into the cellular genome.

Hepatocellular carcinoma occurs in patients with hepatitis B and C virus infections, and Burkitt’s lymphoma and nasopharyngeal carcinoma are associated with the Epstein–Barr virus (EBV). EBV is also linked with Hodgkin lymphoma (see p. 399).

Patients with human immunodeficiency (HIV) infection or immunosuppression from organ transplantation have an increased incidence of EBV-related lymphoma and herpesvirus-8-associated Kaposi’s sarcoma.

Human papillomavirus (HPV) infection types 16 and 18, for which an effective vaccine is now available, is an established cause of the rise in cervical cancer among sexually active women; more recently, it has also been associated with an increase in head and neck cancers. Bacterial infection with Helicobacter pylori predisposes to the development of gastric cancer and gastric lymphoma, while Schistosoma japonicum infection predisposes to the development of squamous cell carcinomas in the bladder.

Medication

Oestrogens have been implicated in the development of vaginal, endometrial and breast carcinoma. Certain cytotoxic drugs, such as those given for Hodgkin lymphoma (see p. 401), are themselves associated with an increased incidence of secondary acute myeloid leukaemia, and bladder and lung cancer. Androgens have been linked with both benign and malignant liver tumours.

Radiation

Accidental

The nuclear disasters of Hiroshima, Nagasaki and Chernobyl led to an increased incidence of leukaemia after 5–10 years in the exposed population, as well as greater incidences of thyroid and breast cancer. Radiation workers are at a higher risk of malignancy due to occupational exposure, unless precautions are taken to minimize the danger by using personal and environmental shielding, and to record and limit the amount of personal exposure.

Therapeutic

Long-term survivors who have been treated with radiotherapy, such as those with Hodgkin lymphoma, for which patients were historically treated with wide radiation fields, have an increased incidence of cancer, particularly at the radiation field margins. These patients should have regular surveillance follow-up: for example, for the early identification of breast malignancy in the Hodgkin cohort of patients.

Diagnostic

Imaging procedures involving radiation exposure are associated with an increased risk of cancer. This risk is cumulative, dose-dependent and time-dependent, and so children are at higher risk than adults. The cancer risk of various common investigations is shown in Box 6.6. All doctors should strive to minimize diagnostic exposure to radiation.

Malignant disease

where possible by using alternative modalities such as ultrasound or magnetic resonance imaging (MRI). Good documentation of radiation doses is required, particularly in children and pregnant women.

Epidemiology

The incidence and mortality from cancer vary by tumour type and geographical region across the world.

Geographical distribution

The incidence of cancer across the world is dependent on local environmental factors, diet and the genetics of the population (see earlier) (Figs 6.4 and 6.5). Age is also a factor, as most cancers occur in those over the age of 65, who comprise 3.3% of the population in Africa, compared with 15.2% in Europe. Reproductive patterns influence the incidence of breast cancer. Migrating individuals often take on the risks associated with local environmental factors.

Other factors

Incidence and mortality are closely linked for those cancers for which treatment has yet to make significant improvements, such as lung, stomach and liver. However, in countries with effective screening programmes, there is an increasing incidence, but decreasing mortality, for breast, cervix, bowel and prostate cancers.

Further reading

SCREENING AND INVESTIGATIONS

Asymptomatic detection through screening

Most common cancers start as focal microscopic clones of transformed cells, and diagnosis becomes likely only once sufficient tumour bulk has accumulated to cause symptoms or signs. In order to try to make an earlier diagnosis and enhance the curative possibilities, an increasing number of screening programmes are being developed that either target the asymptomatic or pre-invasive stages of the cancer, as in cervix, breast and colon, or use serum tumour markers, as in prostate and ovarian cancers. Genetic screening can be used to target screening to those groups at most risk of developing cancer, such as BRCA1-positive individuals who may develop breast cancer (Box 6.7).

The aim of screening programmes is to improve individual and/or population survival by detecting cancer in its very early stages, when the patient is asymptomatic. This strategy is dependent on finding tests that are sufficiently sensitive and specific, using detection methods that identify cancer before it has spread, and having curative treatments that are practical and consistent with maintenance of a normal lifestyle and quality of life.

In the UK, population screening is provided for breast, cervical and colon cancer and also to individuals via annual check-ups; alternatively, it may be opportunistic, when patients see their doctor for other reasons.

Unfortunately, earlier diagnosis does not necessarily mean longer survival and randomized trials are necessary to prove benefit. With lead-time bias, the patient is merely treated at an earlier date and hence the survival appears longer; death still occurs at the same time from the point of genesis of the cancer (Fig. 6.6). With length-time bias, a greater number of slowly growing tumours are detected when asymptomatic individuals are screened, leading to a false impression of an improvement in survival.

The characteristics of effective screening programmes are shown in Box 6.8.

Cervical cancer

The cervical cancer screening test (smear test) is cheap and safe but requires a well-trained cytologist to identify the early changes (dyskaryosis and cervical intraepithelial neoplasia, CIN). However, developments in liquid cytology and co-testing for HPV DNA may overcome this. Effective treatment for high-risk, pre-invasive,

Box 6.8 Characteristics of an effective screening programme

- It must be affordable for the healthcare system
- It must be acceptable to all social groups so that they attend for screening
- It must have a good discriminatory index between benign and malignant lesions
- It must show a reduction in mortality from the cancer

women, with 50–75% of individuals attending for screening when sufficiently educated about the benefits. In North America, there is continuing debate about whether annual mammography from a younger age is more effective.

The cost is estimated to be between £250 000 and £1.3 million per life saved; money which, according to critics, could be used more appropriately for better treatment.

Women from families with BRCA1, BRCA2 and p53 mutations require intensive screening starting at an earlier age, when mammography is inaccurate due to greater breast density and MRI scanning is preferred.

Colorectal cancer

**Faecal occult blood** is a cheap test for the detection of colorectal cancer. Large randomized studies have shown a reduction in cancer-related mortality of 15–33%. However, the false-positive rates are high, meaning many unnecessary colonoscopies (see p. 1219). The UK has introduced a national screening programme using faecal occult blood in patients aged 60–64 years, in which positive tests have identified that 10% have cancer and 40% have adenomas. A randomized trial in Norway has found an increased number of early-stage cancers in the screened population but a high incidence of interval cancers, arising between biennial screens. Patients with an increased risk of developing bowel cancer (those with a family history of familial adenomatous polyposis or Lynch’s syndrome (hereditary non-polyposis colorectal cancer)) will have a more intensive screening programmed, starting at an earlier age.

Colonoscopy is the ‘gold standard’ technique for examination of the colon and rectum and is the investigation of choice for high-risk patients. Universal screening strategies have been recommended in the USA, but the shortage of skilled endoscopists, the expense, the need for full bowel preparation and the small risk of perforation make colonoscopy impractical as a population screening tool at present; CT colonography (‘virtual colonoscopy’) (see Fig. 32.8B) may become an alternative, along with genetic testing and stool DNA tests.

Prostate cancer

Screening for prostate cancer using serum prostate specific antigen (PSA) is discussed on page 294 and page 1480.

Epithelial ovarian cancer

Serum CA125 can be used for the early detection of this cancer and is the subject of on-going trials. An improvement in survival of a screened population can be shown but at the cost of many unnecessary laparotomies, so that further enhancements are being investigated by serial testing and in combination with transvaginal ultrasound scans.

The symptomatic patient with cancer

Patients may offer information about predisposing conditions and family history that alerts the clinician to the likelihood of a cancer diagnosis. Many present with a history of tumour site-specific symptoms, such as

---

**Fig. 6.6 Lead-time bias.** Earlier diagnosis, at X, made by screening tests before the clinical diagnosis, at Y, suggests an increased survival time of a+b. The actual survival time (c) remains unchanged.

Malignant changes reduces the incidence and mortality from cervical cancer, although there are no randomized trials. Screening will continue to be required, despite the introduction of vaccination against HPV infection for women before they become sexually active, because the lag time between infection and the appearance of disease can be in the order of 40–50 years. In the UK, women are offered screening every 3 years from the age of 25 to 64.

Breast cancer

The UK National Health Service Breast Screening Programme (involving biplanar mammography every 3 years for women aged 50–70 years) has been shown to reduce mortality from breast cancer in randomized controlled studies. The test is acceptable to most

pain, and physical signs, such as a mass, which readily identify the primary site of the cancer (Box 6.9). Cancer symptoms typically increase with time and do not respond to measures such as antibiotics. However, some patients seek medical attention only when more systemic and non-specific symptoms occur, such as weight loss, night sweats, fever, fatigue, recurrent infections and anorexia. These usually indicate a more advanced stage of disease, except in some paraneoplastic and ectopic endocrine syndromes. Other patients are diagnosed only on discovery of established metastases, such as the abdominal distension of ovarian cancer, the back pain of metastatic prostatic cancer, or the liver enlargement of metastatic gastrointestinal cancer.

Paraneoplastic syndromes are indirect effects of cancer (Box 6.10 and Fig. 6.7) that are often associated with specific types of cancer and may be reversible with treatment of the cancer. The effects and mechanisms can be very variable. For example, in the Lambert–Eaton syndrome (see p. 895), there is cross-reactivity between tumour antigens and the normal tissue acetylcholine receptors at neuromuscular junctions.

The coagulopathy of cancer may present with thrombophlebitis, deep venous thrombosis and pulmonary embolii, particularly in association with cancers of pancreas, stomach and breast. Some 18% of patients with recurrent pulmonary emboli will be found to have an underlying cancer and many cancer patients are at increased risk of venous thromboembolism (VTE) following diagnosis. Trousseau’s syndrome – superficial thrombophlebitis migrans – refers to this process in the superficial venous system. All patients with active cancer admitted to hospital are at high risk of VTE and should be given prophylaxis with, for example, subcutaneous low-molecular-weight heparin in the absence of any contraindications (see p. 1014).

Other symptoms are related to peptide or hormone release, such as in carcinoid or Cushing’s syndrome.

Cachexia of advanced cancer is thought to be due to release of chemokines such as TNF, as well as the fact that patients lose their appetite. The unexplained loss of more than 10% of a patient’s body weight should always stimulate a search for an explanation.

Cancer-associated immunosuppression can lead to reactivation of latent infections such as herpes zoster (Fig. 6.8) and tuberculosis.

Serum tumour markers

Tumour markers are intracellular proteins or cell surface glycoproteins released into the circulation and detected by immunoassays. Examples are given in Box 6.11. Values in the normal range do not necessarily equate with the absence of disease and a positive result must be corroborated by histology, as these markers can be seen in many benign conditions. They are most useful in the serial monitoring of response to treatment. MicroRNA may be more tumour-specific and offer the possibility of increased sensitivity compared to classical tumour markers.

Cancer imaging

Radiological investigation by experts is required at various stages: at initial diagnosis and staging of the disease, during the monitoring of treatment efficacy, at the detection of recurrence, and for the diagnosis and treatment of complications.

The choice of investigations should be guided by the patient’s symptoms and signs, the site and histology of the cancer, the curative or palliative potential of treatment, and the utility of the information in guiding treatment. Specific investigations are described under each tumour type in the relevant chapter of this book.

Contrast agents are used for increased structural discrimination in cross-sectional imaging and can be further enhanced with functional specificity for metabolically active tissue with 18F-FDG-PET–CT scan, as used extensively in head and neck cancer, lung cancer and lymphoma. Radionuclide imaging of sentinel lymph nodes is used to guide lymphatic surgery in breast cancer and melanoma. Tumour-targeted contrast agents can improve detection rates; examples include the radiolabelled MAb rituximab for lymphoma, or radiolabelled small molecules such as ocreotide for neuroendocrine tumours. Research into the use of reporter agents that become visible only on activation within the tumour environment holds the promise of greater sensitivity and specificity in the future.

Biopsy and histological examination

A diagnosis of cancer may be suspected by both patient and doctor, but advice about treatment can usually be given only on the basis of a tissue diagnosis. This may be obtained by endoscopic,
Screening and investigations

radiologically guided or surgical biopsy, or by cytology (e.g. lung cancer may be diagnosed by sputum cytology). Malignant lesions can be distinguished morphologically from benign ones by the pleomorphic nature of the cells, increased numbers of mitoses, nuclear abnormalities of size, chromatin pattern and nucleolar organization, and evidence of invasion into surrounding tissues, lymphatics or vessels. The degree of differentiation of the tumour has prognostic significance: generally speaking, well-differentiated tumours have a better prognosis than poorly differentiated or anaplastic ones. In some tumours, diagnosis and treatment may be combined within a single surgical procedure, with the exact nature of the procedure being carried out varying depending on the presence of malignancy. An intraoperative provisional histological opinion can be rapidly obtained with a tissue sample processed using ‘frozen section’ techniques, rather than having the sample paraffin embedded, which takes more than a day.

Immunocytochemistry, using MAbs against tumour antigens, is very helpful in differentiating between lymphoid and epithelial tumours, and between some subsets of these (see Box 6.18). However, there is much overlap in the expression of many of these tissue tumour markers, and some adenocarcinomas and squamous carcinomas do not bear any distinctive immunohistochemical markers that are diagnostic of their primary site of origin.

Molecular markers of genetic abnormalities have long been available in the haematological cancers and are increasingly available in solid cancers. For example, fluorescence in situ hybridization (FISH; see p. 27) can be used to look for characteristic chromosomal translocations, as in lymphoma and leukaemia, as well as deletions or amplifications, as in breast cancer (see p. 38). The development of the new targeted MAbs and TKIs has been guided by increasing use of mutation analysis of common oncogenes, such as RAS and RAF in colon cancer and melanoma. Tissue microarrays can identify patterns of multiple genomic alterations and single nucleotide polymorphisms (SNPs), as in breast cancer and lymphoma (see p. 27), and RNA assays with reverse transcriptase polymerase chain reaction (RT-PCR) can be used to identify tissue of origin with prognostic and predictive relevance.

**Genomics and proteomics** are being investigated in order to target new (and expensive) therapies, such as imatinib in chronic myeloid leukaemia and gastrointestinal stromal tumours (GIST);

PRINCIPLES OF CANCER TREATMENT

Aims of treatment

Optimal cancer treatment is delivered by a multidisciplinary team that coordinates the delivery of the appropriate anticancer treatment, supportive and symptomatic care, and psychosocial support.

Establishment of agreed patient pathways has enabled more effective and timely delivery of care and post-treatment rehabilitation. Central to this endeavour is the involvement of the patient, through education as to the nature of their disease and the treatment options available.

A curative approach

For most solid tumours, local control is necessary, but not sufficient, for cure, because of the presence of systemic (microscopic) disease; while haematological cancers are usually disseminated from the outset. Improvement in the rate of cure of most cancers is thus dependent on earlier detection to increase the success of local treatment and effective systemic response. The likelihood of cure of the systemic disease rests on the type of cancer and its expression of appropriate treatment targets, its drug sensitivity and tumour bulk (microscopic or clinically detectable). A few rare cancers are so chemosensitive that even bulky metastases can be cured: for example, leukaemia, lymphoma, gonadal germ cell tumours and choriocarcinoma. For most common solid tumours, such as lung, breast and colorectal cancer, there is no current cure of bulky (clinically detectable) metastases, but micrometastatic disease treated by adjuvant systemic therapy (see below) after surgery can be cured in 10–20% of patients.

Adjuvant therapy for solid tumours

Micrometastatic spread by lymphatic or haematological dissemination often occurs early in the development of the primary tumour and can be demonstrated by molecular biological methods capable of detecting the small numbers (1 in 10⁹) of circulating cells. Studies correlating prognosis with histological features of the primary cancer, such as differentiation, invasion of blood vessels or regional
lymph nodes, and molecular markers like human epidermal growth factor receptor 2 (HER2) in breast cancer, enable risk stratification and increasing individualization of therapy.

- **Adjuvant therapy** is defined as treatment given, in the absence of macroscopic evidence of metastases, to patients at risk of recurrence from micrometastases, following treatment given for the primary lesion.

- **‘Neoadjuvant’ therapy**, alternatively, is given before primary surgery, both to shrink the tumour in order to improve local excision, and to treat any micrometastases as soon as possible.

The success of adjuvant treatment across many tumour types relies on careful selection of patients according to defined risk criteria, and reduction of treatment toxicity to reach a balanced risk/benefit ratio. However, the majority who receive such treatment do not benefit, either because they were already cured or because the cancer is resistant to the treatment. Better tests, such as gene arrays and circulating tumour cells, are being developed to identify those with micrometastases, who really do benefit from treatment.

### A palliative approach

When cure is no longer possible, palliation – that is, relief of tumour symptoms, preservation of quality of life and prolongation of life – is possible in many cancers in proportion to their drug and radiation sensitivity. There is, on average, a 2–18-month prolongation in median life expectancy with treatments for solid tumours (see specific tumour types for details); those individuals with the most responsive tumours experiencing the greatest benefit. In addition, through early assessment during treatment, it is possible to stop if no evidence of benefit is demonstrable early on, so as to minimize exposure to toxic and unsuccessful treatment.

### Assessment before treatment

#### Staging

Before a decision about treatment can be made, not only does the type of tumour need to be established, but also its extent and distribution (see Box 6.2). Various ‘staging investigations’ are therefore performed before a treatment decision is made. To be useful clinically, the staging system must subdivide the patients into groups with different prognoses, which can guide treatment selection. The TNM (tumour, node, metastases) classification (Box 6.12) can be adapted for application to most common cancers.

#### Performance status

In addition to anatomical staging, the person’s age and general state of health need to be taken into account when planning treatment. The latter has been called ‘performance status’ and is of great prognostic significance for all tumour types (Box 6.13). Performance status reflects the effects of the cancer on the patient’s functional capacity. An alternative performance rating scale is provided by Karnofsky. With a performance status of 2 or more, response to, and survival following, treatment are greatly reduced for most tumour types.

### Assessment of the benefits of treatment

A measurable response to treatment can serve as a useful early surrogate marker when deciding whether to continue a given treatment for an individual patient. Trials to assess response to treatment in advanced disease have identified active agents for use in the more curative setting of adjuvant treatment of early-stage disease.

Response to treatment can be subjective or objective.

- **A subjective response** is one perceived by the patient in terms of, for example, relief of pain and dyspnoea, or improvement in appetite, weight gain or energy. Such a subjective response is a major aim of most palliative treatments. Quantitative measurements of these subjective symptoms (patient-reported outcome measures, PROMs) form a part of the assessment of response to chemotherapy, especially in those situations where cure is not possible and where the aim of treatment is to provide prolongation of good-quality life. In these circumstances, measures of quality of life enable an estimate of the balance of benefit and side-effects to be made.

- **An objective response** to treatment is assessed clinically and radiologically (Fig. 6.9). The term ‘remission’ is often used synonymously with ‘response’, which, if complete, means an absence of detectable disease without necessarily implying a cure of the cancer. The terms used to evaluate the responses of tumours are...
Complete response
- Disappearance of all target lesions

Partial response
- $\geq 30\%$ decrease in the baseline sum of the longest diameters of all target lesions

Progression
- $\geq 20\%$ increase in the sum of the longest diameters of all target lesions compared with the smallest recorded sum since treatment started, or the appearance of any new lesions

Stable disease
- All values between partial response and progressive disease

Target lesions
- Measurable lesions up to 5 per organ and 10 in total, selected on size and replicable measurement

Non-target lesions
- Non-measurable lesions recorded as present or absent at baseline and on follow-up

Measurable
- Lesions with the longest diameter in one dimension of $\geq 2.0\, \text{cm}$ or $\geq 1.0\, \text{cm}$ if assessed by spiral CT scan

Non-measurable
- e.g. Bone lesions, meningeal disease, ascites, pleural effusion, inflammatory breast cancer, lymphangitis cutis and pulmonis, cystic lesions

**Box 6.14 RECIST criteria for assessing response to treatment in solid tumours**

**Reciprocal dose–response relationship.**

**Further reading**

**Principles of chemotherapy**

Cytotoxic chemotherapy employs systemically administered drugs that directly damage cellular DNA (and RNA). It kills cells by promoting apoptosis and, sometimes, frank necrosis. Different cytotoxic drugs work at different stages in the cell cycle (Fig. 6.10; see also Fig. 2.10).

There is a narrow therapeutic window between doses necessary for effective treatment of the cancer and those that cause normal tissue toxicity, because cytotoxic drugs are not cancer-specific (unlike some of the targeted biological agents) and the increased proliferation in cancers is often not much greater than in normal tissues. The dose and schedule of the chemotherapy are limited by normal tissue tolerance, especially in those more proliferative tissues of the bone marrow and gastrointestinal tract mucosa. All tissues can be affected, however, depending on the pharmacokinetics of the drug and its affinity for particular tissues (e.g. heavy metal compounds for kidneys and nerves).

The therapeutic effect on the cancer is achieved by a variety of mechanisms that seek to exploit differences between normal and transformed cells. While most drugs in the past (such as alkylating agents) have been derived by empirical testing of many different compounds, new molecular biology is leading to targeted approaches to particular genetic defects in the cancer (see p. 113).

Toxicity to normal tissue can be limited in some instances by supplying growth factors such as granulocyte colony-stimulating factor (G-CSF) or by infusing stem cell preparations to diminish bone marrow toxicity. The use of more specific targeted biological agents with relatively weak pro-apoptotic effects, in combination with general cytotoxics, has also improved the therapeutic ratio (e.g. trastuzumab and breast cancer; see p. 122). Cytotoxic therapies may also be administered into the pleural space, peritoneum or cerebrospinal fluid (CSF), or into the arterial supply of a tumour.

Most tumours rapidly develop resistance to single agents given on their own, through changes in membrane transport and DNA repair pathways. For this reason, the principle of intermittent combination chemotherapy was developed. Several drugs are combined, chosen on the basis of differing mechanisms of action and non-overlapping toxicities. These drugs are given over a period of a few days, followed by a rest of a few weeks, during which time the normal tissues have the opportunity for regrowth. If the normal tissues are more proficient at DNA repair than the cancer cells, it may be possible to deplete the tumour while allowing the restoration of normal tissues between chemotherapy cycles (Fig. 6.11).

In many experimental tumours, it has been shown that there is a log-linear relationship between drug dose and number of cancer cells killed, and that the maximum effective dose is very close to the maximum tolerated dose at which dose-limiting toxicity is reached. With a chemosensitive tumour, relatively small increases in dose may have a large effect on tumour cell kill. It is therefore apparent that, where cure is a realistic option, the dose administered is critical and may need to be maintained despite toxicity. In situations where cure is not a realistic possibility and palliation is the aim, a sufficient dose to exceed the
therapeutic threshold, but not cause undue toxicity, is required, as the short-term quality of life becomes a major consideration.

Classification of cytotoxic drugs
See Box 6.15.

**DNA-damaging drugs**

**Alkylating agents**
These act by covalently binding alkyl groups. Their major effect is to cross-link DNA strands, interfering with DNA synthesis and causing strand breaks. Examples include bendamustine and cyclophosphamide.

**Platinum compounds**
Cisplatin, carboplatin and oxaliplatin cause interstrand cross-links of DNA and are often regarded as non-classical alkylating agents. They have transformed the treatment of testicular cancer (cisplatin) and play a major role against many other tumours.

**Antimetabolites**
Antimetabolites are usually structural analogues of naturally occurring metabolites that interfere with normal synthesis of nucleic acids by falsely substituting purines and pyrimidines in metabolic pathways.

**Folic acid antagonists**
This class includes methotrexate, which is structurally very similar to folic acid and binds preferentially to dihydrofolate reductase, the enzyme responsible for the conversion of folic acid to folinic acid. It is used widely in the treatment of solid tumours and haematological malignancies. Folinic acid is often given to ‘rescue’ normal tissues from the effects of high doses of methotrexate. A related drug, pemetrexed, targets the enzyme thymidylate synthase, as well as glycaminide ribonucleotide formyltransferase (GARFT).

**Pyrimidine antagonists**
5-Fluorouracil (5-FU) consists of a uracil molecule with a substituted fluorine atom. It acts by blocking thymidylate synthase, which is essential for pyrimidine synthesis. Oral capecitabine is metabolized to 5-FU, as is tegafur with uracil.
**DNA-damaging agents**
- Free radicals:
  - Alkylators, e.g. cyclophosphamide, melphalan, chlorambucil, ifosfamide
  - Nitrosoureas, e.g. carmustine (BCNU), lomustine (CCNU), busulfan
  - Tetrazines, e.g. dacarbazine, temozolomide
- DNA cross-linking – platinum, e.g. cisplatin, carboplatin, oxaliplatin

**Antimetabolites**
- Pyrimidine synthesis, e.g. 5-fluorouracil, capecitabine, cytarabine, fludarabine, gemcitabine, cladribine, clofarabine, nelarabine, azacitidine
- Purine synthesis, e.g. mercaptopurine, thioguanine
- Antifolates, e.g. methotrexate, pemetrexed

**DNA repair inhibitors**
- Topoisomerase-I inhibitors, e.g. irinotecan
- Topoisomerase-II inhibitors, e.g. etoposide
- Anthracyclines, e.g. daunorubicin, doxorubicin, epirubicin

**Antitubulin agents**
- Tubulin-binding – alkaloids, e.g. vincristine, vinorelbine
- Taxanes, e.g. paclitaxel, docetaxel
- Eribulin, epothilones

**Others**
- Bleomycin, mitomycin

---

**Box 6.15 Chemotherapy: some cytotoxic drugs**

**Arabinosides**
Arabinosides inhibit DNA synthesis by inhibiting DNA polymerase. Cytarabine is used almost exclusively in the treatment of acute myeloid leukaemia, where it remains the backbone of therapy.

**Purine antagonists**
This class includes 6-mercaptopurine and 6-thioguanine, which are both used almost exclusively in the treatment of acute leukaemia.

**DNA repair inhibitors**

**Epipodophyllotoxins**
These are semisynthetic derivatives of podophyllotoxin, which inhibit the topoisomerase enzymes that allow unwinding and uncoiling of supercoiled DNA, and maintain DNA strand breaks.

**Cytotoxic antibiotics**
The anthracyclines act by intercalating adjoining nucleotide pairs on the same strand of DNA and by inhibiting topoisomerase-II DNA repair. They have a wide spectrum of activity in haematological and solid tumours.

**Antitubulin agents**

**Vincra alkaloids**
 Drugs such as vincristine, vinblastine and vinorelbine act by binding to tubulin and inhibiting microtubule formation during mitosis (see p. 23). They are associated with neurotoxicity due to their antimitotubule effect and must never be given intrathecally, as this is lethal.

**Taxanes**
Paclitaxel and docetaxel bind to tubulin dimers and prevent their assembly into microtubules.

---

**Box 6.16 Side-effects of chemotherapy**

**Common**
- Nausea and vomiting
- Hair loss
- Myelosuppression
- Mucositis
- Fatigue

**Drug-specific**
- Cardiotoxicity, e.g. anthracyclines
- Progressive pulmonary fibrosis, e.g. bleomycin, busulfan
- Neurotoxicity, e.g. cisplatin, vinca alkaloids, taxanes

**Side-effects of chemotherapy**

Chemotherapy carries many potentially serious side-effects and should be used only by trained practitioners; however, an appreciation of its common potential side-effects is necessary for any general physician who is called to see a cancer patient on chemotherapy. The five most common side-effects are vomiting, hair loss, tiredness, myelosuppression and mucositis (Box 6.16). Side-effects are much more directly dose-related than anticancer effects and it has been the practice to give drugs at doses close to their maximum tolerated dose, although this is not always necessary to achieve their maximum anticancer effect. Common combination chemotherapeutic regimens are shown in Box 6.17.

**Common side-effects**

**Extravasation of intravenous drugs**
Cytotoxic drugs should be given only by trained personnel. They cause severe local tissue necrosis if leakage occurs outside the vein. Stop the infusion immediately and institute local measures: for example, aspirate as much of the drug as possible from the cannula, cause severe local tissue necrosis if leakage occurs outside the vein. Stop the infusion immediately and institute local measures: for example, aspirate as much of the drug as possible from the cannula, infiltrate the area with 0.9% saline and apply warm compresses. Antihistamines and corticosteroids may give symptomatic relief.

**Nausea and vomiting**
The severity of these common side-effects varies with the cytotoxicity and are particular problems with platinum analogues. They can be eliminated in 75% of patients by using modern antiemetics. A stepped policy, with antiemetics such as metoclopramide and domperidone, followed by 5-HT₃ (5-hydroxytryptamine, serotonin) antagonists (e.g. ondansetron, granisetron) combined with dexamethasone, should be used to match the emetogenic potential of the chemotherapy. Aprepitant, a neurokinin receptor antagonist, is helpful in preventing acute and delayed nausea and vomiting. It is
used with dexamethasone and a 5-HT₃ antagonist. Drugs such as cyclizine, olanzapine and levomepromazine, and benzodiazepines, can be used to control persistent nausea.

Effects on hair, skin and nails
Many, but not all, cytotoxic drugs are capable of causing hair loss. Scalp cooling can sometimes be used to reduce hair loss but, in general, this side-effect can be avoided only by selection of drugs, where this is possible. Hair regrows on completion of chemotherapy. Nails will demonstrate banding, reflecting periods of cessation of growth during each chemotherapy cycle (Fig. 6.12), and skin toxicity may be particularly pronounced with 5-FU, capecitabine and docetaxel (Fig. 6.13).

Fatigue
This is often significant and may continue beyond completion of therapy. Other problems, such as anaemia or depression, may exacerbate fatigue. Attention should be paid to nutrition, hydration, sleep hygiene, gentle exercise, task prioritization, pacing, realistic target setting and scheduling of rest within the day.

Bone marrow suppression and immunosuppression
Suppression of the production of red blood cells, white blood cells and platelets occurs with most cytotoxic drugs and is a dose-related phenomenon (Fig. 6.14). Severely myelosuppressive chemotherapy may be required if treatment is to be given with curative intent, despite the potential for rare but fatal infection or bleeding. Anaemia and thrombocytopenia are managed by red cell or platelet transfusions. (Neutropenic infection is discussed on p. 116.) The risk of infective problems can be ameliorated by the use of prophylactic antimicrobials, such as ciprofloxacin, or the use of G-CSF as primary prophylaxis in those chemotherapy regimens that carry a significant risk of febrile neutropenia or in those patients on less intensive therapies who are at higher risk due to age or co-morbidity.

Mucositis
This common side-effect of chemotherapy reflects the sensitivity of the mucosa to antimitotic agents. Mucositis causes severe pain in the oropharyngeal region and problems with swallowing and nutrition. It can be generalized throughout the intestinal tract and

can cause life-threatening diarrhoea. Treatment is with antiseptic and anti-candidal mouthwash; if mucositis is severe, fluid and antibiotic support is required, as the mucosa is a portal for entry of enteric organisms. Palifermin, a recombinant keratinocyte-derived growth factor, may ameliorate severe chemotherapy- and radiotherapy-induced mucositis.

Other toxicities

Cardiotoxicity

This is a rare side-effect of chemotherapy and is usually associated with anthracyclines such as doxorubicin; effects can present as an acute arrhythmia during administration or cardiac failure due to cardiomyopathy after chronic exposure (Fig. 6.15). This effect is dose-related and can largely be prevented by restricting the cumulative total dose of anthracyclines within the safe range (equivalent to 450 mg/m² body surface area cumulative doxorubicin dose). The risk of anthracycline cardiomyopathy is also dependent on other treatments, such as trastuzumab or radiotherapy, as well as other cardiac risk factors, such as hypertension, smoking and hypercholesterolaemia. Cardiotoxicity can also be reduced by using the analogue epirubicin or by reducing peak drug concentrations through delayed-release preparations, such as liposomal doxorubicin. 5-FU and its prodrug, capecitabine, can cause cardiac ischaemia.

Neurotoxicity

This occurs predominantly with the vinca alkaloids, taxanes and platinum analogues (but not carboplatin). It is dose-related and cumulative. Chemotherapy is usually stopped before the development of a significant polyneuropathy, which, once established, is only partially reversible. Vinca alkaloids, such as vincristine, must never be given intrathecally, as the neurological damage is progressive and fatal.

Nephrotoxicity

Cisplatin (but not oxaliplatin or carboplatin), methotrexate and ifosfamide can potentially cause renal damage. This can usually be prevented by maintaining an adequate diuresis during treatment to reduce drug concentration in the renal tubules, and by monitoring of renal function.

Sterility and premature menopause

Some anticancer drugs, particularly alkylating agents but also anthracyclines and docetaxel, may cause gonadal damage, resulting in sterility and, in women, the loss of ovarian oestrogen production, which may be irreversible.

In males, storage of sperm prior to chemotherapy should be offered to the patient when chemotherapy is given with curative intent. In females, collection of oocytes to be fertilized in vitro and cryopreserved as embryos for subsequent implantation is most successful; however, it is also possible to collect and freeze by vitrification of unstimulated oocytes. Cryopreservation of ovarian tissue and retrieval of viable oocytes for subsequent fertilization are still experimental. The recovery of gonadal function is dependent on the status before treatment; in women, this is mostly related to age since menarche, with those under 40 years having significantly more ovarian reserve.

Secondary malignancies

Anticancer drugs have mutagenic potential and the development of secondary malignancies, predominantly acute leukaemia, is an uncommon but particularly unwelcome long-term side-effect in patients otherwise cured of their primary malignancies. The alkylating agents, anthracyclines and epipodophyllotoxins are particularly implicated.

Principles of endocrine therapy

Oestrogens are capable of stimulating the growth of breast and endometrial cancers, and androgens can stimulate the growth of prostate cancer. Removal of these growth factors by manipulation of the hormonal environment may result in apoptosis and regression of the cancer. Endocrine therapy can be curative in a proportion of patients treated for micrometastatic disease in the adjuvant setting for breast and prostate cancer, and provides a minimally toxic, non-curative (palliative) treatment in advanced or metastatic disease. The presence of detectable cellular receptors for the hormone is strongly predictive of response. However, this is also modified by the many molecular interactions between the activation pathways of, for example, epidermal growth factor receptor (EGFR), the androgen receptor (AR (see p. 128)) and oestrogen receptor (ER) (see p. 122).

Principles of biological and targeted therapy

Immunotherapy

Certain antigens that are specific to cancer cells, such as sequences of tumour immunoglobulin from melanoma antigens, have been used as tumour vaccines, together with manipulation of the immune system to overcome tolerance. Engineered chimeric antigen receptors (CARs) that direct T cells to specific antigenic targets are emerging as a powerful potential tool in the treatment of a wide range of cancers.

Interferons

Interferons are naturally occurring cytokines that mediate the cellular immune response. Interferon-alpha (IFN-α) has been used to treat advanced melanoma and renal cell carcinoma.

Treatment with IFN has side-effects (see p. 1281): most commonly, influenza-like symptoms, which tend to diminish with time, and fatigue, which generally does not and can be treatment-limiting. IFN used to be given as a daily subcutaneous injection, but conjugation with polyethylene glycol (PEG interferon) has led to a reduction in frequency of injection and severity of side-effects.
**Interleukins**

Interleukin 2 (IL-2), a recombinant protein, is used to activate T-cell responses, often in conjunction with IFN-stimulated B-cell activation. Anti-tumour activity has been observed in renal cell carcinoma and melanoma, with responses in 10–20% of patients, occasionally for prolonged periods. Toxicity is common; acutely, this includes the capillary leak syndrome with hypotension and pulmonary oedema, while autoimmune thyroiditis and vitiligo occur later.

**Immune checkpoint inhibitors**

These new agents directly interfere with the relationship between T cells and antigen-presenting cells or tumour cells to overcome the common problems of immune tolerance and anergy. Ipilimumab is a MAb that blocks the CD152 (CTLA4) receptor responsible for downregulating T-cell responses, and is active in the treatment of melanoma. The inhibitors of the programmed death (PD-1) receptor or its ligands, PD-L1 and PD-L2, on activated T cells, further reactivates tumour-specific cytotoxic T cells, so that ipilimumab plus nivolumab (a PD-1 receptor blocker) doubled the response rate from 20% to 40% in metastatic melanoma. Many clinical trials are now examining these agents in the context of a variety of other cancers.

**Immunomodulatory drugs: thalidomide, lenalidomide, pomalidomide**

This family of immunomodulatory drugs (IMIDs) is increasingly being used in a range of malignancies, such as myeloma, chronic lymphocytic leukaemia and myelodysplastic syndrome, as well as some solid tumours. They have anti-angiogenic functions, as well as effects on cytokine production, tumour/stromal interactions and T-cell co-stimulatory functions. They are all considered teratogenic and should be avoided in women of reproductive potential, unless extra precaution is taken against conception. There is increasing evidence that IMIDs work through binding of the E3 ligase protein, cereblon, which acts to degrade two specific B-cell transcription factors, IKZF1 and IKZF3.

**Targeted therapies**

The fast-developing field of targeted therapies includes MAbs, receptor kinase inhibitors and small molecule receptor blockers. Expression of the targeted molecule is not sufficient of itself to indicate that use of the corresponding drug will be therapeutic because it is also necessary for the drug to be able to interrupt a growth-critical pathway in that cancer.

**Monoclonal antibodies**

Monoclonal antibodies (MAbs; Box 6.18) directed against tumour cell surface antigens are ‘humanized’ by being genetically engineered to have a range of functions, including:

- acting as a carrier molecule to target toxins or radioisotopes to the tumour cells, e.g. trastuzumab or trastuzumab emtansine for breast cancer
- acting as anti-growth factor agents added to chemotherapy by inhibiting dimerization of the extracellular receptor molecules.

Side-effects are those of hypersensitivity to the foreign protein and specific cross-reactivities: for example, trastuzumab for the myocardium, bevacizumab for the mucosa and renal tubule, and cetuximab for the skin follicles.

**Intracellular signal inhibitors**

Many cancer cells are transformed by the activity of the protein products of oncogenes that signal growth by phosphorylation of tyrosine residues on the intracellular portion of growth factor receptors. Small molecule inhibitors (Box 6.19) have many pharmacokinetic advantages over the MAb inhibitors. The first example was the TKI imatinib, which specifically inhibits the BCR-ABL fusion oncoprotein and c-Kit. This compound is an extremely effective treatment for chronic myeloid leukaemia and GIST, which are characterized by the presence of the c-Kit target. Lapatinib,
which inhibits HER2, has increased survival in breast cancer. The less specific TKIs, sunitinib and pazopanib, which inhibit signalling by EGFR and vascular endothelial growth factor receptor (VEGFR), have proved effective in metastatic renal cancer, while afatinib, erlotinib and gefitinib have shown activity in lung cancer. Vemurafenib is a kinase inhibitor and has a specificity for BRAF-V600, as used in malignant melanoma (see p. 691). Many other similar molecules are in pre-clinical or early clinical development, but heterogeneity within a single tumour occurs and genomic anomalies may not all be represented in a single biopsy specimen. Vandetanib, a combined VEGF and C-RET inhibitor, is useful in the treatment of medullary thyroid cancer.

Proteasome inhibitors

The proteasome degrades redundant or damaged proteins that have been labelled by a process called ubiquitination. Such proteins include cyclins and cyclin-dependent kinases, as well as factors in the nuclear factor kappa-B (NFkB) pathway. Inhibition of the proteasome leads to apoptosis in cancer cells and is synergistic with other treatments such as steroids and chemotherapy. Bortezomib is the first of such inhibitors to reach clinical practice and is used in myeloma, as well as some types of non-Hodgkin lymphoma. There are also recent additions to this class, including carfizomib and ixazomib.

Gene therapy

Antisense oligonucleotides are short sequences of DNA bases that specifically inhibit complementary sequences of either DNA or RNA. As a result, they can be generated against genetic sequences, which are specific for tumour cells. Their clinical development has been hampered by poor uptake by tumour cells and rapid degradation by natural endonucleases. However, one antisense sequence directed against the Bcl-2 oncogene has been shown to have an anti-tumour effect in patients with non-Hodgkin lymphoma. Viral vectors for the transfection of tumour cells in vivo are being tested as a way of delivering specific replacement gene therapy in head and neck cancers.

Further reading

Principles of radiation therapy

Radiation is an important modality for the treatment of cancer and can be used with radical, adjuvant or palliative intent. More than 50% of patients with a cancer diagnosis are treated with radiotherapy. In order to justify radiotherapy treatment, it is important to have histological confirmation of cancer and to perform relevant imaging. All treatment options should be discussed with the patient; they should be aware of treatment intentions and side-effects, and must consent to treatment.

Radical radiotherapy aims to deliver a tumoricidal treatment dose to a well-defined target volume with curative intent, sparing the surrounding normal tissues as much as possible. It is usually given as a fractionated course over a number of weeks, with patients receiving daily treatment. Carcinoma of the cervix, for example, can be cured with 5.5 weeks of daily radiotherapy delivered Monday to Friday with concurrent cisplatin chemotherapy.

Adjuvant radiotherapy is used to reduce the risk of tumour recurrence after primary surgery. The aim of treatment is to eradicate occult micrometastatic disease that cannot be demonstrated on imaging, as occurs in a significant percentage of patients. In breast cancer, for example, a patient may have radiotherapy after wide local excision surgery, and this reduces the risk of recurrence to the same level as if they had had a mastectomy.

Palliative radiotherapy can be used to alleviate symptoms of local disease (such as haematuria) or distant metastases (such as bone pain). Treatment is usually given with a small number of fractions, and effective results can also be achieved with a single fraction of radiotherapy.

Theoretical background

Radiotherapy is the therapeutic use of ionizing radiation. X-rays were first used in the treatment of cancer at the end of the 19th century. Since that time, our understanding of the effects of ionizing radiation on malignant and normal tissues has progressed with increased knowledge of radiobiology. In parallel, our knowledge of radiation physics has advanced and there have been significant technological developments in treatment planning and delivery.

Radiation physics

Radiation, used therapeutically, exerts its effects through the ionization of intracellular molecules; the radiation can be electromagnetic or particulate. The two types of electromagnetic radiation used in radiotherapy are X-rays and gamma rays, and both of these can also be described by the term ‘photon’. Gamma rays are produced from the nuclear decay of radioactive isotopes, whereas X-rays are produced artificially by electrical means, usually in a linear accelerator, accelerating electrons to a high energy and then stopping them abruptly in a heavy metal target. Particulate radiation consists of subatomic particles, including alpha particles, protons and neutrons.

Interactions of X-rays with matter

The process by which photons are absorbed depends principally on their energy and the chemical composition of the absorbing material. The radiation effect depends on the intensity of the radiation source, measured as the linear energy transfer or frequency of ionizing events per unit of path, which is subject to the inverse square law as the energy diminishes with distance from the source. The depth of penetration of biological tissues by the photons depends on the energy of the beam. Low-energy photons from an 85 kV source are suitable for superficial treatments, while high-energy 15 mV sources produce a beam with deeper penetration, lower dose at the initial skin boundary (skin-sparing), sharper edges and less absorption by bone. Superficial radiation may also be delivered by electron beams from a linear accelerator, from which the target electrode that generates the X-rays has been removed. The radiation dose is measured in Gray (Gy), 1 Gray being equal to 1 joule (J) absorbed per kilogram of absorbing tissue. There are differing processes of energy absorption, depending on the energy of the photons delivered, but all share in common the fact that the photon causes excitation of electrons within the targeted tissue.

Biological effect

The resultant biological damage is caused in either an indirect or a direct way. X-rays and gamma rays mainly interact with target biological molecules in an indirect way. The interaction is initially with
other atoms and molecules within the cells, producing free radicals, which are highly reactive molecules generated from water and oxygen. These free radicals exert a biological effect through the generation of single- and double-strand DNA breaks, inducing apoptosis of cells as they progress through the cell cycle.

The biological effect is dependent on the dose rate, duration, volume irradiated and tissue sensitivity. Sensitivity to photon damage is greatest during the G2–M phase of the cell cycle (see p. 23) and is also dependent on the DNA repair capacity of the cell.

Radiobiology is the study of the actions of ionizing radiation on living things. The effects of radiation on normal and malignant tissues evolve through a series of steps. Classical radiobiology describes the ‘five Rs’ of the radiation response:

- Repair. This is the ability of cells to repair DNA damaged by ionizing radiation using different DNA repair mechanisms. Delivery of small daily doses of radiotherapy enables repair of DNA in the cells of normal tissues.
- Redistribution. When radiation is delivered, cells in the G2–M phase of the cell cycle are most radiosensitive. Cells in the more radioresistant phases (e.g. S phase) survive and progress through the cell cycle and are then in the more radiosensitive phase when the next fraction of radiotherapy is delivered.
- Reoxygenation. Oxygenated cells are more susceptible to DNA damage by radiation. Due to irregular blood supplies, tumour cells may be hypoxic. After radiation, the more oxygenated cells die, and the surviving hypoxic cells are reoxygenated as oxygen diffuses into these areas, making these cells more susceptible to radiation with the next fraction of treatment.
- Repopulation. During a course of fractionated radiotherapy, viable tumour cells continue to divide and repopulate the tumour. In some cancers – for example, those of the head and neck or cervix – it is important not to extend the overall treatment time if there are gaps in treatment, as the tumour will repopulate.
- Radiosensitivity. Some tumours are more sensitive to radiation than others. For example, squamous cell carcinomas and lymphomas are radiosensitive, whereas melanomas and brain tumours are radioresistant.

Clinical application of radiation therapy

Radiotherapy planning involves both detailed physics of the applied dose and knowledge of the biology of the cancer; it is also necessary to establish whether the intention is to treat the tumour site alone or to include the likely loco-regional patterns of spread. Normal tissue tolerance will determine the extent of the side-effects and, therefore, the total achievable dose to the tumour. A balanced decision is made according to the curative or palliative intent of the treatment and the likely early or late side-effects. The clinician outlines on the planning scan the areas that they wish to treat using all the clinical information available. They also delineate the critical structures that they do not wish to receive a dose. The physicist then uses planning algorithms to enable the best delivery of dose to the tumour, avoiding critical structures as far as possible. Depending on the site of the tumour, the patient is immobilized to allow reproducibility of position for each fraction of treatment. For example, if the brain is being treated, they will wear a mask that keeps them still on the treatment couch.

The cancers for which radiotherapy is usually employed in a primary curative approach, when the tumour is anatomically localized, are listed in Box 6.20, along with those in which radiotherapy has curative potential when added to surgery (adjuvant radiotherapy).

Palliative treatments are frequently used to provide relief of symptoms and to improve quality, if not duration, of survival (Box 6.21). Palliative treatment is usually given in as few fractions as possible over as short a time as possible.

Radiotherapy planning with CT guidance has been complemented by the introduction of three-dimensional planning and volumetric modulated arc therapy (VMAT), which can deliver curved dose distributions to improve the therapeutic ratio. This allows a greater differential in dose between the tumour and critical normal structures, in turn permitting dose escalation or a reduced risk of toxicity.

Four-dimensional radiotherapy planning is also becoming widely available. It varies radiation dose over time: for example, the respiratory cycle during lung cancer treatment.

Types of radiation therapy

**Fractionated external beam radiotherapy** uses photons generated in a linear accelerator. The radiation dose is delivered in increments separated by at least 4–6 hours to try to exploit any advantage in DNA repair between normal and malignant cells.

**Stereotactic radiosurgery/radiotherapy** (γ-knife, CyberKnife or linear accelerator-based treatment) can concentrate X-rays or gamma radiation from multiple sources on to a small volume to generate an ablative dose of radiation with rapid dose fall-off, minimizing the dose to surrounding tissues. Small lung cancers can be treated in this way, and it allows for the more aggressive treatment of cancer that has spread to the brain.

**Proton beam therapy** is an alternative type of external beam radiotherapy that uses charged proton particles. Due to their larger mass the protons have little side-scatter and so offer a much more focused beam with less dose to surrounding structures. Proton therapy is particularly recommended for the treatment of children, in whom radiotherapy can affect normal growth and development.

**Brachytherapy** is the use of radiation sources in close contact with the tissue to provide intense exposure over a short distance to a restricted volume. Such techniques have been used to treat localized breast, prostatic and cervical carcinoma.

**Systemic radionuclides**, such as ¹³¹Iodine- (in thyroid cancer) or radioisotope-labelled MAbs (e.g. anti-CD20 for lymphoma) and hormones (e.g. somatostatin for carcinoid tumours), can be administered by intravenous or intracavitary routes to provide...
radiation targeted to particular tissue uptake via surface antigens or receptors.

**Radiotherapy in combination with systemic therapy**

The local efficacy of radiotherapy can be increased by the simultaneous but not serial addition of chemotherapy with agents such as cisplatin, mitomycin and 5-FU for cancers of the head and neck, lung, oesophagus, stomach, rectum, anus, cervix and bladder. Reduced local recurrence rates have translated into survival benefits and further research is investigating the concurrent use of biological agents (e.g. EGFR inhibitors) and immunotherapy with radiation. The *abscopal effect* occurs when localized radiotherapy induces the regression of non-irradiated metastatic lesions at a distance from the primary site of irradiation by a systemic immune-mediated response, which may be augmented by giving immunotherapy with the radiotherapy. This is an exciting area of oncology that is being explored in a number of tumour sites.

**Side-effects of radiotherapy**

*Early radiotherapy side-effects* may occur within days to weeks of treatment; at this point, they are usually self-limiting but associated with general systemic disturbance (Box 6.22). The side-effects depend on tissue sensitivity, fraction size and treatment volume, and are managed with supportive measures until normal tissue repair occurs. The toxicity may also be enhanced by exposure to other radiation-sensitizing agents, especially some cytotoxics, such as bleomycin, actinomycin, anthracyclines, cisplatin and 5-FU.

*Later side-effects* occur months to years later and are unrelated to the severity of the acute effects because they have a different mechanism. Late effects reflect both the loss of slowly proliferating cells and a local endarteritis that produces ischaemia and proliferative fibrosis. The risks of late side-effects are related to the fraction size and total dose delivered to the tissue. Growth may be arrested if bony epiphyses are not yet fused and are irradiated, leading to distorted skeletal growth in later life.

*Secondary malignancies* following radiotherapy may appear 10–20 years after cure of the primary cancer. Haematological malignancies tend to occur sooner than solid tumours from the irradiated tissues. The latter are very dependent on the status of the tissue at the time of treatment; for example, the pubertal breast is up to 300 times more sensitive to malignant transformation than the breast tissues of a woman in her thirties. Patients who smoke are more liable to develop lung cancer. Treatment of these secondary cancers can be successful, provided there is normal bone marrow to reconstitute the haematopoietic system, or the whole tissue at risk can be resected (e.g. thyroid after mantle radiotherapy for lymphoma).

### Box 6.22 Side-effects of radiotherapy

**Acute temporary side-effects/dependent on region being treated**

- Anorexia, nausea, malaise
- Mucositis, oesophagitis, diarrhoea
- Alopecia
- Myelosuppression

**Late side-effects**

- Skin: ischaemia, ulceration
- Bone: necrosis, fracture, sarcoma
- Mouth: xerostomia, ulceration
- Bowel: stenosis, fistula, diarrhoea
- Bladder: fibrosis, frequency, incontinence
- Vagina: dyspareunia, stenosis
- Lung: fibrosis, breathlessness
- Heart: pericardial fibrosis, cardiomyopathy, vasculopathy
- Central nervous system: myelopathy
- Gonads: infertility, menopause
- Secondary malignancies: e.g. leukaemia, cancer (e.g. thyroid)
- Other: carotid artery stenosis

**Neutropenic sepsis**

This is the most common cause of attendance in the emergency department for any cancer patient and must always be considered in anyone who is unwell within a month of chemotherapy. Neutropenic patients are at high risk of bacterial and fungal infections, most often from enteric bowel flora; hence, some units will advocate a specific neutropenic diet that is low in bacterial and fungal contamination (Box 6.24). Patients must be warned of the possibility of neutropenic fever occurring. Non-specific symptoms are also common, such as nausea, diarrhoea, drowsiness and breathlessness. A fever may not always be present. The critical test is the full blood count. Patients with neutrophils <1.0 × 10^9/L are managed by the...
immediate introduction of broad-spectrum antibiotics. Signs of systemic illness, such as tachycardia, hypotension or oliguria, mandate urgent admission and resuscitation with intravenous treatment (Box 6.25). Initial empirical therapy should be reviewed following microbiological results.

All such patients need to be discussed with the appropriate specialist oncology team and hospitals should have clear protocols for the rapid institution of antibiotics within an hour of arrival in the emergency department. In units practised in the assessment of febrile neutropenia, it is possible to follow a more risk-stratified antibiotic policy and to avoid or curtail admission with oral co-amoxiclav plus ciprofloxacin when low-risk features are present: that is, absence of tachycardia, hypotension, hypoxia and mucositis, and an expected short duration of myelosuppression.

**Pulmonary embolus**

This is a common complication of the coagulopathy of cancer and is a side-effect of chemotherapy (Fig. 6.16). It often presents with unexplained breathlessness and episodic exacerbations from multiple small emboli, rather than chest pain. A high level of suspicion should be maintained in any cancer patient with breathlessness, hypoxia or chest pain. CT pulmonary angiography is the investigation of choice. Prophylactic anticoagulation is given to all immobilized patients (see p. 1013). Warfarin is ineffective (and direct oral anticoagulants are unlicensed) in reversing the coagulopathy of cancer; low-molecular-weight heparin is preferred.

**Superior vena caval obstruction**

Superior vena caval obstruction (Fig. 6.17) can arise from any upper mediastinal mass but is most commonly associated with lung cancer and lymphoma. The patient presents with difficulty breathing and/or swallowing, stridor, a swollen, oedematous face and arms, venous congestion in the neck, and dilated veins in the upper chest.

---

**Box 6.24 Neutropenic diet**

**Foods and drinks that should be avoided**
- All uncooked vegetables and most fruits – peel off thick skin from foods like oranges and bananas
- Raw or rare meat
- Fish
- Uncooked or undercooked eggs
- Foods from salad bars and delicatessen counters
- Soft blue/mould cheeses, e.g. brie, camembert, stilton
- ‘Well’ water – or boil it for 1 min before drinking

**Foods and drinks that are safe**
- Cooked vegetables
- Canned fruits and juices
- Well-done meat
- Hard-boiled eggs (no runny yolks)
- Vacuum-packed lunch meats (not freshly sliced meats)
- Pasteurized milk, cheese, yogurt and other dairy products only
- Tap water if the source is known – or boil it; bottled water

---

**Box 6.25 Management of febrile neutropenia**

- Febrile neutropenia is classed as a one-off reading of ≥38.5°C or a reading of ≥38°C sustained for 1 h
- Patients on antipyretics/steroids and elderly patients may not mount a febrile response
- Hypothermia or clinical deterioration may be the first sign

**Immediate intervention is essential**
- Resuscitate with intravenous fluids to restore circulatory function; monitor urine output, Glasgow Coma Scale score and central venous pressure
- Take cultures of blood, urine, sputum and stool
- Consider the need for admission to critical care and consider inotropic support at an early stage
- Give empirical antibiotics as per local policy and sensitivities:
  - Commonly used antibiotics should include activity against enteric Gram-negative bacteria and *Pseudomonas*, e.g. ceftazidime or piperacillin–tazobactam with gentamicin; or meropenem monotherapy
  - Antibiotics against staphylococci may be needed, e.g. vancomycin, especially with indwelling venous access lines
  - Change antibiotics according to culture results, or empirically increase Gram-negative cover and consider adding Gram-positive cover, if the patient deteriorates clinically and/or temperature is still elevated after 48 h; discuss with the microbiology department
  - Consider imaging, e.g. chest CT, if fever is not responding to broad-spectrum antibiotics, to detect an occult source of fever; consider adding treatment for opportunistic infections:
    - Liposomal amphotericin B or voriconazole – *Candida* and *Aspergillus*
    - High-dose co-trimoxazole – *Pneumocystis*
    - Clarithromycin – *Mycoplasma* and *Legionella*
    - Anti-tuberculous therapy – *Mycobacterium tuberculosis*
and arms. Treatment is with immediate steroids, chemotherapy where the tumour is expected to respond, and possibly mediastinal radiotherapy. Sometimes, vascular stents and anticoagulation are also required. Some tumours, such as lymphomas, small-cell lung cancers and germ cell tumours, are so sensitive to chemotherapy that this is preferred to radiotherapy, as the masses are likely to be both large and associated with more disseminated disease elsewhere. An early decision is necessary and should be based on the patient’s likely prognosis, as ventilatory support may be required until treatment has had time to relieve the obstruction.

**Spinal cord compression**

Spinal cord compression (see p. 823) needs to be rapidly diagnosed, and urgent treatment arranged within 24 hours of onset of paresis, to salvage as much functional capacity as possible. Early neurological clinical features may be incomplete, more subjective than objective, and gradual in onset. Whole spine MRI scanning is the investigation of choice. Treatment should begin with high-dose steroids and both neurosurgical and oncological opinions, with a neurosurgeon advising on spinal stability, the need for spinal precautions for movement, and the role of decompressive surgery and external bracing for limited-extent disease. In the absence of surgery, radiotherapy alone may be used.

**Tumour lysis syndrome**

This occurs if treatment triggers a massive breakdown of tumour cells, leading to increased serum levels of urate, potassium and phosphate, and a secondary hypocalcaemia. These biochemical changes can give rise to cardiac arrhythmias and seizures. Urate deposition in the renal tubules can cause renal failure (hyperuricaemic nephropathy). Vigorous hydration, often with diuretics, is crucial to maintain high urine outputs in such patients; however, a proportion will require dialysis for uraemia, oliguria or severe electrolyte disturbances. The xanthine oxidase inhibitor allopurinol should be given before treatment is started in low-risk patients. Intravenous rasburicase, a recombinant urate oxidase, is used for prophylaxis in high-risk patients and in the treatment of tumour lysis syndrome.

**Acute hypercalcaemia**

This presents with vomiting, confusion, constipation and oliguria. Treatment is by resuscitation with intravenous fluids first, to establish a saline diuresis, and then an intravenous bisphosphonate, such as pamidronate or the more potent zoledronic acid (see Box 21.56). Treating the cause is crucial. Denosumab and calcitonin can be used in intractable cases.

**Raised intracranial pressure**

Raised intracranial pressure due to intracerebral metastases presents classically with headache, nausea and vomiting. There are often no localizing neurological signs and almost never papilloedema until very late in the disease. However, for many, there is a slower onset with non-specific symptoms such as drowsiness or mental deterioration. Treatment is by high-dose steroids and investigation by MRI. Surgery is appropriate if the condition is unifocal and/or threatening the fourth ventricle; otherwise, whole-brain or local stereotactic CyberKnife radiotherapy is required.

**Malignant bile duct obstruction**

This presents with cholestatic jaundice. Lymphomatous obstruction responds very well to prompt initiation of therapy. A small proportion of pancreatic and bile duct tumours are surgically resectable, more commonly those in the distal bile duct as compared to those in the hilar region. However, in the greater proportion of patients, treatment is palliative. In recent years, endoscopic techniques have allowed the insertion of stents into the biliary tree to re-establish bile flow. Self-expanding metal stents have long periods of patency but are at risk of ascending infection. In the small proportion of patients in whom bile duct drainage is not possible endoscopically, the percutaneous route offers an alternative. Endoscopic photodynamic laser therapy with a photoporphyrin sensitizer can also prolong patency.

**Further reading**

### COMMON SOLID TUMOUR TREATMENT

Common cancer mortality is listed in Box 6.26; improvements in survival in recent years have stemmed from advances in prevention, diagnosis and treatment. The presentation, diagnosis, natural history and systemic treatment of the common cancers are described in the relevant chapters of this book; haematological malignancy is presented in Chapter 17. The decision to treat and the aim of that treatment, whether palliation or cure, require knowledge of the natural history of the disease, prognostic and predictive factors, the patient’s performance status and the potential efficacy of treatment. Management should be carried out by a multidisciplinary team, which will usually be led by an oncologist.

LUNG CANCER

The presentation and diagnosis of lung cancer are covered more fully in Chapter 28. Current treatment reflects the fact that the majority of patients are diagnosed at an advanced stage with a poor prognosis; there are therefore many trials assessing different screening strategies to try to achieve earlier diagnosis that would permit more curative treatment.

Prognosis

Lung cancer histology is divided into two main types (Box 6.27):

• **Small-cell lung cancers (SCLC),** which derive from neuroendocrine tissue and which tend to disseminate early in their development.

• **Non-small-cell lung cancers (NSCLC),** which are more likely to be diagnosed in a localized form. As treatments have improved, it has become clear that what previously was simply called non-small-cell lung cancer needs to be separated into individual pathological entities, as management varies and some therapies are effective only in particular subtypes.

> Tumour stage and patient performance status are used in selecting treatment and predicting response and prognosis. While overall 5-year survival has remained approximately 10%, treatment is beginning to have an impact in selected groups.

Staging

Where the technology is available, staging is normally based on PET–CT. In the absence of distant metastases, further evaluation of local/regional lymph nodes is frequently undertaken if:

• lymph nodes are enlarged but of low glucose avidity, or

• lymph nodes do not appear enlarged but do show significant glucose avidity.

In these cases, confirmatory tests are required to yield pathological samples: for example, endobronchial ultrasound (EBUS) and biopsy or, in the case of central nodes closer to the oesophagus, endoscopic ultrasound (EUS)-based biopsy.

General approach to management

This is based on the stage of disease, the histological subtype, the presence of particular genetic mutations, the patient’s performance status (see Box 6.13) and, crucially, the patient’s own wishes.

• **For stage 1–2 disease** the treatment of choice is surgical resection by lobectomy or pneumonectomy, with stereotactic ablative radiotherapy (SABR) when surgery is contraindicated.

• **Selected patients with stage 3A disease** can be managed surgically, but the alternative approach is a combination of chemo-

therapy and radiotherapy, directed by histological subtype and molecular testing.

• **For patients with more advanced disease,** a variety of agents can prolong survival, and specific palliative measures can relieve symptoms and improve quality of life.

Non-small-cell lung cancer

Staging of NSCLC is classified according to the TNM system (see Box 6.12 and Box 28.53); this system divides the disease into local, locally advanced and advanced stages, with 5-year survival varying from 55–67% to 23–40% and 1–3%, respectively.

Management

Surgery

Surgery can be curative in NSCLC (T1,N0,M0) but only 5–10% of all cases are suitable for resection; about 70% of these survive for 5 years. Surgery is rarely appropriate in those over 65 years, as the operative mortality rate in these patients often exceeds the 5-year survival rate. Trial data suggest that neo-adjuvant chemotherapy may downstage tumours to render them operable and may also improve 5-year survival in patients whose tumours are operable at presentation.

In operable disease of stages T1,N0 to T3,N2 (stage I–IIla), adjuvant radiotherapy and chemotherapy following surgery can improve prognosis in patients of good performance status, as shown by the International Adjuvant Lung Cancer Trial and a meta-analysis of 12 randomized controlled trials. Cisplatin-based combination chemotherapy induced a response in 60% and produced a relative risk reduction of 11% with an absolute improvement in 5-year survival for stage II and IIIa disease of 4%, from 40.4% to 44.5%. There appears to be no difference in survival if chemotherapy is given before (neo-adjuvant) or after surgery.

Preoperative assessment includes lung function testing and walking oximetry, which is used to predict postoperative potential. An active life after pneumonectomy is unlikely if the gas transfer is reduced below 50%.

Radiation therapy for cure

In patients who are fit and who have a stage 1 NSCLC, high-dose radiotherapy (65Gy or 6500 rads) can result in a 27-month median survival and a 22% 5-year survival. It is the treatment of choice if surgery is not appropriate; however, poor lung function can also be a relative contraindication to radiotherapy. **Radiation pneumonitis** (defined as an acute infiltrate precisely confined to the radiation area and occurring within 3 months of radiotherapy) develops in 10–15% of cases. **Radiation fibrosis,** a fibrotic change occurring within a year or so of radiotherapy and not precisely confined to the radiation area, occurs to some degree in all cases but is usually asymptomatic.

Tyrosine kinase inhibitors

Increasingly, tissue obtained at biopsy is investigated using next-generation sequencing (NGS, p. 31) to seek the presence of specific oncogenic (activating) mutations (Box 6.28). These are more common in non-smokers, although they account for less than 5% of cases in unselected series. Where mutations are identified, targeting these driver mutations with an appropriate TKI is the first-line treatment (see Box 6.19).

For example, for EGFR mutants, either a first- or second-generation drug may be selected: afatinib or erlotinib. High initial response rates are seen but progression within 1–2 years is usual. At this point, genetic sequencing of circulating blood DNA may reveal

the presence of the T790 mutation, which generates resistance to first-line TKIs. The third-generation drug osimertinib overcomes this mechanism of resistance.

**Immunotherapy**

Programmed death ligand 1 (PDL-1) and its receptor, programmed death protein 1 (PD-1), are often overexpressed in NSCLC, allowing cancer cells to evade destruction by the body’s immune system. In patients who are PDL-1-positive but lack the driver mutations described earlier, pembrolizumab (a MAb that acts as a PD-1 antagonist) is used, sometimes alongside conventional chemotherapy, with significant improvements in survival. The PDL-1 antagonist durvalumab, used every 2 weeks for 1 year alongside cisplatin-based chemotherapy, has been shown to raise the median time to progression or death from 16 to 28 months in NSCLC.

**Conventional chemotherapy**

This is used in the absence of specific driver mutations. Cisplatin (or carboplatin) plus gemcitabine remains the standard treatment (and is superior in this group to regimes based on cisplatin and pemetrexed). An alternative, particularly in older patients, is carboplatin and paclitaxel. Single-agent docetaxel may be offered as second-line therapy if patients are fit.

**Small-cell lung cancer**

**Prognosis**

SCLC is an aggressive neuroendocrine tumour. It is staged in the same way as NSCLC, and stage 1 tumours may benefit from surgery. For non-operable cases, disease is classified as limited- or extensive-stage disease.

**Management**

**Limited-stage disease** is confined to one anatomical area and is present in approximately 30% of patients. It is best treated with concurrent chemotherapy and radiotherapy using either cisplatin or carboplatin, with either etoposide or irinotecan, which increases survival at 5 years from 15% to 25%, compared with radiotherapy alone. Recurrence is usual within 6–12 months; for those who remain fit, further chemotherapy is appropriate. A similar degree of improvement can also be achieved with hyperfractionated radiotherapy. Prophylactic whole-brain radiation to prevent cerebral metastases can reduce symptomatic central nervous system disease and improve overall survival by 5%.

For **extensive disease**, concurrent chemoradiotherapy with cisplatin and etoposide chemotherapy over four cycles, followed by prophylactic cranial irradiation, is considered optimal. This can increase median survival from 6 months to 9–13 months, and the 2-year survival to 20%. Second-line chemotherapy can provide further palliation for patients with good performance status.

**Symptomatic care for lung cancer patients**

The prognosis for the majority of patients remains poor because the disease is diagnosed at an advanced stage and the morbidity from other smoking-related diseases compromises treatment. Therefore, much of the treatment, whether symptomatic or anticancer, is delivered with palliative intent. (General palliative care is discussed in Chapter 7.) Specific issues for lung cancer are the relief of bronchial obstruction and breathlessness, and the alleviation of local pain, for which radiotherapy is often employed alongside appropriate opiate analgesia. Laser therapy, endobronchial irradiation and tracheobronchial stents are used (see p. 980).

**Metastases in the lung**

Metastases are very common and usually present as round shadows (1.5–3.0 cm in diameter). They are usually detected on chest X-ray in patients already diagnosed as having cancers at other sites but may be the initial presentation of disease. Typical sites for the primary tumour include the kidney, prostate, breast, bone, gastrointestinal tract, cervix or ovary.

Metastases usually develop in the parenchyma or pleura and are often relatively asymptomatic, even when the chest X-ray shows extensive disease. Rarely, metastases may develop within the bronchi and present with haemoptysis.

Metastatic carcinomas (particularly of the stomach, pancreas and breast) can involve the mediastinal lymph nodes and spread along the lymphatics of both lungs (lymphangitis carcinomatosa), leading to progressive and severe breathlessness. Chest X-ray signs of hilar lymphadenopathy and basal shadowing are unreliable, compared with the characteristic signs on CT scan of irregular thickening of the interlobular septa in a polygonal pattern around a thick-walled central vessel.

Occasionally, a pulmonary metastasis may be detected as a solitary round shadow on chest X-ray in an asymptomatic patient. The most common primary tumour that presents in this way is a renal cell carcinoma.

The differential diagnosis includes:

- primary bronchial carcinoma
- tuberculosis
- benign tumour of the lung
- hydatid cyst.

Single pulmonary metastases can be removed surgically, but as CT scans usually show the presence of small metastases that remain undetected on chest X-ray, detailed imaging, including PET scanning and assessment, is essential before undertaking surgery.

BREAST CANCER

Breast cancer is the most common cancer in women who do not smoke. The screening programme in the UK has improved the detection of early and curable breast cancer and is a model for other screening programmes. Improvements in multimodality treatment have also increased overall cure rates. Breast-conserving surgery for selected early-disease patients has greatly ameliorated the psychosexual impact of the disease.

Aetiology and pathology

The majority of breast cancers arise from the epithelial cells of the milk ducts and lobules. They reproduce their histological features in a variety of patterns (Box 6.29), of which the most common is an infiltrating ductal carcinoma.

Hormonal effects

At the time of menarche, oestrogen receptors in breast tissue react to ovarián oestrogen secretion. This stimulation causes milk duct epithelial cells to divide (mainly through activation of the cyclin D1/cyclin-dependent phosphorylating enzyme complex, which phosphorylates the retinoblastoma suppressor of G1- to S-phase progression of the cell cycle) and allows the breast to develop physiologically. This pathway for controlling cell division in the breast remains important throughout life and its dysregulation is a key ‘driver’ in the progression of oestrogen receptor (ER)-positive breast cancer (i.e. breast cancers that retain the expression of the oestrogen receptor) – a point of great interest in therapy.

Long-term exposure to the mitotic effects of oestrogens is a predisposing factor to breast cancer development because mutations are more likely to occur at times of DNA replication, and long-term hyperplasia due to oestrogen exposure predisposes to this. Thus, women with early menarche and late menopause, and those on hormone replacement therapy for long periods, are at greater risk of developing breast cancer.

Genetic predisposition

Approximately 5% of patients with breast cancer have a genetic predisposition. The best known are the familial BRCA mutant carriers, who have a very high risk of breast cancer and also ovarian cancer. Men who are positive for BRCA are at risk of male breast cancer and – for BRCA2 mutants – prostate cancer. The BRCA protein product, a tumour suppressor, plays a role in DNA repair. Other familial breast cancer genes are often involved in DNA repair, and if deficient, may leave the cells more sensitive to DNA-damaging events. This phenomenon can be exploited in therapy, and a class of drugs called poly-ADP-ribose polymerase (PARP) inhibitors causes double-stranded DNA breaks to occur. In normal tissue these DNA strand breaks are repaired, but in cancer cells (e.g. those lacking effective BRCA action) repairs cannot be made and so the cell dies – a phenomenon described as ‘synthetic lethality’.

Young breast cancer patients, those with a strong family history of breast cancer in near relatives and those with male breast cancer all require genetic counselling (Box 6.30).

Screening

There may be a long period between induction of breast cancer and invasion. The term ‘in situ’ cancer refers to the development of cancerous changes in milk duct epithelial cells that have not yet breached the basement membrane of the ducts (and hence have no access to routes of spread by lymphatics). This ‘pre-cancer’ stage of the disease can be picked up on mammography when it is still highly curable, usually by breast-conserving surgery (unless changes are widespread in the breast, in which case more radical surgery may be required). In the UK, all women aged 50–70 are offered screening by biplanar digital mammography, often in designated clinics or mobile screening units, every 3 years. Patients with abnormal mammograms are recalled for further assessment.

Clinical features

Most women with symptomatic (rather than screen-detected) breast cancer present with a painless, increasing mass that may also be associated with nipple discharge, skin tethering, ulceration and, in inflammatory cancers, oedema and erythema. Where the cancer may be deeply tethered to pectoralis, the clinician asks the patient to tense the muscle by putting their hands on their iliac crests and pressing inwards; in deep tethering the mass loses its mobility.

The clinician should document:
- the position of the lesion(s) in the breast
- its/their size in centimetres

• the presence or absence of tethering (superficial or deep)
• any other relevant signs, such as nipple discharge, skin oedema (a so-called ‘peau d’orange’ appearance) or inflammatory changes
• the presence or absence of axillary lymphadenopathy.

Where effective screening programmes exist, most breast cancers are detected early; in other settings, including many developing countries, a much higher percentage of patients are likely to present with advanced disease.

Investigations

The triple assessment of any symptomatic breast mass is by:
• palpation
• radiology (mammography, ultrasound and MRI scan)
• fine needle aspiration cytology.

This combination is effective in differentiating breast cancer from benign breast masses, which are 15 times more common. Where cancer is considered likely, large-bore core needle biopsy should follow, to provide histological confirmation and to assess for factors predictive of prognosis and response to treatment. These features include:

- grade of tumour
- Ki-67 proliferation index, by which the proportion of cells staining positive for Ki-67 protein (a marker of cellular proliferation) is measured
- oestrogen, progesterone and HER2 receptor status
- molecular profiling, using an assay such as the Oncotype DX, which compares a number of molecular markers to assess risk of recurrence and benefit of chemotherapy.

Assessment should be carried out in a dedicated one-stop clinic that is able to provide appropriate support and arrange for referral. Staging considers:

- Tumour size and evidence of local invasion.
- Axillary lymph node status, through scanning (and potentially sampling) the ‘sentinel’ nodes that drain the area of the breast in which the cancer lies, identified by dye or radioactive tracer injection. At present, only 20% of patients are diagnosed with no evidence of microscopic nodal metastases.
- Examination of common sites of metastasis in advanced disease, PET–CT being the most sensitive modality of investigation.

Management of early disease

Surgery

In early disease, surgical options include wide local excision and segmental mastectomy with breast conservation for masses of less than 3 cm in diameter; simple mastectomy, with or without reconstruction, is used for larger tumours. The choice is dictated by the location and extent of the breast mass, and patient preference. Clear histological margins around the cancer are important for cure.

In the absence of clinical or ultrasound evidence of lymphadenopathy, surgery to the axilla can be minimized if sentinel lymph node-guided sampling excludes local spread; otherwise, dissection to level three is required if there are clinically involved nodes, in order to gain local control and provide prognostic information to guide adjuvant treatment. The greater the amount of axillary surgery, the greater is the risk of postoperative lymphoedema.

Radiotherapy

All patients who undergo breast-conserving surgery for early breast cancer require postoperative radiotherapy to the breast to provide security of local control equivalent to that conferred by mastectomy (Box 6.31). Those undergoing mastectomy who have disease close to resection margins also require radiotherapy to the chest wall and regional nodes. The axillary nodes are spared radiotherapy if the axilla has been dissected (to avoid arm lymphoedema) but supraclavicular nodes are included, and internal mammary node irradiation is occasionally given in selected higher-risk cases.

Systemic therapy

For locally advanced breast cancers, systemic therapy (neoadjuvant therapy) is sometimes given to downstage the cancer before locoregional treatment with surgery and radiotherapy. This may allow safe breast-conserving therapy in a patient with disease that, at presentation, would have required full mastectomy.

The term ‘adjuvant therapy’ applies to systemic treatment that is given after definitive locoregional therapy in a patient who is perceived to have a significant risk of future relapse. The aim is to destroy microscopic residual disease that may have disseminated elsewhere in the body, and trials have shown benefit from both endocrine treatment and chemotherapy. Typical chemotherapy regimens are discussed later in ‘Management of advanced breast cancer’. Those with node-positive breast cancer, large primaries, oestrogen receptor-negative cancers and HER2 cancers are good examples of patients who would usually derive a significant survival advantage from adjuvant systemic therapy.

Targeted therapy

A range of agents can be used, depending on the receptor status of the underlying disease:

HER2-positive disease

The human epidermal growth factor receptor 2 (HER2) is over-expressed in 20% of all breast cancers and acts as an oncogene, ‘driving’ the cancer to grow. HER2-positive cancers tend to behave aggressively but respond to treatment with HER2 inhibitors such as trastuzumab and pertuzumab; endocrine therapy is used subsequently if tumours are also ER-positive. If indicated, radiotherapy is usually given following systemic therapy, the logic being that the systemic therapy is most likely to cure any microscopic disease when the tumour burden is lowest, and that systemic therapy also treats regional disease and so should be given as soon as possible.

Oestrogen receptor-positive disease

For cancers that present a lesser risk and are ER-positive, adjuvant endocrine therapy is delivered, often for as long as 10 years after surgery. There are two strategies for endocrine therapy:

- oestrogen receptor blockade using tamoxifen (a competitive inhibitor of the oestrogen receptor) or fulvestrant (which also causes degradation of the oestrogen receptor)
- oestrogen deprivation using aromatase inhibitors such as letrozole (which blocks non-ovarian oestrogen synthesis); aromatase inhibitors are not active in premenopausal women.

In a head-to-head study, a slight advantage was proven for use of aromatase inhibitors as adjuvant therapy in postmenopausal
women with ER-positive breast cancer when compared to tamoxifen; consequently, this is now first-line endocrine therapy in this group. In premenopausal women with higher-risk ER-positive disease, there is an advantage for complete ovarian suppression (laparoscopic oophorectomy or luteinizing hormone-releasing hormone (LHRH) agonist therapy) plus aromatase inhibition.

In ER-positive breast cancer the effector pathway that stimulates cellular proliferation is mediated via a cyclic D/cyclin-dependent kinase phosphorylating holoenzyme, which regulates the RB protein (a suppressor of G1 to S-phase progression). The addition of cyclin inhibitors (e.g. palbociclib, abemaciclib) to an aromatase inhibitor or fulvestrant significantly enhances the response rate and duration of this endocrine-based therapy in ER-positive breast cancer.

Follow-up

After the end of therapy (or during the on-going adjuvant endocrine therapy or on-going anti-HER2 therapy), patients are reviewed clinically every 3–6 months by examination and inquiry into weight, energy and general wellbeing. Health economic studies have not supported the usefulness of proactive scanning in patients who have negative follow-ups based on these clinical assessments. However, an annual mammogram – both for the index breast and the contralateral side (where, irrespective of the genetics, there is an increased risk of a new cancer) – is recommended for at least the first decade of follow-up.

Management of advanced disease

The management of patients presenting with metastatic disease depends on the extent and location of disease.

Widespread visceral disease

Patients are advised to have systemic chemotherapy (with or without HER2-directed therapy), followed by endocrine therapy if the cancer is ER-positive. Treatment is unlikely to be curative but may well delay death by long periods, during which quality of life may be good.

The chemotherapy advised for this situation (and, indeed, the adjuvant therapy discussed earlier) is based on combinations of drugs, thereby reducing resistance (the same premise as is applied with multidrug antibiotic therapy for tuberculosis infection). Combinations of drugs are selected for their anti-tumour activity in breast cancer and their non-overlapping toxicities. Anthracyclines, taxanes, alkylating agents, 5-FU and vinca alkaloids all feature in first-line regimens. For triple-negative breast cancer (ER-negative, PR-negative, HER2 non-amplified) the platin also have a role, possibly in combination with a DNA repair inhibitor. Interestingly, the triple-negative group tend to carry a high mutational load and are the only group of breast cancers that may respond well to immunotherapy with checkpoint inhibitors and perhaps other such drugs.

Limited metastatic disease

For patients who present with one or only a few sites of metastatic disease (oligometastatic disease), there may still be a chance of cure. Aggressive treatment with ablative focal therapy to those oligometastatic sites (e.g. radiofrequency ablation, stereotactic radiation or surgical metastatectomy) may be worth pursuing in a fit patient.

Indolent metastatic disease that is not immediately life-threatening

If the cancer is ER-positive, primary endocrine therapy may hold the disease at bay for long periods; chemotherapy may be delayed until the cancer progresses despite this endocrine-based therapy. Breast cancers driven by HER2 or mammalian target of rapamycin (mTOR) may also benefit from cyclin inhibitors or mTOR inhibitors such as everolimus. Such an approach does not prejudice overall survival, and in a situation where therapy is not ultimately curative, there are big advantages to recommend it.

Metastatic disease confined to regional lymph nodes

An aggressive regime of neoadjuvant chemotherapy, surgery to breast and axillary nodes, regional radiotherapy and long-term endocrine or HER2-directed therapy offers a chance of cure.

Relapsed disease after previous systemic therapy

The systemic therapy previously received has to be carefully considered before new therapy is instituted. The timing between the previous therapy and relapse is important, as re-introduction of agents may be sensible only if the cancer has not been exposed to a particular group of drugs for a number of years. New agents (i.e. ones to which the cancer has not been exposed) are preferable, and eribulin is a chemotheraphy agent that has value in this situation. In BRCA-driven cancer, the PARP inhibitors (DNA repair inhibitors that seem to augment the defect of BRCA mutaion in a lethal way) may enhance the efficacy of certain drugs, such as the platin, or be active as single agents. It is sometimes worth obtaining a biopsy at the time of relapse for further genomic analysis of the ‘new’ tumour, as the constant mutational events in a progressing cancer throw up new driver mutations, some of which can be blocked. For example, the phosphoinositide 3-kinase (PI3K) escape pathway may become a driving force in progressing breast cancer and there are now inhibitors of this common escape pathway in multiple relapsing breast cancer. This type of emerging new mutation can sometimes be detected from peripheral blood draw and cancer cell-free DNA (cfDNA) analysis.

Further reading

Upper gastrointestinal cancers

Oesophageal cancer

Presentation and diagnosis are described on page 1171. Early diagnosis, as pioneered in Japan, where there is a particularly high incidence, has shown that it is possible to improve the prognosis of a disease that otherwise is typically diagnosed only when local metastases have already occurred.
Prognosis and management
Pre-treatment histology, stage, age and performance status are critical prognostic factors for treatment decisions, which should be made by a multidisciplinary team in designated units with the surgical expertise to avoid treatment mortality. The prognosis for the majority of symptomatic patients is poor: 50% have distant metastases at the time of diagnosis, and the majority of the remainder having locoregional spread into adjacent mediastinal structures. Staging with endoscopic ultrasound, CT scan and PET-CT scan has improved the selection of patients of good performance status with truly localized disease, for whom curative treatment may be attempted. The overall 5-year survival figures are poor (see p. 1172), only attaining 4% for stage 4 cancers, because 70% of patients present late with stage 3 or higher disease.

Treatment of early-stage disease
Surgery provides the best chance of cure particularly for distal primaries but should be used as the primary modality only when imaging has shown that the tumour has not infiltrated outside the oesophageal wall (stage 1). Patients with locally advanced disease that is potentially resectable are recommended to have neoadjuvant chemotherapy with cisplatin/5-FU prior to surgery; neoadjuvant chemoradiotherapy prior to surgery has recently been shown to improve overall survival further. Response to neoadjuvant therapy is a strong prognostic factor. Radical chemoradiotherapy alone is an alternative approach for patients with squamous cell carcinoma of the thoracic oesophagus, and avoids the morbidity associated with surgery. Those with adenocarcinoma of the oesophago-gastric junction can be treated with perioperative chemotherapy in a combination of docetaxel, oxaliplatin, fluorouracil and leucovorin (FLOT).

Treatment of advanced or metastatic disease
This can be palliated with 5-FU or capecitabine chemotherapy in approximately 30%, increasing to 45–55% with the addition of oxaliplatin or irinotecan for a median duration of 6–8 months.

Palliative approaches
Distressing symptomatic problems with dysphagia can be partially relieved by endoscopic insertion of expanding metal stents, percutaneous endoscopic gastrostomy tubes to support liquid enteral feeding and endoscopic ablation to help control bleeding. The patient and family need considerable support and explanation to enable them to understand that feeding, including parenteral methods, does not improve survival beyond that dictated by the underlying cancer, and may introduce its own complications with adverse effects on quality of life.

Gastric cancer
The presentation and diagnosis of gastric cancer are described on page 1179.

Prognosis and management
The majority of patients are still diagnosed at an advanced stage, except in Japan, which has an active surveillance policy. Thus, in the West, the overall prognosis has not improved above 10% survival at 5 years. Selected groups may do much better and the histological grade and staging, with respect to the presence of serosal involvement (T3), nodal involvement (N1–2) and performance status, are the main factors in determining prognosis and selecting treatment.

Treatment of early-stage disease
Early non-ulcerated, mucosal lesions can be removed endoscopically. Otherwise, surgery remains the most effective form of treatment if the patient is considered ‘operable’ in terms of lack of direct invasion and nodal spread: selection based on operability has reduced the numbers undergoing surgery and significantly improved the overall surgical 5-year survival rates. Perioperative chemotherapy with FLOT improves 3-year overall survival in this patient group from 35% to 57%. If a patient has not had neoadjuvant treatment, adjuvant chemotherapy or chemoradiotherapy can be used.

Treatment of advanced disease
This may be palliated with chemotherapy, such as oxaliplatin and capecitabine combined with cisplatin and infusional 5-FU for patients with squamous cell carcinoma, with a response in 40–50% for a median of 8–12 months in those patients with good performance status (see p. 107). The addition of trastuzumab a and pertuzumab for tumours overexpressing HER2 (see p. 122) has improved median survival from 11 to 16 months. For patients with deficient mismatch repair, high levels of microsatellite instability or PD-L1 overexpression, immune checkpoint inhibitors targeting PD-1 (pembrolizumab) have activity in this tumour type and may be considered in the future for patients who have relapsed. Trifluridine/tipiracil, which interferes with tumour DNA synthesis, may also have activity in the relapsed setting.

Palliative approaches
Supportive care for patients with upper gastrointestinal cancers, more than cancers in any other site, must include attention to nutrition with the use of endoscopic stents to relieve obstruction, nasojejunal and percutaneous gastrostomy feeding tubes, and occasionally parenteral nutrition. When the disease progresses and active anti-cancer treatment is no longer appropriate, management of distressing obstructive symptoms can include octreotide to reduce secretions and, if necessary, a venting gastrostomy.

Gastrointestinal stromal tumours
Gastrointestinal stromal tumours (GISTs) are rare, slow-growing neoplasms that may arise in the stomach or small or large intestine. Prognosis depends on size, site, Ki-67 proliferation index (see p. 1180) and association with neurofibromatosis type 1 (see p. 886). Immunohistochemistry for CD117 and DOG-1 is usually positive; if negative, diagnosis can be reached by analysis of the known mutational sites in c-Kit or PDGFRα oncogenes. These mutations predict response to TKIs such as imatinib (see p. 113). Surgery is potentially curative for localized disease, and imatinib adjuvant therapy for 3 years prolongs survival. In metastatic disease, imatinib treatment should continue until relapse and can induce remissions in 50–80% for a median of 2 years; further responses are possible with alternative TKIs such as sunitinib and nilotinib.

Further reading
Small intestinal cancer
Predisposing factors for small intestinal cancer, and its presentation and treatment, are described on page 1196. The principles of treatment are determined by extrapolation from management of the more common colorectal cancers.

Colorectal cancer
Presentation and diagnosis of colorectal cancer are described on page 1218.

Prevention
A low-fat, high-fibre diet for the prevention of sporadic colorectal cancer, along with endoscopic screening, is recommended for at-risk patients with a strong family history and for inherited syndromes (e.g. familial adenomatous polyposis, Lynch’s syndrome).

Non-steroidal anti-inflammatory drugs (NSAIDs) or aspirin may play a role in prevention. After 5 years’ treatment with daily aspirin, there is a 35% reduction in all gastrointestinal cancers, although caution must be exercised because of the risk of gastric erosion.

Screening
See pages 294 and 1219.

Prognosis
The site of the disease (above or below the pelvic peritoneal reflection), TNM stage (see Box 6.11), surgical margins and the patient’s performance status (see Box 6.2) are the main clinical prognostic factors (Box 6.32). Gene expression profiling, using Oncotype DX and Coloprint, for example, can identify prognostic subgroups, but is not predictive of treatment benefit. High microsatellite instability (MSI) predicts a better prognosis and can be used to identify low-risk patients for whom adjuvant therapy is unlikely to be of benefit. Mutations in BRAF occur in 6–8% and indicate a poor prognosis, as do mutations with predictive effect in KRAS in 40% and NRAS in 10–15% of cancers.

Management
Management should be undertaken by multidisciplinary teams working in specialist units. About 80% of patients with colorectal cancer undergo surgery, although fewer than half of these survive for more than 5 years. The operative procedure depends on the cancer site. The TNM staging system has now largely replaced the older Dukes’ staging system.

Surgery
Rectal cancer
Total mesorectal excision (TME) is used for careful removal of the entire package of mesorectal tissue surrounding the cancer.

A low rectal anastomosis is then performed. Abdomino-perineal excision, which requires a permanent colostomy, is reserved for very low tumours within 5 cm of the anal margin. Local trans-anal surgery is used very occasionally for early superficial rectal cancers.

Colon cancer
A segmental resection and restorative anastomosis, with removal of the draining lymph nodes as far as the root of the mesentery, is employed for cancer elsewhere in the colon. Surgery in patients with obstruction carries greater morbidity and mortality. Where technically possible, preoperative decompression by endoscopic stenting with a mesh-metal stent relieves obstruction; surgery can therefore be elective rather than emergency, and is probably associated with a decrease in morbidity and mortality.

Neoadjuvant chemotherapy and radiotherapy
Neoadjuvant chemoradiation treatment of locally advanced rectal cancers, using 5-FU or capecitabine with 5 weeks of radiotherapy and then a 2-month wait, has increased the proportion of locally advanced tumours that can be resected with clear surgical margins and has improved the local control rate, but has not had a beneficial effect on distant metastatic relapse and overall survival. Preoperative, rather than postoperative, treatment has reduced toxicity to the other pelvic structures due to preservation of the normal anatomical relations. Alternatives include short-course radiotherapy over 1 week with immediate or delayed surgery, and total neoadjuvant treatment with chemotherapy prior to or after chemoradiotherapy in those patients most at risk of metastatic disease, although this has not been proven in large randomized trials. In 20–30% of patients, there is a complete clinical and radiological response to treatment after chemoradiotherapy, and in these individuals it may be possible to avoid surgery with stringent follow-up.

Adjuvant chemotherapy and radiotherapy
Adjuvant chemotherapy with oxaliplatin and 5-FU or capecitabine chemotherapy increases survival in patients with node-positive colorectal cancer, with a 5-year overall survival of 73%. Recent data have demonstrated that in those with lower-risk stage III disease it is possible to give 3 months of adjuvant therapy rather than 6 without reducing survival, sparing patients the neuropathy that is associated with oxaliplatin. Less benefit is seen with adjuvant treatment for stage II, node-negative patients. Those with higher-risk features can be considered for adjuvant single-agent capecitabine. If the tumour is deficient in one of the mismatch repair genes, adjuvant chemotherapy in this patient cohort has been shown not to be effective. Immunotherapy could be considered for these individuals in a trial setting.

Follow-up
In all patients who have surgery a total colonoscopy should be performed before surgery to look for additional lesions. If total colonoscopy cannot be achieved before surgery, a second ‘clearance’ colonoscopy within 6 months of surgery is essential. Patients with stage II or III disease should be followed up with regular colonoscopy and carcinoembryonic antigen (CEA) measurements; rising levels of CEA suggest recurrence. CT scanning to detect operable liver metastases should be performed for up to 5 years post surgery.
Metastatic colorectal cancer

Patients with colorectal cancer can present with liver metastases. With appropriate selection of patients who have a good performance status and in whom MRI and PET–CT scans do not demonstrate disease elsewhere, local treatment can prolong good-quality survival. A variety of methods are used, including surgical resection, stereotactic body radiotherapy, radiofrequency ablation, cryoablation or hepatic artery embolization. Small lesions can be ablated but larger ones are best managed by partial hepatectomy or a combination approach, so that embolization is followed by hepatic regeneration before final resection. Patient selection is critical; long-term survival without recurrence is reported in up to 20% at 3 years with a single lesion of less than 4 cm amenable to resection presenting more than a year from initial diagnosis. More patients can be rendered suitable with perioperative chemotherapy, such as FOLFOX (oxaliplatin, 5-FU, folinic acid) or FOLFIRI (irinotecan and 5-FU) with cetuximab if RAS is wild-type. A similar approach is utilized for patients with lung metastases.

Untreated advanced colorectal cancer has an overall survival of 5–6 months. With sequential chemotherapy regimens (including FOLFOX, CAPOX (oxaliplatin and 5-FU or capecitabine), FOLFIRI and LONSURF (trifluridin–tipiracil)), this can increase to over 2 years. Patients without mutations in the KRAS gene can be considered for treatment with EGFR-targeted agents such as cetuximab and panitumumab. Immunotherapy can be of use in patients with loss of function of one or more of the mismatch repair genes.

Anal cancer

Anal squamous cell carcinoma is radically treated with chemoradiotherapy with mitomycin C and 5-FU or capecitabine. This is organ-preserving treatment, enabling the patient to avoid surgery that would result in a colostomy. Salvage abdominoperineal resection is possible if the tumour recurs. Metastatic anal cancer is treated with carboplatin and paclitaxel chemotherapy. Immune checkpoint inhibitors may have activity in these tumours, as they do in squamous cell carcinoma of the head and neck.

Prognosis and management

Surgical resection of isolated lesions of less than 5 cm in diameter or up to three lesions of less than 3 cm in diameter is associated with a median survival of 5 years, although the remaining liver remains at risk of further recurrence. Liver transplantation offers the only opportunity for cure for patients with a small primary tumour, but is often limited by the underlying cause of the hepatitis and cirrhosis. Other focal treatments include transarterial embolization and chemoembolization, radioembolization, radiofrequency ablation and stereotactic body radiotherapy in patients with small primaries and adequate liver function; these prolong survival, though less successfully than surgery.

In progressive disease, antiangiogenic compounds are being evaluated: sorafenib prolongs survival to 10 months in patients with non-resectable tumours, and lenvatinib is an alternative TKI that is used to treat patients in the first-line advanced setting.

Biliary tract

Cancer of the biliary tract may be intra- or extrahepatic. These malignancies represent approximately 1% of all cancers. A number of associations have been identified, such as choleodochal cyst and chronic infection of the biliary tract with, for example, Clonorchis sinensis. There are also associations with autoimmune disease processes, such as primary sclerosing cholangitis and inflammatory bowel disease.

Carcinoma of the gall bladder

See page 1322.

Cholangiocarcinoma

Cholangiocarcinoma (see also p. 1322) usually presents with jaundice and is detected by imaging: initially ultrasound, and most importantly, magnetic resonance cholangiopancreatography (MRCP). Spread is usually by local lymphatics or local extension. Cholangiocarcinoma of the common bile duct may be resectable at presentation but local extension precludes such management in the majority of more proximal lesions. Localized disease justifies an aggressive surgical approach, including partial hepatic resection. Hepatic transplantation for selected stage 1 and 2 disease has achieved 80% 5-year survival. Palliative chemotherapy for patients with good performance status and advanced disease, using gemcitabine and cisplatin, effects a response in 50% with a median survival of 12 months. Chemoradiation has been used to treat localized small hilar cholangiocarcinomas and radiotherapy can provide good analgesia.

Pancreas

Pancreatic adenocarcinoma

The presentation and initial investigation of pancreatic cancer are covered on page 1333.

Prognosis

The 5-year survival rate for carcinoma of the pancreas is approximately 2–5%, with surgical intervention representing the only chance of long-term survival. Approximately 20% of all cases have a localized tumour suitable for resection, but in an elderly population many individuals have co-morbid factors that preclude such major surgery.

Management

Borderline-resectable tumours can be considered for neoadjuvant therapy to downstage the tumour, but this should generally be
contemplated only as part of a clinical trial. Adjuvant gemcitabine and capectabine chemotherapy can be used where tumours have been removed. Locally advanced pancreatic cancer can be treated with combination chemotherapy, followed by chemoradiotherapy with concurrent capectabine. This can achieve a response in 30% and a median survival of 17 months.

In the majority of cases, management is palliative. Obstruction of the biliary tree and jaundice is a debilitating complication, often associated with severe pruritus and also non-specific malaise, lethargy and anorexia. Endoscopic placement of endoprostheses (stents) offers excellent palliation.

Palliative surgery has a role in duodenal obstruction (a complication seen in 10% of cases), but in advanced disease, self-expanding metal stents can be placed across the duodenal obstruction with excellent short-term results.

Palliative chemotherapy for advanced disease can be managed with combination chemotherapy. First-line treatment for patients with a good performance status is FOLIRINOX (5-FU, leucovorin, irinotecan and oxaliplatin). This combination treatment was found to lead to a median overall survival of 11.1 months. An alternative regimen for patients who are not fit enough for this treatment is gemcitabine and nab-paclitaxel (paclitaxel as albumin-bound nanoparticles). With disease progression, abdominal pain is a frequent complicating factor; it may prove extremely difficult to treat but can sometimes be helped by radiotherapy.

**UROLOGICAL CANCERS**

**Renal cancer**

**Clinical features and diagnosis**

See page 1407.

**Investigations and management**

At diagnosis, renal cancers are staged using CT and/or MRI to assess operability and the presence or absence of metastases.

**Disease confined to the kidney**

A nephrectomy is performed unless bilateral tumours are present, in which case conservative surgery may be indicated. Preservation of as many nephrons as possible is beneficial in the long term, and a partial nephrectomy should be undertaken where possible.

**Metastatic disease**

For patients with metastatic disease, prognosis is predicted on the basis of the International Metastatic renal cell carcinoma Database Consortium (IMDC or Heng) criteria. A point is scored for each of the following poor prognostic features:

- impaired fitness (<80% on the Karnofsky performance status score)
- haemoglobin below the lower limit of normal
- neutrophils above the upper limit of normal
- platelets above the upper limit of normal
- serum calcium above the upper limit of normal
- <12 months from diagnosis to the requirement for systemic chemotherapy.

Those with no adverse prognostic factors have a 2-year survival of more than 75% and are considered to have a good prognosis; those with one or two factors are regarded as having an intermediate prognosis and have an approximately 50% chance of surviving for 2 years; and those with three factors or more have a poor prognosis and a 2-year survival of 7%. Patients with a good prognosis may benefit from a debulking palliative nephrectomy, which is sometimes followed by regression of metastases. Adjuvant therapy reduces the risk of progression but benefit must be weighed against toxicity.

**Systemic therapy**

TKIs are the mainstay of therapy for metastatic disease. When the prognosis is good, either sunitinib or pazopanib is given as first-line treatment. For patients with an intermediate or poor prognosis but preserved performance status, the combination of the MAb pembrolizumab (which targets PD-1) and the TKI axitinib increases survival compared to sunitinib (hazard ratio (HR) −0.53). An alternative in these patients is the combination of the MAbs ipilimumab and nivolumab (HR −0.68 compared to sunitinib). Good-risk patients may benefit from high-dose IL-2, which appears to increase survival by 5–10%. Sequential use of other drugs, such as cabozantinib, lenvatinib and everolimus, can produce further responses and improvement in disease control. Isolated metastases may be amenable to surgery or stereotactic irradiation.

**Urothelial (bladder and ureteric) cancer**

These cancers are usually transitional cell carcinomas (TCCs), associated with smoking and exposure to a range of chemical agents, although squamous cell carcinomas are common in areas where schistosomiasis is endemic. Their clinical presentation is described on page 1407.

**Superficial cancers**

Superficial TCC of the bladder without invasion through the base- ment membrane may be treated by transurethral resection or local diathermy. The risk of recurrence varies according to the degree of differentiation, and follow-up check cystoscopies and cytological examination of the urine are required. Recurrent superficial TCCs can be treated with bladder installation of the mycobacterium BCG (bacille Calmette–Guérin), which activates immune destruction of cancer cells; alternatively, a cytotoxic drug may be used: either gemcitabine or mitomycin.

**Invasive bladder cancer**

For invasive cancers, the strongest evidence is for neoadjuvant chemotherapy followed by either surgery (cystectomy) or chemoradiotherapy:

- **Neoadjuvant chemotherapy** is usually cisplatin-based, most commonly with gemcitabine. It improves absolute survival by 10%, the prognosis ranging from a 5-year survival of 80–90% for lesions not involving bladder muscle to 5–10% for those presenting with metastases.

- **Surgical treatment** involves cystectomy, generally followed by ileal conduit and stoma formation; in some cases, however, a neobladder can be constructed, allowing more normal micturition. This very much depends on the position of the tumour and the absence of extensive carcinoma in situ.
• **Bladder preservation strategies** for those with T1 with grade 3 histology, or T2–T4 tumours can alternatively be offered with chemoradiotherapy using mitomycin and fluorouracil. In many patients, this can achieve complete disease response, bladder preservation with a good quality of life, and comparable long-term survival (30–50% at 5 years) to cystectomy.

**Metastatic urothelial cancer**

Patients with metastatic disease may be palliated by chemotherapy (cisplatin- or carboplatin-based) or immunotherapy (using a PD-1/PDL-1 checkpoint inhibitor such as pembrolizumab or atezolizumab). Responses are seen in approximately 25% of cases with PDL-1 expression. In the UK, these treatments are currently approved in patients who are ineligible for cisplatin treatment or in whom cisplatin-based therapy has failed.

**Upper tract tumours**

Early-stage tumours are treated by nephroureterectomy. The addition of adjuvant therapy with cisplatin and gemcitabine in the management of non-metastatic T2 tumours has been shown to reduce the risk of recurrence by half (HR 0.49).

**Prostate cancer**

**Clinical features and diagnosis**

The pathogenesis, presentation, diagnosis and initial investigation of prostate cancer are discussed on page 1480.

**Prognosis**

The histological appearances are graded and accorded a Gleason score (see Fig. 40.5). Together with the serum PSA level, and accurate staging of the local extent of disease with pelvic MRI (dynamic contrast) and transrectal ultrasound, this score can identify prognostic groups (see Box 40.6). Treatment decisions must balance the age and performance status of the patient with the predicted behaviour of the cancer, which is becoming more objectively identifiable with advances in gene profiling. This allows the selection of patients with a good prognosis for no active treatment; they may reasonably choose to be kept under surveillance and die with, but not because of, their prostate cancer, as do 75% of men over the age of 80. In experienced hands, pre-biopsy MRI may allow targeted biopsy of the prostate and prediction of those who will have clinically significant prostate cancer.

**Management**

**Disease localized to the prostate**

This can be managed by surgical resection, brachytherapy, radiotherapy or watchful waiting with regular surveillance. The optimum approach depends on both features of the disease and the wider patient context. Management of localized disease is discussed on page 1481.

**Locally advanced disease**

Locally advanced prostate cancer (T3,N0) without distant metastases is best treated with combined androgen deprivation (see later) and radiotherapy; this improves 10-year survival, compared with endocrine treatment alone, from 61% to 71%.

**Metastatic disease**

Metastatic prostate cancer is normally treated initially with androgen deprivation to achieve medical castration (see later), and this may effectively palliate 70% of patients for a median duration of 2 years. Once this fails, the disease is termed ‘castration-resistant’; further palliative options are more potent hormonal drugs (such as androgen receptor blockers; see later) or conventional chemotherapy. If chemotherapy fails, a return to hormonal therapy may prolong disease control. The timing of chemotherapy remains unclear; rather as in breast cancer, it may be deferred until all available hormonal therapy has failed or it may be used earlier.

**Endocrine therapy**

Prostate cancer is the most hormone-sensitive malignancy, with the androgen receptor playing a critical role. However, prostate cancer tissue is able to trap circulating androgens so that tissue levels of androgens are maintained, even despite very low levels of circulating androgens. This means that resistance to endocrine therapy often develops over time, commonly involving receptor super-sensitivity and altered ligand binding, allowing other steroids to act as agonists and eventually bypassing the androgen receptor. A number of strategies are employed to reduce or abolish androgen stimulation of cancer cells:

- **Gonadotrophin releasing hormone (GnRH) agonists.** e.g. goserelin and leuprorelin, are as effective as orchidectomy at lowering circulating androgens and inducing responses in prostate cancer. However, in the first week, GnRH agonists produce a rise in luteinizing hormone (LH) and testosterone, which can result in a tumour flare in metastatic disease; they must therefore be combined with an antiandrogen, e.g. flutamide, in the initial phases. An alternative is to use a gonadorelin antagonist, e.g. degarelix. Physical castration, achieved by bilateral orchidectomy, achieves very effective androgen deprivation but is invasive, often unacceptable to patients and generally unnecessary.

- **Androgen receptor blockers** include drugs such as bicalutamide and the more potent antagonist, enzalutamide. They directly block the action of testosterone on prostate cancer cells.

- **Androgen synthesis inhibitors**, such as abiraterone, act by inhibiting CYP17, a key enzyme in the testosterone production pathway.

- **Corticosteroids and oestrogens** may also be helpful in disease that has become refractory to castration. Hormonal agents may also be used after chemotherapy for prostate cancer, and both enzalutamide and abiraterone have been shown to prolong life in this situation. Adjuvant androgen deprivation treatment, such as monthly depot goserelin, has not improved survival following surgery, but when given before and during radiotherapy, can extend the overall survival at 3 years for T1–T3 tumours from 62% to 78%.

**Non-hormonal therapy**

Non-hormonal approaches are frequently used for metastatic disease:

- **Conventional chemotherapy.** The use of docetaxel in the early management of metastatic castration-sensitive disease has led to an improvement in overall survival. The hazard ratio for benefit from docetaxel is constant but when it is used early at a point when survival is greater, this translates into a greater absolute benefit in overall survival than when it is used after failure of hormonal therapy. The timing of chemotherapy versus hormonal treatment is currently not clear in prostate cancer: early use of the androgen synthesis inhibitor abiraterone, as an alternative to docetaxel, in the management of metastatic, castration-sensitive disease seems to confer similar benefits. It is not known whether combining the two approaches will lead to further improvements. If chemotherapy fails, a return to hormonal therapy may prolong disease control. Currently, there is no consensus as to whether chemotherapy should be deferred until all available hormonal therapy has failed, or be used earlier in disease control.
- **PARP inhibitors.** It is clear that a proportion of prostate cancers have deficits in DNA repair, often associated with carriage of the BRCA2 gene. These patients seem to respond to PARP inhibitors such as olaparib, which prevent repair of DNA strand breaks and cause the death of cancer cells.
- **Bone-targeted therapy.** Drugs such as alpharadin (223radium), zoledronic acid and denosumab, alongside palliative radiotherapy, can be used to target painful metastases.

## Penile cancer
Penile cancer is described on page 1482.

## Testicular and ovarian germ cell tumours
Germ cell tumours are the most common cancers in men aged 15–35 years but comprise only 1–2% of all cancers. They are much less common in women. There are two main histological types: *seminoma* (termed 'dysemicoma' in women) and *non-seminoma*. Non-seminomas may be comprised of varying proportions of mature and immature elements; the mature elements are now known as teratoma (previously, this term referred to all non-seminomas). Teratomas in women present as dermoid cysts with low malignant potential (Box 6.33). Germ cell tumours may rarely occur in extragonadal sites in the midline, such as the pituitary, mediastinum or retroperitoneum, but should be treated in a similar manner.

### Clinical features
Most men present with a testicular mass. In women, the mass presents with vague pelvic symptoms but at a younger age than the more common epithelial ovarian cancers (see later).

### Investigations
- **Ultrasound or MRI scanning** of the testicle or ovary is required. Ultrasound is very sensitive and inexpensive, and should be performed in all suspected cases. MRI scanning is more sensitive and specific than ultrasound; however, expense and limited availability reduce its use as an initial diagnostic tool.
- **Assay of serum tumour markers** includes α-fetoprotein (AFP), β-human chorionic gonadotrophin (β-hCG) and lactate dehydrogenase (LDH). A urinary pregnancy test for hCG in the emergency department has saved the lives of young men with metastatic germ cell cancer.
- **CT or MRI scanning** is performed to seek distant metastases.

## Management

### Surgery
- **In men,** surgery is by the inguinal approach, so-called radical inguinal orchidectomy, to avoid spillage of highly metastatic tumour in the scrotum.
- **In women,** surgery for diagnosis and staging should always be conservative, compared to the approach in epithelial ovarian cancer, with preservation of fertility because of the efficacy of chemotherapy.

### Relapsed disease
Patients who relapse following initial chemotherapy may well be cured by subsequent chemotherapy: this is most commonly with further cisplatin-based chemotherapy or high-dose chemotherapy, usually with carboplatin and etoposide, and a stem cell transplant. The timing of high-dose chemotherapy is uncertain: some clinicians prefer to defer it and use it only after standard-dose salvage treatment has failed. Others feel that the best results are seen if it is used on first relapse.

Although approximately 20% of men will be infertile due to azoospermia at the time of diagnosis, the majority of the remainder will retain their fertility after chemotherapy and be able to father children normally. Similarly, most women retain their fertility, although less is known about the association with infertility at presentation owing to the much lower frequency of germ cell tumours in women.

GYNAECOLOGICAL CANCERS

The main gynaecological cancers are those of the cervix, the body of the uterus (endometrium) and ovary. The presentation and investigation of these cancers are introduced in Box 39.8. All are important and enormous progress has been made in therapy.

Cervical cancer

In high-income countries the incidence of invasive cervical cancer has diminished substantially in recent years due to positive effects of screening and the HPV vaccine; worldwide, however, the incidence remains high.

Aetiology and pathophysiology

Infection with high-risk types of HPV is the most important risk factor for developing cervical cancer. HPV 16 and 18 are the main predisposing viruses and account for 70% of cases in the UK. Infection may be related to a high number of sexual partners and social deprivation, but HPV infection is very common in many populations. Other predisposing factors include smoking and immunodeficiency.

Cervical cancer derives from the squamous epithelium of the cervix. It has a long pre-cancerous phase, when it is termed a ‘carcinoma intraepithelial neoplasm’ (CIN), at which point the cancer has not breached the basement membrane.

Screening

The long pre-invasive phase makes cervical cancer ideal for screening because, at the CIN stage, it is almost universally curable. The cervical screening programme has great importance in cancer prevention worldwide, and even when screening takes place at extended intervals (e.g. in India) it confers great benefit in terms of preventing invasive disease. In the UK the recommendations are that screening should be performed 3-yearly from age 25 to 50, and 5-yearly from age 50 to 64.

Management and prognosis

CIN is classified into three grades, according to the thickness of the cervical epithelium involved: CIN1, CIN2 and CIN3. Removal of abnormal cells is recommended in most CIN2 and all CIN3 disease, and is most commonly achieved by a colposcopic loop electrosurgical excision procedure (LEEP).

Localised disease

Early-stage cancer may be treated using limited surgical techniques that preserve the function of the cervix and are compatible with future fertility. More deeply invasive disease that remains non-metastatic is still highly curable by more major resection of the uterus, ovaries and pelvic nodes (which are the first site of metastatic disease in most cases); this is termed the Wertheim hysterectomy. When disease is more advanced or surgery is contraindicated for reasons of age or co-morbidity, pelvic radiotherapy (usually with concomitant chemotherapy with cisplatin and a transvaginal radiation brachytherapy boost to the cervix) is advised; this confers a similarly high chance of cure.

Metastatic disease

There are no curable options but platin-based chemotherapy, often together with a taxane, is recommended for fitter patients and will delay progression for some time in many. Immunotherapy trials in progress aim to quantify the advantages of this type of therapy for advanced disease.

Endometrial cancer

Cancer of the body of the uterus is less common than cervical cancer, and arises from the endometrial lining of the uterine body. It is almost exclusively a postmenopausal cancer, and patients nearly always present with postmenopausal vaginal bleeding – a ‘red flag’ symptom.

Aetiology

Predisposing factors include a long menstrual life (early menarche and late menopause), endometrial hyperplasia (the partial oestrogen agonist tamoxifen can be a precipitating cause) and obesity (which, in itself, can lead to higher levels of oestrogen, largely oestrone, in postmenopausal women). There is no link to smoking but a weak familial tendency has been observed.

Diagnosis and management

Urgent gynaecological investigation is required for women with postmenopausal bleeding. Transvaginal ultrasound shows a thickened endometrium, and this is followed by cervical dilation and curettage to allow histological diagnosis. Patients usually present at an early stage, as bleeding occurs early.

Early disease

When the cancer is diagnosed at an early stage and is confined to the uterus, hysterectomy is the recommended treatment. The 5-year survival rate exceeds 80%.

Advanced and metastatic disease

When disease is more advanced, postoperative pelvic radiotherapy lowers the risk of local recurrence when the cancer has penetrated deep into the myometrium. For those with disease outside the uterus, chemotherapy may delay progression for some time. Genomically targeted therapy may be useful (the mTOR pathway may be one such ‘driver’ cancer path, targetable using the mTOR inhibitor everolimus), and progestogens may have a small retarding role for those with advanced disease or those too frail to benefit from systemic chemotherapy.

Ovarian cancer

Ovarian cancer arising from the surface epithelial cells (‘epithelial ovarian carcinoma’, EOC) is discussed in this section; other rarer cancers arising from the ovary include stromal cell tumours or germ cell tumours (see earlier and Box 6.34).

Aetiology and epidemiology

Ovarian carcinoma is the seventh most common cancer in women and accounts for 30 cases per 100 000 of the UK population. Most occur in older women, with half of new cases arising in patients above the age of 63 years.

In younger patients, a familial cause (inherited mutation) should be suspected. Mutations of the BRCA1 or BRCA2 gene are the most common familial cause, present in 10% overall, and a genetics review of those with a family history of ovarian or breast cancer should be
Box 6.34 Ovarian cancer pathology

- Serous cystadenocarcinoma

  - Dysgerminoma
  - Embryonal cancer
  - Endodermal sinus tumour
  - Choriocarcinoma
  - Teratoma – immature/mature
- Brenner, Sertoli–Leydig tumour, carcinoid tumours
- Other stromal cell tumours

considered. Prophylactic oophorectomy in BRCA carriers, after they have had their family, is recommended (along with bilateral mastectomies) because the risk of developing cancer is so high (Box 6.35).

There is a consistent relationship between the risk of EOC and the frequency and duration of ovulation. While not fully understood, this provides an explanation for the reduced risk of EOC with early pregnancy and use of the oral contraceptive pill.

Clinical features

Ovarian cancer often presents late, as its early progress is clinically silent. It arises from the surface epithelial cells and these have a tendency to shed when malignant; transcoelomic spread (across the peritoneum) therefore occurs early, and this peritoneal disease evokes ascites. When significant, the ascites leads to abdominal swelling, discomfort, bloating and other abdominal symptoms: indigestion, early satiety, acid reflux and shortness of breath, due to increasing pressure within the abdomen (Box 6.36). Symptoms of irritable bowel syndrome can be confused with those of ovarian cancer but rarely present for the first time over the age of 50, and so the presence of new-onset symptoms should stimulate investigation for ovarian cancer.

Diagnosis

The majority of patients present with a pelvic mass and advanced stage III (spread within the peritoneal cavity) or IV (extraperitoneal) disease. Imaging may reveal ascites, an ovarian mass and peritoneal deposits. Usually, transvaginal ultrasound is performed first, with MRI being the definitive imaging technique for the pelvis, and PET–CT scans assisting in staging the patient. The risk of malignancy index (RMI) (Box 6.37) can predict the chances of an adnexal mass being malignant, but confirmation with ascitic fluid cytology or with surgically obtained tissue is required for diagnosis.

Screening (see pp. 102–3) with the serum tumour marker CA125 and transvaginal ultrasound scan does detect some early cancers, with improved survival; however, it is being further refined with serial tests to avoid too many negative laparotomies and is thus still considered a research tool.

Prognosis

Histological subtype (clear cell and mucinous are worse), grade/differentiation, stage, extent of residual disease following surgery (macroscopic versus microscopic or none) and performance status are all significant independent prognostic factors for survival (Box 6.38).

BRCA mutation status should be assessed in patients with a positive family history (see Box 6.30) and in those with high-grade serous adenocarcinoma histology under the age of 50. Five-year survival rates for stage III disease vary with BRCA mutational status: 44% with BRCA1 and 61% with BRCA2 mutations, compared to 25% in BRCA-negative disease. BRCA status is also a predictive marker for increased sensitivity to platinum and anthracycline cytotoxics, and to PARP inhibitors like olaparib.

Management

Early disease

Curative treatment inevitably requires radical surgery (laparotomy with bilateral salpingo-oophorectomy, hysterectomy and omentectomy). Because of the high risk of peritoneal dissemination, all but patients with very early, ovary-confined cancers benefit from postoperative adjuvant chemotherapy, which is given despite complete macroscopic resection of all visible disease. Clinical trials have
shown that such postoperative chemotherapy reduces the chance of subsequent relapse when the subsequent relapse risk is high.

Advanced disease

In patients presenting with widespread peritoneal disease, or metastatic disease beyond the abdomen and pelvis, neoadjuvant chemotherapy is usually used first to shrink the cancer down to minimal proportions before debulking surgery is attempted. Among the chemotherapy options used for treating ovarian cancer – adjuvantly or for advanced disease – the platinum group are the best single agents and a taxane is usually the partnering cytotoxic. A good majority of advanced cancers respond to these agents. The VEGF inhibitor bevacizumab may be usefully added in advanced disease cases.

Relapsed disease

Response to therapy may be assessed clinically, by scanning and by measurement of the useful ovarian tumour marker CA125: rising CA125 suggests relapse. Drugs used for relapsed disease include other cytotoxics but new agents too are making an impact on therapy. The realization that ovarian cancer is driven by DNA repair faults and that the protein PARP1 is significant in this repair has led to the use of PARP inhibitors to treat advanced ovarian cancer, particularly in cancers that have a known DNA repair deficit such as BRCA or PALB2 mutations. PARP inhibitors used in combination with a DNA ‘toxin’ that causes strand breaks, such as platin chemotherapy, achieves a ‘synthetic lethality’ – a new concept in cancer therapy that made its first inroads in ovarian cancer. It is also predicted that immunotherapy will have a role in advanced ovarian cancer but it is too early to review the data.

Palliative approaches

Up to 30% of those with metastatic disease may be alive after 5 years, although this falls to 5–10% if it is not possible to debulk the cancer at operation or if it has spread outside the peritoneal cavity. Bulky disease in the peritoneum commonly causes progressive bowel obstruction, which may require palliative surgery or expert palliative care support to manage the terminal phases of the illness.

BRAIN TUMOURS

The most common intracranial tumours are secondary brain metastases, which can be solitary or multifocal. Primary brain tumours account for 3% of total cancer cases in the UK. The clinical presentation and initial investigation of brain tumours are on pages 875–876.

Brain metastases

Any cancer can metastasize to the brain but the most common tumours to do so are those arising from:

- lung
- breast
- skin (melanoma)
- kidney.

Management

Cerebral oedema surrounding the tumours responds to steroid therapy. Many systemic therapies for the primary tumour do not cross the blood–brain barrier and therefore do not control brain metastases. There has therefore been a move in recent years to treat brain metastases more aggressively, and it is possible to resect some brain metastases neurosurgically. An alternative option is to employ stereotactic radiotherapy (gamma knife/CyberKnife or linear accelerator-based therapy). In these techniques, focused high-dose radiotherapy is delivered to small areas within the brain, leading to an improvement in overall survival. There is still occasionally a role for whole-brain radiotherapy when there are large numbers of brain metastases or they are too large to treat with stereotactic radiotherapy.

Primary brain tumours

Glioma

Gliomas can be low- or high-grade; this has an impact on prognosis, although low-grade tumours nearly always transform into high-grade tumours eventually. Survival is generally limited, with a median overall duration of 12–18 months (with treatment) in glioblastoma (grade 4 astrocytoma).

Knowledge of molecular pathology can also inform prognosis, predict response to treatment, and may direct therapy in the future:

- Mutations in isocitrate dehydrogenase 1 or 2 (IDH1 or IDH2) indicate that a tumour may be slower-growing. If they are found in a patient with a high-grade tumour, it may indicate that the tumour has transformed from a low-grade one rather than arising de novo.
- Loss of heterozygosity of 1p and 19q genes is associated with oligodendrogliomas, and a better prognosis and response to treatment.
- Promoter methylation of the O6-methylguanine-DNA methyltransferase (MGMT) gene causes inactivation of the gene and predicts a better response to temozolomide chemotherapy, conferring a better prognosis.

Gliomas can be low- or high-grade; this has an impact on prognosis, although low-grade tumours nearly always transform into high-grade tumours eventually. Survival is generally limited, with a median overall duration of 12–18 months (with treatment) in glioblastoma (grade 4 astrocytoma). Knowledge of molecular pathology can also inform prognosis, predict response to treatment, and may direct therapy in the future:

- Mutations in isocitrate dehydrogenase 1 or 2 (IDH1 or IDH2) indicate that a tumour may be slower-growing. If they are found in a patient with a high-grade tumour, it may indicate that the tumour has transformed from a low-grade one rather than arising de novo.
- Loss of heterozygosity of 1p and 19q genes is associated with oligodendrogliomas, and a better prognosis and response to treatment.
- Promoter methylation of the O6-methylguanine-DNA methyltransferase (MGMT) gene causes inactivation of the gene and predicts a better response to temozolomide chemotherapy, conferring a better prognosis.
Management
The management of gliomas depends on the grade, the molecular pathology (if known), the site of the tumour and the patient’s performance status and wishes. Options include:

- **Surveillance.** Low-grade tumours were traditionally followed up with serial imaging alone, but a more proactive approach with earlier intervention is now also considered an option.
- **Surgery.** Craniotomy and maximum debulking surgery are carried out, if possible. This depends on the site of the glioma, as it is not possible to resect a tumour in an area of the brain that would cause significant disability if removed. As gliomas spread along white matter tracts, full resection of a high-grade glioma is never possible. A stereotactic biopsy via a burr hole to inform diagnosis may be a preferable option to debulking surgery.
- **Adjuvant treatment.** Treatment after surgery can include radiotherapy with or without chemotherapy. The chemotherapy must cross the blood–brain barrier: options include temozolomide (an oral alkylating agent), which is commonly used both during radiotherapy (in the case of high-grade tumours) and after radiotherapy.

At relapse, further surgery, radiotherapy or chemotherapy (temozolomide or procarbazine, lomustine and vincristine (PCV)) may all play a part. The role of immunotherapy in the treatment of patients with gliomas is still under investigation, as are agents targeting IDH1 and PARP inhibitors, which sensitize cancers to the effect of radiotherapy. Anti-angiogenic agents may also have a role in the relapse setting but have not been shown to improve survival.

Meningioma
The majority of meningiomas are low-grade but may not behave in a ‘benign’ manner, as they can cause significant disability to the patient: for instance, by causing mass effect, eroding adjacent structures or obstructing the flow of CSF. Surgery is the definitive treatment but may not be feasible due to the location of the tumour. There is a role for fractionated external beam radiotherapy and also stereotactic radiosurgery in the management of inoperable, recurrent and residual meningiomas.

Neurofibroma/schwannoma
Stereotactic radiosurgery is commonly used to treat these tumours and prevent hearing loss; otherwise, surgery may be required.

**HEAD AND NECK CANCER**

The term ‘head and neck cancer’ generally describes squamous cell cancers arising from the mucosa lining the aerodigestive tract. (Thyroid cancer is discussed on pages 621–622.)

Aetiology and pathophysiology
Constant stimulation of the squamous mucosa to divide and repair is an important precancerous phenomenon; mitosis is the most vulnerable time in the cell cycle for DNA replication errors to creep in, and some of these escape DNA repair mechanisms. The accumulation of these mutations in the genome of the daughter cells can lead to eventual cancer formation.

Predisposing factors for head and neck cancer include those that stimulate mucosal division and repair, and those that directly cause damage to DNA. They include:

- the irritant effects of spices, spirits and tobacco smoking
- poor oral hygiene, leading to chronic low-grade periodontal inflammation, or irritation of the tongue as it rubs against a sharp tooth
- the mutagenic effects of air pollution or tobacco smoking
- the effects of viruses (HPV for oropharyngeal cancer and EBV for nasopharyngeal cancer)
- some chronic inflammatory conditions (such as lichen planus of the mouth).

Squamous head and neck cancer describes a group of cancers that spread ‘logically’: first to regional lymph nodes (the horizontal group – occipital, post-auricular, pre-auricular, facial, submandibular and submental, or the vertical deep cervical chain) before spreading elsewhere – often to the lung. Furthermore, a considerable time frequently elapses before disease spreads beyond the primary site and nodes. This provides a greater chance for cure in the form of local and regional therapy, such as surgical resection with local radiotherapy. Most cases of early head and neck cancer are curable.

Clinical features
Presenting symptoms depend on the cancer’s site of origin. Hoarseness of the voice is a ‘red flag’ for general practitioners, as it is an early symptom of laryngeal cancer, while a persistent lump or ulcer in the mouth is a ‘red flag’ for dentists, in that it may be an early symptom of oral cancer. An enlarged lump in the neck (that persists after an obvious upper respiratory tract infection) similarly needs to be regarded with suspicion. Ear, nose and throat clinic review is warranted, with consideration of biopsy or cytology.

Staging
Biopsy-proven cancer requires staging using the TNM system. PET scanning is often useful for staging distant disease, while MRI is best for obtaining anatomical detail of local spread and depth of invasion. Viral status (HPV or EBV) may have implications for therapy. Genomic analysis and predictive tests for immunotherapy have roles in the relapsed patient.

Management
**Early disease**
Where early cases are easily operable with margins clear of disease, surgery is usually curative. Elective dissection of the deep cervical chain is sometimes indicated to treat ‘one step ahead of the cancer’s spread’: that is, resecting the next most likely site to harbour microscopic disease. Where surgical resection of the primary may lead to great morbidity (e.g. laryngectomy for early laryngeal cancer), and radiotherapy, to which this type of cancer is sensitive, has an equivalent chance of cure, radiotherapy is preferred. Where the cancer is invading cartilage or bone, it is considered to be more radiotherapy-resistant and surgery may be the better option.

**Locally advanced disease**
In more locally advanced cases for which radiotherapy is chosen, chemotherapy (usually cisplatin) in conjunction with the radiotherapy enhances the radiation effect. The EGFR inhibitor cetuximab can be used to inhibit signal transduction within cancer cells, again in conjunction with radiotherapy.

Metastatic disease
The lungs and bones are the most common sites for spread after local lymph node groups. Chemotherapy with cisplatin-based regimens, often given alongside 5-FU, is first-line therapy, and again, cetuximab may have a role. Immunotherapy agents, such as the PD-1 inhibitor nivolumab, may have significant efficacy and can induce remarkable remissions in some cases, presumably due to the high mutational load and PDL-1 expression of these squamous cancers.
Patients presenting with symptoms of metastases, or with an incidental finding on imaging without a clinically obvious primary cancer after investigation, represent a common clinical problem and comprise 5–10% of patients in a specialist oncological centre. Clinical guidelines are based on several systematic studies, some with postmortem follow-up. Patients predicted to have a poor prognosis (based on performance status, histology, and site and extent of disease) can be spared the discomfort of intensive investigation and be given more appropriate palliative care.

### Diagnosis
Diagnosis requires histology first and foremost, as it will lead to the identification of several distinct groups.

- **Squamous cancers** mostly present in the lymph nodes of the cervical region; 80% are associated with an occult head and neck primary, the remainder arising from the lung. Inguinal nodes usually point to a primary of the genital tract or anal canal. Treatment with radiotherapy and chemotherapy may have curative potential, especially in the head and neck area, and even in the absence of an identifiable primary on pan-endoscopy.

- **Poorly differentiated or anaplastic cancers** include a number of potentially curable cancers, such as high-grade lymphomas and germ cell tumours, and should be suspected in all young patients with midline masses. They are sometimes identifiable by their immunocytochemistry and tumour markers. Gene markers, such as i12p for germ cell tumours in cancer of unknown primary, and BCL-2 for lymphomas, are increasingly available to aid diagnosis. Treatment and prognosis are as outlined for lymphoma (see Ch. 17) and germ cell tumours (p. 129).

- **Adenocarcinomas** form the majority of cases of metastatic cancer of unknown primary. Their investigation should be guided by the desire to identify the most treatable options, and the knowledge that the largest proportion will have arisen from the lung or pancreas, with relatively poor treatment prospects.

### Investigations
Investigations should always start with a thorough review of the histology and imaging, such as CT of the chest, abdomen and pelvis. In men, further investigations should include serum PSA and rectal ultrasound to identify prostate cancers; in women, mammography and breast MRI to identify occult breast cancer, and pelvic MRI to identify ovarian cancer should be undertaken (Box 6.39).

Tissue tumour markers can be helpful (Box 6.40) and, increasingly, gene profiles are able to identify the primary site of origin by

</table>
gene expression microarray and RT-PCR. Mutation analysis is more easily available to identify potential targets for treatment, such as RAS, EGFR and RET; however, clinical trials are still needed to establish whether specific pathway inhibitors have a therapeutic effect.

For good-prognosis patients wishing to have palliative chemotherapy, investigations such as endoscopy to identify lung, colon or stomach primaries are indicated to guide the choice of chemotherapy agents, although the diagnostic yield of 4–5% must be set against the discomfort and risks. Serum tumour markers for other solid cancers, although highly sensitive, are too non-specific and unreliable to be useful as diagnostic aids in this situation.

Further investigation may require PET–CT for head and neck, lung and possibly other primaries, and radio-isotope scans for thyroid and carcinoid tumours. PET–CT may also be used to seek other metastatic sites if surgery is being considered for unifocal disease.

**Prognosis**

Most large series report an overall median survival of 12 weeks but a considerably better rate among subgroups, such as patients presenting with isolated nodal metastases, who have a significantly better prognosis than the majority with visceral and/or bone metastases. These better-prognosis patients may warrant more extensive investigation.

**Management**

If investigations have not identified a primary site, surgery may be considered for unifocal adenocarcinoma of unknown primary (ACUP) metastases in lymph nodes, lung, liver and brain, especially if due to suspected melanoma and so having the potential for long-term survival.

In women, an isolated axillary lymph node metastasis should be treated as for lymph node-positive breast cancer; this has a similar prospect for long-term cure, though without the need for breast surgery. Malignant ascites in women should be treated with a trial of chemotherapy, as for primary peritoneal, fallopian tube or epithelial ovarian cancer. The prognosis for those responding to the therapeutic trial is similar to that in disease of known primary origin. Primary chemotherapy that achieves an excellent response on imaging and CA125 criteria should be followed by debulking surgery; if successful, this carries a median survival in excess of 4 years.

For men, the occasional occult prostatic cancer found because of a raised serum PSA offers some palliative treatment prospects.

For the patient presenting with hepatic metastases, which are most commonly associated with an occult gastrointestinal primary, there is increasing choice and efficacy of chemotherapy agents for gastrointestinal cancers that have the potential to improve their palliation.

If there is an excellent response, suitable patients may even be considered for hepatic ablation or resection. If, after all efforts, no primary has been identified, palliative chemotherapy can achieve responses in 20–40% in highly selected series, with a median survival of 9–10 months, and 5–10% surviving to 5 years.

Palliative care in non-malignant disease 146

CORE SKILLS AND KNOWLEDGE

Palliative care is the active total care of patients who have advanced, progressive, life-shortening disease. It is based on needs and not diagnosis, and is required in non-malignant diseases as well as in cancer. Knowledge of the principles of palliative medicine is essential for all healthcare professionals, and can be applied throughout medical practice so that all patients, across all care settings, receive and have access to good palliative care.

Palliative care is delivered by multidisciplinary teams that include doctors, nurses, therapists, chaplains, psychologists and social workers. It may be given in the patient’s own home, during acute hospital admissions, and through hospices, which typically provide both inpatient and outpatient services. There is a focus on addressing all aspects of a patient’s care needs, promoting independence, and supporting patients and their families through the dying process.

Key skills to acquire in palliative care include:

- learning to talk openly and sensitively with patients about disability, uncertainty, deterioration and death
- learning about the range of interventions used in managing common symptoms such as pain and nausea
- working within a multidisciplinary team to provide holistic care for patients.

Opportunities for learning these skills include visiting a hospice and talking with patients and those close to them, shadowing different members of a palliative care team as they visit patients, and attending palliative care clinics to observe how healthcare professionals communicate with patients and address their needs.

INTRODUCTION AND GENERAL ASPECTS

Palliative care is an approach that has relevance in medicine well beyond the final weeks of death from malignant disease. It is based on needs and not diagnosis, and is required in non-malignant diseases as well as in cancer. Knowledge of the principles of palliative medicine is essential for all healthcare professionals, and can be applied throughout medical practice so that all patients, across all care settings, receive and have access to good palliative care.

Palliative care is delivered by multidisciplinary teams that include doctors, nurses, therapists, chaplains, psychologists and social workers. It may be given in the patient’s own home, during acute hospital admissions, and through hospices, which typically provide both inpatient and outpatient services. There is a focus on addressing all aspects of a patient’s care needs, promoting independence, and supporting patients and their families through the dying process.

Key skills to acquire in palliative care include:

- learning to talk openly and sensitively with patients about disability, uncertainty, deterioration and death
- learning about the range of interventions used in managing common symptoms such as pain and nausea
- working within a multidisciplinary team to provide holistic care for patients.

Opportunities for learning these skills include visiting a hospice and talking with patients and those close to them, shadowing different members of a palliative care team as they visit patients, and attending palliative care clinics to observe how healthcare professionals communicate with patients and address their needs.

Who provides palliative care?

A hallmark of palliative care is the multiprofessional team, as single professionals cannot provide the breadth of necessary expertise. The emotional demands of working in this area require team support to enable balanced, compassionate and professional care. Members of the team can include, but are not restricted to, clinical nurse specialists, doctors, psychologists, therapists (occupational, physical, music and creative), chaplains and social workers. In some centres the term supportive care is used instead of palliative care.
Box 7.1 Key points in palliative care and key components of a modern palliative care service

**Key points in palliative care**
- Patients should always be involved in decisions about their care.
- Quality of life is increased when treatment goals are clearly understood by everyone, including patient and carer.
- The multidisciplinary team provide a high standard of care but there must be realism and honesty about what can be achieved.
- End-of-life care is delivered in all settings: the patient’s usual place of residence, hospitals and hospices.
- Care at home should be encouraged for as long as possible, even if the patient’s preferred place of death is elsewhere.
- Discussions about end-of-life care planning are best held outside times of crisis, with clinicians with whom the patient has a good relationship. An unplanned admission can be a trigger for advance care planning discussions.
- Discussions must be recorded and made known to everyone involved in the patient’s care.

**Key components of a modern palliative care service**
- Management based on needs, not diagnosis: the symptom burden of non-malignant disease often equals that of cancer.
- Care that is independent of the patient’s location and that helps patients to remain at home if possible, avoiding unwanted admissions to hospital.
- Rehabilitation for people with advanced disease.
- Support for carers.
- Bereavement care for people with complicated grief.
- Advice for other clinicians; dissemination of palliative care knowledge.
- Education (surrounding palliative and end-of-life care) for clinicians of all disciplines and at all levels.

Box 7.2 Problems arising when specialist palliative care is delayed until the end of life

- There is insufficient time to achieve good symptom control by combining non-pharmacological and pharmacological components.
- Specialist palliative care services are deemed less acceptable by patient and family, being associated with ‘dying’, ‘giving up’ or ‘giving in’ to illness.
- Psychological distress and physical symptoms become intractable and contribute to complex grief.
- It becomes too late to adopt a rehabilitative approach or teach/use non-pharmacological interventions that need a degree of training and patient motivation (e.g. cognitive behavioural approaches, mindfulness meditation, attendance at day therapy).

All healthcare providers should have basic palliative care skills and know how to access SPC advice. The latter may come from teams based in hospitals, hospices or in the community, as palliative care crosses all healthcare settings. Clinicians should be aware of the services that their local SPC teams offer and recognize when referral is appropriate. Palliative care can be used from the time of diagnosis of potentially life-threatening or life-limiting illness, even when cure is considered possible (‘hoping for the best, preparing for the worst’). A problem-based approach to disease management will ensure that patients and carers obtain access to appropriate support services, including SPC, and avoid an either/or approach (‘either curative treatment or palliative care’).

Patients may have very close relationships with their usual medical team and an integrated approach is needed to allow optimization of disease-directed intervention as well as palliation. Excellent communication between all members of the healthcare team, and between patient and carer, underpins the successful management of advanced disease and end-of-life care. Effective liaison between the hospital, primary care centre and hospice is also essential.

When should palliative care needs be assessed – problems rather than prognosis?

Early assessment of needs is crucial to achieving the best outcome for maintaining or improving quality of life for both patient and carer. Palliative care is most effective when included as part of routine care as soon as possible after diagnosis, alongside disease-specific therapy. Early referral links palliative care with quality-of-life improvements; positive associations increase the likelihood that patients and families continue to use palliative care services when they need them over the course of the illness. In cancer, there is good evidence that integrating palliative care and anti-tumour treatment soon after diagnosis reduces long-term distress and even increases survival in selected cases.

If palliative care is seen as relevant only to the end-of-life phase, patients may be denied expert help for complex symptoms. Timely management of physical and psychosocial issues earlier in the course of disease prevents intractable problems later (see Box 7.2). It can be difficult to know when to consider palliative care in non-malignant conditions due to their variable disease trajectories (Fig. 7.1) but using the ‘Surprise Question’ (Box 7.3) may help clinicians decide; it is the basis of the Gold Standards Framework tool that is commonly used to help tailor care to the right time and place. Anyone with symptoms or complex family issues, whatever their prognosis, may benefit from support from the palliative care team.

![Fig. 7.1 Trajectories of different disease types. Green = cancer, red = chronic non-malignant disease, blue = multimorbidity and increasing frailty. (From Murray SA, Kendall M, Boyd K et al. Illness trajectories and palliative care. BMJ 2005; 330:1007.)](https://www.goldstandardsframework.org.uk/ The Gold Standards Framework, 2011)

**Box 7.3 The ‘Surprise Question’**

Would you be surprised if this patient died within the next 12 months?

Further resources

their wishes and acknowledging their concerns, will help the team plan and implement effective support. Validated questionnaires, such as the integrated Palliative Care Outcome Scale (iPOS), have been developed and are routinely used to aid this. Patients will have differing needs for information and will deal with ‘bad news’ in different ways. A sensitive approach, respecting individual requirements, is crucial.

### How can patients use palliative care services?

Changes in the provision of SPC services have been forced by the increase in the number of patients who survive malignant disease (‘living with and beyond cancer’), and the ageing and increasing rates of multimorbidity in the population, as well as recognition of the needs of patients who have non-malignant disease. Palliative care services can be accessed for specialist symptom management and psychological support, not just care in the last few weeks and days of life, and patients should be informed of this. They may use inpatient SPC services for a limited period (days to weeks) for complex problems to be intensively addressed, and then may be discharged with community palliative care follow-up. They have the opportunity for re-referral if help is required later. Many patients are managed at home by community palliative care in close conjunction with primary care services.

### Further reading

### SYMPTOM CONTROL

Good palliative care integrates non-pharmacological approaches, such as anxiety management and rehabilitation, with pharmacological control of symptoms. Medications should be rationalized to reduce polypharmacy. A key, and usually initial, component of palliative care is actively identifying and managing reversible problems that could be contributing to inadequate symptom control (Box 7.5). Symptom management runs in parallel with these active treatments.

### Pain

Pain is the most feared symptom at the end of life. At least two-thirds of people with cancer suffer significant pain. Pain has a number of causes, and not all pains respond equally well to opioid analgesics. It may be related to the tumour either directly (e.g. pressure on surrounding structures) or indirectly (e.g. due to weight loss or pressure ulcers), and can result from comorbidity such as arthritis. Various scales can be used to assess a patient’s pain (Fig. 7.2). Emotional and spiritual distress may be expressed as, and can exacerbate, physical pain.

The term ‘total pain’ encompasses a variety of influences that contribute to pain:

- **biological**: the disease itself, disease-modifying therapy (drugs, surgery, radiotherapy)
- **social**: family distress, loss of independence, financial problems
- **psychological**: fear of dying, of pain, or of being in hospital; anger at dying or at the process of diagnosis and perceived delays, with anxiety and/or depression stemming from all of these
- **spiritual**: fear of death, questions about life’s meaning, guilt, why me?

### Box 7.5 Examples of reversible problems that can be treated to improve symptoms

**Patient 1**

Mr K has metastatic prostate cancer with known spinal metastases at multiple levels. He complains of worsening back pain and leg weakness. This warrants urgent magnetic resonance imaging to rule out metastatic spinal cord compression, which could be treated with steroids and radiotherapy leading to an improvement in his symptoms and functioning.

**Patient 2**

Mrs S has metastatic breast cancer. She describes a history of general deterioration, nausea, abdominal pain, constipation and low mood. This warrants a set of blood tests that may reveal hypercalcemia, which can improve with intravenous fluids and bisphosphonates; there may even be resolution of symptoms.

**Patient 3**

Mrs B has metastatic ovarian cancer. She has a similar history to that of Mrs S. A thorough clinical examination may reveal tense ascites as a cause of abdominal discomfort, nausea and constipation, which could be alleviated by paracentesis.
The WHO analgesic ladder

Most cancer pain can be managed with oral or commonly used transdermal preparations. The World Health Organization (WHO) cancer pain relief ladder guides the choice of analgesic according to pain severity (Fig. 7.3).

If regular use of optimum dosing (e.g. paracetamol 1 g four times daily) for step 1 does not control pain, then an analgesic from the next step of the ladder is prescribed. As pain has different physical aetiologies, an adjuvant analgesic may be needed: for example, a gabapentoinoid for neuropathic pain (see Box 7.9).

Strong opioid drugs

Dose titration and route

Morphine is the drug of choice and, in most circumstances, should be given regularly by mouth. The dose should be tailored to the individual’s needs by allowing ‘as required’ doses up to every 1–2 hours. Morphine for cancer pain does not have a ‘ceiling’ effect but there may be a limit to the usefulness of opioids in chronic non-cancer pain. If a patient has needed further doses in addition to the regular daily dose and they have been effective, then the amount in the additional doses can be added to the following day’s regular dose. This up-titration can be repeated until the daily requirement becomes stable (Box 7.6). When a stable daily dose requirement has been established, the morphine can be changed to a modified-release preparation and the patient given ‘as required’ doses of immediate-release morphine, which are usually one-sixth of their total daily morphine dose.

The starting dose of morphine is usually 5–10 mg every 4 hours, depending on patient size, renal function and whether a weak opioid is already being given. If an individual is already on step 2 of the WHO ladder, explaining conversions between medications can be helpful to gain patient confidence. For example, maximum-dose codeine (60 mg four times daily) is equivalent to a total of 24 mg morphine per day (Box 7.7). If there is renal dysfunction, morphine should be used in low doses, or oxycodone considered in mild to moderate renal dysfunction (hepatic metabolism). Modified-release preparations ought to be avoided. However, if renal dysfunction is significant (estimated glomerular filtration rate <30 mL/min), an alternative opioid, such as alfentanil, should be considered because of the risk of metabolite accumulation. If there is concurrent significant hepatic dysfunction, oxycodone should be avoided. Dosing is not an exact science in palliative care: Advice can be sought from the SPC team.

Strong opioids come in transdermal preparations, such as buprenorphine or fentanyl patches (Box 7.8). These are useful in patients with stable pain. Serum levels do not change quickly with transdermal patches; they can therefore be hazardous if the pain stimulus is removed, and are cumbersome to titrate in patients with escalating or unstable pain. The patient should be reassessed and reasons for the escalation in pain sought; if necessary, advice should be requested. Be aware that transdermal patches may be administered every 72 hours or weekly, depending on the dose and brand – always check this when prescribing.

If a patient is unable to take oral medication due to weakness, swallowing difficulties or nausea and vomiting, the opioid should be given parenterally. This may be via continuous subcutaneous infusion, whereby the opioid dose is administered continuously via a syringe pump over the course of 24 hours.

Box 7.6 Opioid titration examples

**Scenario 1**

A patient regularly takes 20 mg of morphine sulphate immediate release every 4 hours. What long-acting preparation could they be started on?

- 20 mg every 4 hours = 120 mg morphine per day
- 60 mg twice daily of a 12-h morphine sulphate modified-release (MR) preparation

**Scenario 2**

The same patient has started morphine sulphate MR 60 mg twice a day with ‘as required’ immediate-release morphine 20 mg every 1–2 hours. A few months later, their pain escalates due to disease progression and they require an additional 4 doses per day of immediate-release morphine. What should their long-acting morphine be increased to?

- 20 mg x 4 = additional 80 mg morphine per day
- Total daily morphine dose including morphine MR = 200 mg
- 100 mg twice daily of a 12-h morphine sulphate MR

**Top tip:** Always thoroughly check dose conversions. Dosing is not an exact science - discuss with SPC if unsure.
Doctors and patients may have worries, such as the fear of addiction, which mean that adequate doses of opioids are not prescribed or taken. Iatrogenic addiction is very rare (<0.01% risk), but the adverse effects and morbidity from uncontrolled pain are much higher. Patients and carers should be reassured about their medications and the rationale for their use, and it is good practice to provide written information regarding opioids. Regular review is necessary to achieve optimal pain control, including regular assessment to distinguish pain severity from distress due to pain.

The opioid epidemic
In 2018 there were 6000 deaths from opioid overdose in the USA. These deaths were mainly in young people who had first become addicted to opioids in the form of legally available drugs, some then switching to other, more potent, opioids from illegal sources. Many of those involved came from stable, middle-class backgrounds. The epidemic of addiction has had profound societal consequences and is beginning to affect the status of opioids for medical use: for example, there is shorter postoperative prescription of drugs, and opioids for non-malignant pain have been withdrawn. It may yet have a further impact, as legal action is being taken against drug companies for providing misleading information in the ‘selling’ of opioids: for example, their statement that modified-release oxycodone is not addictive. Be aware of the dependency potential of longer-term opioids and ensure that family members know the dangers of using the patient’s pain and breathlessness medication.

Side-effects
The most common side-effects of strong opioids are:
- **Nausea and vomiting.** These can be managed with use of antiemetics.
- **Constipation.** This is common and should be anticipated; best practice guidelines advocate that all opioids should be co-prescribed with laxatives. Newer laxatives for opioid-induced constipation – e.g. naloxegol or methylnaltrexone, peripherally acting opioid receptor antagonists – can be used if response to other laxatives is poor.

If side-effects are intractable, a change of opioid is often helpful. Some patients find transdermal preparations of opioids less constipating.

Toxicity
Confusion, persistent and undue drowsiness, myoclonus, nightmares and hallucinations indicate opioid toxicity. This may follow rapid dose escalation and responds to dose reduction and slower titration. It may indicate pain that is poorly responsive to opioids and the need for adjuvant analgesics. Patients should be assessed for reversible factors contributing to reduced tolerance of opioids, such as sepsis. Importantly, respiratory depression (respiratory rate <8 breaths/min) is a late sign and indicates significant toxicity that needs management as an emergency. Consider stopping any long-acting opioid preparation and administering naloxone if respiratory depression is severe. Dependency on opioids used in the longer term does occur and means that sudden reversal (with naloxone) or withdrawal of opioids is not advisable, unless absolutely necessary.

Antipsychotics such as haloperidol may help settle the patient’s distress while waiting for toxicity to resolve. Some individuals will tolerate an alternative opioid such as oxycodone better, or an alternative route such as subcutaneous injection.

Adjuvants and alternatives
**Box 7.9** outlines the most commonly used adjuvant analgesics. Neuropathic pain often responds well to adjuvants in the antiepileptic or tricyclic antidepressant class. Other treatments, such as radio- or chemotherapy, interventional pain strategies (e.g. nerve blocks, epidurals) and transcutaneous electrical nerve stimulation (TENS), may be useful in selected patients. Multidisciplinary team working is essential to manage patients’ pain optimally, and joint working between palliative care and pain teams helps to achieve this.

Additionally, to improve their symptoms and wellbeing, patients facing incurable illness are increasingly turning to less conventional therapies to complement, and serve as alternatives to, prescribed medical treatments. These include acupuncture and herbal and massage therapies. Although there may not be a strong evidence base to support some of these, this does not mean that they do not have a beneficial contribution to make to the holistic care of patients. There has been significant recent interest in certain agents, such as cannabinoids. Evidence is mounting that points to the benefits of medicinal cannabis in a wide variety of conditions, and it has a good risk:benefit profile. This has led certain countries to legalize cannabis and allow its prescription. As ever, more research is needed into these compounds and therapies to demonstrate their effectiveness clearly, and the picture will evolve over time. Institutions and organizations are increasingly developing guidance and policies.

Palliative care and symptom control

Gastrointestinal symptoms

Nausea and vomiting

These symptoms are common and may have numerous causes: both physical and psychological factors can contribute. Careful choice of antiemetic targeted towards the underlying cause of the nausea and/or vomiting is essential. Nausea and vomiting are associated with:

- **Chemotherapy.** Certain agents, e.g. cisplatin, confer a high risk of nausea and vomiting. A 5-hydroxytryptamine3 (5-HT3) antagonist, such as ondansetron 8mg three times daily, may help. Aprepitant, a neurokinin-1 (NK-1) antagonist, is increasingly being used as an adjunct in chemotherapy-induced nausea and vomiting.
- **Chemical causes, e.g. hypercalcaemia, hepatic failure, uraemia or drugs.** Haloperidol 0.5–1.5mg as required every 4 hours, up to a maximum of 5mg daily, is the first choice.
- **Gastric stasis and distension.** Metoclopramide 10mg three times daily is a prokinetic and promotes gastric emptying. The prokinetic effects can also ameliorate constipation.
- **Raised intracranial pressure, e.g. brain tumour.** Cyclizine 50mg three times daily is most useful.
- **Mechanical causes of vomiting.** It may be necessary to start antiemetic therapy parenterally by continuous subcutaneous infusion to gain control. If the patient has gastrointestinal obstruction or poor oral/gastrointestinal absorption, this route may need to be continued. Levomepromazine is a second-line antiemetic if initial therapy is not successful; 6.25mg as required, up to a maximum of 25mg per day, is recommended. Other medications to aid nausea and vomiting include corticosteroids, particularly in the case of bowel obstruction, where reducing tumour oedema may alleviate the obstruction and improve symptoms.

Constipation

This is common, occurring in up to 45% of hospice patients and 90% of patients on opioids. It is best managed with a combination of pharmacological and non-pharmacological strategies. Non-pharmacological measures can include maintaining hydration, mobility, dietary advice, optimal positioning, privacy and comfort to aid relaxation when trying to open bowels.

Pharmacological strategies – that is, laxatives (Box 7.10) – are targeted to the cause of the constipation and a careful history is required. Often, opioid-induced constipation responds to a combination of stool softener and stimulant, e.g. docusate and senna. Doses will require individual titration. Some patients may need suppositories or enemas. Those with reduced sensation and mobility – for example, due to spinal cord compression – may require a bowel regimen of regular suppositories and maintenance of a relatively firm stool to facilitate best care. Many are likely to need to continue regular laxatives, as they will develop troublesome constipation again on cessation of these medications.

Bowel obstruction

This is common in advanced cancer (3%), and especially so in gynaecological and colorectal cancers. It is caused by mechanical obstruction of the bowel lumen and/or peristaltic failure due to infiltration of the nerves. Presenting symptoms include pain, vomiting, colic and constipation. It can be partial or complete, at single or multiple sites, and carries a poor prognosis. Palliative management of bowel obstruction focuses on medications to improve symptoms, as opposed to the surgical approach, which uses a large-bore nasogastric tube (to decompress) and intravenous fluids, coupled with keeping the patient nil by mouth. Consideration should be paid to nutrition, including parenteral. The patient’s prognosis and further treatment options, among other things, should be taken into account.

Metoclopramide’s prokinetic effect can be employed in partial obstruction to encourage the bowels to function again. However, it should be avoided in complete obstruction where the bowel is physically blocked, as it will worsen colic. In this situation, an antispasmodic, such as hyoscine butylbromide, is preferred, along with regular analgesia and an antiemetic such as haloperidol. A dose of 60–120mg/24h s.c. is usually recommended but much higher doses (300–480mg) may be needed, as parenteral hyoscine butylbromide can be rapidly inactivated.

Octreotide (a somatostatin analogue) is used as second-line treatment in bowel obstruction to improve symptoms, which it does by reducing gut secretions and the volume of vomitus. However, there is only low-level evidence of benefit in management of symptoms, and a small number of randomized controlled trials have failed to show any benefit. Further studies are needed. Ranitidine may have a role in reducing gastric secretions.

Physical measures, such as a defunctioning colostomy or a venting gastrostomy, may be helpful. Occasionally, a lower bowel obstruction is resolved with insertion of a stent or transrectal resection of tumour in selected individuals. Steroids can shorten the length of episodes of obstruction, if resolution is possible.

In advanced disease, where the obstruction is irreversible, patients should be encouraged to drink and take small amounts of soft diet for comfort as they wish. With good mouth care (see later),
the sensation of thirst can be managed and parenteral fluids may not be needed. If these are indicated, they should be introduced as a trial to improve symptoms and patients counselled about the benefits and risks, including their possible contribution to increased gut secretions and volume of vomitus; in this case the fluids may be ceased.

**Anorexia, weight loss and malaise**

These result from the cachexia syndrome of advanced disease and are poor prognostic factors. Although attention must be paid to nutrition, the syndrome is mediated through chronic stimulation of the acute phase response and tumour-secreted substances. Thus, calorie–protein support alone gives limited benefit; parenteral feeding has been shown to make no difference to patient survival or quality of life.

Management is generally supportive and advice from dieticians may be helpful. Patients and their carers should be reassured that decreased appetite is to be expected, and advising ‘little and often’ and ‘what you want, when you want’ can be useful.

Corticosteroids are occasionally used as appetite stimulants. However, the weight gained is usually fluid retention, and muscle catabolism is accelerated, causing proximal myopathy. Any benefit in appetite stimulation tends to be short-lived, which must be explained clearly to patients and carers. Thus, use of corticosteroids should be limited to the short term and reviewed regularly.

Other interventions – for example, a rehabilitative palliative care programme encompassing nutritional supplementation and exercise in advanced cancer – are being trialled.

**Respiratory symptoms**

**Breathlessness**

Chronic breathlessness (dyspnoea) is a common but frightening symptom of many advanced malignant and non-malignant diseases but often goes unrecognized and untreated. Its features have been described as ‘breathlessness that persists despite optimal treatment of the underlying pathophysiology and that results in disability’. It is also terrifying for carers, who often feel helpless. Carer anxiety may exacerbate a patient’s breathlessness and it is therefore essential to involve them in treatment strategies and support them in their own right. Recent advances have helped to establish effective treatments to reduce the impact of breathlessness, but palliative care or specialist breathlessness services are often needed to provide optimal care.

The sensation of being breathless is generated in the central nervous system through the integration of peripheral and central signals by a complex network involving structures in the mid brain, higher cortical regions and the limbic system (Fig. 7.4). Individual assessment is key, as is reversal of any contributory factors, such as optimizing treatment of underlying medical conditions, although in advanced disease many of these are irreversible.

The first step in assessing breathlessness (Box 7.11) is to ask directly about it, as many patients with severe breathlessness will not be troubled at rest. Best practice in managing breathlessness rests on a complex intervention comprised of a number of non-pharmacological and pharmacological approaches (Boxes 7.11 and 7.12). Careful assessment of the patient – for example, utilizing the ‘Breathing, Thinking, Functioning’ clinical model (Fig. 7.5) – guides the choice of initial non-pharmacological approach (Box 7.12). Pharmacological measures should be reserved for those with severe breathlessness on exertion or at rest, or with advanced progressive disease such as untreated lung cancer or heart failure. Morphine is the drug with the best evidence base; other treatments, such as mirtazapine, are being
investigated. Benzodiazepines should not be used routinely to manage breathlessness, as there is no evidence of their benefit; they may, however, be prescribed in those at the end of life or when there is a limited prognosis. Oxygen is not helpful in relieving the sensation of breathlessness but may be essential in managing the underlying medical condition and improving exercise capacity. There are specific assessment tools, such as the Dyspnoea-12 and numerical rating scales (NRS), which can help initial management and subsequent monitoring of treatment strategies.

Cough
This is an unpleasant symptom that can affect the lives of both patient and carer. Drug approaches (e.g. opioids or gabapentin) have limited impact but may be needed. Recently, specialist multi-disciplinary non-pharmacological approaches have been developed for both non-malignant and malignant disease.

Secretions
Excessive respiratory secretions at the end of life can be treated with **glycopyrronium** 200–400μg every 2–4 hours, maximum 1.2–2.4mg per
Symptom control

24 hours, or **hyoscine butylbromide** 20mg every 1–2 hours, maximum 120mg per 24 hours. These can be given by continuous subcutaneous infusion. Both give a dry mouth and care must be taken not to dry secretions significantly in a patient who is still able to cough well, as they may become too sticky to expectorate, leading to significant discomfort.

**Further reading**

**Other physical symptoms**

People with cancer may develop other physical symptoms caused by the tumour directly (e.g. hemiplegia due to brain metastases) or indirectly (e.g. bleeding or venous thromboembolism due to coagulopathy). Symptoms may also result from treatment, such as lymphoedema in breast cancer, or heart failure secondary to chemotherapy. The principles of holistic assessment, treatment of reversible factors, and appropriate involvement of the multiprofessional team should be applied.

**Fatigue**

Fatigue is a significant and debilitating problem for palliative patients. It has physical, cognitive and affective components; unlike normal tiredness, it is not relieved by usual sleep or rest. An assessment for reversible contributory factors, such as anaemia, hypokalaemia or over-sedation due to poorly optimized medication, should be undertaken. Management strategies are mainly non-pharmacological: relaxation, sleep hygiene, resting ‘proactively’ rather than collapsing when exhausted, and planning, pacing and prioritizing daily activities. Trials of pharmacological agents – such as methylphenidate, a central nervous system stimulant – are currently under way but drug-free approaches remain best practice, as previous randomized controlled trials have proved drugs to be ineffective.

**Mouth symptoms**

Dry mouth is common in advanced disease and may be a result of medications used to treat other symptoms, such as pain or nausea. It can be managed with artificial saliva substitutes and good mouth care to keep mucous membranes moist. Careful inspection of the mouth identifies any reversible causes contributing to oral discomfort: for example, candidiasis, which is common in the immunocompromised but treatable with antifungals. As patients lose weight, dentures may become ill-fitting, causing ulceration to the gums. This can be managed with analgesia, denture cushions, and topical treatments to numb the sore parts of the mouth.

Patients receiving courses of radiotherapy for haematological disorders or head and neck cancers can develop painful mucositis (pain and inflammation of the mucous membrane, which may present as painful mouth ulceration affecting any or all intraoral surfaces). This is a common reason for referral to hospital palliative care teams, even when the treatment aims are curative. Management is with meticulous mouth care, including mouthwashes to maintain oral hygiene, as well as to provide pain relief. Some patients with severe mucositis will require enteral feeding and management of their pain with continuous subcutaneous infusion until it settles.

**Loss of function, disability and rehabilitation**

Some of the most pressing concerns include increasing physical frailty, loss of independence, and perception of being a burden on others. Evidence suggests that functional problems are not routinely assessed, and not as well managed as other symptoms.

Palliative rehabilitation in long-term incurable illness aims to enable patients to achieve their functional and social priorities in
Palliative care and symptom control

the context of physical decline, as well as to adjust to change in physical ability, role and sense of self. Patients and carers often appreciate a focus on what is still possible, rather than what is lost.

Rehabilitation may include exercise to address reversible physical decline and fatigue, which may be especially evident following an exacerbation or relapse. Understandably, sustaining motivation to maintain physical activity can be difficult. Setting small and achievable goals may help maintain motivation and promote self-efficacy. Involving carers in rehabilitation sessions may reduce over-protectiveness.

Rehabilitation includes supporting adaptation by encouraging patients to do things differently, including the use of mobility aids or equipment. Aids and adaptations may be seen as symbols of ‘giving up’ by some patients. They need to be presented in a positive light as ‘enablers’ that assist people to achieve their goals and that may also reduce carer burden. Psychological support to accept change may be required.

Hospices take a ‘rehabilitative approach’, with most having physical and occupational therapists and exercise equipment. Referral to hospice day therapy, pulmonary rehabilitation, community exercise groups or community physical or occupational therapy may be appropriate. However, patients have to have an active desire to engage in rehabilitation. Some may see therapy as an additional unwanted drain on their time and their wishes should be ascertained, as well as discussing the merits and disadvantages of engaging.

Functional problems and fatigue should not be seen as inevitable, unavoidable and insoluble. All healthcare professionals have a role in promoting the benefits of patients keeping as active as they are able, to help maintain their strength and ability in long-term incurable illness. Barriers to this, including misconceptions about exercise and activity being harmful, should be discussed and addressed, as well as considering psychological barriers such as anxiety and depression. Throughout illness, there is a need to take into account changing performance status, as well as changes in goals and priorities.

Poor sleep

This is common, and patients may have longstanding difficulties with sleep that worsen during their illness. Discomfort in bed, leading to worsening symptoms and psychological concerns surrounding their condition and the future, can compound the problem. Eliciting and listening to patients’ concerns, explaining the concept of sleep hygiene and discouraging lengthy day-time naps, can be helpful, as well as therapy team review of the bed and provision of equipment that will optimize symptom management. Pharmacological measures – for example, hypnotics such as zopiclone or melatonin – should be used only temporarily and are not long-term solutions to sleep problems. Complementary therapies are available in hospices and some hospitals, and may offer relaxation to patients to aid sleep.

Psycosocial issues

Depression is a common feature of life-limiting and disabling illness, and is often missed or dismissed as ‘understandable’. However, it may respond to antidepressant drugs and/or to non-pharmacological measures such as cognitive behavioural therapy, increased social support and support for family relationships. Antidepressants can take several weeks to take effect and a patient’s prognosis must therefore be considered if they are initiated. The ‘side-effects’ of certain antidepressant medications are sometimes utilized to benefit patients. For example, mirtazapine can improve sleep, anxiety, appetite and low mood, but may also be helpful to treat pain and nausea; evidence is also emerging for its benefits in gastroparesis. Such interventions can make a big difference to the patient’s quality of life and ability to manage their situation.

Further reading

Chronic respiratory disease

Chronic obstructive pulmonary disease (COPD) is the most common chronic respiratory disease. Patients with COPD may live increasingly restricted lives for years, rather than months or weeks, once they become breathless. This can lead to depression, isolation, frustration and sometimes guilt associated with previous smoking habits. As with many chronic conditions, patients can reach older age before becoming very disabled, and an elderly spouse often has to carry significant physical carer burdens.
Palliative care in non-malignant disease

Palliative care breathlessness support services can be very helpful for patients unable to manage pulmonary rehabilitation or those with complex psychosocial needs that require individual assessment. Emergency admissions to hospital for non-medical reasons are often due to severe anxiety (in patient and/or carer), and the support offered by community palliative care services and/or breathlessness services working with respiratory teams can help reduce these.

In advanced disease, patients may be using non-invasive ventilation (NIV) regularly at home. This may provide considerable symptom relief but early discussions should take place regarding management of NIV during exacerbations of COPD and at the end of life.

Pulmonary fibrosis, another chronic respiratory illness that often requires palliative care, has a trajectory similar to that of cancer, with rapidly developing breathlessness and cough. The breathlessness of pulmonary fibrosis can be particularly frightening but may respond well to opioids; early access to hospice services is particularly relevant to help with symptom control and anxiety. Long-term oxygen therapy may be necessary to manage severe hypoxaemia and maintain function in these patients.

Opioid titration in non-malignant respiratory disease

In non-malignant respiratory disease, opioid titration may need to follow a different pattern from that used in malignant disease, in which many patients are already on opioids for pain control before they develop breathlessness. Individual assessment is essential. Some clinicians recommend a cautious approach in starting opioids in chronically breathless patients who have non-malignant disease, but the evidence indicates that those with adequate renal function and without type 2 respiratory failure may safely be started on 5–10mg per day modified release morphine, given appropriate monitoring. Significant respiratory depression has not been noted in various trials of opioids in advanced respiratory disease.

Further reading

Renal disease

All care for patients who have end-stage chronic kidney disease (CKD) is directed towards maintenance or improvement of renal function. Prescribing is complicated, particularly in those receiving dialysis. Drugs are variably removed by dialysis and this must be taken into account; the renal drug database (see ‘Further reading’) is helpful. Care must be taken not to cause inadvertent renal damage with potentially nephrotoxic medication, and close liaison with renal physicians is mandatory.

In patients who have CKD, co-morbidities such as cardiovascular disease, diabetes or osteoporosis may cause greater problems than the renal disease itself. Those with a fluctuant course of symptoms, such as the 25–33% who have coexisting cardiac disease, bear disproportionately greater physical and psychological burdens.

Withdrawal of dialysis

Withdrawal of dialysis is necessary when the effort of attendance becomes burdensome, there is little improvement in quality of life and the impact of other co-morbidities becomes intrusive.

If there is no residual renal function (i.e. the patient is anuric), survival after withdrawal of dialysis is likely to be a few days at most. In contrast, patients who have some residual function may live for months or even a year after withdrawal. Patients and carers need to understand these differences in order to make informed choices.

Patients who are not on dialysis

There may not be any survival benefit conferred by starting dialysis as opposed to conservative management of renal dysfunction in the elderly. Conservative management may allow more time out of hospital and better quality of life for these patients. Maximizing and preserving remaining renal function are critical considerations in deciding which medications can or should be prescribed.

- Medication that accelerates loss of renal function, such as NSAIDs, may markedly reduce survival in patients who can live with very little remaining renal function.
- The renal impact of both dose and drug choice must be taken into account. For example, morphine and diamorphine metabolites accumulate in end-stage renal dysfunction; thus alternative opioids such as alfentanil or fentanyl should be used instead. These may have to be given parenterally.

Further reading

Neurological disease

People with chronic degenerative neurological diseases have a considerable burden of palliative care needs, which may include:

- difficulties in swallowing (e.g. in motor neurone disease and multiple sclerosis)
- excessive difficulty clearing secretions, and weak cough leading to fear of choking
- progressive loss of physical function with associated pain and vulnerable pressure areas
- loss of mental capacity (see p. 83), anxiety and depression.

The multidisciplinary team is vital to the care of these patients, and may provide physiotherapy and occupational therapy to manage loss of function, as well as speech and language therapy to optimize communication. Discussions regarding the patient’s care preferences and practical wishes (e.g. writing a will) should take place early so that these can be supported, if the patient is able to participate and when communication is easier.

Motor neurone disease

Motor neurone disease is usually rapidly progressive, often requiring hospice support. Percutaneous endoscopic gastrostomy feeding may be needed. Secretions, such as excess saliva, can be problematic and treatment may entail careful balancing of anti-secretory medication: for example, hyoscine hydrobromide, which is available as a transdermal preparation. In addition, if ventilatory failure develops, NIV may be offered. Patients and their carers need to understand:

- why this treatment has been offered (to prevent hypercapnia and associated morning headache and confusion; it can confer a survival benefit)
- when this treatment will be withdrawn (when it is no longer helping to maintain or improve quality of life in the face of advancing disease; guidelines are widely available to help with these specialist discussions).
Patients need to have a clear understanding of what alternative symptom control will be offered at withdrawal.

**Multiple sclerosis**

Pain is often prominent in multiple sclerosis because of muscle spasm. This is managed with regular physiotherapy, medications and, in severe cases, botulinum toxin, nerve blocks or surgery. Patients may become too disabled to attend outpatient clinics and then receive little surveillance or support. Hospice day therapy services, rehabilitation, and support for the family can have a huge impact on quality of life. A person can live for many years disabled and symptomatic, and regular surveillance and support are essential.

**Dementia**

Dementia-related palliative care needs arise in the context of neurological conditions that:

- **tend to occur in older people** (Alzheimer’s disease and vascular dementia)
- **also affect younger people** (e.g. Parkinson’s disease, multiple sclerosis, Huntington’s disease).

It is often difficult to ascertain whether these patients are in pain. An assessment tool that assesses behavioural response to pain can be useful, such as the Abbey or Dolopius pain scale; these are based on vocalization (e.g. groaning), facial expression (e.g. frowning), and body language (fidgeting, rocking), behaviour (e.g. confusion, refusal to eat) and physical changes.

Mental capacity orders and Deprivation of Liberty Safeguards (DoLS) may need to be considered where a patient is effectively ‘deprived’ of their liberty in a care home or hospital.

---

**Children and young people**

Increasing numbers of children are living with life-threatening and life-limiting illness, such as cystic fibrosis and severe cerebral palsy. Palliative care supports these children and their families to achieve the best possible quality of life and care. The model of palliative care in young people is different to that in adult services, as many children are supported for years by hospices; generally, they are cared for in their own homes and the number of deaths is small compared to that in adults. Many conditions are extremely rare and may be familial. As well as symptom management, hospices can provide short respite breaks for families caring for seriously ill children. An increasing number of these patients will now survive to adulthood, and ensuring a smooth transition to adult services is an evolving area of development.

**Box 7.13 Components of personalized care plans for the last days of life**

- Recognition of the dying phase and communication with patient and carers
- Initial assessment (which includes the patient’s and carers’ understanding, wishes and psychological state)
- Resuscitation status and treatment escalation plans
- Discussion surrounding how symptoms will be managed
- Discussion about feeding and fluids
- Ongoing assessment and monitoring
- Support for the carers after the patient’s death

---

**CARE OF THE DYING**

Most people express a wish to die in their own homes, provided their symptoms are controlled and their carers are supported. However, patients die in any setting and all healthcare professionals should therefore be proficient in end-of-life care.

Hospitals and communities have developed individualized or personalized care plans for the last days of life that help to prompt discussions surrounding the dying process, and how physical, psychological, social, spiritual and carer concerns will be addressed (Box 7.13).

The decision to provide support through a personalized care plan for the last days of life is reached by a multiprofessional team through careful assessment of the patient, exclusion of reversible causes of deterioration, and excellent communication with carers or family.

Hospitals in England take part in yearly national audits to assess end-of-life care. The data are used to allow development of quality improvement initiatives to continuously improve end of life care.

**Do not attempt resuscitation orders and treatment escalation plans**

The resuscitation status of every patient should be discussed by senior doctors at the time of admission to hospital, or when deterioration is noted that is not thought to be reversible. This decision must be clearly documented in the notes. Treatment escalation plans and ‘ceilings of care’ determining what treatments are likely to be beneficial or futile should be discussed at the same time in line with patient wishes.

Hospitals and communities have specific ‘do not attempt resuscitation’ (DNAR) forms. Deciding a person’s resuscitation status is a careful balance of risk versus benefit. Co-morbidities, pre-morbid quality of life and the patient’s wishes should be taken into account.

DNAR orders and treatment escalation plans are medical treatment decisions. However, the patient and family must be involved in discussions, unless they have specifically requested not to be, and the reasoning behind decisions should be explained. In the UK in 2014 the Court of Appeal ruled in the case of Tracey vs Cambridge University Hospitals NHS Foundation Trust that a failure to discuss the making of a DNAR order with a patient who had expressed a wish to be involved in decision-making around their care constitutes a breach of their human rights. Concern regarding possible patient distress is no justification for not discussing resuscitation, though it will guide the way the subject is considered with the patient. Only if it is felt that there will be significant psychological or physical harm resulting from the discussion can it be postponed. If the patient requests that cardiopulmonary resuscitation is not performed in the event of cardiopulmonary arrest, this should be respected.

Remember that a decision not to resuscitate a patient is not the same as a decision to withhold other treatment. A patient who is ‘not for resuscitation’ may still be eligible for, and benefit from, antibiotics, fluids, endoscopy and even surgery. Management should remain positive and proactive, allowing the patient to die free of distress and with dignity.
ReSPECT (Recommended Summary Plan for Emergency Care and Treatment) is starting to be implemented in many hospitals. It is a process that creates and records personalized recommendations for a person’s clinical care in a future emergency in which they are unable to make or express choices. It is likely to be useful in those with complex health needs, integrating discussion surrounding DNAR and treatment escalation.

Sepsis is a serious complication of infection in which a dysregulated immune response leads to organ dysfunction and sometimes death. It is the final common pathophysiological pathway in patients who die from infection. It is estimated that, worldwide, 49 million people develop sepsis every year, and 11 million die.

Sepsis is a medical emergency; antibiotics must be empirically prescribed within 1 hour of presentation and then reviewed at 72 hours when culture results become available. All healthcare staff should be aware of sepsis, which may present via the hospital emergency department or develop on general medical or surgical wards. Specialist care for patients with severe complications of sepsis may be provided in a critical care unit. Infectious Diseases (ID) physicians become involved in managing patients with complex or disseminated infections, and may run Outpatient Antibiotic Treatment (OPAT) services and specialist ID clinics.

Key skills in this chapter area include:
• identifying sepsis and instituting emergency management using the Sepsis Six care bundle
• appreciating the potential complications of sepsis, and recognizing the need for appropriate escalation of care in acutely unwell or deteriorating patients
• becoming familiar with the appropriate use of antibiotics to treat commonly encountered infections.

Opportunities for students to learn about sepsis and infection are gained by reviewing patients with suspected infection in the emergency department or acute assessment units, ID wards or critical care settings, or those deteriorating on general wards who may be identified by attending critical care outreach rounds. Observing specialist ID and OPAT clinics (including multidisciplinary team meetings) provides an insight into the longer-term follow-up of patients with infection.
Symptoms
- Duration
- Symptoms of inflammatory response: fevers, chills, rigors, malaise, confusion, vomiting
- Localizing symptoms indicating site of infection:
  - Chest: cough, sputum, shortness of breath
  - Urinary tract: dysuria, urgency, flank pain
  - Central nervous system: headache, meningism
  - Biliary tract: upper abdominal pain, jaundice, vomiting
  - Skin and soft tissue: signs of cellulitis, pain

Past medical history
- Immunosuppression (diabetes, asplenia, human immunodeficiency virus, etc.)
- Previous sepsis

Drug history
- Immunosuppressant medication
- Recent courses of antibiotics

Risk factors for specific pathogen types
- Recent contact with medical institutions
- Previous infection with antibiotic-resistant organisms
- Travel history

**End-organ failure**
- Systolic blood pressure (SBP) <90 mmHg or >40 mmHg fall from baseline or mean arterial pressure (MAP) <65 mmHg
- Bilateral pulmonary infiltrates with no new need for oxygen to maintain saturations >90% or with \( \text{PaO}_2/\text{FiO}_2 \) ratio <300 mmHg or 39.9 kPa
- Serum lactate >2.0 mmol/L
- Serum creatinine >170 µmol/L or urine output <0.5 mL/kg per hour for 2 successive hours
- INR >1.5 or an (activated) partial thromboplastin time (PTT) >60 sec
- Platelet count <100 × 10⁹/L
- Bilirubin >32 µmol

**Fig. 8.1** Management of suspected sepsis.

### SITES AND SIGNS OF INFECTION

**Observation chart**
- **Fever**
- **Tachypnoea** (a key sign of clinical deterioration)
- **Tachycardia and hypotension**
- **Hypoxia** (may suggest lower respiratory tract infection)

**Central nervous system**
- Drowsiness and confusion common signs of sepsis
- Examine for signs of meningitis

**Jugular venous pressure**
- May be reduced in dehydration/volume depletion

**Heart**
- New or changed murmur may indicate infective endocarditis

**Indwelling devices** (e.g. Hickman lines)
- Examine for signs of intravenous device infection such as discharge or induration
- Obtain additional culture from line where possible

**Abdomen**
- Examine for signs of peritonitis
- Right upper quadrant tenderness common in biliary sepsis
- Right lower quadrant tenderness seen in appendicitis, pelvic inflammatory disease and cystitis
- Left-sided tenderness common in diverticulitis

**Back**
- Localized tenderness may indicate discitis or spinal abscess
- Loin tenderness common in pyelonephritis

**Genital examination**
- Males – signs of epididymo-orchitis
- Females – pelvic inflammatory disease; consider retained tampons causing toxic-shock syndrome

**Extremities**
- Coolness (may indicate hypotension or intravascular volume depletion)
- Cellulitis or soft tissue infection (consider devastating infection such as necrotizing fasciitis – see p. 669)
- High index of suspicion for septic arthritis if any joints are swollen

**Foot**
- Infected ulcers (especially in patients with diabetes)
Sepsis is a rare but serious complication of infection. The syndrome arises when the adaptive immune response to infection becomes maladaptive, leading to organ dysfunction. Multi-organ failure in septic shock is the final common pathway for most patients who die from infection.

### PATHOPHYSIOLOGY

The pathophysiology of sepsis is complex. Pathogen-associated molecular patterns (PAMPs) include components of bacterial, fungal and viral pathogens; these activate the innate immune system, which is chiefly comprised of macrophages, monocytes, granulocytes, natural killer cells and dendritic cells (see p. 43). This activation occurs through Toll-like and C-type lectin receptors on cell surfaces and nucleotide-binding oligomerization domain (NOD)-like and retinoic acid-inducible gene-1 (RIG-I) like receptors in the cytosol. The downstream effects of these activation events, mediated through the upregulation of multiple genes, include the production of pro-inflammatory cytokines such as tumour necrosis factor-alpha (TNF-α) and interleukins 1 (IL-1) and 6 (IL-6). Further effects include increased innate immune activity, production of hepatic acute phase proteins (e.g., complement, fibronogen and C-reactive protein (CRP)), release of microparticles containing inflammatory, pro-oxidant and procoagulant lipids and proteins, and elaboration of neutrophil extracellular traps (NETs), which are scaffolds of DNA and antimicrobial proteins and enzymes. The release of microparticles and NETs, combined with increased intravascular tissue factor expression, leads to the phenomenon of ‘immunothrombosis’, whereby microbes are trapped in microthrombi, which in turn attract and further activate leucocytes.

This highly preserved innate response is usually very effective at controlling and neutralizing local infection. When the response exceeds a certain threshold, damage to the host becomes clinically evident. This may be mediated through mitochondrial dysfunction, leading to deficient adenosine triphosphate (ATP) production, and through widespread immunothrombosis as complement activation increases vascular permeability and causes disseminated intravascular coagulation (DIC); this leads to further inflammation, impaired microvascular function and subsequent organ dysfunction. Sepsis becomes a self-reinforcing pathophysiological phenomenon, associated with fierce catabolism to fuel it.

#### Organ dysfunction

At organ level, sepsis represents a systemic loss of homeostasis, the dysfunction of each organ system adversely affecting the function of every other. The physiological demand requires an increased cardiac output, which most patients achieve after fluid resuscitation. However, the syndrome itself, and associated acidosis, can exert a negatively inotropic influence on the heart. Vasoplasgia leads to reduced total peripheral resistance, and capillary leak of plasma and protein-rich fluid causes tissue oedema, which in turn impairs oxygen delivery to cells. In the lungs, it can cause acute lung injury and adult respiratory distress syndrome. Epithelial disruption in the gut can lead not only to malabsorption, but also to translocation of bacteria into the bloodstream, further amplifying the septic insult. Acute kidney injury is common and associated with an increased risk of death. Brain dysfunction manifests as septic encephalopathy, ranging from mild drowsiness and confusion to coma.

### Consensus definition (Sepsis-3)

The complexity of the sepsis syndrome does not lend itself to a simple diagnostic test. Many biomarkers have been proposed but none is specific enough to be used to define the condition.

In 1991, the first consensus conference to agree a definition of sepsis allied it to the concept of the systemic inflammatory response syndrome (SIRS). This definition was modestly revised in 2001. In the light of intercurrent research and growing knowledge, the latest definition was published in 2016. In anticipation of further updates as our understanding of the syndrome evolves, it was given the name ‘Sepsis-3’.

Sepsis is currently defined as ‘life-threatening organ dysfunction caused by a dysregulated host response to infection’. ‘SIRS’ is no longer used to define sepsis; the term ‘sepsis’ is reserved for the syndrome described above, as opposed to simple infection. Clinicians must be clear about the diagnosis. Inappropriate use of the term ‘urosepsis’ to describe a simple urinary tract infection (UTI), for example, is misleading and distorts healthcare statistics.

Examination of a large dataset of electronic patient records enabled the authors of the Sepsis-3 definition to construct clinical criteria that best predicted which patients with infection developed life-threatening organ dysfunction, for which the surrogate measure of in-hospital mortality was used. In intensive care this consisted of changes in the Sequential Organ Failure Assessment (SOFA) score (Box 8.2). The best predictor of death or a requirement for 3 days or more of intensive care for ward patients was a new construct, the ‘quick SOFA’ (qSOFA). Patients are deemed positive for qSOFA if they have two of:

- Glasgow Coma Scale score of <15 (see Box 26.28)
- respiratory rate of ≥22 breaths/min
- systolic blood pressure of ≤100 mmHg.

In the UK, the Royal College of Physicians recommends using a National Early Warning Score (NEWS 2) of 5 or more as an indicator that a patient is at high risk of having sepsis (see Fig. 10.1). Remember that neither the qSOFA nor the NEWS 2 is diagnostic of sepsis; they merely indicate that a patient is at higher risk of having sepsis and should be assessed for the condition.

### Septic shock

The term ‘septic shock’ is reserved for the subset of patients with sepsis whose circulatory and metabolic dysfunction is such that their risk of death is significantly increased. Clinically, patients are identified as septic who require vasopressor support to maintain a mean arterial pressure of 65 mmHg or more, and who have an elevated serum lactate concentration (>2 mmol/L) despite adequate volume resuscitation.

### RECOGNITION OF SEPSIS

#### At-risk groups

Whether a simple infection will progress to sepsis or not depends on a range of factors, including the virulence of the pathogen, the microbial load, the site of infection and the host response. The latter
is influenced by genetic make-up, co-morbidities, past medical history and chronic treatments. Groups at higher risk of developing sepsis include:

- older people (>65 years of age) and the very young (neonates)
- people who have previously had sepsis
- people with immunosuppressive medical conditions (such as HIV, asplenia, cirrhosis, autoimmune diseases)
- people who are iatrogenically immunosuppressed (those on immunosuppressive drugs, including systemic corticosteroids)
- patients with indwelling devices, especially if they breach normal barriers against infection
- pregnant women
- people who abuse alcohol or intravenous drugs.

**In-hospital surveillance**

Inpatients have a higher risk of developing sepsis that patients in the community. Hospitals should therefore have systems in place to identify deteriorating patients early, aligned with processes that enable a prompt medical response. In the UK the NEWS 2 score (see earlier) assigns a numerical score to patients’ observations, weighted according to the degree of deviation from normal values. It has long been known that cardiac arrest is usually preceded by several hours of increasingly deranged physiology, reflected by an increasing NEWS 2 score.

Most hospitals empower ward staff to call for help at certain NEWS 2 thresholds. In many instances this will be on the basis of a total NEWS 2 of 5 or more, or on clinical concern, which should always trump a numerical score. The request for assistance (conveyed using the SBAR approach, for example; see p. 11) should prompt an urgent medical review, including screening for sepsis.

There is no binary test for sepsis. Screening consists of a risk assessment, carried out by an experienced and informed clinician, of the likelihood that a deteriorating patient is developing sepsis. That likelihood is increased in the presence of extreme physiological derangement, highly suspicious elements of recent medical history, acute kidney injury or raised serum lactate, as incorporated into a recent NICE guideline (Box 8.3). The diagnosis should be made on the basis of bedside observations and limited point-of-care testing, in order to minimize the time to treatment. Given that early antimicrobial therapy may alter the natural history of the syndrome, waiting for laboratory blood tests and other investigations to confirm the presence of organ dysfunction is counterproductive. Where available, point-of-care lactate measurement can be especially useful. Lactate level is prognostic in patients with sepsis; a raised lactate should never be ignored and is usually a sign of organ dysfunction, even in patients who might otherwise seem relatively well.

### Origins of sepsis

Sepsis may be either community-acquired, healthcare-associated or hospital-acquired. Community-acquired disease is defined as sepsis occurring within 48 hours of hospital admission, whereas in hospital-acquired disease sepsis occurs after 48 hours. Healthcare-associated sepsis, a subset of community-onset sepsis, is defined as sepsis occurring in:

- patients within 30 days of hospital discharge
- nursing home residents but not those living in residential homes
- patients accessing medical treatment in the community (e.g. patients on haemodialysis).

**Community-acquired infection** tends to be severe and is likely to be caused by virulent but more antibiotic-sensitive organisms. Examples include *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Escherichia coli*, Klebsiella pneumoniae and Neisseria meningitidis. The most common sites of infection are the urinary tract, biliary tract and lower respiratory tract (pneumonia); rarely, there may be infective endocarditis or meningitis.

In contrast, organisms causing **hospital-acquired infection** are less virulent but often multidrug-resistant; they are therefore harder to treat. Examples include Stenotrophomonas maltophilia and Acinetobacter baumannii. Infection is often procedure- or medical device-related. The risk of procedure-related sepsis (e.g. following surgical procedures or tissue biopsy) can be minimized by appropriate antibiotic prophylaxis, and where sepsis is associated with a medical device (e.g. a blocked urinary catheter or infected intravascular catheter), this should be removed (termed ‘source control’).
Sepsis and the treatment of bacterial infection

Clinical features

Early sepsis can be difficult to diagnose. Signs and symptoms evolve in variable fashion along a continuum from those of localized infection (e.g. cough, dysuria) to more systemic evidence of organ dysfunction (e.g. confusion, oliguria, petechial haemorrhage). Some patients’ organ dysfunction evolves gradually, while others may exhibit a precipitous deterioration from minor symptoms to multi-organ failure in a matter of hours. No symptom is pathognomonic but patients typically complain of rigors, breathlessness, muscle pain, vomiting, mottled skin and a feeling of being extremely unwell, in addition to the symptoms relating to their underlying infection. Signs correspond to those of the infective source, together with those of systemic inflammation, such as tachycardia, tachypnoea, hypotension, warm, dilated peripheries, oliguria, confusion or drowsiness. Immunosuppressed patients may display relatively few signs and symptoms of inflammation, although those relating to the physiological response should still be present.

Investigations reveal non-specific evidence of inflammation and organ dysfunction, such as raised white cell count and CRP, rising creatinine and bilirubin, falling platelet count, possible infiltrates on chest X-ray, and dysrhythmias on the electrocardiogram (ECG). Imaging may help identify the site of infection.

Sepsis in special situations

Returning travellers

A detailed history is required, with dates of travel, areas visited and onset of symptoms. Exposures that put travellers at risk of tropical infections (e.g. insect bites or fresh-water swimming) should be elicited, and enquiry should be made as to whether patients took malaria prophylaxis or were immunized prior to travel. Assessments should be carried out for viral haemorrhagic fever (in patients with fever within 21 days of return from an endemic region, see p. 531) and Middle East respiratory syndrome coronavirus (MERS-CoV) (in patients with onset of respiratory symptoms within 14 days of arrival from the Middle East, see p. 521). Minimum investigations include blood cultures and a malaria screen, in addition to routine blood tests. The approach to a returned traveller is covered more fully in Chapter 20.

People who inject drugs

Most episodes of sepsis are related to infected thrombophlebitis or local abscesses at or around injection sites. The most common causative bacteria are meticillin-sensitive and meticillin-resistant *S. aureus* (MSSA and MRSA, respectively) and *Streptococcus pyogenes*. Occasionally, staphylococcal infections can disseminate to distant sites, including heart valves, the vertebral column and joints (see Box 20.23). If the tricuspid valve becomes infected, embolization to the lungs may occur, resulting in multiple lung abscesses. In addition to source control (e.g. drainage of paraspinal collections, washout of peripheral joints and, rarely, tricuspid valve replacement), patients often require weeks of antibiotic treatment.

People who inject drugs are more prone to aspiration pneumonia or empyema because of diminished cough reflex and fluctuating levels of consciousness. Rarely, when lemon juice is used as a solvent, yeasts in the blood may cause ocular endophthalmitis. Optimal management requires vitreal amphotericin implants and prolonged antifungal treatment.

Neutropenic patients
Most commonly, sepsis occurs in haematological oncology patients post chemotherapy (see Ch. 17). Due to the risk of overwhelming pseudomonal infection, most empirical treatment includes piperacillin/tazobactam (tazocin) with or without an aminoglycoside.

Paralysed patients
Acutely, these patients are most commonly cared for in a critical care setting. The greatest risk is that posed by medical devices (e.g. central venous catheters, urinary catheters and endotracheal tubes). Implementation of care bundles around the placement and aftercare of such devices minimizes the risk of infection, which may be caused by multidrug-resistant organisms that, consequently, are often harder to treat. Pressure sores can be prevented by use of appropriate mattresses and regular turning the patient. Individuals with spinal cord injuries may present with signs and symptoms of autonomic dysreflexia rather than infection if the site is below the level of injury.

MANAGEMENT OF SEPSIS

Surviving Sepsis Campaign guidelines
The cornerstones of management for sepsis are urgent treatment of the infection and support of failing organs. It is likely the patient will need to be admitted to a critical care unit in order to access specialized organ support. Suspected sepsis is a medical emergency, however, so initial treatment and resuscitation should start without delay. The Sepsis Six is a suggested bundle of care, which includes early broad-spectrum antibiotics (Box 8.4).

The Surviving Sepsis Campaign (SSC) produces regularly updated international guidelines on the management of sepsis and septic shock. The various recommendations and suggestions are graded according to the quality of research evidence available. The key recommendations are given in Box 8.5.

Supporting a failing circulation: fluid resuscitation
Fluid resuscitation is a first step in supporting organ perfusion. The SSC recommends infusing at least 30 mL/kg of crystalloid solution within 3 hours of diagnosis. Such early high-volume resuscitation is common practice in well-resourced healthcare systems. However, trial evidence is emerging that bolus resuscitation is not beneficial in all populations. Two high-quality trials conducted in low-income countries demonstrated that fluid resuscitation in patients with sepsis increased mortality, despite early improvement in indices of perfusion. Proposed explanations for these unexpected findings include lack of critical care support to counteract harmful side-effects of high-volume fluid resuscitation, and excessive reperfusion injury, which may be worse in a population that presents later in the natural history of the condition.

Aborting the microbial driver: antimicrobials and source control
A retrospective study of patients with sepsis found that, after the onset of hypotension, for every hour’s delay in the administration of broad-spectrum antibiotics, the risk of death rose by 7.6%. More recent data from 49 331 emergency department patients in New York State confirm a directly proportional rise in mortality with time to first antibiotic administration. This finding is biologically plausible, given that it is the microbial burden that is driving the immune response, which is, in turn, giving rise to the sepsis syndrome.

Not every infection can be cured with antimicrobials alone. Infected collections with an inadequate or absent blood supply, such as deep abscesses, infected prostheses or intravascular devices, need physical removal. This process, whether it requires open surgery or percutaneous drainage, is termed source control (see later).

Box 8.4 The Sepsis Six
1. Give oxygen to maintain $SpO_2 > 94$
2. Take blood cultures
3. Give broad-spectrum intravenous antibiotics
4. Give a fluid challenge
5. Measure lactate
6. Measure urine output and chart hourly fluid balance

Box 8.5 Surviving Sepsis Campaign: main recommendations for early management

**Initial resuscitation**
- Instigate i.v. fluid resuscitation with 30 mL/kg crystalloid within the first 3 h
- Give further fluid guided by haemodynamic assessment and use of dynamic variables to ascertain fluid responsiveness
- Target mean arterial pressure to 65 mmHg
- Guide resuscitation to normalize lactate in patients with raised lactate

**Screening**
- Have in place systems to screen acutely ill high-risk patients for sepsis

**Diagnosis**
- Obtain cultures before starting antibiotic treatment

**Antimicrobial therapy**
- Give i.v. antibiotics within 1 h of recognition of sepsis
- Start with broad-spectrum empirical therapy, with the aim of de-escalating once the pathogen and its sensitivities are known; assess for de-escalation daily

**Source control**
- Establish anatomical diagnosis and arrangements for emergency source control as soon as possible
- Remove potentially infected vascular access devices as soon as new access is obtained

**Fluid therapy**
- Apply a fluid challenge technique when on-going fluid administration is required
- Use crystalloids, the recommended fluid of choice
- Consider human albumin solution in addition, when large volumes of fluid are required
- Avoid hydroxyethyl starches
Useful diagnostic samples and laboratory processing

There is always time to obtain blood cultures before starting empirical antibiotic treatment. This is critical, even in an acutely septic or unstable patient. In adults, a minimum of 5 mL of blood should be inoculated into both aerobic and anaerobic blood culture bottles. The one exception is in suspected meningococcal septicaemia, where antibiotic administration should never be delayed. Administration of antibiotics prior to sample collection may result in sterile blood cultures, but polymerase chain reaction (PCR) testing for bacterial DNA in whole blood may still enable detection of the causative bacterial pathogen (Box 8.6).

For other acute infections, the ability to take further samples before antibiotics will depend on the stability of the patient. Examples include mid-stream urine (MSU), cerebrospinal fluid (CSF), stool, intravenous line tips and pus. Where bacteria are cultured in pure growth, these samples can help to define sites of infection. The laboratory can also provide susceptibility data for bacteria, particularly when resistance to commonly used antibiotics is unpredictable. An example is a UTI associated with Gram-negative bacteraemia, typically with *E. coli* or *K. pneumoniae*, in which susceptibility to beta-lactams, quinolones and aminoglycosides, often used as empirical therapy, is highly unpredictable. In stable patients whose site of infection remains undefined, imaging may reveal collections that require drainage or surgical intervention.

Culture-independent molecular methods of identifying pathogens may improve the speed and sensitivity of microbiological diagnosis, although the use of these technologies is not yet widespread (see Box 8.6). For example, if samples from a tissue collection are culture-negative post antibiotic exposure, they should be processed additionally for 16S PCR, a molecular test capable of identifying bacterial DNA.

In established chronic infections (e.g. diabetic foot infection, osteomyelitis and chronic respiratory disorders), where patients rarely exhibit signs of sepsis, empirical treatment can be delayed while deep-tissue, pus or sputum samples are obtained. Superficial swabs are rarely useful and may confuse management. Samples should always be transported to the laboratory in a timely fashion. As most results are available within 72 hours, this is the point when they may help with rationalizing antibiotic choices.

**Source control**

Management of infection requires not only appropriate antibiotic treatment but also an understanding of the site of infection. Occasionally, interventions at these sites are required and this is termed ‘source control’. For example:

- Biomedical devices are commonly associated with infection and source control necessitates the removal of infected intravascular and urinary catheters, particularly when these are blocked.
- Obstructed biliary and urinary tract systems are common causes of sepsis and, under these circumstances, placement of a common bile duct stent, urinary catheter or nephrostomy tube may be required.
- Intra-abdominal collections require drainage, as do empyemas and paraspinal collections.
- If a native peripheral joint is infected, an arthroscopic washout is required, and an infected prosthetic joint may require debridement and removal of the prosthesis.
- Valvectomy is increasingly used to optimize management of infective endocarditis, particularly for acute infections caused by *S. aureus*.
- Surgical debridement of infected tissue is required for optimal management of monomicrobial necrotizing fasciitis caused by *S. pyogenes* or Fournier’s gangrene.

---

**Box 8.6 Molecular identification of infectious agents causing sepsis**

While traditional culture-based methods remain the gold standard, their disadvantages include:

- delay in obtaining results (it generally takes around 24 h for cultures to become positive, and 48 h for a firm bacterial identification to be made)
- the fact that cultures may be negative if antibiotics were administered before samples were taken.

Two methods have become widely accepted into clinical practice:

**16S polymerase chain reaction (PCR) sequencing**

- 16S ribosomal RNA is a component of the 30S small subunit of all prokaryotic ribosomes
- Due to the slow evolution of ‘conserved’ areas within the gene, to which DNA primers can anneal (allowing PCR amplification), sequencing of the hyper-variable regions can be used to detect and speculate bacteria from a variety of clinical specimens (e.g. pus and deep tissue samples)
- Unlike culture, this diagnostic test does not provide susceptibility data but is of particular value for clinical samples that are culture-negative due to antibiotic exposure

**Matrix-assisted laser desorption/ionization-time of flight (MALDI-TOF) mass spectroscopy**

- Bacterial isolates are fixed in a matrix, which is then fragmented and subjected to mass spectroscopy
- Each protein-containing fragment of matrix has a different mass/charge profile, allowing a spectral profile to be generated that is unique to individual bacterial species
- Sometimes, genes conferring antibiotic resistance are detectable by MALDI-TOF, e.g. meticillin-resistant *Staphylococcus aureus* (MRSA) produces a different spectral profile to that of meticillin-sensitive *Staphylococcus aureus* (MSSA)
Antimicrobial stewardship, or the prudent use of antibiotics, is a key component in the fight against the emergence of multidrug-resistant organisms. It is both a national and an international public health priority. In lay terms, it can be summarized as administering the right antibiotic for the right condition, given at the right dose, for the right duration.

UK-based targets

In 2017, Commissioning for Quality and Innovation (CQUIN) targets were introduced in the UK for hospital-based National Health Service (NHS) trusts. Key performance indicators (KPIs) were a reduction in total antibiotic prescribing, particularly of carbapenems and tazobactam–piperacillin (tazocin), and a documented antibiotic review at 72 hours. In subsequent years the reduction in total prescribing and carbapenem usage targets has continued but hospital doctors are now required to specify different prescribing options at 72 hours (see later). In general practice, KPIs are based on reductions in ciprofloxacin and amoxicillin/clavulanate usage and, for uncomplicated UTIs, prescribing nitrofurantoin rather than trimethoprim (as it is more effective against common urinary pathogens, including multidrug-resistant E. coli).

Considerations before starting empirical antibiotics

Most hospitals will have an empirical antimicrobial policy. Policies differ, depending on the local prevalence of antimicrobial resistance to key surveillance organisms. To prescribe appropriately, the likeliest site of infection must be determined, based on clinical assessment and other investigations. Previous microbiology results, such as previous infection/colonization with extended-spectrum beta-lactamase (ESBL)-producing Enterobacteriaceae, may help to determine appropriate choices of antimicrobial: for example, whether or not to prescribe a carbapenem.

Considerations that should be documented when choosing an initial antibiotic regimen include:

- route of administration
- frequency
- duration of treatment
- monitoring for potential toxicity
- where appropriate, drug levels (e.g. pre-dose gentamicin or amikacin levels)
- dose adjustment in renal/hepatic failure
- need for adjuvant therapy (e.g. rifampicin or fusidic acid for severe S. aureus infection)
- alternative antibiotics for severe or non-severe penicillin allergy.

Antimicrobial decision-making at 72 hours

At 72 hours, when most culture results are available, one of the following five decisions should be made:

- **Stop antibiotic treatment.** Symptoms of sepsis, such as confusion, may be caused by many different factors. After a period of observation and review of investigations, cessation of antibiotics is the appropriate action when patients are thought not to have had an infection after all.

- **Step down to an oral alternative.** For uncomplicated infections, e.g. pneumonia or pyelonephritis, treatment can normally be switched from intravenous to oral after 2–3 days if the patient is clinically stable and is showing signs of clinical improvement.

- **Switch treatment.** This may be necessary because of an unanticipated site of infection (e.g. infective endocarditis requiring prolonged intravenous antibiotic treatment) or unanticipated resistance (such as urosepsis and bacteraemia caused by an ESBL-producing E. coli requiring treatment with an intravenous carbapenem).

- **Continue with intravenous treatment.** The patient has a more complicated or difficult-to-treat infection, such as meningitis or septic arthritis.

- **Discharge on outpatient parenteral antibiotic treatment.** This is defined as the provision of intravenous antibiotics to patients out of hospital in either the community or an ambulatory care setting. For conditions such as skin and soft tissue infection, urinary tract infections and bone and joint infection, where the patient is otherwise well, treatment may be continued in the community, provided proper governance arrangements are in place (see later).

Where a switch or step down to an oral alternative is made, a key component of good antimicrobial stewardship is the choice of a narrow-spectrum agent when culture results are available. This reduces the risk of Clostridium difficile infection and colonization with multidrug-resistant organisms, and is therefore both safe for patients and cost-effective.

Outpatient parenteral antimicrobial treatment

Outpatient parenteral antimicrobial treatment (OPAT) has been cited as one of five antimicrobial prescribing decision options in UK Department of Health guidance on antibiotic stewardship after 72 hours of treatment. It may be accessed via several routes:

- through the hospital emergency or ambulatory care department, where patients can be clinically assessed, investigated and commenced on intravenous antibiotics for conditions such as lower limb cellulitis without hospital admission; OPAT is increasingly used for admission avoidance

- following a hospital admission for infections requiring inpatient admission (such as severe community-acquired pneumonia requiring supplementary oxygen), after the patient improves clinically but still requires intravenous antibiotics

- following a hospital admission required for source control (e.g. surgical removal of an infected joint prosthesis); OPAT is an option for carefully selected groups of patients, as it allows hospital discharge earlier than expected.

OPAT is associated with high levels of patient satisfaction, as most prefer to be treated out of hospital. Because there is less clinical supervision, governance arrangements around patient care are important, and clinical guidelines, published in both the UK and USA, should be complied with.

Conditions suitable for OPAT services

Skin and soft tissue infections – in particular, lower limb cellulitis – are the most common medical conditions referred to OPAT services. Patients are typically treated for 3–5 days with intravenous antibiotics but those with lymphoedema or underlying skin conditions typically require longer courses. Increasingly, multidrug-resistant
UTIs may be treated in the community with intravenous antibiotics, and patients may be recruited for OPAT by direct laboratory referral after a multi-resistant organism is grown. Those with bone and joint infection, such as vertebral osteomyelitis or native or prosthetic joint infection, invariably require prolonged intravenous antibiotic courses. Other conditions suitable for OPAT include infected diabetic foot ulcers (with or without osteomyelitis), infective endocarditis, empyema and abscesses of the brain and liver, once patients are deemed clinically stable.

The suitability of a patient to receive OPAT needs careful assessment and is dependent on age, co-morbidities and severity of infection. OPAT also requires patients to engage reliably with therapy. Therefore, intravenous drug users and patients with serious mental health problems are generally not suitable.

Delivery of OPAT services

Commonly used antibiotics are given once daily and reduce nursing time, although some teams can administer intravenous antibiotics four times per day. Examples of antibiotics suitable for once-daily dosing include ceftiraxone, ertapenem, amikacin, teicoplanin and daptomycin. Some services insist on the first dose of antibiotic being given in hospital when there is a history of antibiotic allergy, but many now give the first dose of intravenous antibiotics in the community. OPAT teams may need to monitor drug levels (e.g. pre-dose teicoplanin levels for efficacy, or pre-dose amikacin levels for nephrotoxicity). For most intravenous antibiotics, full blood count, urea and electrolytes, CRP and liver function tests should be monitored on a weekly basis at least.

Antibiotics can be administered through a peripheral intravenous cannula, but for longer durations of treatment (>7 days) administration through a Hickman line or a peripherally inserted central catheter (PICC) is preferable. Insertion by a suitably trained healthcare professional or interventional radiologist reduces the risk of line infection. Patients can also be taught to self-administer or attach ‘infusion devices’, commonly known as elastomeric devices, which save district nurse time.

There are different models for delivering OPAT services. These are community-based (nurses deliver treatment within the patient’s home) or hospital-based (patients attend hospital or an ambulatory care centre on a daily basis for intravenous antibiotic treatment). Ideally, an OPAT multidisciplinary team should consist of doctors, hospital-based nurses, community nurses and a pharmacist.

Monitoring patients in OPAT services

Patients must be appropriately monitored with clinical assessments, blood tests and, where relevant, imaging at appropriate intervals. Some NHS trusts capture patients on virtual wards, which facilitates clinical ownership and follow-up. Good practice includes regular multidisciplinary team meetings (where cases are discussed with an infection specialist), the taking of blood tests and organization of other investigations. While many conditions can be managed exclusively by a clinical microbiologist or ID physician, joint care is required for orthopaedic or neurosurgical cases. The treatment of lower limb cellulitis can be managed by nurses and requires minimal involvement from medical staff.

Because of there being less clinical supervision there are risks associated with OPAT, unless strict governance arrangements are in place. Adverse drug reactions are not uncommonly reported and central venous access can be associated with access site infections and thrombophlebitis. Overuse of broad-spectrum intravenous antibiotics can be associated with C. difficile infection and, depending on the condition being treated, relapse and hospital re-admission can occur. There should therefore be formal re-admission pathways to secondary care. Evidence suggests that OPAT is safe, provided it is administered through a formal service, designed to minimize risk, with doctors and nurses working together across primary and secondary care. OPAT services are likely to expand in the UK, driven by good safety data, high levels of patient satisfaction and healthcare efficiencies.

Assessment of allergy risk

Around 10% of the population report a history of penicillin allergy but data show that the true figure is only around 1%. In some infections, penicillins are the first-choice antibiotic and other agents are associated with a worse outcome.

Anaphylaxis to penicillins or any antibiotic can be fatal, so careful evaluation is required. The timing of the reaction is of paramount importance:

- **Immediate hypersensitivity reactions**, which include anaphylaxis, are immunoglobulin E (IgE)-mediated and classically begin within 1 h of the dose, and often within minutes. Typically, they are characterized by facial swelling, rash and severe shortness of breath.

- **Delayed reactions** appear after multiple doses of treatment, typically after days or weeks. While they may be immune-mediated, they are not associated with anaphylaxis, although in some rare cases they can lead to severe or life-threatening conditions such as Stevens-Johnson syndrome and toxic epidermal necrolysis (see p. 697).

When a patient reports an antibiotic allergy, the following information should be ascertained:

- the name(s) of the antibiotic(s) they report an allergy to
- the timing between starting the antibiotic and the symptoms or signs
- the nature of the symptoms or signs, asking specifically about rash, wheeze, swelling and loss of consciousness
- time to resolution of the symptoms
- whether they tried the same or similar antibiotics since.

Severe allergy is typically a hypersensitivity reaction but occasionally can also be a delayed reaction. In type 1 (IgE-mediated allergy, p. 62) and other severe penicillin allergies, cephalosporins and carbapenems should also be avoided.

Non-severe allergy is typically non-IgE-mediated and is commonly described as a mild rash. In these circumstances, cephalosporins, carbapenems and monobactams can be cautiously used. Other antibiotic classes are safe alternatives.

Selected patients reporting a penicillin allergy should be referred to allergy services for formal testing. These include:

- patients with a history of an allergic reaction when on multiple drugs, e.g. during general anaesthesia
- patients allergic to multiple antibiotics
- patients for whom there is no reliable alternative antibiotic
- patients in whom there is a current requirement for a prolonged course of antibiotics and an allergy to ‘gold standard’ treatment
- patients with an absolute requirement for penicillin, e.g. those with central nervous system syphilis, immunodeficiency or cardiac valve disorders requiring prophylaxis, or post splenectomy
- patients likely to need repeated courses of antibiotics, e.g. those with haematological malignancies, cystic fibrosis or inflammatory bowel disease.

It is possible to desensitize patients with carefully introduced, gradually increasing doses of specific antibiotics. For example, a
well-recognized protocol for co-trimoxazole sensitization has been used since the late 1990s.

**Antibiotic chemoprophylaxis**

The value of antibiotic chemoprophylaxis has been questioned, as there are relatively few controlled trials to prove efficacy. The evidence for chemoprophylaxis against infective endocarditis is an example. National Institute for Health and Care Excellence (NICE) guidelines recognize that procedures can cause bacteraemia but without a significant risk of infective endocarditis. Even patients at ‘high risk’, such as those with previous infectious endocarditis, prosthetic heart valves and surgical shunts, do not always require prophylaxis (Box 8.7). However, there are a number of indications for which the prophylactic use of antibiotics is still advised. These include surgical procedures carrying a high risk of infection (ie colon surgery), or with potentially serious consequences of infection (organ transplantation, post-splenectomy sepsis). The choice of agent(s) is determined by the likely infectious risk and the established efficacy and safety of the regimen. Antibiotic prophylaxis for the vast majority of surgical or radiological procedures should not extend for more than 24 hours post procedure and, for most operations, a single dose at induction is all that is required.

| Due to meningococci                   | To prevent infection in close contacts   | Adults: rifampicin 600 mg twice daily for 2 days  
Children: <1 year: 5 mg/kg; >1 year: 10 mg/kg  
Alternative (single-dose) ciprofloxacin 500 mg (p.o.) or ceftriaxone 250 mg (i.m.) |
| Due to *Haemophilus influenzae* type b | To reduce nasopharyngeal carriage and prevent infection in close contacts | Adults: rifampicin 600 mg daily for 4 days  
Children: <3 months 10 mg/kg; >3 months 20 mg/kg |
| Tuberculosis                          | To prevent infection in exposed (close contacts)  
tuberculin-negative individuals, infants of infected mothers, and immunosuppressed patients | Oral isoniazid 300 mg daily for 6 months  
Children: 5–10 mg/kg daily |

**Endocarditisb**

Antibacterial prophylaxis and chlorhexidine mouthwash are not recommended for the prevention of endocarditis in patients undergoing dental procedures

Antibacterial prophylaxis is not recommended for the prevention of endocarditis in patients undergoing procedures of the:
- upper and lower respiratory tract (including ear, nose and throat procedures and bronchoscopy)  
- genitourinary tract (including urological, gynaecological and obstetric procedures)  
- upper and lower gastrointestinal tract

Any infection in patients at risk of endocarditis should be investigated promptly and treated appropriately to reduce the risk of endocarditis

If patients at risk of endocarditis are undergoing a gastrointestinal or genitourinary tract procedure at a site where infection is suspected, they should receive appropriate antibacterial therapy that includes cover against organisms that cause endocarditis

Patients at risk of endocarditis should be:
- advised to maintain good oral hygiene  
- told how to recognize signs of infective endocarditis and advised when to seek expert advice

---

a Unless stated, doses are those recommended in adults. For surgical procedure, see individual procedures in text.

\(^a\)European Committee on Antimicrobial Susceptibility Testing (EUCAST) breakpoints are based on these dosages. Alternative dosing regimens that result in equivalent exposure are acceptable. The table should not be considered exhaustive guidance for dosing in clinical practice, and does not replace specific local, national or regional dosing guidelines.
common ring structure. Modifications to the β-lactam ring and/or the side-chain may expand the antimicrobial spectrum to include many Gram-negative and positive organisms. Following the discovery of penicillin, dozens of β-lactam-based drugs (first to fifth generations) have been developed for clinical use, either from bacterial or fungal sources (e.g. cephalosporins, carbapenems) or by chemical engineering of the β-lactam ring. All β-lactams block bacterial cell-wall synthesis by binding to and inactivating specific penicillin-binding proteins, peptidases, which are involved in the final stages of cell-wall assembly and division. They are generally bactericidal to susceptible bacterial cells in a time-dependent manner.

Many bacteria produce β-lactamase enzymes, which inactivate antibiotics of this class. The emergence of Gram-negative organisms producing extended-spectrum β-lactamases (ESBLs) and carbapenemases (see below) has rendered some bacteria resistant to all β-lactams.

Penicillins

*Benzylpenicillin* can only be given parenterally and is still the drug of choice for some serious infections. However, due to increasing antimicrobial resistance, it should not be used empirically in serious infections without laboratory confirmation that the organism is penicillin-sensitive. Uses include serious streptococcal infections (including infective endocarditis), group A streptococcus (*Streptococcus pyogenes*) necrotizing fasciitis and gas gangrene (usually combined with other antibiotics).

*Flucloxacillin* is used in infections caused by penicillinase-producing staphylococci and remains the drug of choice for serious infections caused by *MSSA*.

*Amoxicillin* is susceptible to β-lactamase but its antimicrobial activity includes streptococci, pneumococci and enterococci, as well as Gram-negative organisms such as *Salmonella* spp., *Shigella* spp., *E. coli*, *Haemophilus influenzae* and *Proteus* spp. The extended-spectrum penicillin *ticarcillin* is active against *Pseudomonas* infections, as is the acylureidopenicillin *piperacillin* in combination with tazobactam (tazoцин). *Pivmecillinam* is used for the treatment of UTI and has activity against Gram-negative bacteria, including ESBL-producing *E. coli*, *Klebsiella*, *Enterobacter* and *Salmonella* spp. but not *Pseudomonas aeruginosa*.

*Temocillin* is active against Gram-negative bacteria only, including many ESBL producers. It appears to be less actively likely to trigger *C. difficile* infection, and is increasingly used because of resistance but also as a carbapenem-sparing agent. It is not active against *Pseudomonas* or *Acinetobacter* spp.

Generally, the penicillins are safe. Hypersensitivity (skin rash, urticaria, anaphylaxis), encephalopathy and tubulointerstitial nephritis can occur. Amoxicillin and ampicillin produce a hypersensitivity rash in approximately 90% of patients with infectious mononucleosis (glandular fever) who receive this drug. Amoxicillin/clavulanate (co-amoxiclav) (see below) causes cholestatic jaundice six times more frequently than amoxicillin, as does flucloxacillin.

Cephalosporins

The cephalosporins (Fig. 8.2) have an advantage over penicillins in that they are not inactivated by staphylococcal penicillinases. Except for the newer fifth-generation cephalosporins *ceftaroline* and *ceftobiprole*, they are not active against MRSA. Activity extends to many Gram-negative and positive organisms, except for enterococci and Gram-negative anaerobic bacteria. Only certain cephalosporins (e.g. *ceftazidime* and *cefepime*) are active against *P. aeruginosa*.

Second- and third-generation cephalosporins are reserved for the treatment of specific serious infections, as empirical use against Gram-negative infections can be rendered ineffective due to ESBL production, and has been associated with an increased risk of *C. difficile* infection.

The toxicity is similar to that of the penicillins but is less commonly encountered. Some 10% of patients allergic to one group are also allergic to the other. The early cephalosporins caused proximal tubule damage, although the newer derivatives have fewer nephrotoxic effects.

Monobactams

*Aztreonam* is the only member of this class available. It is a synthetic β-lactam and, unlike the penicillins and cephalosporins, has no ring other than the β-lactam one: hence its description as a monobactam. Aztreonam’s spectrum of activity is limited to aerobic Gram-negative bacilli. It is a useful alternative to aminoglycosides in combination therapy, largely for the treatment of intra-abdominal sepsis, as it has activity against some carbapenem-resistant strains that produce metallo-β-lactamases. It is also used in *P. aeruginosa* infection (including lung infection in cystic fibrosis).

Carbapenems

The carbapenems are semi-synthetic β-lactams and include *imipenem*, *meropenem*, *doripenem* and *ertapenem*. They currently have the broadest spectrum of the antibiotics, being active against the majority of Gram-positive, Gram-negative and anaerobic bacterial pathogens (but not against MRSA). Ertapenem, unlike the others, is not active against *Pseudomonas* or *Acinetobacter* spp. They differ in their dosage and frequency of administration. Imipenem is partially inactivated in the kidney by enzymatic inactivation and is therefore administered in combination with cilastatin.

Carbapenems are the mainstay of treatment for severe ESBL-producing Gram-negative infections (e.g. urinary tract or biliary tract sepsis) and are also used for severe hospital-acquired infections when multidrug-resistant Gram-negative bacilli or mixed aerobic and anaerobic infections are suspected.

Their side-effect profile is similar to that of β-lactam antibiotics. Nausea, vomiting and diarrhoea occur in less than 5% of cases. Imipenem and ertapenem may cause seizures and should not be used to treat meningitis. Meropenem is safe for this indication.

β-lactam/β-lactamase inhibitor combinations

One approach to the problem of β-lactamase-mediated resistance is to combine β-lactams with ‘inhibitor’ molecules (BLIs). Classical ‘inhibitors’ include clavulanic acid, sulbactam and tazobactam given

Fig. 8.2 The structure of a cephalosporin.
in combination with amoxicillin (amoxicillin/clavulanate), ticarcillin (ticarcillin/clavulanate), ampicillin (ampicillin/sulbactam), piperacillin (piperacillin/tazobactam) and ceftolozane (ceftolozane/tazobactam). These BLIs are themselves β-lactamase enzymes; it has recently been developed and combined with ceftazidime (ceftazidime/avibactam). The combination appears to be stable to most ESBLs and some carbapenemase (KPC, OXA-48) enzymes in Enterobacteriales.

Quinolones

The quinoline group of drugs inhibits bacterial DNA synthesis by inhibiting topoisomerase IV and DNA gyrase, the enzymes responsible for maintaining the super-helical twists in DNA.

Extended-spectrum quinolones such as ciprofloxacin have activity against Gram-negative bacteria, including *P. aeruginosa*, and some Gram-positive bacteria. They are useful in Gram-negative bloodstream infections, bone and joint infections, urinary and respiratory tract infections, meningococcal carriage, some sexually transmitted diseases such as gonorrhoea and non-specific urethritis due to *Chlamydia trachomatis*, as well as in severe cases of travellers’ diarrhoea. The newer oral quinolones (e.g. levofloxacin, moxifloxacin) provide an alternative to β-lactams in the treatment of community-acquired lower respiratory tract infections and are effective against *S. pneumoniae*, *H. influenzae* and the ‘atypical’ respiratory pathogens. They can also be used in the treatment of tuberculosis.

In many countries, a high proportion of *E. coli* and *Klebsiella* spp. are now resistant (>80%). Resistance is also an emerging problem among *Salmonella*, *Vibrio cholerae*, *S. pneumoniae* and *S. aureus*.

Gastrointestinal disturbances, photosensitive rashes and occasional neurotoxicity can occur. Use should be avoided in pregnancy and childhood, and in patients taking corticosteroids, unless the benefit outweighs the risk. Tendon damage, including rupture, can occur within 48 hours of use. MRSA and *C. difficile* infections in hospitals have been linked to high prescribing rates of quinolones, particularly when the O27 hypervirulent strain of *C. difficile* was endemic in most UK hospitals. Use is discouraged where an effective alternative is available. There is concern about QTc prolongation, and concomitant prescribing with other QTc prolongation drugs should be avoided whenever possible.

Aminoglycosides

Aminoglycosides (Fig. 8.3) interrupt bacterial protein synthesis by inhibiting ribosomal function (messenger RNA reading and transfer RNA binding). *Gentamicin* and *tobramycin* are given parenterally. They are highly effective against many Gram-negative organisms, including *Pseudomonas* spp. They are synergistic at low doses with penicillins against *Enterococcus* spp. and *Streptococcus viridans*, and are therefore often used in endocarditis. *Amikacin* has a similar spectrum but is more resistant to the aminoglycoside-modifying enzymes (phosphorylating, adenylylating or acetylaying) produced by some bacteria, in particular ESBL-producing Enterobacteriales. Its use should be restricted to gentamicin-resistant organisms.

Dose-related nephrotoxicity and otootoxicity (vestibular and auditory) can occur, particularly in the elderly. Enhanced nephrotoxicity occurs with other nephrotoxic drugs, and enhanced otoxicity with some diuretics. The *m.1555A>G* mutation has been associated with gentamicin otoxicity but appears to occur in less than 1% of the general population. Monitoring is necessary to ensure therapeutic and non-toxic drug concentrations. Once-daily dosing is used for most indications, with a serum drug level taken at 6–14 hours post dose, followed by application of an appropriate nomogram to determine the subsequent frequency of dosing (e.g. every 24 or 48 hours). When aminoglycosides are used for endocarditis, low doses are prescribed every 12 hours with different target pre- and post-dose level ranges than for once-daily dosing. Alternatively, and more simply, a pre-dose level can be checked prior to drug administration and appropriate drug adjustments made with subsequent doses. Neuromuscular blockade can occur with curariform drugs and aminoglycosides should be avoided in patients with myasthenia gravis.

Glycopeptides

The glycopeptides are active against Gram-positive bacteria and act by inhibiting cell-wall synthesis. *Vancomycin* is given intravenously for MRSA and other multiresistant, Gram-positive organisms. It is only slowly bactericidal (in contrast to β-lactams). It is also used for treatment of and prophylaxis against Gram-positive infections in penicillin-allergic patients. It is given in *S. pneumoniae* meningitis, in combination with other effective antibiotics, when disease is caused by penicillin-resistant strains.

Vancomycin can cause otoxicity and nephrotoxicity, and thus pre-dose (trough) serum levels should be monitored regularly. Serum levels at 1 hour post dose (peak) are also monitored to optimize drug efficacy. Care must be taken to avoid extravasation at the injection site, as this causes necrosis and thrombophlebitis. Too rapid infusion can produce symptomatic release of histamine (red man syndrome).

*Teicoplanin* is less nephrotoxic than vancomycin. It has more favourable pharmacokinetic properties, allowing once-daily or thrice-weekly dosage. It is given intravenously and pre-dose (trough) serum levels are monitored to optimize efficacy.

Lipopeptides

*Daptomycin* is a lipopeptide with a similar spectrum to that of vancomycin, and is given by the intravenous route. It is used particularly for complicated skin and soft tissue infections, including those caused by MRSA, and is also a useful alternative agent for endocarditis, bone and joint infections, and Gram-positive bloodstream infections. Lipopeptides with very long elimination times, such as *dalbavancin*, are used as single-dose therapies for skin and soft tissue infections.

Oxazolidinones

*Linezolid* was the first oxazolidinone antibacterial to be developed. *Tedizolid* has recently been approved for use in skin and skin structure infections. These drugs act by inhibiting protein synthesis,
binding to the bacterial 23S ribosomal RNA of the 59S subunit, thereby preventing the formation of a functional 70S complex that is essential to bacterial translation.

Oxazolidinones are active against a variety of Gram-positive pathogens, including vancomycin-resistant Enterococcus faecium (although resistant organisms have been reported), MRSA and penicillin-resistant S. pneumoniae. They are also active against group A and group B streptococci. Clinical experience with linezolid has demonstrated efficacy in a variety of hospitalized patients with severe to life-threatening infections, including bacteraemia, hospital-acquired pneumonia, skin and soft tissue infection, and bone and joint infection. These drugs can be given both intravenously and by mouth, and are almost 100% bioavailable by the oral route in patients with normal gastrointestinal absorption.

Oxazolidinones interact reversibly as non-selective inhibitors of monoamine oxidase and have the potential for interacting with serotonergic and adrenergic agents. Side-effects include gastrointestinal disturbances, headache, rash, hypertension, reversible but potentially severe cytopenias, and occasional reports of optic and peripheral neuropathy in patients receiving linezolid for longer than 28 days. Tedizolid is less myelotoxic and can also be given once daily (in contrast to twice-daily linezolid). Weekly monitoring of the full blood count for cytopenias, and for other serious adverse effects, is mandatory. Safety has not yet been shown in pregnancy but linezolid has been used successfully for serious infections in children.

**Tetracyclines**

These are bacteriostatic drugs possessing a four-ring hydronaphthacene nucleus (Fig. 8.4). Included among the tetracyclines are tetracycline, oxytetracycline, doxycycline and minocycline. Tigecycline is an injectable glycyclcline that is structurally related to the tetracyclines.

Tetracyclines inhibit bacterial protein synthesis by interrupting ribosomal function (transfer RNA binding) and are active against Gram-positive and Gram-negative bacteria. Tigecycline is active against many organisms resistant to tetracycline, as it avoids common bacterial efflux pump systems. This includes vancomycin-resistant enterococci, MRSA and Gram-negative bacilli, such as Acinetobacter baumannii, but not Pseudomonas or Proteus spp. Tigecycline is increasingly used in combination with other antibiotics (e.g. polymyxins) to treat infections caused by highly resistant, carbapenemase-producing, Gram-negative bacteria. The licensed indications are complicated skin and soft tissue infections and intra-abdominal sepsis. Tigecycline is also used to treat spirochaetal and rickettsial infections, and also has a role as malaria prophylaxis. However, a 2010 US Food and Drug Administration (FDA) alert raised concerns about the efficacy of tigecycline in some serious infections (notably ventilator-associated pneumonia) and it should be used only on expert advice. The efficacy of tetracyclines is reduced by antacids and oral iron-replacement therapy.

Tetracyclines are generally safe drugs but they may enhance established or incipient renal failure, although doxycycline is safer than others in this group. They cause brown discoloration of growing teeth and thus are not given to children or pregnant women. Photosensitivity occurs in approximately 1 in 20 patients. Nausea and vomiting are the most frequent adverse effects of tigecycline.

**Macrolides**

Macrolides inhibit protein synthesis by interrupting ribosomal function. **Erythromycin** has a similar (but not identical) antibacterial spectrum to that of penicillin and may be useful in individuals with penicillin allergy, especially in the management of bacterial respiratory infections. It can be given orally or parenterally, but oral intake is associated with significant gastrointestinal side-effects, while the intravenous formulation is very irritant and causes phlebitis. For these reasons, **clarithromycin** (which has similar antimicrobial properties but fewer side-effects) is often preferred. These drugs are useful in the treatment of pneumonias caused by Legionella and Mycoplasma spp. They are also effective in the treatment of infections due to Bordetella pertussis (whooping cough), Campylobacter and Chlamydia spp. Macrolides are otherwise not usually used for life-threatening or serious infections, such as endocarditis and meningitis.

Other macrolides include **azithromycin** and **telithromycin**. They have a broad spectrum of activity that covers selective Gram-negative organisms (Salmonella, Shigella). Compared with erythromycin, they have superior pharmacokinetic properties with enhanced tissue and intracellular penetration and a longer half-life that allows once-daily dosage. Concern has been raised about the use of azithromycin in bloodstream infections (bacteraemia) because of low serum bioavailability. Azithromycin is also employed for trachoma, cholera and some sexually transmitted infections.

Erythromycin and other macrolides interact with theophyllines, carbamazepine, digoxin and ciclosporin, occasionally necessitating dose adjustment of these agents. Diarrhoea, vomiting and abdominal pain are the main side-effects of erythromycin (less so with clarithromycin and azithromycin) as a consequence of the intestinal prokinetic properties of the macrolides. QTc prolongation is a recognized cardiac effect of the macrolides and may lead to the potentially life-threatening syndrome of ‘torsades de pointes’ (see p. 1064). Concomitant use of other drugs that cause QTc prolongation should be avoided unless absolutely essential.

**Polymyxins (polymyxin B, colistimethate sodium (polymyxin E))**

This is an old antibiotic class that, until recently, was rarely used in clinical practice because of concerns about neuro- and nephrotoxicity. The emergence of multidrug-resistant Gram-negative bacteria, in particular carbapenemase-producing Enterobacteriales, has resulted in the increased use of drugs in this class as an agent of last resort, often in combination with other antibiotics. Colistimethate sodium (CMS) is an inactive prodrug, metabolized in vivo to the active component colistin. This complicates dosing strategies and increases the potential for toxicity. The mechanism of bacterial killing of polymyxins is thought to be disruption of the bacterial cell membrane following binding to the lipopolysaccharide (LPS) component. They are active against most Gram-negative bacilli (except Proteus and Providencia spp.) and are administered intravenously for serious infections. Plasmid-mediated resistance, due to the
MCR-1 phosphoethanolamine enzyme that modifies bacterial LPS, has recently been described, although mostly in veterinary strains in South and South-east Asia.

**Sodium fusidate**
Sodium fusidate has a structure resembling that of bile salts and is a potent inhibitor of bacterial protein synthesis. Its entry into cells is facilitated by the detergent properties inherent in its structure. It is mainly used for penicillinase-producing *S. aureus* infections, such as osteomyelitis (it is well concentrated in bone) or endocarditis, and as an adjunctive agent for other staphylococcal infections accompanied by septicaemia. The drug is well absorbed orally but must be given in combination with another staphylococcal agent to prevent resistance, which may occur rapidly.

Sodium fusidate commonly causes gastrointestinal adverse effects and may occasionally be hepatotoxic; however, it is generally a safe drug and can be given during pregnancy if necessary. Concomitant statin use is avoided. Sodium fusidate is also available in topical preparations for use in minor skin conditions (impetigo) but these should be avoided to limit the risk of emerging resistance.

**Sulphonamides and trimethoprim**
The sulphonamides are all derivatives of the prototype sulfanilamide, and act by blocking thymidine and purine synthesis by inhibiting microbial folic acid synthesis. Trimethoprim is a 2,4-diaminopyrimidine, which prevents the bacterial reduction of dihydrofolate to tetrahydrofolate.

Sulphonamides and trimethoprim (as co-trimoxazole). Because of its adverse effect profile, use in developed countries was largely restricted to the treatment and prevention of *Pneumocystis jiroveci* infection and listeriosis; however, it is increasingly being prescribed in hospitals again for other infections, such as acute exacerbations of chronic bronchitis and UTI, as it appears to carry a relatively lower risk for triggering *C. difficile* infection and remains useful for some resistant Gram-negative infections. It may also be used for toxoplasmosis and nocardiosis. *Trimethoprim* alone is often used for empirical treatment of UTIs.

Resistance to sulphonamides is often plasmid-mediated and results from the production of a sulphonamide-resistant dihydropyrimidate synthase. Sulphonamides potentiate oral anticoagulants and some hypoglycaemic agents.

The adverse effects of co-trimoxazole are most commonly due to the sulphonamide component. Sulphonamides cause a variety of skin eruptions, including toxic epidermal necrolysis, the Stevens-Johnson syndrome, thrombocytopenia, folate deficiency and megaloblastic anaemia with prolonged usage. They can provoke haemolysis in individuals with glucose-6-phosphate dehydrogenase deficiency and therefore should not be used in such people. Trimethoprim is similar in molecular structure to the potassium-sparing diuretic amiloride; monitoring of renal function is required when using trimethoprim or co-trimoxazole, particularly when the patient is prescribed other potassium-sparing drugs (e.g. angiotensin-converting enzyme (ACE) inhibitors) and during prolonged therapy to avoid hyperkalaemia.

**Nitroimidazoles**
These agents are active against anaerobic bacteria and some pathogenic protozoa. The most widely used drug is *metronidazole* (Fig. 8.5). Others include *tinidazole* and *nimorazole*. After reduction of their ‘nitro’ group to a nitrosohydroxyl amino group by microbial enzymes, nitroimidazoles cause strand breaks in microbial DNA.

Metronidazole plays a major role in the treatment of anaerobic bacterial infections, particularly those due to *Bacteroides* spp. It is also used prophylactically in colonic surgery. It may be given orally, by suppository (well absorbed and cheap) or intravenously (more expensive). It is also the treatment of choice for mild *C. difficile* infection, amoebiasis, giardiasis and infection with *Trichomonas vaginalis*.

Nitroimidazoles can produce a disulfiram-like reaction with ethanol and enhance the anticoagulant effect of warfarin; patients should be warned not to drink alcohol while taking them. They are tumorigenic in animals and mutagenic for bacteria, although carcinogenicity has not been described in humans. They cause a metallic taste and polyneuropathy with prolonged use. High-dose regimens should be avoided in pregnancy and during breast-feeding, unless the benefit is deemed to outweigh the risk.

**Other antibiotics**

**Clindamycin**
This is not widely used because of its strong association with *C. difficile* infection. It is active against Gram-positive cocci, including some penicillin-resistant staphylococci, and is a useful agent for severe streptococcal or staphylococcal cellulitis. It has the added effect of inhibiting staphylococcal toxic shock syndrome toxin 1 (TSST-1) and alpha toxin production, and has a role in infections caused by *S. aureus*-secreting Pantone Valentine leukocidin (PVL). It is also active against anaerobes, especially *Bacteroides*. It is well concentrated in bone and used for osteomyelitis.

**Nitrofurantoin**
This is an old agent that is still widely used as an oral treatment for uncomplicated UTI. It is active against almost all the common urinary pathogens, with the exception of *Proteus* spp., and resistance remains rare. It is extensively metabolized, with only about 20% of the active component excreted in the urine, which makes it unsuitable for complicated UTI or pyelonephritis. Nausea is the main side-effect and there are rare reports of peripheral neuropathy, usually in patients with pre-existing renal impairment. It can cause haemolysis in patients with glucose-6-phosphate dehydrogenase deficiency and should be avoided in this group.

**Mupirocin**
Mupirocin prevents bacterial RNA and protein synthesis. It is only used topically, mainly for the nasal eradication of *S. aureus*, including MRSA, but can also be employed for minor skin infections and
treatment of peritoneal dialysis catheter site infection. High-level resistance to mupirocin in MRSA due to plasmid-encoded MupA may lead to failure of topical therapies.

**Fosfomycin**
This is a relatively old antibiotic that has been used in some European countries for many years. It inhibits bacterial peptidoglycan biosynthesis. It requires a functional sugar transport system (glucose-6-phosphate) for uptake by Enterobacteriaceae, thus requiring modifications to standard susceptibility testing methods. It is active against many Gram-positive organisms and *E. coli*, but many other Gram-negative bacteria have been slow to produce an enzyme (FosA) that is able to destroy the drug. The clinical significance of FosA-mediated resistance is unclear. Fosfomycin retains activity against many ESBL-producing *E. coli* and is therefore the subject of renewed interest. It is increasingly used in the UK, particularly for resistant UTI, and is available in oral and intravenous formulations.

**Rifaximin**
This is a rifamycin with poor gastrointestinal absorption. It is used in portosystemic encephalopathy (see p. 1297) and the prevention of travellers’ diarrhoea; it may be of short-term benefit in irritable bowel syndrome.

---

**Treatment of infection caused by multidrug-resistant organisms**

**Meticillin-resistant Staphylococcus aureus**
Meticillin resistance is mediated through changes in the cell-wall penicillin-binding protein 2a, an enzyme that catalyses cell-wall cross-linking, which meticillin or flucloxacillin is unable to inhibit. In the UK, most MRSA infections are healthcare-associated. Uncomplicated infections are typically associated with intravascular catheters or devices; in these cases, line removal (source control) should form part of management. In approximately 5% of cases, infection may disseminate, with haematogenous spread to bones, joints and heart valves.

For decades, the treatment drug of choice has been intravenous vancomycin; pre-levels of 15–20 mg/L are required for maximum therapeutic efficacy. Renal function should be closely monitored, as vancomycin is nephrotoxic. Treatment is for a minimum of 2 weeks and, for complicated infection, the addition of a second agent should be considered (e.g. fusidic acid, rifampicin, gentamicin or ciprofloxacin). There is, however, no good evidence that this improves clinical outcomes: recently, a large UK trial of adjunctive rifampicin demonstrated no clinical benefit in staphylococcal bacteraemia.

An alternative to intravenous vancomycin is the oxazolidinone linezolid. The major advantage is that it can be taken orally and is not nephrotoxic. However, it can cause reversible myelosuppression, in particular thrombocytopenia, and so weekly full blood count monitoring is required. In the longer term, there is a smaller risk of peripheral neuropathy or optic neuritis.

While MRSA is primarily seen in the UK in association with intravascular devices, in the USA it has been described as frequently causing severe skin and soft tissue infections. Empirical treatment therefore includes antibiotics such as linezolid, clindamycin or co-trimoxazole.

**Vancomycin-resistant enterococci**
Vancomycin resistance in enterococci is mediated through changes in the peptidoglycan precursor from D-Ala-D-Ala to D-Ala-D-Lac, preventing glycopeptides (vancomycin and teicoplanin) binding to these cell-wall precursors and inhibiting cell-wall synthesis. Most infections caused by vancomycin-resistant enterococci (VRE) are healthcare-associated. This organism is of low virulence but is difficult to treat, and with the exception of infective endocarditis, infection with VRE is generally of low consequence. More common sites of infection include the urinary and biliary tracts. The only oral treatment is linezolid; intravenous options include daptomycin and tigecycline.

**Carbenapenem-resistant Pseudomonas**
The most common cause of carbapenem resistance in *Pseudomonas* is increased expression of efflux systems or increased impermeability due to decreased porin expression. Most commonly, carbapenem-resistant *Pseudomonas* causes device-related infections or infection of the lower respiratory tract. If disease is monoresistant, treatment options include ciprofloxacin, gentamicin, ceftazidime and piperacillin/tazobactam (tazocin). Often, however, isolates are multidrug-resistant, with the exception of intravenous colistin. This needs to be dosed appropriately and pre-drug levels should be taken, to minimize the risk of both nephrotoxicity and neurotoxicity. More recently, ceftolozane/tazobactam has become available, and is effective against multidrug-resistant *Pseudomonas*, as well as less toxic than colistin.

**Extended-spectrum β-lactamase-producing Enterobacteriaceae**
ESBLs are inactivating enzymes that confer resistance to most β-lactam antibiotics, including penicillins, cephalosporins and aztreonam. In the UK, ESBL-producing *E. coli* of the CTX-M-15 type suddenly emerged in 2004 and approximately 15% of all *E. coli* bacteraemic isolates are now ESBL producers. Other Enterobacteriaceae, most commonly *K. pneumoniae*, can also be ESBL producers. The most common sites of infection for ESBL-producing Enterobacteriaceae are the urinary tract and, less frequently, the gastrointestinal or hepatobiliary tract. For both organisms, these isolates are often multidrug-resistant, and may express resistance to antibiotics such as ciprofloxacin, co-trimoxazole and gentamicin. The mainstay of treatment is a carbapenem, either intravenous meropenem three times daily or, if OPAT is considered, once-daily intravenous ertapenem. Potential carbapenem-sparing options include intravenous amikacin or intravenous temocillin but the suitability of these choices depends on sites of infection. Even when the infecting organism is shown to be susceptible to penicillins by minimum inhibitory concentration (MIC), a carbapenem should be used, as piperacillin/tazobactam has been found to be inferior to carbapenems in a recent trial.

**Carbenapenem-resistant Enterobacteriaceae**
Carbenapenem resistance is mediated through the production of enzymes that inactivate carbapenems, together with most β-lactams, and are therefore called carbapenemases. Like ESBL-producing Enterobacteriaceae, carbapenem-resistant Enterobacteriaceae (CRE) most frequently cause UTIs. Worldwide, the five most common types of carbapenemase are *K. pneumoniae* carbapenemases (KPC), New Delhi metallo-β-lactamases (NDM), Verona integron-encoded metallo-β-lactamase (VIM), imipenemase (IMP) metallo-β-lactamase and the oxacillin carbapenemase (OXA). In the UK, the most common CRE types are OXA-48, NDM and...
KPC. Carbapenem-resistant isolates with OXA-48 or KPC production may be susceptible to quinolones and aminoglycosides, and so other commonly used therapeutic options are available for treatment. Resistance to ceftazidine/avibactam in KPC and OXA-48 producers has been reported but remains rare. Isolates that produce NDMs tend to be pan-resistant, with the exception of colistin, fosfomycin and tigecycline. Susceptibility testing for each of these drugs against CRE isolates is not well standardized. Genetic analysis suggests that Klebsiella is intrinsically resistant to fosfomycin and that heteroresistance to colistin and tigecycline can emerge during therapy. In these circumstances, colistin is the mainstay of treatment, with tigecycline and sometimes fosfomycin used as adjuvant therapy, depending on susceptibility data. Meropenem, given as a bolus or an infusion, is also of benefit as targeted therapy when organisms demonstrate intermediate sensitivity, as evidenced by a MIC of 8–16 mg/L. An understanding of the mechanisms of CRE production is therefore helpful when choosing different treatment options.

**Further reading**
Learning about fluid and electrolyte disorders and acid–base physiology can be a daunting experience for medical students and practicing physicians alike. However, these disorders form some of the most common presentations to hospital and may complicate a wide range of other conditions, and so all doctors need to be confident when approaching them.

This chapter reviews the physiology that underpins normal fluid, electrolyte and acid–base balance, and discusses disorders of blood chemistry caused by dietary factors, underlying medical conditions, and medical treatments. These imbalances may be acute or chronic, may occur with varying degrees of severity, and may or may not be partially compensated by the body's regulatory mechanisms.

Key skills to master for undergraduates include:
- comprehensively assessing a patient's fluid status and gaining confidence in prescribing intravenous fluids and diuretics appropriately
- developing an appropriate diagnostic approach to abnormalities of common electrolytes including sodium and potassium
- understanding the implications of an abnormal blood pH and diagnosing the common causes of acidosis and alkalosis.

These skills can be best learned by experience – particularly in assessing patients presenting to the hospital emergency department or who have been admitted to critical care units. Take the opportunity to review patients' fluid balance charts on ward rounds and try (with supervision) to practise prescribing intravenous fluids appropriately. Review the results of blood gas analyses and work through any abnormalities shown.
Assessing a patient’s fluid status is a key skill for all doctors, requiring key clinical skills in history-taking (Box 9.1), examination (figure at bottom of this page), and data interpretation (Box 9.2). Many patients are hypovolaemic on admission to hospital as a result of acute illness. The algorithm on page 182 helps guide decision-making regarding intravenous fluid therapy in such patients. Others will exhibit signs of increased extracellular volume and require diuretic therapy (see p. 173).

**Box 9.2 Clues to volume status on basic investigations**

**Evidence for increased extracellular volume**
- ‘Haemodilution’: fall in blood haemoglobin concentration and packed cell volume (haematocrit)
- Fluid overload on chest X-ray (see p. 928)
- Evidence of volume overload or cardiac dysfunction on transthoracic echocardiogram

**Evidence for decreased extracellular volume**
- ‘Haemoconcentration’: rise in blood haemoglobin and packed cell volume (haematocrit)
- Acute kidney injury (see p. 1387)
- Disproportionate rise in serum urea compared with serum creatinine
- Rise in serum sodium and osmolality
- Concentrated urine: specific gravity (measured on dipstick) >1.025

**Clues to volume status on clinical examination**

**Signs of increased extracellular volume**
- Observation chart
  - Hypoxia if pulmonary oedema/pleural effusions present
  - BP may be high (esp. in volume overload associated with renal disease) or low (in heart failure or cirrhosis)
- Face
  - Periorbital oedema
- Neck
  - Raised JVP (see p. 1031)
- Chest
  - Fine inspiratory bi-basal crackles
  - Signs of pleural effusions
- Heart
  - Gallop rhythm with third heart sound
  - Thrusting apex beat
- Abdomen
  - Ascites
  - Upper leg/buttock/sacral oedema (particularly in patients in bed)
  - Peripheral ‘pitting’ oedema

**Signs of decreased extracellular volume**
- Observation chart
  - Tachycardia
  - Hypotension if severe volume depletion
  - Postural hypotension (fall of systolic BP >20 mmHg after standing for 2 min)
- Face
  - Dry mouth
- Neck
  - Reduced JVP
- Axillae
  - No axillary sweating
- Hands
  - Cool peripheries
  - Low-volume pulse
  - Prolonged capillary refill time (>2 sec)
  - Peripheral cyanosis
- Urine output
  - Oliguria (<0.5 ml/kg urine)
- Skin
  - Reduced turgor
Assessing acid-base disturbance

Arterial or venous blood gas analysis is readily carried out in most hospitals using table-top blood gas analysers (Fig. 9.1), which measure:

- blood pH
- partial pressures of carbon dioxide ($PCO_2$) and oxygen ($PO_2$)
- calculated base excess (BE) and bicarbonate ($HCO_3^-$)
- blood electrolytes including sodium and potassium concentrations
- other molecules including glucose and lactate.

This information is vital in assessing respiratory failure, critical illness (failure to maintain blood pH in the normal range is often a poor prognostic marker) as well as chronic disorders affecting acid–base homeostasis.

A stepwise approach to interpreting blood gas analyses is shown in Fig. 9.2. It is always worth going through a blood gas analysis report fully, describing all the abnormalities present, before pulling the different abnormalities together into a complete description.

**Fig. 9.1** The ABL800FLEX blood gas analyser. (From Al-Shaikh B, Stacey SG. Essentials of Equipment in Anaesthesia, Critical Care and Peri-Operative Medicine, 5th edn. Edinburgh: Elsevier, 2019, Fig. 13.5, courtesy Radiometer Ltd.)

**Fig. 9.2** Stepwise approach to interpreting blood gas analysis.
WATER AND ELECTROLYTES

In normal healthy people, the total body water constitutes 50–60% of lean body weight in men and 45–50% in women. In a healthy 70 kg male, total body water is approximately 42 L. This is contained in three major compartments:

- intracellular fluid (28 L, about 35% of lean body weight)
- extracellular – the interstitial fluid that bathes the cells (9.4 L, about 12%)
- plasma (also extracellular) (4.6 L, about 4–5%).

In addition, small amounts of water are contained in bone, dense connective tissue and epithelial secretions, such as the digestive secretions and cerebrospinal fluid (CSF).

The intracellular and interstitial fluids are separated by the cell membrane; the interstitial fluid and plasma are separated by the capillary wall (Fig. 9.3). In the absence of solute, water molecules move randomly and in equal numbers in either direction across a semipermeable membrane. However, if solutes are added to one side of the membrane, the intermolecular cohesive forces reduce the activity of the water molecules. As a result, water tends to stay in the solute-containing compartment because there is less free diffusion across the membrane. This ability to hold water in the compartment can be measured as the osmotic pressure.

Osmotic pressure

Osmotic pressure is the primary determinant of the distribution of water among the three major compartments. The concentrations of the major solutes in the compartments differ, each having one solute that is primarily limited to that compartment and therefore determines its osmotic pressure:

- The intracellular fluid contains mainly potassium (K⁺) (most intracellular Mg²⁺ is bound and osmotically inactive).
- In the extracellular compartment, Na⁺ salts predominate in the interstitial fluid, and proteins in the plasma.

Regulation of the plasma volume is somewhat more complicated because of the tendency of the plasma proteins to hold water in the vascular space by an oncotic effect that is partly counterbalanced by the hydrostatic pressure in the capillaries that is generated by cardiac contraction (see Fig. 9.3). The composition of intracellular and extracellular fluids is shown in Box 9.3.

Osmotically active solutes cannot freely leave their compartment. The capillary wall, for example, is relatively impermeable to plasma proteins, and the cell membrane is ‘impermeable’ to Na⁺ and K⁺ because the Na⁺/K⁺-adenosine triphosphatase (ATPase) pump largely restricts Na⁺ to the extracellular fluid and K⁺ to the intracellular fluid. By contrast, Na⁺ freely crosses the capillary wall and achieves similar concentrations in the interstitium and plasma; as a result, it does not contribute to fluid distribution between these compartments. Similarly, urea crosses both the capillary wall and the cell membrane, and is osmotically inactive. Thus, the retention of urea in renal failure does not alter the distribution of the total body water.

Body Na⁺ stores are the primary determinant of the extracellular fluid volume. Thus, the extracellular volume – and therefore tissue perfusion – are maintained by appropriate alterations in Na⁺ excretion. For example, if Na⁺ intake is increased, the extra Na⁺ will initially be added to the extracellular fluid. The associated increase in extracellular osmolality will cause water to move out of the cells, leading to extracellular volume expansion. Balance is restored by excretion of the excess Na⁺ in the urine.

Distribution of different types of replacement fluid

Figure 9.4 shows the relative effects on the compartments of the addition of identical volumes of water, saline and colloid solutions.

One litre of water given intravenously as 5% glucose (which is rapidly metabolized to generate energy, water and carbon dioxide) is distributed equally into all compartments, whereas the same amount of 0.9% saline remains in the extracellular compartment. The latter is thus the correct treatment for extracellular water depletion – sodium keeping the water in this compartment. The addition of 1 L of colloid with its high oncotic pressure stays in the vascular compartment and used to be a treatment for hypovolaemia, although generally 0.9% saline is now used.

Regulation of extracellular volume

The extracellular volume is determined by the sodium concentration. The regulation of extracellular volume is dependent upon a tight control of sodium balance, which is exerted by normal kidneys (Fig. 9.5). Renal Na⁺ excretion varies directly with the effective circulating volume. In a 70-kg man, plasma fluid constitutes one-third of extracellular volume (4.6 L); of this, 85% (3.9 L) lies in the venous circulation and only 15% (0.7 L) resides in the arteries.

The fullness of the arterial vascular compartment (effective arterial blood volume, EABV) is the primary determinant of renal...

sodium and water excretion: that is, the effective circulatory volume for the purposes of body fluid homeostasis.

The fullness of the arterial compartment depends upon a relationship between cardiac output and peripheral arterial resistance. Thus, diminished EABV is initiated by a fall in cardiac output or a fall in peripheral arterial resistance (an increase in the holding capacity of the arterial vascular tree). When the EABV is expanded, the urinary Na⁺ excretion is increased and can exceed 100 mmol/L. By contrast, the urine can be rendered virtually free of Na⁺ in the presence of EABV depletion and normal renal function.

These changes in Na⁺ excretion can result from alterations both in the filtered load, determined primarily by the glomerular filtration rate (GFR), and in tubular reabsorption, which is affected by multiple factors. In general, changes in tubular reabsorption constitute the main adaptive response to fluctuations in the effective circulating volume. How this occurs can be appreciated from Box 9.4 and Fig. 9.4, and from Fig. 36.3, which depicts the sites and determinants of segmental Na⁺ reabsorption. Although the loop of Henle and distal tubules make a major overall contribution to net Na⁺ handling, transport in these segments primarily varies with the amount of Na⁺ delivered; that is, reabsorption is flow-dependent. In comparison, the neurohumoral regulation of Na⁺ reabsorption according to body needs occurs primarily in the proximal tubules and collecting ducts.

The diseases associated with malfunction of each section of the tubule are shown in Box 9.5.

Neurohumoral regulation of extracellular volume

This is mediated by volume receptors that sense changes in the EABV rather than alterations in the sodium concentration. These receptors are distributed in both the renal and cardiovascular tissues.

- **Intrarenal receptors.** Receptors in the walls of the afferent glomerular arterioles respond, via the juxtaglomerular apparatus, to changes in renal perfusion, and control the activity of the renin–angiotensin–aldosterone system (see p. 1347). In addition, sodium concentration in the distal tubule and sympathetic nerve activity alter renin release from the juxtaglomerular cells. Prostaglandins I₂ and E₂ are also generated within the kidney in response to angiotensin II, acting to maintain GFR and sodium and water excretion, and modulating the sodium-retainig effect of this hormone.

- **Extrarenal receptors.** These are located in the vascular tree in the left atrium and major thoracic veins, and in the carotid sinus body and aortic arch. These volume receptors respond to a slight reduction in effective circulating volume and this results in increased sympathetic nerve activity and a rise in catecholamines. In addition, volume receptors in the cardiac atria control the release of a powerful natriuretic hormone – atrial natriuretic peptide (ANP) – from granules located in the atrial walls (see p. 1346). High-pressure arterial receptors (carotid, aortic arch, juxtaglomerular apparatus) predominate over low-pressure volume receptors in volume control in mammals.

Aldosterone and possibly ANP are responsible for day-to-day variations in Na⁺ excretion, through their respective ability to augment and diminish Na⁺ reabsorption in the collecting ducts.

- **A salt load,** for example, leads to an increase in the effective circulatory and extracellular volume, raising both renal perfusion pressure, and atrial and arterial filling pressure. The increase in the renal perfusion pressure reduces the secretion of renin, and subsequently that of angiotensin II and aldosterone (see Fig. 36.6), whereas the rise in atrial and arterial filling pressure increases the release of ANP. These factors combine to reduce Na⁺ reabsorption in the collecting duct, thereby promoting excretion of excess Na⁺.

- **By contrast,** in patients with a low Na⁺ intake or in those who become volume-depleted as a result of vomiting or diarrhoea, the ensuing decrease in effective volume enhances the activity of the renin–angiotensin–aldosterone system and reduces the secretion of ANP. The net effect is enhanced Na⁺ reabsorption in the collecting duct, leading to a fall in Na⁺ excretion. This increases the extracellular volume towards normal.

With **more marked hypovolaemia,** a decrease in GFR leads to an increase in proximal and thin ascending limb Na⁺ reabsorption, which contributes to Na⁺ retention. This is brought about by enhanced sympathetic activity acting directly on the kidneys and indirectly by stimulating the secretion of renin/angiotensin II (see Fig. 9.5B) and non-osmotic release of antidiuretic hormone (ADH), also called vasopressin. The pressure natriuresis phenomenon may be the final defence against changes in the effective circulating volume. Marked persistent hypovolaemia leads to systemic hypotension and increased salt and water absorption in the proximal tubules and ascending limb of Henle. This process is partly mediated by changes in renal interstitial hydrostatic pressure and local prostaglandin and nitric oxide production. Recurrent episodes of hypovolaemia may, over time, lead to chronic kidney disease (CKD), such as in the recently described syndrome Mesoamerican nephropathy, where recurrent episodes of
heat-stress in young to middle-aged male agricultural workers along the Pacific coast in Central America is thought to be a cause.

Volume regulation in oedematous conditions
Sodium and water are retained despite increased extracellular volume in oedematous conditions such as cardiac failure, hepatic cirrhosis and hypoalbuminaemia. Here the principal mediator of salt and water retention is the concept of arterial underfilling due to either reduced cardiac output or diminished peripheral arterial resistance. Arterial underfilling in these settings leads to reduction of pressure or stretch (i.e. ‘unloading’ of arterial volume receptors), which results in activation of the sympathetic nervous system, activation of the renin–angiotensin–aldosterone system and non-osmotic release of ADH. These neurohumoral mediators promote salt and water retention in the face of increased extracellular volume (see Fig. 9.5A).

Mechanism of impaired escape from actions of aldosterone and resistance to ANP
Not only is the activity of the renin–angiotensin–aldosterone system increased in oedematous conditions such as cardiac failure, hepatic
This escape from mineralocorticoid-mediated sodium retention explains why oedema is not a characteristic feature of primary hyperaldosteronism. The escape is dependent on an increased delivery of sodium to the site of action of aldosterone in the collecting ducts. The increased distal sodium delivery is achieved by high extracellular volume-mediated arterial overfilling. This suppresses sympathetic activity and angiotensin II generation, and increases cardiac release of ANP with resultant increase in renal perfusion pressure and GFR. The net result of these events is reduced sodium absorption in the proximal tubules and increased distal sodium delivery, which overwhelms the sodium-retainning actions of aldosterone.

**In patients with the oedematous conditions described**, such as heart failure, escape from the sodium-retaining actions of aldosterone does not occur and therefore they continue to retain sodium in response to aldosterone. Accordingly, they have substantial natriuresis when given spironolactone, which blocks mineralocorticoid receptors. Alpha-adrenergic stimulation and elevated angiotensin II increases sodium transport in the proximal tubule, and reduced renal perfusion and GFR further increase sodium absorption from the proximal tubules by presenting less sodium and water in the tubular fluid. Sodium delivery to the distal portion of the nephron, and thus the collecting duct, is reduced. Similarly, increased cardiac ANP secretion reduces renal perfusion and GFR, so that there is no escape from the sodium-retaining effects of aldosterone.

Fig. 9.6 The nephron – electrolyte and water exchange. Some 180 L of water and 26 000 mmol of sodium/day enter the nephrons via the afferent arterioles to the kidneys. Removal or addition of electrolytes results in the excretion of approximately 1 L of water and 60–180 mmol of sodium/day.

cirrhosis and hypoalbuminaemia, but also the action of aldosterone is more persistent than in normal subjects and patients with primary hyperaldosteronism (Conn’s syndrome), who have increased aldosterone secretion (see p. 606).

**In normal subjects**, high doses of mineralocorticoids initially increase renal sodium retention so that the extracellular volume is increased by 1.5–2L. However, renal sodium retention then ceases, sodium balance is re-established, and there is no detectable oedema.
release in these conditions requires optimum sodium concentration at the site of its action in the collecting duct for its desired natriuretic effects. Decreased sodium delivery to the collecting duct is therefore the most likely explanation for the persistent aldosterone-mediated sodium retention, absence of escape phenomenon and resistance to natriuretic peptides in these patients (see Fig. 9.5B).

Regulation of water excretion

Body water homeostasis is affected by thirst and the urine-concentrating and diluting functions of the kidney. These, in turn, are controlled by intracellular osmoreceptors, principally in the hypothalamus, to some extent by volume receptors in capacitance vessels close to the heart, and via the renin–angiotensin system. Of these, the major and best-understood control is via osmoreceptors. Changes in the plasma Na\(^+\) concentration and osmolality are sensed by osmoreceptors that influence both thirst and the release of ADH (vasopressin) from the supraoptic and paraventricular nuclei of the anterior hypothalamus.

ADH plays a central role in urinary concentration by increasing the water permeability of the normally impermeable cortical and medullary collecting ducts. There are three major G-protein coupled receptors for vasopressin (ADH):

- \(V_2\) receptors in the principal cells of the kidney distal convoluted tubule and collecting ducts: these mediate the ADH response.
- \(V_1\) receptors for vasopressin (ADH) found in vascular smooth muscle cells: activation induces vasoconstriction.
- \(V_1B\) receptors in the anterior pituitary and throughout the brain: this mediates the effect of ADH on the pituitary, leading to adrenocorticotrophic hormone (ACTH) release.

The ability of ADH to increase the urine osmolality is related indirectly to transport in the ascending limb of the loop of Henle, which reabsorbs NaCl without water. This process, which is the primary step in the counter-current mechanism, has two effects: it makes the tubular fluid dilute and the medullary interstitium concentrated.

In the absence of ADH, little water is reabsorbed in the collecting ducts, and a dilute urine is excreted. By contrast, the presence of ADH promotes water reabsorption in the collecting ducts down the favourable osmotic gradient between the tubular fluid and the more concentrated interstitium. As a result, there is an increase in urine osmolality and a decrease in urine volume.

The cortical collecting duct has two cell types (see also p. 1343) with very different functions:

- **Principal cells** (about 65%) have sodium and potassium channels in the apical membrane and, as in all sodium-reabsorbing cells, Na\(^+\)/K\(^-\)-ATPase pumps in the basolateral membrane.
- **Intercalated cells**, in comparison, do not transport NaCl (since they have a lower level of Na\(^+\)/K\(^-\)-ATPase activity) but play a role in hydrogen and bicarbonate handling and in potassium reabsorption in states of potassium depletion.

The ADH-induced increase in collecting duct water permeability occurs primarily in the principal cells. ADH acts on \(V_2\) (vasopressin) receptors located on the basolateral surface of principal cells, resulting in the activation of adenyl cyclase. This leads to protein kinase activation and to pre-formed cytoplasmic vesicles that contain unique water channels (called aquaporins) moving to, and then being inserted into, the luminal membrane. The water channels span the luminal membrane and permit water movement into the cells down a favourable osmotic gradient (Fig. 9.7). This water is then rapidly returned to the systemic circulation across the basolateral membrane. When the ADH effect has worn off, the water channels are removed from the luminal membrane by endocytosis and returned to the cytoplasm. A defect in any step in this pathway, such as in attachment of ADH to its receptor or the function of the water channel, can cause resistance to the action of ADH and an increase in urine output. This disorder is called **nephrogenic diabetes insipidus**.

Plasma osmolality

In addition to influencing the rate of water excretion, ADH plays a central role in osmoregulation because its release is directly affected by the plasma osmolality. At a plasma osmolality of <275 mosmol/kg, which usually represents a plasma Na\(^+\) concentration of <135–137 mmol/L, there is essentially no circulating ADH. As the plasma osmolality rises above this threshold, however, the secretion of ADH increases progressively.

Two simple examples will illustrate the basic mechanisms of osmoregulation, which is so efficient that the plasma Na\(^+\) concentration is normally maintained within 1–2% of its baseline value.

- **Ingestion of a water load** leads to an initial reduction in the plasma osmolality, thereby diminishing the release of ADH. The ensuing reduction in water reabsorption in the collecting ducts allows the excess water to be excreted in a dilute urine.
- **Water loss** resulting from sweating is followed by, in sequence, a rise in both plasma osmolality and ADH secretion, enhanced water reabsorption, and the appropriate excretion of a small volume of concentrated urine. This renal effect of ADH minimizes further water loss but does not replace the existing water deficit. Thus, optimal osmoregulation requires an increase in water intake, which is mediated by a concurrent stimulation of thirst. The importance of thirst can also be illustrated by studies in patients with central diabetes insipidus, who are deficient in ADH. These patients often complain of marked polyuria, which is caused by the decline in water reabsorption in the collecting ducts. However, they do not typically become hypernatraemic because urinary water loss is offset by the thirst mechanism.
Osmoregulation versus volume regulation

A common misconception is that regulation of the plasma Na⁺ concentration is closely correlated with the regulation of Na⁺ excretion. It is, however, related to volume regulation, which has different sensors and effectors (volume receptors) from those involved in water balance and osmoregulation (osmoreceptors).

The roles of these two pathways should be considered separately when evaluating patients.

- **A water load** is rapidly excreted (in 4–6 h) by inhibition of ADH release so that there is little or no water reabsorption in the collecting ducts. This process is normally so efficient that volume regulation is not affected and there is no change in ANP release or in the activity of the renin–angiotensin–aldosterone system. Thus, a dilute urine is excreted and there is little alteration in the excretion of Na⁺.

- **0.9% saline** administration, by contrast, causes an increase in volume but no change in plasma osmolality. In this setting, ANP secretion is increased, aldosterone secretion is reduced and ADH secretion does not change. The net effect is the appropriate excretion of the excess Na⁺ in a relatively iso-osmotic urine.

In some cases, both volume and osmolality are altered but both pathways are activated. For example, if a person with normal renal function eats salted crisps or peanuts without drinking any water, the excess Na⁺ will increase the plasma osmolality, leading to osmotic water movement out of the cells and increased extracellular volume. The rise in osmolality will stimulate both ADH release and thirst (the main reason why many restaurants and bars supply free salted foods), whereas the hypervolaemia will enhance the secretion of ANP and suppress that of aldosterone. The net effect is increased excretion of Na⁺ without water.

This principle of separate volume and osmoregulatory pathways is also evident in the syndrome of inappropriate antidiuretic hormone secretion (SIADH). Patients with SIADH (see p. 643) have impaired water excretion and hyponatraemia (dilutional) caused by the persistent presence of ADH. However, the release of ANP and aldosterone is not impaired and, thus, Na⁺ handling remains intact. These findings have implications for the correction of the hyponatraemia in this setting, which initially requires restriction of water intake. ADH is also secreted by non-osmotic stimuli such as stress (e.g. surgery, trauma), markedly reduced effective circulatory volume (e.g. cardiac failure, hepatic cirrhosis), psychiatric disturbance and nausea, irrespective of plasma osmolality. This is mediated by the effects of sympathetic overactivity on supraoptic and paraventricular nuclei. In addition to water retention, ADH release in these conditions promotes vasoconstriction owing to the activation of V₁A (vasopressin) receptors distributed in the vascular smooth muscle cells.

### Increased extracellular volume

Increased extracellular volume occurs in numerous disease states. The physical signs depend on the distribution of excess volume and on whether the increase is local or systemic. According to Starling principles, distribution depends on:

- venous tone, which determines the capacitance of the blood compartment and thus hydrostatic pressure
- capillary permeability
- oncotic pressure – mainly dependent on serum albumin
- lymphatic drainage.

Depending on these factors, fluid accumulation may result in expansion of interstitial volume, blood volume or both.

#### Clinical features

Peripheral oedema is caused by expansion of the extracellular volume by at least 2 L (15%). The ankles are normally the first part of the body to be affected. Oedema may be noted in the face, particularly in the morning, or if the patient is in bed, oedema may accumulate in the sacral area. Expansion of the interstitial volume also causes pulmonary oedema, pleural effusions, pericardial effusion and ascites. Expansion of the blood volume causes a raised jugular venous pressure, cardiomegaly, added heart sounds and basal crackles, as well as a raised arterial blood pressure.

#### Aetiology

Extracellular volume expansion is due to renal sodium chloride retention. Increased oral salt intake does not normally cause volume expansion because of rapid homeostatic mechanisms that increase salt excretion. However, a rapid intravenous infusion of a large volume of saline will cause volume expansion.

#### Heart failure

Reduction in cardiac output and the consequent fall in effective circulatory volume and arterial filling lead to activation of the renin–angiotensin–aldosterone system, non-osmotic release of ADH, and increased activity of the renal sympathetic nerves via volume receptors and baroreceptors (see Fig. 9.5B). Sympathetic overdrive also indirectly augments ADH and renin–angiotensin–aldosterone response in these conditions. The cumulative effect of these mediators results in increased peripheral and renal arterial resistance and water and sodium retention. These factors lead to extracellular volume expansion and increased venous pressure, causing oedema formation.

#### Hepatic cirrhosis

The mechanism is complex but involves peripheral vasodilatation, due to increased nitric oxide generation, resulting in reduced EABV and arterial filling. This leads to an activation of a chain of events common also to other conditions with marked peripheral vasodilatation and heart failure (see Fig. 9.5). The cumulative effect results in increased water and sodium retention, and oedema formation.

#### Nephrotic syndrome

Interstial oedema is a common clinical finding with hypoalbuminaemia, particularly in the nephrotic syndrome. Expansion of the interstitial compartment is secondary to the accumulation of sodium in the extracellular compartment. This is due to an imbalance between oral (or parenteral) sodium intake and urinary sodium loss, as well as alterations of fluid transfer across capillary walls. The intrarenal site of sodium retention is the cortical collecting duct (CCD), where Na⁺/K⁺-ATPase expression and activity are increased threefold along the basolateral surface (see Fig. 9.8). In addition, amiloride-sensitive epithelial sodium channel activity is also increased in the CCD. The renal sodium retention should normally be counterbalanced by increased secretion of sodium in the inner medullary collecting duct, brought about by the release of ANP. This regulatory pathway is altered in patients with nephrotic syndrome by enhanced **kidney-specific** catabolism of cyclic guanosine monophosphate (cGMP, the second messenger for ANP) following phosphodiesterase activation.

Oedema generation was classically attributed to the decrease in plasma oncotic pressure and the subsequent increase in the trans-capillary oncotic gradient. However, the oncotic pressure and trans-capillary oncotic gradient remain unchanged and the transcapillary hydrostatic pressure gradient is not altered.

The mechanism for oedema seen in nephrotic syndrome is increased capillary hydraulic conductivity (a measure of...
permeability). In addition, increased circulating ANP can increase capillary hydraulic conductivity by altering the permeability of intercellular junctional complexes. Furthermore, reduction in effective circulatory volume and the consequent fall in cardiac output and arterial filling can lead to a chain of events, as in cardiac failure and cirrhosis (see earlier and Fig. 9.2). These factors result in extracellular volume expansion and oedema formation.

Sodium retention

A decreased GFR decreases the renal capacity to excrete sodium. This may be acute, as in the acute nephritic syndrome (see p. 1360), or may occur as part of the presentation of CKD. In end-stage renal failure, extracellular volume is controlled by the balance between salt intake and its removal by dialysis.

Numerous drugs cause renal sodium retention, particularly in patients whose renal function is already impaired:

- **Oestrogens** cause mild sodium retention, due to a weak aldosterone-like effect. This is the reason for weight gain in the premenstrual phase.
- **Mineralocorticoids and liquorice** (the latter potentiates the sodium-retaining action of cortisol) have aldosterone-like actions.
- **Non-steroidal anti-inflammatory drugs (NSAIDs)** cause sodium retention in the presence of activation of the renin-angiotensin-aldosterone system by heart failure, in cirrhosis and in renal artery stenosis.
- **Thiazolidinediones (TZDs)** (see p. 718) are widely used to treat type 2 diabetes. Their mechanism of action is attributed to binding and activation of the peroxisome proliferator-activated receptor gamma (PPAR-γ) system. PPARs are nuclear transcription factors, essential to the control of energy metabolism, which are modulated via binding with tissue-specific fatty acid metabolites. Of the three PPAR isoforms, γ has been extensively studied and is expressed at high levels in adipose and liver tissues, macrophages, pancreatic β cells and principal cells of the collecting duct. These drugs have been associated with salt and water retention and are contraindicated in patients with heart failure. TZD-induced oedema is also due to upregulation of epithelial Na transporter channel (ENaC) but by different pathways. The diuretics of choice for TZD-induced oedema are amiloride and triamterene.
- **Substantial amounts of sodium and water may accumulate in the body without clinically obvious oedema or evidence of raised venous pressure. In particular, several litres may accumulate in the pleural space or as ascites; these spaces are then referred to as ‘third spaces’. Bone may also act as a ‘sink’ for sodium and water.**

Other causes of oedema

- **Initiation of insulin treatment for type 1 diabetes and re-feeding after malnutrition are both associated with the development of transient oedema. The mechanism is complex but involves upregulation of ENaC in the principal cell of the collecting duct. This transporter is amiloride-sensitive, which makes amiloride or triamterene the diuretic of choice in insulin-induced oedema.**
- **Oedema may result from increased capillary pressure owing to relaxation of pre-capillary arterioles. The best example is the peripheral oedema caused by dihydrospiridine calcium-channel blockers such as amlodipine, which affects up to 10% of patients. Oedema is usually resolved by stopping the offending drug.**
- **Oedema is also caused by raised intrstitial oncotic pressure as a result of increased capillary permeability to proteins. This can occur as part of a rare complement-deficiency syndrome; with therapeutic use of interleukin 2 in cancer chemotherapy; or in ovarian hyperstimulation syndrome (see p. 632).**

Idiopathic oedema

This tends to occur in women without heart failure, hypoalbuminaemia, and renal or endocrine disease. Oedema is intermittent and often worse in the premenstrual phase. The condition remits after the menopause. Patients complain of swelling of the face, hands, breasts and thighs, and a feeling of being bloated. Sodium retention during the day and increased sodium excretion during recumbency are characteristic; an abnormal fall in plasma volume on standing, caused by increased capillary permeability to proteins, may be the cause of this. The oedema may respond to diuretics but returns when they are stopped. A similar syndrome of diuretic-dependent sodium retention can be caused by abuse of diuretics – for instance, as part of an attempt to lose weight – and the syndrome was described before diuretics were introduced for clinical use, so the cause remains unclear.

Local increase in oedema

This does not reflect disturbances of extracellular volume control per se but can cause clinical confusion. Examples are ankle oedema due to venous or lymphatic damage following thrombosis or surgery, ankle or leg oedema due to immobility, oedema of the arm due to subclavian thrombosis, and facial oedema due to superior vena caval obstruction.

Management

The underlying cause should be treated where possible. Heart failure, for example, should be treated and offending drugs such as NSAIDs withdrawn.

Sodium restriction has only a limited role but is useful in patients who are resistant to diuretics. Sodium intake can easily be reduced to approximately 100 mmol (2 g) daily; reductions below this are often difficult to achieve without affecting the palatability of food.

Manoeuvres that increase venous return (e.g. strict bed rest or water immersion) stimulate salt and water excretion by effects on cardiac output and ANP release, but they are seldom of practical value.

The mainstay of treatment is the use of diuretic agents, which increase sodium, chloride and water excretion in the kidney (Box 9.6). These agents act by interfering with membrane ion pumps that are present on numerous cell types; they mostly achieve specificity for the kidney by being secreted into the proximal tubule, resulting in much higher concentrations in the tubular fluid than in other parts of the body.

Clinical use of diuretics

Loop diuretics

These potent diuretics are useful in the treatment of any cause of systemic extracellular volume overload. They stimulate excretion of both sodium chloride and water by blocking the sodium-potassium-2-chloride (NKCC2) channel in the thick ascending limb of Henle (Fig. 9.8) and are useful in stimulating water excretion in states of relative water overload. They also act by causing increased venous capacitance, resulting in rapid clinical improvement in patients with left ventricular failure, preceding the diuresis. Unwanted effects include:

- urate retention, causing gout
- hypokalaemia
- hypercalciuria leading to increased risk of calcium-based renal stones
- hypomagnesaemia
- decreased glucose tolerance
- allergic tubulointerstitial nephritis and other allergic reactions
- myalgia – especially with high-dose bumetanide

CCF, congestive cardiac failure; CKD, chronic kidney disease; SIADH, syndrome of inappropriate antidiuretic hormone secretion.

- ototoxicity (due to an action on sodium pump activity in the inner ear) – particularly with furosemide
- interference with excretion of lithium, resulting in toxicity.

Thiazide diuretics

Thiazide diuretics (see p. 1073) are less potent than loop diuretics. They act by blocking a sodium chloride channel in the distal convoluted tubule (producing an induced form of Gitelman’s syndrome, which is associated with reduced function of this channel; see p. 188) (Fig. 9.9). They cause relatively more urate retention, glucose intolerance and hypokalaemia than loop diuretics. They interfere with water excretion and may cause hyponatraemia, particularly if combined with amiloride or triamterene. This effect is clinically useful in diabetes insipidus. Thiazides reduce peripheral vascular resistance by mechanisms that are not completely understood but do not appear to depend on their diuretic action, and are widely used in the treatment of essential hypertension. They are also used extensively in mild to moderate cardiac failure. Thiazides reduce calcium excretion. This effect is useful in patients with idiopathic hypercalciuria but may cause hypercalcaemia. Numerous agents are available, with varying half-lives but little else to choose between them. Metalazone is not dependent for its action on glomerular filtration, and therefore retains its potency in renal impairment.

Potassium-sparing diuretics

Potassium-sparing diuretics (Fig. 9.10) are of two types:
- **Aldosterone antagonists**, which compete with aldosterone in the collecting ducts and reduce sodium absorption, e.g. spironolactone and eplerenone (which has a shorter half-life). Spironolactone is used in patients with heart failure because it significantly reduces the mortality in these individuals by antagonizing the fibrotic effect of aldosterone on the heart. Eplerenone may be preferred because it is devoid of antiandrogenic or antiprogestosterone properties.
- **Amiloride and triamterene**, which inhibit sodium uptake by blocking epithelial sodium channels in the collecting duct and

![Fig. 9.8 Transport mechanisms in the thick ascending limb of the loop of Henle. Sodium chloride is reabsorbed in the thick ascending limb by the bumetanide-sensitive sodium–potassium-2–chloride co-transporter (NKCC2), which is the target of loop diuretics such as furosemide. The electroneutral transporter is driven by the low intracellular sodium and chloride concentrations generated by the Na$^+$/K$^+$-ATPase and the kidney-specific basolateral chloride channel (CLC-Kb). The availability of luminal potassium is rate-limiting for NKCC2, and recycling of potassium through the ATP-regulated potassium channel (renal outer medulla K$^+$ channel, ROMK) ensures the efficient functioning of the NKCC2 and generates a lumen-positive transepithelial potential. Calcium and magnesium, along with potassium and sodium, are also absorbed paracellularly in the thick ascending loop. Barter's syndrome: loss of function mutations for the different types of syndrome. (a) NKCC2 (type I). (b) ROMK (type II). (c) CLC-Kb (type III). (d) Barttin (type IV). In addition, type V may be caused by a gain-of-function mutation of the calcium-sensing receptor (not shown).
reduce renal potassium excretion by reducing lumen-negative transepithelial voltage. They are mainly used as potassium-sparing agents with thiazide or loop diuretics.

Carbonic anhydrase inhibitors
These are relatively weak diuretics and are seldom used, except in the treatment of glaucoma. They cause metabolic acidosis and hypokalaemia.

Aquaretics (vasopressin or ADH antagonists)
Vasopressin V2 receptor antagonists are very useful agents in the treatment of conditions associated with elevated levels of vasopressin, such as heart failure, cirrhosis and SIADH (see p. 643). Non-peptide vasopressin V2 receptor antagonists are efficacious in producing free water diuresis in humans. Studies in patients with heart failure and cirrhosis suggest that such agents will allow normalization of serum osmolality with less water restriction (see p. 186).

Sodium–glucose co-transporter 2 (SGLT2) inhibitors
This recently developed class of medications for type 2 diabetes have demonstrated significant cardiac and renal protection in large clinical trials and act by blocking glucose and sodium reabsorption in the proximal tubule leading to an osmotic diuresis and a natural- esis. SGLT2 inhibitors therefore lead to glycosuria (with a modest caloric deficit) and an improvement in diabetic control along with a modest diuretic and antihypertensive effect, which may in part be responsible for their favourable cardiovascular protection data.

Resistance to diuretics
Resistance may occur as a result of:
- poor bioavailability
- reduced GFR, which may be due to decreased circulating volume despite oedema (e.g. nephrotic syndrome, cirrhosis with ascites) or intrinsic renal disease
- activation of sodium-retaining mechanisms, particularly aldosterone.

Intravenous administration of diuretics may be required to establish a diuresis, and high doses of loop diuretics are needed to achieve adequate concentrations in the tubule if GFR is depressed. However, the daily dose of furosemide must be limited to a maximum of 2 g for an adult because of ototoxicity. Intravenous albumin solutions restore plasma oncotic pressure temporarily in the nephrotic syndrome and allow mobilization of oedema but do not increase the natriuretic effect of loop diuretics.

Combinations of various classes of diuretics are extremely helpful in patients with resistant oedema. A loop diuretic plus a thiazide inhibit two major sites of sodium reabsorption; this effect may be further potentiated by addition of a potassium-sparing agent. Mety-iazone in combination with a loop diuretic is particularly useful in refractory congestive cardiac failure because its action is less dependent on glomerular filtration. However, this potent combination can cause severe electrolyte imbalance.

Effects on renal function
All diuretics may increase plasma urea concentrations by increasing urea reabsorption in the medulla. Thiazides may also promote protein breakdown. In certain situations, diuretics also decrease GFR:
- Excessive diuresis causes volume depletion and pre-renal failure.
- Diuretics can cause allergic tubulointerstitial nephritis.
- Thiazides may directly cause a drop in GFR; the mechanism is complex and not fully understood.

Decreased extracellular volume

Deficiency of sodium and water causes shrinkage both of the interstitial space and of the blood volume, and may have profound effects on organ function.

Clinical features

Symptoms
Thirst, muscle cramps, nausea and vomiting, and postural dizziness occur. Severe depletion of circulating volume causes hypotension and impairs cerebral perfusion, causing confusion and eventual coma.

Signs
Signs can be divided into those due to loss of interstitial fluid and those due to loss of circulating volume.

- **Loss of interstitial fluid** leads to loss of skin elasticity (‘turgor’) – the rapidity with which the skin recoils to normal after being pinched. Skin turgor decreases with age, particularly at the peripheries. The turgor over the anterior triangle of the neck or on the forehead is less dependent on age and so may be more useful.

- **Loss of circulating volume** leads to decreased pressure in the venous and (if severe) arterial compartments. Loss of up to 1 L of extracellular fluid in an adult may be compensated for by venoconstriction and may cause no physical signs. Loss of more than this amount causes the following:

  - **Postural hypotension** Normally, the blood pressure rises if a subject stands up, as a result of increased venous return due to venoconstriction (this maintains cerebral perfusion). Loss of extracellular fluid (underfill) prevents this and causes a fall in blood pressure. This is one of the earliest and most reliable signs of volume depletion, as long as the other causes of postural hypotension are excluded (Box 9.7).

  - **Low jugular venous pressure** In hypovolaemic patients, the jugular venous pulsation can be seen only with the patient lying completely flat, or even head down, because the right atrial pressure is lower than 5 cmH$_2$O.

- **Peripheral vasoconstriction** This causes cold skin with empty peripheral veins (which are difficult to cannulate just when the patient needs intravenous therapy the most!) This sign is often absent in sepsis, where peripheral vasodilatation contributes to effective hypovolaemia.

  - **Tachycardia** This is not always a reliable sign. Beta-blockers and other antiarrhythmics may prevent tachycardia, and hypovolaemia may activate vagal mechanisms and actually cause bradycardia.

Aetiology
Salt and water may be lost from the kidneys, the gastrointestinal tract or the skin (Box 9.8).

In addition, there are a number of situations where signs of volume depletion occur despite a normal or increased body content of sodium and water:

- Septicaemia causes vasodilation of both arterioles and veins, resulting in greatly increased capacitance of the vascular space. In addition, increased capillary permeability to plasma proteins leads to loss of fluid from the vascular space to the interstitium.

- Diuretic treatment of heart failure or nephrotic syndrome may lead to rapid reduction in plasma volume. Mobilization of oedema may take much longer.

- There may be inappropriate diuretic treatment of oedema (e.g. when the cause is local rather than systemic), causing systemic hypovolaemia.

Investigations
Blood tests are, in general, not helpful in the assessment of extracellular volume. Plasma urea may be raised owing to increased urea reabsorption and, later, to pre-renal failure (when the creatinine rises as well), but this is very non-specific. Urinary sodium is low if the kidneys are functioning normally, but is misleading if the cause of the volume depletion involves the kidneys (e.g. diuretics, intrinsic renal disease). Urine osmolality is high in volume depletion (owing to increased water reabsorption) but may also often mislead.

Assessment of volume status is shown in Box 9.9.

Management
The overriding principle is to replace what is missing.

Haemorrhage
The rational treatment of acute haemorrhage is the infusion of a combination of red cells and a plasma substitute or (if unavailable)
whole blood. (Chronic anaemia causes salt and water retention rather than volume depletion by a mechanism common to conditions with peripheral vasodilation.)

Loss of plasma
Loss of plasma, as occurs in burns or severe peritonitis, should be treated with human plasma or a plasma substitute (see p. 221).

**Loss of water and electrolytes**
Loss of water and electrolytes, as occurs with vomiting, diarrhoea or excessive renal losses, should be treated by replacement of the loss. If possible, this should be with oral water and sodium salts. These are available as slow sodium (600 mg, approximately 10 mmol each of Na\(^+\) and Cl\(^-\) per tablet), the usual dose of which is 6–12 tablets/day with 2–3 L of water. They are used in mild or chronic salt and water depletion, such as that associated with renal salt wasting.

Sodium bicarbonate (500 mg, 6 mmol each of Na\(^+\) and HCO\(_3^-\) per tablet) is given in doses of 6–12 tablets/day with 2–3 L of water. This is used in milder chronic sodium depletion with acidosis (e.g. CKD, post-obstructive renal failure, renal tubular acidosis). Sodium bicarbonate is less effective than sodium chloride in causing positive sodium balance. Oral rehydration solutions are described in Box 20.36.

**Intravenous fluids**
Intravenous fluids are sometimes required (Box 9.10, Fig 9.11). Rapid infusion (e.g. 1000 mL per hour or even faster) of 0.9% NaCl is best achieved by simple clinical observations, which you should carry out yourself (see figure on p. 170). Check:
- Jugular venous pressure
- Central venous pressure: both basal and after intravenous fluid challenge (see p. 210)
- Postural changes in blood pressure
- Chest X-ray
- Serial weights of the patient
- Urine output measurements at regular intervals

**Box 9.9 Assessment of volume status**
Best achieved by simple clinical observations, which you should carry out yourself (see figure on p. 170). Check:
- Jugular venous pressure
- Central venous pressure: both basal and after intravenous fluid challenge (see p. 210)
- Postural changes in blood pressure
- Chest X-ray
- Serial weights of the patient
- Urine output measurements at regular intervals

\(^a\)1. Volume expansion in hypovolaemic patients. Rarely, to maintain fluid balance when there are large losses of sodium. The sodium (150 mmol/L) is higher than in plasma and hypernatraemia can result. It is often necessary to add KCl 20–40 mmol/L.
3. To replace water. Can be given with or without potassium chloride. May be alternated with 0.9% saline as an alternative to (2).
4. For volume expansion in hypovolaemic, acidicotic patients, alternating with (1). Occasionally, for maintenance of fluid balance combined with (2) in salt-wasting, acidicotic patients.
5. For volume expansion in hypovolaemic patients. May be better than 0.9% saline for patients with sepsis and relative hypovolaemia.

\(^b\)Hartmann’s solution also contains 2 mmol/L of calcium.

**Existing fluid or electrolyte deficits or excesses**
Check for:
- Dehydration
- Fluid overload
- Hyperkalaemia/hypokalaemia
Estimate deficits or excesses

**Ongoing abnormal fluid or electrolyte losses**
Check ongoing losses and estimate amounts. Check for:
- Vomiting and nasogastric tube loss
- Biliary drainage loss
- High-volume ileal stoma loss
- Diarrhoea/excess colostomy loss
- Ongoing blood loss, e.g. melena
- Sweating/fever/dehydration
- Pancreatic/jejunal fistula/stoma loss
- Urinary loss, e.g. post AKI polyuria

**Redistribution and other complex issues**
Check for:
- Gross oedema
- Severe sepsis
- Hypokalaemia/hyperkalaemia
- Renal, liver and/or cardiac impairment
- Postoperative fluid retention and redistribution
- Malnutrition and re-feeding issues
Seek expert help if necessary and estimate requirements

Prescribe by adding to or subtracting from routine maintenance, adjusting for all other sources of fluid and electrolytes (oral, enteral and drug prescriptions)

Monitor and reassess fluid and biochemical status by clinical and laboratory monitoring

Fig. 9.11 Adult intravenous fluid therapy. AKI, acute kidney injury.
is necessary if there is hypotension and evidence of impaired organ perfusion (e.g. oliguria, confusion). However, in critically ill patients the use of balanced crystalloids (Hartmann’s solution or Plasma-Lyte, which have lower chloride concentrations than saline) have been shown to result in a lower rate of the composite outcome of death from any cause, new renal-replacement therapy or persistent renal dysfunction than the use of saline, particularly if large volumes of replacement fluids are given.

Repeated clinical assessments are vital in this situation. Severe hypovolaemia induces venoconstriction, which maintains venous return; over-rapid correction does not give time for this to reverse, resulting in signs of circulatory overload (e.g. pulmonary oedema), even if a total body extracellular fluid deficit remains. In less severe extracellular fluid depletion, the fluid should be replaced at a rate of 1000 mL every 4–6 h, again with repeated clinical assessment. If all that is required is avoidance of fluid depletion during surgery, 1–2 L can be given over 24 h, remembering that surgery is a stimulus to sodium and water retention and that over-replacement may be as dangerous as under-replacement. Regular monitoring by fluid balance charts, body weight and plasma biochemistry is crucial.

**Loss of water alone**

This causes extracellular volume depletion only in severe cases because the loss is spread evenly among all the compartments of body water. In the rare situations where there is a true deficiency of water alone, as in diabetes insipidus or in a patient who is unable to drink (e.g. after surgery), the correct treatment is to give water.

If intravenous treatment is required, water is given as 5% glucose with K⁺ because pure water would lead to osmotic lysis of blood cells.

**Further reading**

## Disorders of sodium concentration

These are generally best thought of as disorders of body water content. As discussed above, sodium content is regulated by volume receptors; water content is adjusted to maintain, in health, a normal osmolality and (in the absence of abnormal osmotically active solutes) a normal sodium concentration. Disturbances of sodium concentration are caused by disturbances of water balance.

However, recently non-invasive quantitative sodium magnetic resonance imaging (Na-MRI) studies in patients have shown that:

- remarkable amounts of Na are stored in muscle, bones and skin without water
- fluids in the skin interstitium are hypertonic compared with plasma
- interstitial osmotic stress induces local immune cell and lymphatic-capillary driven mechanisms for electrolyte clearance and maintenance of the internal environment, suggesting that Na homeostasis requires additional extrarenal regulatory mechanisms.

### Hyponatraemia

Hyponatraemia (Na <135 mmol/L) is the most common biochemical abnormality in hospitalized patients, with up to 35% of inpatients developing hyponatraemia during their stay. The causes depend on the associated changes in extracellular volume:

- **hyponatraemia with hypovolaemia**
- **hyponatraemia with euvoalaemia**
- **hyponatraemia with hypervolaemia**

Rarely, hyponatraemia may be a ‘pseudo-hyponatraemia’. This occurs in hyperlipidaemia (either high cholesterol or high triglyceride) or hyperproteinæmia where there is a spuriously low measured sodium concentration, the sodium being confined to the aqueous phase but having its concentration expressed in terms of the total volume of plasma. In this situation, plasma osmolality is normal and therefore treatment of ‘hyponatraemia’ is unnecessary. Note that artefactual ‘hyponatraemia’, caused by taking blood from the limb into which fluid of low sodium concentration is being infused, should be excluded.

### Hyponatraemia with hypovolaemia

This is due to salt loss in excess of water loss; the causes are listed in Box 9.11. In this situation, ADH secretion is initially suppressed (via the hypothalamic osmoreceptors) but, as fluid volume is lost, volume receptors override the osmoreceptors and stimulate both thirst and the release of ADH. This is an attempt by the body to defend circulating volume at the expense of osmolality.

With extrarenal losses and normal kidneys, the urinary excretion of sodium falls in response to the volume depletion, as does water excretion, leading to concentrated urine containing <10 mmol/L of sodium. However, in salt-wasting kidney disease, renal compensation cannot occur and the only physiological protection is increased water intake in response to thirst.

### Clinical features

With sodium depletion, the clinical picture is usually dominated by features of volume depletion (see p. 181). The diagnosis is usually obvious where there is a history of gut losses, diabetes mellitus with significant hyperglycaemia, or diuretic abuse. Examination of the patient is often more helpful than the biochemical investigations, which include plasma and urine electrolytes and osmolality.

**Box 9.12** shows the potential daily losses of water and electrolytes from the gut. Losses due to renal or adrenocortical disease may be less easily identified but a urinary sodium concentration of >20 mmol/L, in the presence of clinically evident volume depletion, suggests a renal loss.

**Box 9.11 Causes of hyponatraemia with decreased extracellular volume (hypovolaemia)**

Management
This is directed at the primary cause whenever possible.

In a healthy patient:
- Give oral electrolyte-glucose mixtures (see p. 543).
- Increase salt intake with slow sodium 60–80 mmol/day.
  In a patient with vomiting or severe volume depletion:
- Give intravenous fluid with potassium supplement, that is 1.5–2 L 5% glucose (with 20 mmol K+) and 1 L 0.9% saline over 24 h plus measurable losses.
- Correction of acid–base abnormalities is usually not required.

Hyponatraemia with euvoalaemia
Hyponatraemia with euvoalaemia (Box 9.13) results from an intake of water in excess of the kidneys’ ability to excrete it (dilutional hyponatraemia); there is no change in body sodium content but the plasma osmolality is low.
- With normal kidney function, dilutional hyponatraemia is uncommon even if a patient drinks approximately 1 L per hour.
- The most common iatrogenic cause is over-generous infusion of 5% glucose into postoperative patients; in this situation, it is exacerbated by an increased ADH secretion in response to stress.
- Postoperative hyponatraemia is a common clinical problem (seen in almost 1% of patients) with symptomatic hyponatraemia occurring in 20% of these patients.
- Marathon runners who drink excess water can become hyponatraemic. Even so-called ‘isotonic sports drinks’ can lead to hyponatraemia, as they contain little sodium, their osmolality being made up with carbohydrates, which are metabolized into energy and water.
- Premenopausal females are at most risk for developing hyponatraemic encephalopathy postoperatively, with postoperative ADH values in young females being 40 times higher than in young males.
  To prevent hyponatraemia, avoid using hypotonic fluids postoperatively and administer 0.9% saline unless clinically contraindicated. The serum sodium should be measured daily in any patient receiving continuous parenteral fluid.
  Some degree of hyponatraemia is usual in acute oliguric kidney injury, while in CKD it is most often due to ill-advised advice to ‘push’ fluids.

Syndrome of inappropriate ADH secretion
This is described on page 643. There is inappropriate secretion of ADH, causing water retention and hyponatraemia.

Clinical features
Symptoms of dilutional hyponatraemia are common when hyponatraemia develops acutely (<48 h, often postoperatively). Overt neurological symptoms rarely occur until the serum sodium is less than 125 mmol/L, and are more usually associated with values around 115 mmol/L or lower, particularly when chronic. In elderly patients, however, even mild hyponatraemia with a serum sodium of 130–135 mmol/L has been associated with increased falls risk and subtle changes in cognition. They are due to the movement of water into brain cells in response to the fall in extracellular osmolality.

Hyponatraemic encephalopathy
Symptoms and signs include headache, confusion and restlessness leading to drowsiness, myoclonic jerks, generalized convulsions and eventually coma. Magnetic resonance imaging (MRI) of the brain may reveal cerebral oedema but, in the context of electrolyte abnormalities and neurological symptoms, can help to make a confirmatory diagnosis.

Risk factors for developing hyponatraemic encephalopathy
The brain's adaptation to hyponatraemia initially involves extrusion of blood and CSF, as well as sodium, potassium and organic osmoles, in order to decrease brain osmolality. Various factors can interfere with successful adaptation. These factors, rather than the absolute change in serum sodium, predict whether a patient will suffer hyponatraemic encephalopathy.
- **Children** under 16 years are at increased risk due to their relatively large brain-to-intracranial volume ratio compared with adults.
- **Premenopausal women** are more likely to develop encephalopathy than postmenopausal females and males because of inhibitory effects of sex hormones and the effects of vasopressin on cerebral circulation, resulting in vasoconstriction and hypoperfusion of the brain.
- **Hyponatraemia** is a major risk factor for hyponatraemic encephalopathy. Patients with hyponatraemia who develop hypoxia, from any cause, have a high risk of mortality. Hyponatraemia is the strongest predictor of mortality in patients with symptomatic hyponatraemia.

Investigations
The cause of hyponatraemia with apparently normal extracellular volume requires investigation:
• **Plasma and urine electrolytes and osmolalities.** The plasma concentrations of sodium, chloride and urea are low, giving a low osmolality. The urine sodium concentration is usually high and the urine osmolality is typically higher than the plasma osmolality.

• **Further investigations.** These are needed to exclude Addison’s disease, hypothyroidism, syndrome of inappropriate ADH secretion (SIADH) and water retention induced by drugs, e.g. chlorpropamide.

Potassium depletion and magnesium depletion potentiate ADH release and are causes of diuretic-associated hyponatraemia. SIADH is often over-diagnosed. Some causes are associated with a lower set-point for ADH release, rather than completely autonomous ADH release; an example is chronic alcohol use.

**Management**

The underlying cause should be corrected where possible (Box 9.14).

• **Most patients.** Most cases are simply managed by restriction of water intake (to 1000 or even 500 mL/day) with review of diuretic therapy. Magnesium and potassium deficiency must be corrected. In mild sodium deficiency, 0.9% saline given slowly (1 L over 12 h) is sufficient.

• **Acute onset with symptoms.** The most common cause of acute hyponatraemia in adults is postoperative iatrogenic hyponatraemia. Excessive water intake associated with psychosis, marathon running and use of Ecstasy (a recreational drug) are other causes. All are acute medical emergencies and should be treated aggressively and immediately. In patients who demonstrate severe neurological signs, such as fits, coma or cerebral oedema, **hypertonic saline** (3%, 513 mmol/L) should be used. It must be given very slowly (not more than 70 mmol/h), the aim being to increase the serum sodium by 4–6 mmol/L in the first 4 h, but the absolute change should not exceed 15–20 mmol/L over 48 h. In general, the plasma sodium should not be corrected to >125–130 mmol/L. Assuming that total body water comprises 50% of total body weight, 1 mL/kg of 3% sodium chloride will raise the plasma sodium by 1 mmol/L.

• **Symptomatic hyponatraemia in patients with intracranial pathology.** This should be managed aggressively and immediately with 3% saline, as for acute hyponatraemia.

• **Chronic/asymptomatic hyponatraemia.** If hyponatraemia has developed slowly, as it does in the majority of patients, the brain will have adapted by decreasing intracellular osmolality and the hyponatraemia must be corrected slowly.

However, clinically, it can be difficult to know how long the hyponatraemia has been present for and 3% hypertonic saline may still be required.

**Osmotic demyelination syndrome**

**Avoiding osmotic demyelination syndrome**

A rapid rise in extracellular osmolality, particularly if there is an ‘overshoot’ to high serum sodium and osmolality, will result in the osmotic demyelination syndrome (ODS), formerly known as central pontine demyelination, which is a devastating neurological complication. Plasma sodium concentration in patients with hyponatraemia should not rise by more than 8 mmol/L per day. The rate of rise of plasma sodium should be even lower in patients at higher risk for ODS: for example, those with alcohol excess, cirrhosis, malnutrition or hypokalaemia. Other factors predisposing to demyelination are pre-existing hyponaemia and central nervous system radiation. ODS is diagnosed by the appearance of characteristic hypointense lesions on T1-weighted images and hyperintense lesions on T2-weighted images on MRI; these can take 2 weeks or more to appear.

The pathophysiology of ODS is not fully understood. The most plausible explanation is that the brain loses organic osmolytes very quickly in order to adapt to hyponatraemia so that osmolality is similar between the intracellular and extracellular compartments. However, neurons take up organic osmolytes slowly in the phase of rapid correction of hyponatraemia, resulting in a hypo-osmolar intracellular compartment and shrinkage of cerebral vascular endothelial cells. Consequently, the blood–brain barrier is functionally impaired, allowing lymphocytes, complement and cytokines to enter the brain, damage oligodendrocytes, activate microglial cells and cause demyelination.

The most crucial issue in the treatment of hyponatraemia is to **prevent rapid correction** as it can be fatal. A rapid rise in plasma sodium is almost always due to a water diuresis, which happens when vasopressin (ADH) action stops suddenly; for example, with volume repletion in patients with intravascular volume depletion, cortisol replacement in patients with Addison’s disease, or resolution of non-osmotic stimuli for vasopressin release such as nausea or pain. Sometimes, however, chronic hyponatraemia can develop in the absence of vasopressin excess. Even in these cases, water diuresis due to **increased distal delivery of filtrate** is the main cause of rapid rise in plasma sodium.

In the absence of vasopressin, it is *generally assumed* that the total urine volume is equal to the volume of filtrate delivered to the distal nephron, which is the GFR minus the volume reabsorbed in the proximal convoluted tubule. Approximately 80% of the GFR is reabsorbed in proximal convoluted tubule under normal circumstances (and this increases even more in the presence of intravascular volume depletion). However, in real life, water excretion will be less than the volume of distal delivery of filtrate, even in the absence of vasopressin, because a significant degree of water is reabsorbed in the inner medullary collecting duct through its residual water permeability, prompted by a very high osmotic force in the interstitium (see Fig. 36.3).

Even a modest water diuresis in the elderly with reduced muscle mass is large enough to cause a rapid rise in plasma sodium. Moreover, there is a higher risk for ODS if hypokalaemia is present. In such cases, if plasma sodium rises too quickly due to anticipated water diuresis, administration of desmopressin to stop the water diuresis is beneficial. If plasma sodium rises regardless, then lowering plasma sodium to the maximum limit of correction (<8 mmol/L per day) with the administration of 5% glucose solution is the best strategy.
Reversible hyponatraemia culminating in hypernatraemia

In many patients, the cause of water retention is reversible (e.g. hypervolaemia, thiazide diuretics). On correction of the cause, vasopressin levels fall and plasma sodium rises by up to 2 mmol/L per hour as a result of excretion of dilute urine. This excessive water diuresis should be anticipated and prevented by use of desmopressin.

Patients who are chronically hyponatraemic with concomitant hypokalaemia are especially susceptible to overcorrection. Plasma sodium is a function of the ratio of exchangeable body sodium plus potassium to total body water, so potassium administration increases sodium concentration. For example, a mildly symptomatic hyponatraemic patient with a plasma sodium of <120 mmol/L and potassium of <2 mmol/L can potentially develop ODS as a result of overcorrection of hyponatraemia simply as a direct result of replacing the large potassium deficit.

Antidiuretic hormone antagonists (vasopressin antagonists)

Vasopressin V₂ receptor antagonists (see p. 180), which produce a free water diuresis, are being used in clinical trials for the treatment of hyponatraemic encephalopathy. Three oral agents, lixivaptan, tolvaptan and satavaptan, are selective for the V₄ (antidiuretic) receptor, while conivaptan blocks both V₄ and V₂ receptors.

These agents produce a selective water diuresis without affecting sodium and potassium excretion; they raise the plasma sodium concentration in patients with hyponatraemia caused by SIADH, heart failure and cirrhosis.

The efficacy of oral tolvaptan in ambulatory patients has been demonstrated in individuals with hyponatraemia (mean plasma sodium 129 mmol/L) caused by SIADH, heart failure or cirrhosis who had a sustained rise in plasma sodium to 136 mmol/L for 4 weeks. Tolvaptan is now approved for use in patients with euvoalaemic hyponatraemia and those with SIADH. In addition, intravenous conivaptan is available and is also approved for the treatment of euvoalaemic hyponatraemia (i.e. SIADH) in some countries. The approved dosing for conivaptan is a 20 mg bolus followed by continuous infusion of 20 mg over 1–4 days. The continuous infusion increases the risk of phlebitis, which requires the use of large veins and change of infusion site every 24 h.

Hyponatraemia with hypervolaemia

The common causes of hyponatraemia due to water excess are shown in Box 9.15. In all these conditions, there is usually an element of reduced GFR with avid reabsorption of sodium and chloride in the proximal tubule. This leads to reduced delivery of chloride to the ‘diluting’ ascending limb of the loop of Henle and a reduced ability to generate ‘free water’, with a consequent inability to excrete dilute urine. This is commonly compounded by the administration of diuretics that block chloride reabsorption and interfere with the dilution of filtrate either in the loop of Henle (loop diuretics) or distally (thiazides).

Hypernatraemia

This is much rarer than hyponatraemia and nearly always indicates a water deficit. Causes are listed in Box 9.16.

Hypernatraemia is always associated with increased plasma osmolality, which is a potent stimulus to thirst. None of the factors listed in Box 9.16 causes hypernatraemia unless thirst sensation is abnormal or access to water limited. For instance, a patient with diabetes insipidus will maintain a normal serum sodium concentration by maintaining a high water intake until an intercurrent illness prevents this. Thirst is frequently deficient in elderly people, making them more prone to water depletion. Hypernatraemia may occur in the presence of normal, reduced or expanded extracellular volume, and does not necessarily imply that total body sodium is increased.

Clinical features

Symptoms of hypernatraemia are non-specific. Nausea, vomiting, fever and confusion may occur. A history of longstanding polyuria, polydipsia and thirst suggests diabetes insipidus. Assessment of extracellular volume status guides resuscitation. Mental state should be assessed. Convulsions occur in severe hypernatraemia.

Investigations

Simultaneous urine and plasma osmolality and sodium should be measured. Plasma osmolality is high in hypernatraemia. Passage of urine with an osmolality lower than that of plasma in this situation is clearly abnormal and indicates diabetes insipidus. In pituitary diabetes insipidus, urine osmolality will increase after administration of desmopressin; the drug (a vasopressin analogue) has no effect in nephrogenic diabetes insipidus (see p. 643). If urine osmolality is high, this suggests either an osmotic diuresis due to an unmeasured solute (e.g. in parental feeding) or excessive extrarenal loss of water (e.g. heat stroke).

Management

Treatment is that of the underlying cause. For example:

- In ADH deficiency, replace ADH in the form of desmopressin, a stable non-pressor analogue of ADH.
- Remember to withdraw nephrotoxic drugs where possible and replace water either orally or, if necessary, intravenously.

Box 9.15 Causes of hyponatraemia with increased extracellular volume (hypervolaemia)

- Heart failure
- Liver failure
- Oliguric kidney injury
- Hypoalbuminaemia

Box 9.16 Causes of hypernatraemia

Antidiuretic hormone (ADH) deficiency

- Pituitary diabetes insipidus (see p. 641)
- Iatrogenic
  - Administration of hypertonic sodium solutions
  - Administration of drugs with a high sodium content (e.g. piperacillin)
  - Use of 8.4% sodium bicarbonate after cardiac arrest

Insensitivity to ADH (nephrogenic diabetes insipidus)

- Lithium
- Tetracyclines

- Amphotericin B
- Acute tubular necrosis
- Osmotic diuresis
- Total parenteral nutrition
- Hyperosmolar hyperglycaemic state (see p. 725)

Plus

- Deficient water intake: impaired thirst or consciousness
- Excessive water loss through skin or lungs
In severe (>170 mmol/L) hypernatraemia, 0.9% saline (150 mmol/L) should be used initially. Avoid too rapid a drop in serum sodium concentration; the aim is correction over 48 h, as over-rapid correction may lead to cerebral oedema.

In less severe (e.g., >150 mmol/L) hypernatraemia, the treatment is 5% glucose or 0.45% saline; the latter is obviously preferable in hyperosmolar diabetic coma. Very large volumes – 5 L/day or more – may need to be given in diabetes insipidus.

If there is clinical evidence of volume depletion (see p. 181), this implies that there is a sodium deficit as well as a water deficit. Treatment of this is discussed on page 185.

DISORDERS OF POTASSIUM CONCENTRATION

Regulation of serum potassium concentration
The World Health Organization (WHO) recommends a dietary intake of 90 mmol/day to reduce blood pressure; most people have a dietary intake of between 80 and 150 mmol daily, depending upon fruit and vegetable intake. Most of the body’s potassium (>3500 mmol in an adult) is intracellular. Serum potassium levels are controlled by:

- uptake of K+ into cells
- renal excretion
- extrarenal losses (e.g., gastrointestinal).

Uptake of potassium into cells is governed by the activity of the Na+/K+-ATPase in the cell membrane and by H+ concentration. Uptake is stimulated by:

- insulin
- α-adrenergic stimulation
- theophyllines.

Uptake is decreased by:

- β-adrenergic stimulation
- acidoses – K+ exchanged for H+ across cell membranes
- cell damage or cell death – resulting in massive K+ release.

The kidney plays the pivotal role in the maintenance of potassium balance by varying its secretion with changes in dietary intake. Over 90% of the filtered potassium is reabsorbed in the proximal tubule and the loop of Henle and only <10% of the filtered load is delivered to the early distal tubule. Potassium absorption in the proximal tubule is entirely passive and follows that of sodium and water, while its reabsorption in the thick ascending limb of the loop of Henle is mediated by the sodium–potassium–2–chloride co-transporter. However, potassium is secreted by the principal cells in the cortical and outer medullary collecting tubule. Secretion in these segments is very tightly regulated in health and can be varied according to individual needs; it is responsible for most of urinary potassium excretion.

Renal excretion of potassium is increased by aldosterone, which stimulates K+ and H+ secretion in exchange for Na+ in the principal cells of the collecting duct (see Fig. 9.10). Because H+ and K+ are interchangeable in the exchange mechanism, acidosis decreases and alkalosis increases the secretion of K+. Aldosterone secretion is stimulated by hyperkalaemia and increased angiotensin II levels, as well as by some drugs, and this acts to protect the body against hyperkalaemia and against extracellular volume depletion. The body adapts to dietary deficiency of potassium by reducing aldosterone secretion. However, because aldosterone is also influenced by volume status, conservation of potassium is relatively inefficient, and significant potassium depletion may therefore result from prolonged dietary deficiency.

A number of drugs affect K+ homeostasis by affecting aldosterone release (e.g., heparin, NSAIDs) or by directly affecting renal potassium handling (e.g., diuretics).

Other endogenous proteins and metabolites also affect potassium homeostasis. Klotho, an anti-ageing protein expressed in the distal tubule (and other organs), increases potassium excretion. CD63, a tetra-spanning protein, inhibits its excretion. Moreover, protein kinase A- and C-mediated phosphorylation inhibits conduction of K+ channels in the principal cells of the collecting duct but the cytochrome P450-epoxygenase-mediated metabolite of arachidonic acid (11–12-epoxyeicosatrienoic acid) activates these channels and plays a role in overall potassium homeostasis.

Normally, only about 10% of daily potassium intake is excreted in the gastrointestinal tract. Vomit contains around 5–10 mmol/L of K+, but prolonged vomiting causes hypokalaemia by inducing sodium depletion, stimulating aldosterone, which increases renal potassium excretion. Potassium is secreted by the colon, and diarrhoeal fluid contains 10–30 mmol/L of K+; severe diarrhea may rarely produce profuse diarrhoea and marked K+ loss.

Hypokalaemia

Aetiology
Common causes
The most common causes of chronic hypokalaemia are diuretic treatment (particularly thiazides) and hyperaldosteronism. In hospitalized patients acute hypokalaemia is most often caused by diuretic (thiazide or loop) use and intravenous fluids without potassium, and redistribution into cells, particularly in the case of diabetic ketoacidosis (see p. 722), where the use of fluids without potassium combined with insulin treatment can cause a rapid fall in the serum potassium. The common causes are shown in Box 9.17.

Rare causes
These rare causes are discussed in detail because they show the mechanisms of how diuretics can affect the kidney.

Bartter’s syndrome
Bartter’s syndrome (clinically similar to the effects of treatment with loop diuretics) consists of metabolic alkalosis, hypokalaemia, hypercalciuria, occasionally hypomagnesaemia (see p. 191), normal blood pressure, and an elevated plasma renin and aldosterone. The primary defect in this disorder is an impairment in sodium and chloride reabsorption in the thick ascending limb of the loop of Henle (see Fig. 9.8). Mutation in the genes encoding either the sodium–potassium–2–chloride co-transporter (NKCC2), the ATP-regulated

Renal excretion of potassium is increased by aldosterone, which stimulates K+ and H+ secretion in exchange for Na+ in the principal cells of the collecting duct (see Fig. 9.10). Because H+ and K+ are interchangeable in the exchange mechanism, acidosis decreases and alkalosis increases the secretion of K+. Aldosterone secretion is stimulated by hyperkalaemia and increased angiotensin II levels, as well as by some drugs, and this acts to protect the body against hyperkalaemia and against extracellular volume depletion. The body adapts to dietary deficiency of potassium by reducing aldosterone secretion. However, because aldosterone is also influenced by volume status, conservation of potassium is relatively inefficient, and significant potassium depletion may therefore result from prolonged dietary deficiency.

A number of drugs affect K+ homeostasis by affecting aldosterone release (e.g., heparin, NSAIDs) or by directly affecting renal potassium handling (e.g., diuretics).

Other endogenous proteins and metabolites also affect potassium homeostasis. Klotho, an anti-ageing protein expressed in the distal tubule (and other organs), increases potassium excretion. CD63, a tetra-spanning protein, inhibits its excretion. Moreover, protein kinase A- and C-mediated phosphorylation inhibits conduction of K+ channels in the principal cells of the collecting duct but the cytochrome P450-epoxygenase-mediated metabolite of arachidonic acid (11–12-epoxyeicosatrienoic acid) activates these channels and plays a role in overall potassium homeostasis.

Normally, only about 10% of daily potassium intake is excreted in the gastrointestinal tract. Vomit contains around 5–10 mmol/L of K+, but prolonged vomiting causes hypokalaemia by inducing sodium depletion, stimulating aldosterone, which increases renal potassium excretion. Potassium is secreted by the colon, and diarrhoeal fluid contains 10–30 mmol/L of K+; severe diarrhea may rarely produce profuse diarrhoea and marked K+ loss.

Hypokalaemia

Aetiology
Common causes
The most common causes of chronic hypokalaemia are diuretic treatment (particularly thiazides) and hyperaldosteronism. In hospitalized patients acute hypokalaemia is most often caused by diuretic (thiazide or loop) use and intravenous fluids without potassium, and redistribution into cells, particularly in the case of diabetic ketoacidosis (see p. 722), where the use of fluids without potassium combined with insulin treatment can cause a rapid fall in the serum potassium. The common causes are shown in Box 9.17.

Rare causes
These rare causes are discussed in detail because they show the mechanisms of how diuretics can affect the kidney.

Bartter’s syndrome
Bartter’s syndrome (clinically similar to the effects of treatment with loop diuretics) consists of metabolic alkalosis, hypokalaemia, hypercalciuria, occasionally hypomagnesaemia (see p. 191), normal blood pressure, and an elevated plasma renin and aldosterone. The primary defect in this disorder is an impairment in sodium and chloride reabsorption in the thick ascending limb of the loop of Henle (see Fig. 9.8). Mutation in the genes encoding either the sodium–potassium–2–chloride co-transporter (NKCC2), the ATP-regulated
renal outer medullary potassium channel (ROMK) or kidney-specific basolateral chloride channels (CLC-Kb) – Bartter’s syndrome types I, II and III, respectively – causes loss of function of these channels, with consequent impairment of sodium and chloride reabsorption. Loss-of-function mutations of the protein Barttin cause type IV Bartter’s syndrome, which is associated with sensorineural deafness and renal failure.

In summary, these defects in sodium chloride transport initiate the following sequence, which is almost identical to that seen with chronic ingestion of a loop diuretic: the initial salt loss leads to mild volume depletion, resulting in activation of the renin–angiotensin–aldosterone system; the combination of hyperaldosteronism and increased distal flow (owing to the reabsorptive defect) enhances potassium and hydrogen secretion at the secretory sites in the collecting tubules, leading to hypokalaemia and metabolic alkalosis.

Diagnostic pointers include high urinary potassium and chloride despite low serum values, as well as increased plasma renin. (N.B. In primary aldosteronism, renin levels are low.) Hyperplasia of the juxtaglomerular apparatus is seen on renal biopsy (exclusion of diuretic abuse is necessary). Hypercalciuria is a common feature but magnesium wasting, though rare, also occurs.

Treatment is with combinations of potassium supplements, amiloride and rarely indomethacin to block prostaglandin, which then restores vaso responsiveness to angiotensin II and potassium. 

Gitelman’s syndrome

Gitelman’s syndrome (similar to the effects of treatment with thiazide diuretics) is a phenotype variant of Bartter’s syndrome characterized by hypokalaemia, metabolic alkalosis, hypocalciuria, hypomagnesaemia, normal blood pressure, and elevated plasma renin and aldosterone. There are striking similarities between Gitelman’s syndrome and the biochemical abnormalities induced by chronic thiazide diuretic administration. Thiazides act in the distal convoluted tubule to inhibit the function of the apical sodium–chloride co-transporter (NCCT) (see Fig. 9.9). Analysis of the gene encoding the NCCT has identified loss-of-function mutations in Gitelman’s syndrome.

As in Bartter’s syndrome, defective NCCT function leads to increased solute delivery to the collecting duct, with resultant solute wasting, volume contraction and an aldosterone-mediated increase in potassium and hydrogen secretion. Impaired function of NCCT causes hypocalciuria, as does thiazide administration. Impaired sodium reabsorption across the apical membrane, coupled with continued intracellular chloride efflux across the basolateral membrane, causes the cell to become hyperpolarized. This in turn stimulates calcium reabsorption via apical, voltage-activated calcium channels. Decreased intracellular sodium also facilitates calcium efflux via the basolateral sodium–calcium exchanger. The mechanism for urinary magnesium losses is described on pages 190–192.

Treatment consists of potassium and magnesium supplementation (MgCl₂) and a potassium-sparing diuretic. Volume resuscitation is usually not necessary, because patients are not dehydrated.

Liddle’s syndrome

This is characterized by potassium wasting, hypokalaemia and alkalosis, but is associated with low renin and aldosterone production, and high blood pressure. There is a mutation in the gene encoding for the amiloride-sensitive epithelial sodium channel in the distal tubule/collecting duct. This constitutive activation of the epithelial sodium channel results in excessive sodium reabsorption with coupled potassium and hydrogen secretion. Unregulated sodium reabsorption across the collecting tubule causes volume expansion, inhibition of renin and aldosterone secretion, and development of low-renin hypertension (see Fig. 9.10).

Treatment consists of sodium restriction, along with amiloride or triamterene administration. Both are potassium-sparing diuretics that directly close the sodium channels. The mineralocorticoid antagonist spironolactone is ineffective, since the increase in sodium-channel activity is not mediated by aldosterone.

Clinical features

Hypokalaemia is usually asymptomatic but severe hypokalaemia (<2.5 mmol) causes muscle weakness. Potassium depletion may also cause symptomatic hyponatraemia (see p. 184).

Hypokalaemia is associated with an increased frequency of atrial and ventricular ectopic beats. This association may not always be causal because adrenergic activation (for instance, after myocardial infarction) results in both hypokalaemia and increased cardiac irritability. Hypokalaemia in patients without cardiac disease is unlikely to lead to serious arrhythmias.

Hypokalaemia seriously increases the risk of digoxin toxicity by increasing binding of digoxin to cardiac cells, potentiating its action and decreasing its clearance.

Chronic hypokalaemia is associated with interstitial renal disease but the pathogenesis is not completely understood.

Management

The underlying cause should be identified and treated where possible. Box 9.18 shows some examples.

Acute hypokalaemia may correct spontaneously. In most cases, withdrawal of oral diuretics or purgatives, accompanied by the oral administration of potassium supplements in the form of slow-release
potassium or effervescent potassium, is all that is required. Intravenous potassium replacement is needed only in conditions such as cardiac arrhythmias, muscle weakness or severe diabetic ketoacidosis. When intravenous therapy is used in the presence of poor renal function, replacement rates <2 mmol per hour should only be used, with hourly monitoring of serum potassium and electrocardiogram changes. Ampoules of potassium should be thoroughly mixed in 0.9% saline; do not use a glucose solution, as this would make hypokalaemia worse.

The treatment of adrenal disorders is described in Chapter 21. Failure to correct hypokalaemia may be due to concurrent hypomagnesaemia. Serum magnesium should be measured and any deficiency corrected.

## Hyperkalaemia

### Aetiology

#### Common causes

Acute self-limiting hyperkalaemia occurs normally after vigorous exercise and is of no pathological significance. Hyperkalaemia in all other situations is due either to increased release from cells or to failure of excretion (Box 9.19). The most common causes are renal impairment and drug interference with potassium excretion. The combination of angiotensin-converting enzyme (ACE) inhibitors with potassium-sparing diuretics or NSAIDs is particularly dangerous.

#### Rare causes

**Hyporeninaemic hypoaldosteronism**

This is also known as type 4 renal tubular acidosis (see p. 199). Hyperkalaemia occurs because of acidosis and hypoaldosteronism.

**Pseudohypoaldosteronism type 1 (autosomal recessive and dominant types)**

This is a disease of infancy, apparently due to resistance to the action of aldosterone. It is characterized by hyperkalaemia and evidence of sodium wasting (hyponatraemia, extracellular volume depletion). Autosomal recessive forms result from loss of function because of mutations in the gene for epithelial sodium-channel activity (the opposite to Liddle's syndrome). Pseudohypoaldosteronism type 1 involves multiple organ systems and is especially marked in the neonatal period. With aggressive salt replacement and control of hyperkalaemia, these children can survive and the disorder appears to become less severe with age. The autosomal dominant type is due to mutations affecting the mineralocorticoid receptor (see Fig. 9.10). These patients present with salt wasting and hyperkalaemia but do not have other organ-system involvement.

### Hyperkalaemic periodic paralysis

Hyperkalaemic periodic paralysis (see p. 897) is precipitated by exercise, and is caused by an autosomal dominant mutation of the skeletal muscle sodium-channel gene.

**Gordon's syndrome (familial hyperkalaemic hypertension, pseudohypoaldosteronism type 2)**

This appears to be a mirror image of Gitelman's syndrome (see p. 188), in which primary renal retention of sodium causes hypertension, volume expansion, low renin/aldosterone, hyperkalaemia and metabolic acidosis. There is also an increased sensitivity of sodium reabsorption to thiazide diuretics, suggesting that the thiazide-sensitive sodium–chloride co-transporter (NCCT) is involved (see Fig. 9.9). Genetic analyses, however, have excluded abnormalities in NCCT. The involvement of two loci on chromosomes 1 and 12 and further genetic heterogeneity have also been found. These genes do not correspond to ionic transporters but to unexpected proteins, WNK (with no lysine kinase) 1 and WNK 4, which are two closely related members of a novel serine–threonine kinase family. WNK 4 normally inhibits NCCT by preventing its membrane translocation from the cytoplasm. Loss-of-function mutation in WNK 4 results in escape of NCCT from normal inhibition and its overactivity, as seen from the patient's phenotype. WNK 1 is an inhibitor of WNK 4 and, in some patients with Gordon's syndrome, gain-of-function mutation in WNK 7 results in functional deficiency of WNK 4 and overactivity of NCCT. Use of calcineurin inhibitors can cause hypertension due to an acquired Gordon's syndrome-type phenotype, and may respond to thiazide diuretics.

### Increased release from cells

(Due to Na⁺/K⁺-ATPase activity)

- Acidosis
- Diabetic ketoacidosis
- Rhabdomyolysis/tissue damage

ACE, angiotensin-converting enzyme; NSAIDs, non-steroidal anti-inflammatory drugs; RTA, renal tubular acidosis. ²Common causes.

#### Spurious

- Increased in vitro release from abnormal cells
- Leukaemia
- Infectious mononucleosis
- Thrombocytosis
- Familial pseudohyperkalaemia, e.g. haemolytic crisis in pregnancy
- Increased release from muscles
- Vigorous fist clenching during phlebotomy

ACE, angiotensin-converting enzyme; NSAIDs, non-steroidal anti-inflammatory drugs; RTA, renal tubular acidosis.

¹Common causes.

**Box 9.19 Causes of hyperkalaemia**
Suxamethonium and other depolarizing muscle relaxants

These cause release of potassium from cells. Induction of muscle paralysis during general anaesthesia may result in a rise of plasma potassium of up to 1 mmol/L. This is not usually a problem unless there is pre-existing hyperkalaemia.

Clinical features

Serum potassium of >7.0 mmol/L is a medical emergency and is associated with ECG changes (Fig. 9.12). Severe hyperkalaemia may be asymptomatic and may predisperse to sudden death from asystolic cardiac arrest. Muscle weakness is often the only symptom, unless (as is commonly the case) the hyperkalaemia is associated with metabolic acidosis, causing Kussmaul respiration. Hyperkalaemia causes depolarization of cell membranes, leading to decreased cardiac excitability, hypotension, bradycardia and eventual asystole.

Management

Hyperkalaemia is a potentially life-threatening emergency all too commonly encountered in routine hospital practice.

Treatment for severe hyperkalaemia requires emergency, acute and subacute measures to prevent cardiac arrest and to keep potassium down, as summarized in Box 9.20. The cause of the hyperkalaemia should be found and treated.

High potassium levels are cardiotoxic, as they inactivate sodium channels. Divalent cations, e.g. calcium, restore the voltage dependability of the channels. Calcium ions protect the cell membranes from the effects of hyperkalaemia but do not alter the potassium concentration.

Supraphysiological intravenous insulin (10–20 units) drives potassium into the cell and lowers plasma potassium by 1 mmol in 60 min, but must be accompanied by intravenous glucose to avoid hypoglycaemia. Regular measurements of blood glucose for at least 6 h after use of insulin should be performed and extra glucose must be available for immediate use. The use of glucose alone in non-diabetic patients, to stimulate endogenous insulin release, does not produce the high levels of insulin required and therefore is not recommended.

Intravenous or nebulized salbutamol (10–20 mg) has not yet found widespread acceptance and may cause disturbing muscle tremors at the doses required.

Correction of acidosis with hypertonic (8.4%) sodium bicarbonate causes volume expansion due to the high sodium concentration, and should only be used in emergency situations; 1.26% is used with severe acidosis (pH <6.9). Gastric aspiration will remove potassium and leads to alkalosis.

Patiromer and sodium zirconium cyclosilicate (ZS9) are new non-absorbed agents that bind potassium in the gastrointestinal (GI) tract to facilitate faecal excretion. Clinical trials of patiromer and ZS9 have demonstrated clear evidence of a dose-dependent potassium-lowering effect. Patiromer and ZS9 have improved upon the age-old standard ion-exchange resins for the treatment of hyperkalaemia, and are now used particularly in patients with heart failure and CKD to attenuate ACE inhibitor/ARB-induced hyperkalaemia.

Ion-exchange resins (polystyrene sulphonate resins, SPS, such as calcium resonium) are an older form of gut-acting maintenance therapy to keep potassium down after emergency treatment. They make use of the ion fluxes that occur in the gut to remove potassium. They may cause fluid overload (resonium contains Na+) or hypercalcaemia (calcium resonium). Resins do not appear to enhance the excretion of potassium significantly, beyond the effect of diarrhoea induced by osmotic or secretory cathartics, and their use has now been superseded by the newer gut-acting potassium binders described above.

In general, all of these measures are simply ways of buying time either to correct the underlying disorder or to arrange removal of potassium by dialysis, which is the definitive treatment for hyperkalaemia in severe acute or chronic renal failure.

Further reading

Magnesium ($\text{Mg}^{2+}$) plays a pivotal role in many biological processes such as enzymatic reactions, gene transcription, bone remodelling and neuromuscular stability. Approximately 99% of the $\text{Mg}^{2+}$ in the body is in the intracellular compartment, mainly in bone (approximately 85%) and in muscle and soft tissues (approximately 14%). The other 1% is in the extracellular fluid.

Plasma magnesium levels are normally maintained within the range 0.7–1.1 mmol/L (1.4–2.2 mEq/L). The average daily magnesium intake is 15 mmol, which is absorbed mainly in the small intestine and, to a lesser extent, in the colon. In the healthy adult, there is no net gain or loss of magnesium from bone, so that balance is achieved by the urinary excretion of the net magnesium absorbed. The kidney reabsorbs between approximately 95% and 98% of the filtered $\text{Mg}^{2+}$ and plays a major role in maintaining plasma $\text{Mg}^{2+}$ concentrations within the normal range.

### Control and renal handling of magnesium

#### Cortical thick ascending limb of Henle

Approximately 30% of $\text{Mg}^{2+}$ is bound to plasma proteins but the remaining fraction is freely filterable. The major site of magnesium transport is the cortical thick ascending limb of the loop of Henle, where 65–70% of the filtered load is reabsorbed, with only 10–20% being reabsorbed in the proximal tubule (see Fig. 9.8). This transport is passive, paracellular and carried out by tight junction proteins (paracellin-1 and claudins). This process is driven by the lumen-positive electrochemical gradient, characteristic of this segment. This voltage gradient is created by the apical disproportionate net transport of two Cl$^-$ to one Na$^+$ (by the bumetanide-sensitive sodium–potassium–2–chloride transporter) and the secretion of K$^+$ (via the ROMK) (see Fig. 9.8). Loss-of-function mutations in these key reabsorptive processes lead to hypomagnesaemia as part of the distinctive clinical syndromes described later.

#### Bartter’s syndrome

Hypomagnesaemia is rare in Bartter’s syndrome (see p. 187). This is because the transepithelial voltage, which is responsible for magnesium reabsorption, is preserved and any additional filtered magnesium will be offset by a compensatory increase in absorption in the distal convoluted tubule.

#### Familial hypomagnesaemia, hypercalciuria and nephrocalcinosis

Familial hypomagnesaemia, hypercalciuria and nephrocalcinosis (FHHNC) is characterized by excessive renal magnesium and calcium wasting; the main defect lies in cTAL. Ten different mutations have been identified in a novel gene that encodes for paracellin-1 and claudins 16/19 complex, in the tight junction proteins.

Individuals develop bilateral nephrocalcinosis and progressive CKD. Patients also have elevated parathyroid hormone levels, which precedes any reduction in GFR. A substantial proportion of patients show incomplete distal renal tubular acidosis, hypocitraturia and hyperuricaemia. Extrarenal involvement, such as myopia, nystagmus and chorioretinitis, has been reported.

### Distal convoluted tubule

The reabsorption rate in the distal convoluted tubule (DCT) – 10% – is much lower than in the cTAL, but it defines the final urinary excretion, as there is no significant reabsorption in the collecting duct; 3–5% of filtered magnesium is finally excreted in the urine. Magnesium reabsorption in the DCT is transcellular and active (see Fig. 9.9). The DCT has a slight lumen-negative voltage of approximately −5 mV. The luminal $\text{Mg}^{2+}$ concentration in the DCT ranges between 0.2 and 0.7 mmol/L, whereas the intracellular concentration of $\text{Mg}^{2+}$ is estimated to be maintained at around 0.2–1.0 mmol/L. Therefore, the voltage difference across the apical membrane plays a key role in $\text{Mg}^{2+}$ transport within the DCT.

### Magnesiotropic proteins

These include the following:

- **TRPM6**, the transient receptor potential channel melastatin member 6, is an $\text{Mg}^{2+}$-permeable channel that is also expressed in the luminal membrane of the intestinal epithelium.
- **The pro-epidermal growth factor (EGF)** resides on the basolateral surface of the DCT cells. It markedly stimulates the activity of TRPM6. Cancer therapies that inhibit EGF also cause hypomagnesaemia by the above mechanism.
- **Thiazide-sensitive Na$^+$/Cl$^-$ co-transporter in the DCT** plays a role in sodium and chloride absorption and maintenance of lumen-negative voltage. Loss-of-function mutation in this co-transporter results in *Gitelman’s syndrome* (see p. 188 and Fig. 9.9). Hypomagnesaemia is likely to be due to a reduced abundance of TRPM6. The observed hypocalciuria is caused by an increased proximal tubular reabsorption, a process that occurs in response to the mild volume depletion.
- **The γ-subunit of the Na$^+$/K$^+$/ATPase** on the basolateral aspect of the DCT plays a pivotal role in the sodium and chloride absorption and maintenance of lumen-negative voltage (a key requirement for magnesium absorption) in this segment of the nephron.
- **ATP-sensitive inward rectifier potassium channel 10 (Kir4.1)** is present on the basolateral surface of the DCT. It allows K$^+$ ions to recycle across the basolateral membrane, thereby maintaining an adequate supply of K$^+$ to sustain the high Na$^+$/K$^+$-ATPase activity observed in this segment.

### Hypomagnesaemia

In addition to the familial causes described earlier, hypomagnesaemia most often develops as a result of deficient intake, defective gut absorption (associated with the use of proton pump inhibitors), or excessive gut or urinary loss (Box 9.21). It can also occur with acute pancreatitis, possibly owing to the formation of magnesium soaps in the areas of fat necrosis and drug treatment with aminoglycosides and cisplatinum compounds. Due to the severe effects of hypomagnesaemia, routine measurements of serum $\text{Mg}^{2+}$ should be conducted in the critically ill, as well as in patients who are exposed to drugs and other conditions associated with $\text{Mg}^{2+}$ deficiency.

#### Clinical features

Symptoms and signs (indicating a deficit of 0.5–1 mmol/kg) include irritability, tremor, ataxia, carpopedal spasm, hyper-reflexia, confusional and hallucinatory states, and epileptiform convulsions. An ECG may show a prolonged QT interval, broad flattened T waves and occasional shortening of the ST segment.

#### Management

This involves the withdrawal of precipitating agents such as diuretics or purgatives. If symptomatic (or with hypocalcaemia), give a parenteral infusion of 50 mmol of magnesium chloride in 1 L of 5% glucose or other isotonic fluid over 12–24 h. This should be...
repeated daily and continued for 2 days after normal plasma levels have been achieved.

Relationship between hypomagnesaemia and plasma calcium
Calcium deficiency usually, but not always, develops with hypomagnesaemia. Hypomagnesaemia can be further subdivided into three main groups:
- **Hypercalciuria with hypomagnesaemia.** This occurs from defects in Mg$^{2+}$ absorption in cTAL, such as in several forms of Bartter’s syndrome, loop diuretics, and FHHNC.
- **Normocalciuria.** This includes autosomal dominant hypomagnesaemia due to mutations in the EGF gene.
- **Hypocalciuria with hypomagnesaemia.** This is a hallmark feature of thiazide diuretic use and Gitelman’s syndrome, and has also been reported in EAST syndrome, due to mutations in NCC and Kir$\text{d}_4.1$, respectively. Genetic defects of β-cell function and isolated dominant hypomagnesaemia (IDH) also lead to hypomagnesaemia with accompanying hypocalciuria.

Relationship between hypomagnesaemia and plasma potassium
Magnesium depletion can lead to refractory hypokalaemia. The normal concentration of intracellular magnesium usually blocks secretory K$^+$ currents through ROMK channels. Magnesium depletion promotes K$^+$ loss by releasing ROMK from magnesium-mediated inhibition. Close monitoring, with potassium supplements if necessary, is required in patients presenting with primary symptomatic low plasma magnesium levels.

**Hypermagnesaemia**

This primarily occurs in patients with acute or CKD given magnesium-containing laxatives or antacids. It can also be induced by magnesium-containing enemas. Mild hypermagnesaemia may occur in patients with adrenal insufficiency. Causes are given in Box 9.22.

### Box 9.21 Causes of hypomagnesaemia

- Decreased magnesium absorption
  - Malabsorption (severe)
  - Malnutrition
  - Alcohol excess
  - Proton pump inhibitors
- Increased renal excretion
  - Drugs:
    - Loop diuretics
    - Thiazide diuretics
    - Digoxin
    - Diabetic ketoacidosis
    - Hyperaldosteronism
    - SIADH
    - Alcohol excess
- Hypercalciuria
  - 1,25-(OH)$_2$-vitamin D$_3$ deficiency
- Drug toxicity:
  - Amphotericin
  - Aminoglycosides
  - Cisplatin
  - Ciclosporin
- Gut losses
  - Prolonged nasogastric suction
  - Excessive purgation
  - Gastrointestinal/biliary fistulae
  - Severe diarrhoea
- Inherited tubular wasting
  - Bartter’s syndrome
  - Familial hypomagnesaemia, hypercalciumia and nephrocalcinosis
  - Isolated dominant hypomagnesaemia
  - Gitelman’s syndrome (see p. 188)
  - Isolated recessive hypomagnesaemia
  - Hypomagnesaemia with secondary hypocalcaemia
- Miscellaneous
  - Acute pancreatitis.

### Box 9.22 Causes of hypermagnesaemia

- Impaired renal excretion:
  - Chronic kidney disease
  - Acute kidney injury
- Increased magnesium intake:
  - Purgatives, e.g. magnesium sulphate
  - Antacids, e.g. magnesium trisilicate
- Hydration with high [Mg$^{2+}$] dialysate

**Clinical features**
Symptoms and signs relate to neurological and cardiovascular depression, and include weakness with hyporeflexia proceeding to narcosis, respiratory paralysis and cardiac conduction defects. Symptoms usually develop when the plasma magnesium level exceeds 2 mmol/L (4 mEq/L).

**Management**
Treatment requires withdrawal of any magnesium therapy. An intravenous injection of 10 mL of calcium gluconate 10% (2.25 mmol calcium) is given to antagonize the effects of hypermagnesaemia, along with glucose and insulin (as for hyperkalaemia; see p. 189) to lower the plasma magnesium level. Dialysis may be required in patients with severe kidney disease.

**Further reading**

### Disorders of phosphate concentration
Phosphate forms an essential part of most biochemical systems. The regulation of plasma phosphate level is both directly and closely linked to that of calcium.

About 85% of all body phosphorus is within bone, plasma phosphate normally ranging from 0.80 to 1.15 mmol/L (2.5–3.6 mg/dL) and accounting for only 1% of the total body phosphate. However, plasma phosphate levels correlate in most circumstances with total body sodium. Phosphate reabsorption from the glomerular filtrate occurs entirely and actively in the renal proximal tubule and is hormonally regulated. It is decreased by parathyroid hormone (PTH), mediated by a cAMP-dependent mechanism; thus, primary hyperparathyroidism is associated with low plasma levels of serum phosphate. Other factors that are known to control phosphate reabsorption in the proximal tubule are 1,25-dihydroxyvitamin D$_3$, sodium delivery to the proximal tubule, serum concentrations of calcium, bicarbonate, and the percentage of dietary phosphorus absorbed.

Osteoblast-secreted phosphaturic factors (phosphatonin), such as fibroblast growth factor 23 (FGF23), matrix extracellular phosphoglycoprotein (MEPG) and frizzled-related protein 4 (FRP-4), play a role in phosphate homeostasis. FGF23 is the most extensively investigated phosphatonin. It binds to its receptor, FGFR1, in the kidney and causes phosphaturia; it also regulates vitamin D by inactivation of 1α-hydroxylase (CYP27B1) and upregulation of 24 hydroxylase (CYP24A1) enzymes, with the net result of low 1,25-vitamin D synthesis. Serum FGF23 is also the earliest marker of abnormal phosphate handling in CKD patients, occurring before changes in serum phosphate, calcium or PTH (Fig. 9.13). Moreover,
FGF23 requires Klotho (see p. 187) to act as a co-receptor with FGFR1 for its activity. Loss-of-function mutation in either FGF23 or Klotho results in a similar phenotype of shortened lifespan, premature ageing and hyperphosphataemia, and, as expected from the mode of action, increases 1,25 vitamin D levels. Klotho can also inhibit phosphate absorption directly in the absence of FGF23 or PTH.

Phosphate absorption is an active process carried out by a family of sodium–phosphate co-transporters (NPT) in the gut and kidneys. NPT2a and NPT2c are expressed in the brush border of the renal proximal tubule while NPT2b is expressed in lungs and intestine. NPT2a plays a central role in the renal reabsorption of phosphate but requires a companion protein called sodium hydrogen exchanger regulatory factor 1 (NHERF1) for membrane sorting. Intestinal absorption is carried out by NPT2b but its mutation does not cause any alteration in serum phosphate due to compensation by the renal expression of NPT2a and possibly NPT2c. Under normal circumstances, plasma phosphate levels are kept constant; for example, after a phosphate-rich meal, the bone releases FGF23, which inhibits NPT2a and causes phosphate excretion. Moreover, phosphate in the plasma causes the release of PTH, either directly or indirectly by lowering ionized calcium. PTH also inhibits NPT2a, NPT2c and NHERF1, resulting in phosphaturia (see Fig. 9.13). These two principal mechanisms keep plasma phosphate levels within normal limits on a daily basis.

### Hypophosphataemia

Significant hypophosphataemia (<0.4 mmol/L or <1.25 mg/dL) occurs in a number of clinical situations, owing to redistribution into cells, renal losses or decreased intake (Box 9.23).

Clinical features include:
- muscle weakness, e.g. diaphragmatic weakness, decreased cardiac contractility, skeletal muscle rhabdomyolysis
- a left shift in the oxyhaemoglobin dissociation curve (reduced 2,3-bisphosphoglycerate, 2,3-BPG) and rarely haemolysis
- confusion, hallucinations and convulsions.

---

**Fig. 9.13** PHEX and PTH regulation of phosphate transport and vitamin D metabolism in the proximal tubule.

1. **Fibroblast growth factor 23 (FGF23)** inhibits the sodium–phosphate co-transporter (NPT2a, c), causing phosphaturia.
2. **Binding of FGF23 to the FGFR1–Klotho complex** leads to lower levels of the active form of vitamin D (1,25-vitamin D) by inhibiting 1α-hydroxylase.
3. It also increases levels of **inactive vitamin D** (24,25-vitamin D) by stimulating 24α-hydroxylase.
4. **PHEX** (phosphate-regulating gene with homologies to endopeptidase on the X chromosome) acts as a competitive inhibitor, binding FGF23 and blocking its action.
5. **Parathyroid hormone (PTH)** also inhibits NPT2a, which leads to phosphaturia.
6. **PTH** has opposite effects on vitamin D metabolism compared with FGF23 by stimulating 1α-hydroxylase and inhibiting 24α-hydroxylase.
Mild hypophosphataemia often resolves without specific treatment. However, diaphragmatic weakness may be severe in acute hypophosphataemia, and may impede the weaning of a patient from a ventilator. Interestingly, chronic hypophosphataemia (in X-linked hypophosphataemia) is associated with normal muscle power.

**Aetiology**

Primary hyperparathyroidism is a common cause of hypophosphataemia. Very rarely, gain-of-function mutations of the PTH1 receptor cause hypophosphataemia and Jansen’s metaphyseal chondrodysplasia due to constitutive activation of PTH signalling, even in the presence of low or absent circulating PTH levels.

Hypophosphataemia can be part of osteomalacia and rickets due to vitamin D deficiency, either dietary (globally, the most common cause) or genetic, and is usually accompanied by hypocalcaemia (calcipenic) and secondary hyperparathyroidism.

**Vitamin D-dependent rickets type I**

Also known as pseudo-vitamin D-deficient rickets, this is caused by 1α-hydroxylase deficiency due to inactivating mutations in its gene. This condition manifests clinically in the first year of life with severe hypocalcaemia, often complicated by tetany, moderate hypophosphataemia and enamel hypoplasia. The characteristic biochemical findings are normal serum levels of 25-hydroxyvitamin D, low values of 1,25-dihydroxyvitamin D and, usually, relatively high PTH levels. The treatment of choice is replacement therapy with calcitriol.

**Vitamin D-dependent rickets type II**

This is a form of vitamin D resistance and is known as hereditary vitamin D-resistant rickets. It is an autosomal recessive disorder and is usually caused by loss-of-function mutations in the gene encoding the vitamin D receptor. The clinical manifestations vary widely, depending upon the type of mutation within the vitamin D receptor and the amount of residual vitamin D receptor activity. Affected children usually develop rickets within the first 2 years of life, with alopecia in two-thirds of cases, which is due to lack of vitamin D receptor action within keratinocytes. The treatment involves a therapeutic trial of calcitriol and calcium supplementation. Long-term infusion of calcium into a central vein is a possible alternative for severely resistant patients. Oral calcium therapy may be sufficient once radiographic healing has been observed.
Moreover, the receptors for reabsorption of low-molecular-weight proteins and albumin in the proximal tubules (megalin and cubilin) are decreased in Dent’s disease. This explains the low-molecular-weight proteinuria and excessive urinary leaks of cytokines, hormones and chemokines. This urinary profile is associated with progressive renal fibrosis and more rapid decline in renal function.

Re-feeding syndrome

Hypophosphataemia may also occur as part of the ‘re-feeding syndrome’ (see p. 1253), which occurs in significantly malnourished patients (e.g. in people with anorexia nervosa) who rapidly recommence feeding via oral, enteral or parenteral routes.

Following starvation, the body’s stores of phosphate are low due to reduced intake. After a carbohydrate load, insulin is released, which causes rapid cellular uptake of phosphate, along with potassium and magnesium, leading to a fall in the serum concentrations of these electrolytes.

Furthermore, insulin stimulates production of adenosine triphosphate (ATP) thus increasing the cellular requirement for phosphate. The inability to phosphorylate ADP to ATP due to inadequate phosphate concentrations leads to cardiac dysfunction and arrhythmias, respiratory failure due to weakness of the diaphragm, rhabdomyolysis and seizures.

Re-feeding syndrome can be prevented by correcting electrolyte disturbances before re-feeding and avoiding rapid increases of caloric intake above the resting energy requirements.

Management is essentially supportive; patients may require hospitalization for electrolyte replacement and monitoring.

Diagnosis

Patients with hypophosphataemia should have their urinary fractional excretion of phosphate measured. A value of <0.7 mmol/L indicates renal phosphate wasting. If PTH levels are high, then the patient is very likely to have hyperparathyroidism, either primary or secondary to vitamin D deficiency (acquired or genetic) or Dent’s disease. If PTH levels are low, then the only possibility is gain-of-function mutation in PTH1R. If PTH levels are normal, then assess FGF23 levels. High FGF23 serum levels will indicate possible mutated genes in FGF23/Klotho, PHEX and DMP1. Normal FGF23 and PTH levels point to mutations in NPT2a, NPT2c and NHERF1.

Management

Oral phosphate supplementation and calcitriol (1,25-dihydroxy vitamin D) administration is required if there is vitamin D deficiency.

Treatment of acute hypophosphataemia is with intravenous phosphate at a maximum rate of 9 mmol every 12 h. Repeated measurements of calcium and phosphate are required, as over-rapid administration of phosphate may lead to severe hypocalcaemia, particularly in the presence of alkalosis. Chronic hypophosphataemia can be corrected with oral effervescent sodium phosphate. The anti-FGF23 neutralizing antibody (burosumab) is a novel therapeutic agent that has successfully reversed biochemical and clinical phenotypic manifestations in patients with genetically elevated FGF23, and may become standard care for such patients.

Hyperphosphataemia

Hyperphosphataemia is common in patients with CKD (see p. 1394; Box 9.24). Hyperphosphataemia is usually asymptomatic but may result in precipitation of calcium phosphate, particularly in the presence of a normal or raised calcium level or of alkalosis. Uraemic itching may be caused by a raised calcium phosphate product. Prolonged hyperphosphataemia causes hyperparathyroidism and periarticular and vascular calcification.

Familial tumoural calcinosis is characterized by calcifications of muscles, skin, eyelids and vessels, as well as hyperostosis. In this condition, absence of glycosylation of FGF23 makes it unstable and more sensitive to proteolysis. This results in its deficiency and hyperphosphataemia due to increased renal phosphate reabsorption through increased NPT2a activity.

Usually, no treatment is required for acute hyperphosphataemia, as the causes are self-limiting. Treatment of chronic hyperphosphataemia is with gut phosphate binders and dialysis (see p. 1395).

ACID–BASE DISORDERS

The concentration of hydrogen ions in both extracellular and intracellular compartments is extremely tightly controlled, and very small changes lead to major cell dysfunction. The blood pH is tightly regulated and is normally maintained between 7.38 and 7.42. Any deviation from this range indicates a substantial change in the hydrogen ion concentration [H+] because blood pH is the negative logarithm of [H+]. Box 9.25. The [H+] at a physiological blood pH of 7.40 is 40 nmol/L. An increase in the [H+] (a fall in pH) is termed acidemia. A decrease in [H+] (a rise in the blood pH) is termed alkalaemia. The disorders that cause these changes in the blood pH are acidosis and alkalosis, respectively.

Normal acid–base physiology

The normal adult diet contains 70–100 mmol of acid (H⁺). Throughout the body there are buffers that minimize any changes in blood pH that these ingested hydrogen ions might cause. Such buffers include intracellular proteins (e.g. haemoglobin) and tissue components (e.g. the calcium carbonate and calcium phosphate in bone), as well as the bicarbonate–carbonic acid buffer pair generated by the hydration of carbon dioxide. This buffer pair is clinically most relevant, in part because its contribution can be measured and because alterations in this buffer pair reveal changes in all other buffer systems. Bicarbonate ions [HCO₃⁻] and carbonic acid (H₂CO₃) exist in equilibrium; and in the presence of carbonic anhydrase, carbonic acid dissociates to carbon dioxide and water, as expressed in the following Henderson–Hasselbalch equation, a fall in the plasma [HCO₃⁻] increases [H⁺] and thus lowers blood pH:

\[
[H^+]] = 181 \times P_aCO_2[HCO_3^-] \]

where [H⁺] is expressed in mmol/L, PₐCO₂ in kilopascals, [HCO₃⁻] in mmol/L and 181 is the dissociation coefficient of carbonic acid. Alternatively, the equation can be expressed as:

\[
\text{pH} = pK + \log\left(\frac{[HCO_3^-]}{[H_2CO_3]}\right) \]

where pK = 6.1. Thus, the bicarbonate used in the buffering process must be regenerated to maintain normal acid–base balance.

Although the acidemia stimulates an increase in ventilation, which blunts this change in pH, increased ventilation does not regenerate the bicarbonate used in the buffering process. Consequently, the kidney must excrete hydrogen ions to return the plasma [HCO₃⁻] to normal. Maintenance of a normal plasma [HCO₃⁻] under physiological conditions depends not only on daily regeneration of bicarbonate but also on reabsorption of all bicarbonate filtered across the glomerular capillaries.

Renal reabsorption of bicarbonate

The plasma [HCO₃⁻] is normally maintained at approximately 25 mmol/L. In individuals with a normal GFR (120 mL/min), about 4500 mmol of bicarbonate is filtered each day. If this filtered bicarbonate were not reabsorbed, the plasma [HCO₃⁻] would fall, along with blood pH. Thus, maintenance of normal plasma [HCO₃⁻] requires that essentially all of the bicarbonate in the glomerular filtrate be reabsorbed (Fig. 9.14).

The proximal convoluted tubule reclaims 85–90% of filtered bicarbonate; by contrast, the distal nephron reclaims very little. This difference is caused by the greater quantity of luminal (brush border) carbonic anhydrase in the proximal tubule than in the distal nephron. As a result of these quantitative differences, bicarbonate that escapes reabsorption in the proximal tubule is excreted in the urine.

Proximal tubular bicarbonate reabsorption is catalyzed by the Na⁺/K⁺-ATPase pump located in the basolateral cell membrane. By exchanging peritubular potassium ions for intracellular sodium ions, the pump keeps the intracellular sodium concentration low, allowing sodium ions to enter the cell by moving down the sodium concentration gradient from the tubule lumen to the cell interior. Hydrogen ions are transported in the opposite direction (at the Na⁺–H⁺ antiporter), thereby maintaining electroneutrality. Before bicarbonate enters the proximal tubule, it combines with secreted hydrogen ions, forming carbonic acid. In the presence of luminal carbonic anhydrase (CA-IV), carbonic acid rapidly dissociates into carbon dioxide and water, which can then rapidly enter the proximal tubular cell. In the cell, carbon dioxide is hydrated by cytosolic carbonic anhydrase (CA-II), ultimately forming bicarbonate, which is then transported down an electrical gradient from the cell interior, across the membrane into the peritubular fluid, and into the blood. In this process, each hydrogen ion secreted into the proximal tubule lumen is reabsorbed and can be resecreted; there is no net loss of hydrogen ions or net gain of bicarbonate ions.

Renal excretion of [H⁺]

More acid is secreted into the proximal tubule (up to 4500 mmol of hydrogen ions each day) than in any other nephron segment (Fig. 9.15). However, the hydrogen ions secreted into the proximal tubule are almost completely reabsorbed with bicarbonate; consequently, proximal tubular hydrogen ion secretion does not contribute significantly to hydrogen ion elimination from the body. The excretion of the daily acid load requires hydrogen ion secretion in more distal nephron segments.

Most dietary hydrogen ions come from sulphur-containing amino acids that are metabolized to sulphuric acid (H₂SO₄), which then reacts with sodium bicarbonate as follows:

\[
H_2SO_4 + 2NaHCO_3 \rightarrow Na_2SO_4 + 2CO_2 + 2H_2O. \]

Excess sulphate is excreted in the urine, whereas excess hydrogen ions are buffered by bicarbonate and lower the plasma [HCO₃⁻].
Aldosterone also stimulates directly the H⁺-ATPase in the α-intercalated cell, further enhancing hydrogen ion secretion. The H⁺ to be secreted arises from the reassociation of H₂O and CO₂ in the presence of carbonic anhydrase; thus, a bicarbonate molecule is regenerated each time an H⁺ is eliminated in the urine.

When hydrogen ions are secreted into the lumen of the collecting tubule, a tiny, but physiologically critical, fraction of these excess hydrogen ions remains in solution. Here, they increase the urinary [H⁺] and lower urinary pH below 4.0. Nevertheless, below this urine pH, inhibition of proton-secreting pumps, such as H⁺-ATPase, severely restricts kidney secretion of more hydrogen ions. Consequently, secretion of hydrogen ions depends on the presence of buffers in the urine that maintain the urine pH at a level higher than 4.0.

In the presence of alkali excess, the homeostatic needs are reversed. Although the kidney can excrete excess alkaline load by reducing reabsorption of filtered bicarbonate in the proximal and distal tubule, the collecting ducts also contribute by secreting bicarbonate brought about by switching to β-intercalated cells. This switch enables kidneys to secrete bicarbonate and conserve H⁺ ions.

**Buffer systems in acid excretion**

Two buffer systems are involved in acid excretion: the titratable acids, such as phosphate, and the ammonia system. Each system is responsible for excreting about half of the daily acid load of 50–100 mmol under physiological conditions (see Fig. 9.15).

**Titratable acid**

A titratable acid is a filtered buffer substance having a conjugate anion that can be titrated within the pH range occurring physiologically in the urine. Phosphoric acid (pKₐ 6.8) is the usual titratable urinary buffer. Hydrogen ions bind to the conjugate anions of the titratable acids and are excreted in the urine. For each hydrogen ion excreted in this form, a bicarbonate ion is regenerated within the cell and returned to the blood (see Fig. 9.15).

**Ammonium (NH₄⁺)**

In the setting of metabolic acidosis, titratable acids cannot increase significantly because the availability of titratable acid is fixed by the plasma concentration of the buffer and by the GFR. The ammonia buffer system, by contrast, can increase several hundred-fold when necessary. Consequently, impaired renal excretion of hydrogen ions is always associated with a defect in ammonium excretion (Fig. 9.16).

All ammonia used to buffer urinary hydrogen ions in the collecting tubule is synthesized in the proximal convoluted tubule. Glutamine is the primary source of ammonia. It undergoes deamination catalyzed by glutaminase, resulting in α-ketoglutaric acid (see Fig. 9.16) and ammonia. Once formed, ammonia can diffuse into the proximal tubule lumen and become acidified, forming ammonium. Once in the proximal tubule lumen, ammonium flows along the tubule to the thick ascending limb of the loop of Henle. Here, it is transported out of the tubule into the medullary interstitium. Ammonium then dissociates to ammonia, leading to a high interstitial ammonia concentration. The notion that ammonia diffuses down its concentration gradient into the lumen of the collecting tubule has been challenged by the discovery of rhesus (Rh)-associated glycoproteins acting as ammonia transport proteins, also called RhCG/Rhcg, which are expressed in the basolateral and apical surfaces of the DCT, inner medullary collecting duct and type α-intercalated cells. These proteins play a fundamental role in renal ammonia excretion under both basal and acidic states. Once secreted, NH₃ reacts with the hydrogen ions secreted by the collecting tubular cells to form ammonium. Because ammonium (NH₄⁺) is not lipid-soluble, it is trapped in the lumen and excreted in the urine as ammonium.
chloride. Two conditions predominantly promote ammonia synthesis by the proximal tubular cell: systemic acidosis and hypokalaemia.

Aetiology of acid–base disturbance

Acid–base disturbance may be caused by:

- abnormal CO₂ removal in the lungs (‘respiratory’ acidosis and alkalosis)
- abnormalities in the regulation of bicarbonate and other buffers in the blood (‘metabolic’ acidosis and alkalosis).

Both may, and usually do, coexist. For instance, metabolic acidosis causes hyperventilation (via medullary chemoreceptors, see Fig. 28.5), leading to increased removal of CO₂ in the lungs and partial compensation for the acidosis. Conversely, respiratory acidosis is accompanied by renal bicarbonate retention, which could be mistaken for primary metabolic alkalosis. The situation is even more complex if a patient has both respiratory disease and a primary metabolic disturbance.

Diagnosis

Clinical history and examination usually point to the correct diagnosis. Box 9.26 shows the typical blood changes, but in complicated patients the acid–base nomogram (Fig. 9.17) is invaluable. The [H⁺] and \( P_a \)CO₂ are measured in arterial blood (for precautions), as well as the bicarbonate. If the values from a patient lie in one of the bands in the diagram, it is likely that only one abnormality is present. If the [H⁺] is high (pH low) but the \( P_a \)CO₂ is normal, the intercept lies between two bands: the patient has respiratory dysfunction, leading to failure of CO₂ elimination, but this is partly compensated for by metabolic acidosis, stimulating respiration and CO₂ removal (this is the most common ‘combined’ abnormality in practice).

Fig. 9.16 The ammonia buffering system in the kidney. All ammonia used to buffer H⁺ in the collecting duct is synthesized in the proximal convoluted tubule, and glutamine is the main source of this ammonia. As glutamine is metabolized, \( \alpha \)-ketoglutarate (\( \alpha \)-KG) is formed, which ultimately breaks down to bicarbonate that is then secreted into the peritubular fluid at an Na⁺-HCO₃⁻ co-transporter.

Fig. 9.17 The Flenley acid–base nomogram. This was derived from a large number of observations in patients with ‘pure’ respiratory or metabolic disturbances. The bands show the 95% confidence limits representing the individual varieties of acid–base disturbance. The central white box shows the approximate limits of arterial pH and \( P_a \)CO₂ in normal individuals.

Respiratory acidosis and alkalosis

This is caused by retention of CO₂, commonly seen in chronic obstructive pulmonary disease (COPD). The \( P_a \)CO₂ and [H⁺] rise. Renal retention of bicarbonate may partly compensate, returning the [H⁺] towards normal (see p. 214).

Respiratory alkalosis

Increased removal of CO₂ is caused by hyperventilation, so there is a fall in \( P_a \)CO₂ and [H⁺] (see p. 214).

Metabolic acidosis and alkalosis

This is due to the accumulation of any acid other than carbonic acid, and there is a primary decrease in the plasma [HCO₃⁻]. Several disorders can lead to metabolic acidosis: acid administration, acid generation (e.g., lactic acidosis during shock or cardiac arrest), impaired acid excretion by the kidneys, or bicarbonate...
losses from the gastrointestinal tract or kidneys. Calculation of the plasma anion gap is extremely useful in narrowing this differential diagnosis.

Anion gap
The first step is to identify whether the acidosis is due to retention of $H^+\text{Cl}^-$ or to another acid. This is achieved by calculation of the anion gap.

- The normal cations present in plasma are $Na^+$, $K^+$, $Ca^{2+}$ and $Mg^{2+}$.
- The normal anions present in plasma are $Cl^-$, $HCO_3^-$ and negative charges present on albumin, phosphate, sulphate, lactate and other organic acids.
- The sums of the positive and negative charges are equal.
- Measurement of plasma $[Na^+]$, $[K^+]$, $[Cl^-]$ and $[HCO_3^-]$ is usually easily available.

As there are more unmeasured anions than cations, the normal anion gap is $12–16$ mmol/L, although calculations with more sensitive methods place this at $3–9$ mmol/L. Albumin normally makes up the largest portion of these unmeasured anions. As a result, a fall in the plasma albumin concentration from the normal value of about $40$ g/L to $20$ g/L may reduce the anion gap by as much as $6$ mmol/L because each $1$ g/L of albumin has a negative charge of $0.2–0.28$ mmol/L.

Metabolic acidosis with a normal anion gap
If the anion gap is normal in the presence of acidosis, this suggests that $H^+\text{Cl}^-$ is being retained or that $Na^+\text{HCO}_3^-$ is being lost. Causes of a normal-anion-gap acidosis are given in Box 9.27. In these conditions, plasma bicarbonate decreases and is replaced by chloride to maintain electroneutrality. Consequently, these disorders are sometimes referred to collectively as hyperchloraemic acidosis.

Renal tubular acidosis
The term ‘renal tubular acidosis’ (RTA) refers to systemic acidosis caused by impairment of the ability of the renal tubules to maintain acid–base balance. This group of disorders is uncommon and only rarely a cause of significant clinical disease.

Type 4 renal tubular acidosis
This results from a deficiency or unresponsiveness to aldosterone and, as such, type 4 RTA is also called ‘hyporeninaemic hypoaldosteronism’. This is the most common form of RTA. The cardinal features are hyperkalaemia and acidosis occurring in a patient with mild CKD, usually caused by tubulointerstitial disease (e.g. reflux nephropathy) or diabetes. Hyperkalaemia maintains the acidosis through impairment of ammonia production in the proximal tubule leading to a reduction in net acid excretion. Gordon’s syndrome (see p. 189) shares biochemical abnormalities but differs in having normal GFR and hypertension. Plasma renin and aldosterone are found to be low, even after measures that would normally stimulate their secretion. Features of type 4 RTA are shown in Box 9.28. An identical syndrome is caused by chronic ingestion of NSAIDs, which impair renin and aldosterone secretion. In the presence of acidosis, urine pH may be low. Treatment is with fludrocortisone, sodium bicarbonate, diuretics or gut-acting potassium binders, or a combination of these. Resolution of hyperkalaemia may correct the metabolic acidosis through increased ammonium excretion. Dietary potassium restriction alone is ineffective.

Type 3 renal tubular acidosis
This condition is vanishingly rare, and represents a combination of type 1 and type 2 RTA. Inherited type 3 RTA is caused by mutations resulting in carbonic anhydrase type II deficiency, which is characterized by osteopetrosis, RTA of mixed type, cerebral calcification and mental retardation.

Type 2 (‘proximal’) renal tubular acidosis
This is very rare in adult practice. It is caused by failure of sodium bicarbonate reabsorption in the proximal tubule. The cardinal features are acidosis, hypokalaemia, an inability to lower the urine pH below 5.5 despite systemic acidosis, and the appearance of bicarbonate in the urine despite a subnormal plasma bicarbonate. This disorder normally occurs as part of a generalized tubular defect, together with other features such as glycosuria and amino-aciduria. Inherited forms of isolated type 2 RTA are described as both autosomal dominant and recessive patterns of inheritance, where putative mutations are in the $Na^–H^+$ antiporter in the apical membrane and $Na^++\text{HCO}_3^–$ co-transporter in the basolateral membrane of proximal tubular cells, respectively (see Fig. 9.10). Treatment is with sodium bicarbonate; massive doses may be required to overcome the renal ‘leak’.

Type 1 (‘distal’) renal tubular acidosis
This is due to a failure of $H^+$ excretion in the distal tubule (Box 9.29). It consists of:

- acidosis
- hypokalaemia (few exceptions)
- inability to lower the urine pH below 5.3 despite systemic acidosis
- low urinary ammonium production.

These features may be present only in the face of increased acid production, hence the need for an acid load test in diagnosis (Box 9.30). Other features include:

- low urinary citrate (owing to increased citrate absorption in the proximal tubule, where it can be converted to bicarbonate)
- hypercalciuria.

These abnormalities result in osteomalacia, renal stone formation and recurrent urinary infections:

- **Osteomalacia** is caused by buffering of $H^+$ by $Ca^{2+}$ in bone, resulting in depletion of calcium from bone.
- **Renal stone formation** is caused by hypercalciuria, hypocitraturia (citrate inhibits calcium phosphate precipitation) and alkaline urine (which favours precipitation of calcium phosphate).
- **Recurrent urinary infections** are caused by renal stones. Both autosomal dominant and recessive inheritance patterns have been reported in primary distal RTA. In autosomal recessive
Box 9.28 Features of type 4 renal tubular acidosis (hyporeninaemic hypoaldosteronism)

- Hyperkalaemia (in the absence of drugs known to cause hyperkalaemia)
- Low plasma bicarbonate and hyperchloremia
- Normal adrenocorticotropic hormone (ACTH) stimulation test (see p. 590)
- Low basal 24 h urinary aldosterone
- Subnormal response of plasma renin and plasma aldosterone to stimulation: samples taken over 2 h supine and again after 40 mg furosemide (80 mg if creatinine >120 μmol/L) and 4 h upright posture
- Correction of hyperkalaemia by fludrocortisone 0.1 mg daily

*May also cause proximal renal tubular acidosis.

Box 9.30 Diagnosis of renal tubular acidosis

Plasma HCO₃⁻ <21 mmol/L, urine pH >5.3 = renal tubular acidosis.

**Distal RTA: defect in dietary acid excretion. Urine pH always >5.5**

**Proximal RTA: defect in bicarbonate reabsorption. Urine pH variable**

**Bicarbonate infusion test**
Differentiates between proximal and distal RTA:
- Use a bicarbonate infusion (0.5–1 mmol/kg per hour) to raise serum bicarbonate to 18–20 mmol/L.
- If urine pH rises to >7.5 and the fractional excretion of bicarbonate (Fe HCO₃⁻)³ rises to >15%, the defect is bicarbonate reabsorption and the diagnosis is proximal RTA.

**Acid load test**
Required if plasma HCO₃⁻ is >21 mmol/L but there is suspicion of partial RTA (e.g. nephrocalcinosis-associated diseases):
- Give 100 mg/kg ammonium chloride by mouth
- Check urine pH hourly and plasma HCO₃⁻ at 3 h
- Plasma HCO₃⁻ should drop below 21 mmol/L unless the patient vomits (in which case the test should be repeated with an antiemetic).
- If urine pH remains >5.3 despite a plasma HCO₃⁻ of 21 mmol/L, the diagnosis is confirmed.

This calculation can be used to distinguish the normal-anion-gap acidosis caused by diarrhoea (or other gastrointestinal alkali loss) from that caused by distal RTA. In both disorders, the plasma [K⁺] is characteristically low. In patients with RTA, urinary pH is always greater than 5.3.

Although excretion of urinary hydrogen ions in the patient with diarrhoea should acidify the urine, hypokalaemia leads to enhanced ammonia synthesis by the proximal tubular cells. Despite acidemia, the excess urinary buffer increases the urine pH to a value above 5.3 in some patients with diarrhoea. Whenever urinary acid is excreted as ammonium chloride, the increase in urinary chloride excretion decreases the urinary anion gap. Thus, the urinary anion gap should be negative in the patient with diarrhoea regardless of the urine pH. On the other hand, although hypokalaemia may result in enhanced proximal tubular ammonia synthesis in distal RTA, the inability to secrete hydrogen ions into the collecting duct in this condition limits ammonium chloride formation and excretion; thus, the urinary anion gap is positive in distal RTA.

**Metabolic acidosis with a high anion gap**

If the anion gap is increased, there is an unmeasured anion present in increased quantities. This is either one of the acids normally present in small but unmeasured quantities, such as lactate, or an exogenous acid. See later and Box 9.31 for causes of a high-anion-gap acidosis.

**Chronic kidney disease**

Chronic kidney disease is most often caused by CKD, in which there is a failure to excrete fixed acid. Up to 40 mmol of hydrogen ions may accumulate daily. These are buffered by bone, in exchange for calcium. Chronic kidney disease is therefore a major risk factor for renal osteodystrophy and hypercalciumia.

Chronic kidney disease has also been shown to be a risk factor for muscle wasting in renal failure, and may also contribute to the inexorable progression of some types of renal disease.

Kidney disease causes acidosis in several ways:
- Reduction in the number of functioning nephrons decreases the capacity to excrete ammonia and H⁺ in the urine.
- Tubular disease may cause bicarbonate wasting.

Acidosis is a particular feature of those types of CKD in which the tubules are particularly affected, such as reflux nephropathy and chronic obstructive uropathy.

Uraemic acidosis should be corrected because of the effects on growth, muscle turnover and bones. Oral sodium bicarbonate 2–3 mmol/kg daily is usually enough to maintain serum bicarbonate above 20 mmol/L but may contribute to sodium overload. Calcium carbonate improves acidosis and also acts as a phosphate binder and calcium supplement, and is commonly used. Acidosis in end-stage kidney disease is usually fully corrected by adequate dialysis.

**Lactic acidosis**

Increased lactic acid production occurs when cellular respiration is abnormal, because of either a lack of oxygen in the tissues (*type A*) or a metabolic abnormality, such as that induced by drugs such as metformin (*type B*). The most common cause in clinical practice is type A lactic acidosis, occurring in septic or cardiogenic shock (see p. 218). Significant acidosis can occur despite a normal blood pressure and P₅ₐCO₂ owing to splanchic and peripheral vasoconstriction. Acidosis worsens cardiac function and vasoconstriction further, contributing to a downward spiral and fulminant production of lactic acid.
Acid-base disorders

As mentioned earlier, acidosis stimulates potassium loss from cells, which may lead to potassium deficiency if renal function is normal, or to hyperkalaemia if renal potassium excretion is impaired.

General treatment of acidosis

Treatment should be aimed at correcting the primary cause. In lactic acidosis caused by poor tissue perfusion (‘type A’), treatment should be aimed at maximizing oxygen delivery to the tissues by protecting the airway, and improving breathing and circulation. This usually requires inotropic agents, mechanical ventilation and invasive monitoring. In ‘type B’ lactic acidosis, treatment is directed at the underlying disorder – for example:

- insulin in diabetic ketoacidosis
- treatment of methanol and ethylene glycol poisoning with ethanol
- removal of salicylate by dialysis.

The question of whether severe acidosis should be treated with bicarbonate is extremely controversial:

- Rapid correction of acidosis may result in tetany and fits owing to a rapid decrease in ionized calcium.
- Administration of sodium bicarbonate (8.4%) provides 1 mmol/mL of sodium, which may lead to extracellular volume expansion, exacerbating pulmonary oedema.
- Bicarbonate therapy increases CO₂ production and will therefore correct acidosis only if ventilation can be increased to remove the added CO₂ load.
- The increased amounts of CO₂ generated may diffuse more readily into cells than bicarbonate, worsening intracellular acidosis.

Administration of sodium bicarbonate (50 mmol, as 50 mL of 8.4% sodium bicarbonate i.v.) is still occasionally given during cardiac arrest and is often necessary before arrhythmias can be corrected. Correction of hyperkalaemia associated with acidosis is also of undoubted benefit. In other situations, there is no clinical evidence to show that correction of acidosis improves outcome, but it is standard practice to administer sodium bicarbonate when [H⁺] is above 126 mmol/L (pH <6.9), using intravenous 1.26% (150 mmol/L) bicarbonate infused over 2–3 hours with electrolyte and pH monitoring. Intravenous sodium lactate should never be given.

Metabolic alkalosis

Metabolic alkalosis is common, comprising half of all the acid-base disorders in hospitalized patients. This observation should not be surprising since vomiting, the use of diuretics and nasogastric suction are common among hospitalized patients. The mortality associated with metabolic alkalosis is substantial; the mortality rate is 45% in patients with an arterial pH of 7.55 and 80% when the pH is over 7.65. Although this relationship is not necessarily causal, severe alkalosis should be viewed with concern.

Classification and definitions

Metabolic alkalosis has been classified on the basis of underlying pathophysiology (Box 9.32):

- chloride depletion, the most common cause, which can be corrected without potassium repletion
- potassium depletion, usually with mineralocorticoid excess
- metabolic alkalosis, due to both potassium and chloride depletion.

Chloride may be lost from the gut, kidney or skin. The loss of gastric fluid rich in acid results in alkalosis because bicarbonate generated during the production of gastric acid returns to the circulation. In Zollinger–Ellison syndrome (see p. 1336) or gastric outflow
Box 9.32 Causes of metabolic alkalosis

**Chloride depletion**
- Gastric losses: vomiting, mechanical drainage, bulimia
- Chloruretic diuretics, e.g. bumetanide, furosemide, chlorothiazide, metolazone
- Diarrhoeal states: villous adenoma, congenital chloridorrhea
- Cystic fibrosis (high sweat chloride)

**Potassium depletion/mineralocorticoid excess**
- Primary aldosteronism
- Secondary aldosteronism
- Apparent mineralocorticoid excess: primary deoxycortico- terone excess: 11α- and 17α-hydroxylase deficiencies

**Potassium depletion**
- Drugs: liquorice (glycyrrhizic acid) as a confection or flavouring, carbexonolone
- Liddle’s syndrome
- Bartter’s and Gitelman’s syndromes and their variants
- Laxative abuse, clay ingestion

**Hypercalcaemic states**
- Hypercalcaemia of malignancy
- Acute or chronic milk–alkali syndrome

**Others**
- Amoxicillin or penicillin therapy
- Bicarbonate ingestion: massive or smaller ingestion with kidney disease
- Recovery from starvation
- Hypoalbuminaemia

Chloride depletion, these losses can be massive. Although sodium and potassium loss in the gastric juice is variable, the obligate urinary loss of these cations is intensified by bicarbonaturia, which occurs during disequilibrium.

**Chloruretic agents** all directly produce loss of chloride, sodium and fluid in the urine. These losses in turn promote metabolic alkalosis by several mechanisms:
- Diuretic-induced increases in sodium delivery to the distal nephron enhance potassium and hydrogen ion secretion.
- Extracellular volume contraction stimulates renin and aldosterone secretion, which blunts sodium losses but accelerates potassium and hydrogen ion secretion.
- Potassium depletion augments bicarbonate reabsorption in the proximal tubule and stimulates ammonia production, which in turn will increase urinary net acid excretion.

Urinary losses of chloride exceed those for sodium and are associated with alkalosis, even when potassium depletion is prevented. The cessation of events that generate alkalosis is not necessarily accompanied by resolution of the alkalosis. A widely accepted hypothesis for the maintenance of alkalosis is chloride depletion rather than volume depletion. Although normal functioning of the proximal tubule is essential for bicarbonate absorption, the collecting duct appears to be the major segment of the nephron for altered electrolyte and proton transport in both maintenance and recovery from metabolic alkalosis. During maintenance, the α-intercalated cells in the CCD do not secrete bicarbonate because insufficient chloride is available for bicarbonate exchange. When chloride is administered and luminal or cellular chloride concentration increases, bicarbonate is promptly excreted and alkalosis is corrected.

Metabolic alkalosis in hypokalaemia is generated primarily by an increased intracellular shift of hydrogen ion, causing intracellular acidosis. Potassium depletion is also associated with enhanced ammonia production and increased obligate net acid excretion. This is the corollary to the acidosis seen with hyperkalaemia in type 4 RTA. Infusion of potassium alone can correct systemic alkalosis and intracellular acidosis as cells exchange extracellular potassium for intracellular hydrogen, which can then buffer extracellular bicarbonate.

**Milk–alkali syndrome**, in which both bicarbonate and calcium are ingested, produces alkalosis by vomiting, calcium-induced bicarbonate absorption and reduced GFR.

**Clinical features**

The symptoms of metabolic alkalosis per se are difficult to separate from those of chloride, volume or potassium depletion. Tetany (see Box 21.58), apathy, confusion, drowsiness, cardiac arrhythmias and neuromuscular irritability are common when alkalosis is severe. The oxyhaemoglobin dissociation curve is shifted to the left. Respiration may be depressed.

**Management**

**Chloride-responsive metabolic alkalosis**

Although replacement of the chloride deficit is essential in chloride depletion states, selection of the accompanying cation – sodium, potassium or proton – is dependent on the assessment of extracellular fluid volume status (see p. 182), the presence or absence of associated potassium depletion, and the degree and reversibility of any depression of GFR. If kidney function is normal, bicarbonate and base equivalents will be excreted with sodium or potassium, and metabolic alkalosis will be rapidly corrected as chloride is made available.

If chloride and extracellular depletion coexist, then isotonic saline solution is appropriate therapy.

In the clinical setting of fluid overload, saline is contraindicated. In such situations, intravenous hydrochloric acid or ammonium chloride can be given. If GFR is adequate, acetazolamide, which causes bicarbonate diuresis by inhibiting carbonic anhydrase, can also be used. When the kidney is incapable of responding to chloride repletion, dialysis is necessary.

**Chloride-resistant metabolic alkalosis**

Metabolic alkalosis due to potassium depletion is managed by correction of the underlying cause (see ‘Hypokalaemia’, p. 187). Mild to moderate alkalosis requires oral potassium chloride administration. However, the presence of a cardiac arrhythmia or generalized weakness requires intravenous potassium chloride.

**Further reading**

Critical care medicine describes the care given to some of the sickest patients in the hospital (Box 10.1). This might be provided initially by outreach teams in clinical areas such as the emergency department or general medical or surgical wards, but appropriate patients are transferred to either an ICU or an HDU.

ICUs are usually reserved for patients with established or impending organ failure and provide facilities for the diagnosis, prevention and treatment of multiple organ dysfunction. They are fully equipped with monitoring and technical facilities, including an adjacent laboratory and ‘near-patient testing’ devices for the rapid determination of blood gases and simple biochemical data such as serum potassium, blood glucose and serum lactate levels. Technological advances have introduced more compact and complex devices to manage ventilation and cardiac and renal support. Portable ultrasound and echocardiography equipment is commonly available. Most importantly, patients receive continuous expert nursing care and the constant attention of appropriately trained medical staff.

HDUs offer a level of care between that available on the general ward and that provided in an ICU. They ensure monitoring of and support for patients with acute (or acute-on-chronic) single-organ failure and for those who are at risk of developing organ failure. They can also provide a ‘step-down’ facility for patients being discharged from intensive care.

Recognition and diagnosis of critical illness

Early recognition, immediate resuscitation and stabilization are fundamental to the successful management of the critically ill. In order to facilitate identification of ‘at-risk’ patients on the ward and early referral to the critical care team, a number of early warning systems have been devised (e.g. the Modified Early Warning Score, MEWS). These are based primarily on bedside recognition of deteriorating physiological variables and can be used to supplement clinical
intuition. The MEWS score has been superseded by the National Early Warning Score (NEWS2) in the UK, which has been optimized to recognize sepsis and new-onset confusion (Fig. 10.1).

These early warning systems are not infallible and have not been universally implemented. It is therefore imperative that clinicians are trained to recognize critically ill patients at the bedside. The initial assessment may elicit obvious signs. The patient may be unduly agitated or, perhaps more worryingly, unresponsive. Of particular concern is the obtunded patient who is unable to protect their own airway from aspiration of gastric or oral contents. Snoring, grunting or other respiratory sounds may indicate an obstructed airway, which can be caused by posterior displacement of the tongue due to lax oropharyngeal musculature in a comatose patient, or perhaps by secretions pooling in the oropharynx in a patient with a depressed cough reflex. Obvious use of the accessory respiratory muscles and a tracheal tug are sensitive signs of impending respiratory decompensation. Patients in severe respiratory distress frequently sit forwards, grasp the sides of the bed and cannot complete sentences in a single breath. Review of the nursing observations may reveal a sudden deterioration in recorded variables, such as a sharp rise in temperature, increasing heart rate, a fall in blood pressure or decreased urine output.

On examination, cool peripheries in conjunction with diaphoresis indicate increased sympathetic drive and may be a sign of cardiogenic shock, hypovolaemia or hypoglycaemia. In contrast, flushed, warm peripheries may be a sign of a hyperdynamic circulation consistent with sepsis (see Ch. 8). Abdominal catastrophes are a common cause of an acute deterioration; an abdominal examination should always be performed and may reveal a distended, tender abdomen and often absent or altered bowel sounds consistent with a perforated viscus or ischaemic bowel. Blood gas analysis should be performed as soon as possible. Acid–base status, haemoglobin concentration, blood glucose and electrolyte levels obtained from an arterial blood gas sample are helpful when assessing the cause and severity of acute illness. Increased lactate levels usually indicate severe illness. An electrocardiogram (ECG) can allow the rapid diagnosis of treatable conditions, as can a portable chest X-ray.

Frequently, the precise underlying diagnosis is initially unclear but, in all cases, the immediate objective is to preserve life and prevent, reverse or minimize damage to vital organs such as the lungs, brain, kidneys and liver. A systematic approach to the recognition and initial treatment of acute illness should be adopted, as well as the performance of investigations to search for the underlying cause. A rapid assessment following the ABC approach (Airway, Breathing, Circulation; see Fig. 10.24) should be undertaken, with simultaneous institution of treatment. In practice, resuscitation, assessment and diagnosis usually proceed in parallel.

General aspects of managing the critically ill

Critically ill patients require multidisciplinary care that should include the following elements.

Intensive skilled nursing care

In the UK, this usually entails a 1:1 nurse to patient ratio in an ICU (level 3 care) or 1:2 in an HDU (level 2 care). Frequent clinical observations and treatment are required.

Specialized physiotherapy

This should include chest physiotherapy, mobilization and rehabilitation.

Management of pain and distress

There should be judicious administration of analgesics and sedatives (see p. 227).

Constant reassurance and support

Critically ill patients easily become disorientated; delirium (a transient alteration in consciousness, attention, orientation, perception or behaviour) is common. Delirium may be hypoactive, agitated (hyperactive) or a combination of the two. Pain, advanced age, sleep/sensory deprivation, sedative administration (especially benzodiazepines), alcohol/drug withdrawal, neurological injury, severe illness and medical comorbidities all play a role. Patients with delirium are more difficult to wean from ventilation, require larger doses of sedatives and have an associated increased mortality and length of hospital stay. Treatment focuses on effective pain control, minimizing sensory deprivation, early mobilization, avoidance of benzodiazepines and limiting sedative administration. Newer sedative agents, such as the α2 agonist dexmedetomidine, may reduce the incidence of delirium and time on the ventilator.

Gastric protection

H2-receptor antagonists or proton pump inhibitors reduce gastric acidity and prevent stress-induced ulceration. They may, however, encourage bacterial overgrowth in the upper gastrointestinal tract and predispose patients to ventilator-associated pneumonia; they are also associated with Clostridium difficile colitis.
Deep vein thrombosis prevention
This should be instigated with use of compression stockings, pneumatic compression devices and subcutaneous low-molecular-weight heparin.

Mouth care, tooth-brushing and oropharyngeal suction
These measures help to reduce hospital-acquired infections and ventilator-associated pneumonia by reducing the burden of pathogenic oral flora that may be aspirated into the respiratory tree. Chlorhexidine body washes may reduce the total carriage of resistant microorganisms.

Prevention of constipation and pressure ulcers
Steps should be taken to prevent constipation and pressure ulcers developing.

Organ support
For example, inotropes and vasopressors may be required for cardiovascular support, invasive and non-invasive ventilation for respiratory failure, and dialysis for renal failure. Specialized units may provide extracorporeal membrane oxygenation (ECMO) for severe respiratory failure, mechanical support of the circulation for cardiac failure, and advanced liver support in the form of liver dialysis (e.g. the molecular adsorbent recirculation system, MARS).

Nutritional support
(See p. 1231.) Protein–energy malnutrition is common in critically ill patients and is associated with muscle wasting, weakness, delayed mobilization, difficulty weaning from ventilation, immune compromise and impaired wound healing. *Enteral nutrition*, usually delivered via a fine-bore nasogastric tube, is preferred because it is less expensive, preserves gut mucosal integrity, is more physiological and is associated with fewer complications. However, the value of enteral nutrition early in the course of an acute illness remains uncertain. If enteral feeding is not possible due to the gut dysmotility and malabsorption associated with critical illness, the alternative is *intravenous (parenteral) nutrition* (see p. 1255). This is more invasive and expensive, and can be complicated by deranged liver function tests, hypertriglyceridaemia, hyperglycaemia and an increased susceptibility to hospital-acquired infections. Hypocaloric enteral nutrition is usually continued for up to a week in previously well-nourished patients before parenteral nutrition is considered. Administering parenteral nutrition early in order to maintain caloric input and prevent an energy deficit may be detrimental.

Although all nutrition should contain carbohydrate, protein, lipids and some micronutrients, the precise optimal formulation is unclear. Supplementation with the amino acid glutamine has theoretical advantages in some conditions (burns and trauma) but not in multi-organ failure. The omega-3 fatty acids derived from fish oils also have potentially beneficial antioxidant activity but have not been convincingly shown to improve outcome, as has been the case for micronutrient supplementation with selenium, copper, manganese, zinc, iron and vitamins.

Many critically ill patients are at risk of developing a *re-feeding syndrome* (see p. 1235) when nutritional support is first initiated and should be monitored closely.
Insulin treatment

Treatment should be given for critical illness-induced hyperglycaemia. Insulin is often required in high doses, to combat insulin resistance and hyperglycaemia (which is associated with hospital-acquired infections, renal impairment and poor wound healing, see p. 738). Although the use of intensive insulin therapy to achieve ‘tight glycaemic control’ (blood glucose level between 4.4 and 6.1 mmol/L) was initially shown to improve outcome, subsequent studies found that this approach is associated with an unacceptably high incidence of hypoglycaemia, and possibly increased mortality. Current recommendations suggest that blood glucose levels should be maintained below 10 mmol/L.

Discharge from the ICU/HDU

Discharge of patients from intensive care should normally be planned in advance and ideally take place during normal working hours. Frequently, when the condition of critically ill patients improves, they are initially ‘stepped down’ to HDU (level 2) care. Premature or unplanned discharge from the ICU or HDU, especially during the night, has been associated with higher hospital mortality and is best avoided. A discharge summary, including ‘points to review’, should be included in the clinical notes, with a detailed handover to the receiving team (medical and nursing). The intensive care team should continue to review the patient (who might deteriorate following discharge) on the ward and be available for advice on further management (e.g. tracheostomy care, nutritional support). In this way, deterioration and re-admission to intensive care (which is associated with a particularly poor outcome), or even cardiorespiratory arrest, might be avoided.

This chapter concentrates on cardiovascular, respiratory, renal and neurological problems. Many patients also have failure of other organs, such as the liver; treatment of these is dealt with in more detail in the relevant chapters.

APPLIED CARDIORESPIRATORY PHYSIOLOGY

Oxygen delivery and consumption

Normal cellular, tissue and organ functions depend on adequate delivery of oxygen and fuel to mitochondria, a process requiring the heart, lungs, vascular and haematological systems. Adequate blood flow needs proper functioning of the three components of the circulation: that is, the muscle pump, circulating volume and arterial resistance to flow to perfuse distal tissues; each area has its own regulatory system and may develop pathology.

The term oxygen delivery (\(\text{DO}_2\)) describes the total amount of oxygen supplied to the body per unit time (Fig. 10.2). Its main determinants are the amount of blood pushed through the microcirculation by the cardiac output (Q) and the amount of oxygen carried in that blood (i.e. arterial oxygen content, \(\text{CaO}_2\)). Oxygen is transported primarily in combination with haemoglobin: the amount combined is determined by its oxygen capacity (usually 1.34 mL of oxygen per gram) and percentage saturation (\(\text{SO}_2\)). Oxygen is also carried dissolved in plasma; this depends on the partial pressure of oxygen (\(\text{PO}_2\)) and is usually insignificant.

‘Global’ oxygen delivery as a concept is of limited clinical value, as differing tissues have differing metabolic requirements and blood flow. Generally, delivery is matched to individual metabolic requirements. Some organs (such as the heart) have high oxygen requirements relative to their blood flow and may receive insufficient oxygen, even if overall delivery appears adequate. Microcirculatory flow is also reduced by increased blood viscosity.

Oxygenation of the blood

Oxyhaemoglobin dissociation curve

The saturation of haemoglobin with oxygen is determined by the partial pressure of oxygen (\(\text{PO}_2\)), this relationship being described by the oxyhaemoglobin dissociation curve (Fig. 10.3). The sigmoid shape of this curve is significant for a number of reasons:

- Modest falls in the partial pressure of oxygen in arterial blood (\(\text{PaO}_2\)) have little effect on oxygen content, provided percentage saturations remain above about 92%.
- Increasing the \(\text{PaO}_2\) to above normal has only a minimal effect on oxygen content, unless hyperbaric oxygen is administered (when the amount of oxygen in solution in plasma becomes significant).
- On the slope of the curve (percentage saturation below 90%), a small decrease in \(\text{PaO}_2\) can cause large falls in oxygen content, whereas increasing \(\text{PaO}_2\) only slightly, e.g. by administering 28% oxygen to a patient with chronic obstructive pulmonary disease (COPD), can lead to a useful increase in oxygen saturation and content. If the PCO\(_2\) increases, the oxyhaemoglobin curve moves to the right, facilitating oxygen unloading to the tissues (Bohr effect).

![Fig. 10.2 Tissue oxygen delivery and consumption in a normal 70 kg person breathing air. Oxygen delivery (\(\text{DO}_2\)) = cardiac output \(\times\) (haemoglobin concentration \(\times\) oxygen saturation (\(\text{S}_a\text{O}_2\)) \(\times\) 1.34). In normal adults, oxygen delivery is roughly 1000 mL/min, of which 250 mL is taken up by tissues. Mixed venous blood is thus 75% saturated with oxygen, \(\text{C}_v\text{O}_2\), arterial oxygen content; \(\text{C}_p\text{O}_2\), mixed venous oxygen content; \(\text{S}_v\text{O}_2\), mixed venous oxygen saturation.](image-url)
The $P_{\text{a}}O_2$ is influenced, in turn, by the alveolar oxygen tension ($P_{\text{a}}O_2$), the efficiency of pulmonary gas exchange, and the partial pressure of oxygen in mixed venous blood ($P_{\text{v}}O_2$).

**Alveolar oxygen tension ($P_{\text{a}}O_2$)**

The partial pressures of inspired gases are shown in Fig. 10.4. By the time the inspired gases reach the alveoli, they are fully saturated with water vapour at body temperature (37°C), which has a partial pressure of 6.3 kPa (47 mmHg), and contain CO2 at a partial pressure of approximately 5.3 kPa (40 mmHg); the $P_{\text{a}}O_2$ is thereby reduced to approximately 13.4 kPa (100 mmHg).

The clinician can influence $P_{\text{a}}O_2$ by administering oxygen or by increasing the barometric pressure (hyperbaric therapy).

**Pulmonary gas exchange**

In normal subjects, a small alveolar–arterial oxygen difference ($P_{\text{a}}O_2–P_{\text{a}}O_2$) exists due to:

- a small (0.133 kPa (1 mmHg)) pressure gradient across the alveolar membrane
- a small amount of blood (2% of total cardiac output) bypassing the lungs via the bronchial and thebesian veins
- a small degree of ventilation/perfusion mismatch.

There are three pathological causes of an increased $P_{\text{a}}O_2$ difference:

- **Diffusion defect.** This is not a major cause of hypoxaemia, even in conditions such as lung fibrosis, in which the alveolar–capillary membrane is considerably thickened. Carbon dioxide is also not affected, as it is more soluble than oxygen.

- **Right-to-left shunts.** In cyanotic congenital heart disease or following collapse of a lung segment, a proportion of venous blood passes to the left side of the heart without taking part in gas exchange, causing arterial hypoxaemia that cannot be corrected by administering oxygen to increase the $P_{\text{a}}O_2$ because blood leaving normal alveoli is already fully saturated; further increases in $P_{\text{a}}O_2$ will not, therefore, significantly affect its oxygen content. On the other hand, because of the shape of the carbon dioxide dissociation curve (Fig. 10.5), the high $PCO_2$ of the shunted blood is compensated for by overventilating patent alveoli; hence many patients with acute right-to-left shunts hyperventilate, producing a low or normal $P_{\text{a}}CO_2$.

- **Ventilation/perfusion mismatch** (see p. 933). This happens when parts of the lung ventilate without much blood flow (e.g. pulmonary embolism), or when there is blood flow but no ventilation, such as in parenchymal lung disease (pneumonia, pulmonary oedema). Both of these states result in hypoxaemia. The increased dead space can be compensated for by increasing overall ventilation. In contrast to the hypoxia resulting from a true right-to-left shunt, that due to areas of low $V/Q$ can be partially corrected by administering oxygen and thereby increasing the $P_{\text{a}}O_2$.

![Fig. 10.4 The composition of inspired and alveolar gas. (Partial pressures in kPa.)](image)

![Fig. 10.5 The carbon dioxide dissociation curve. Note that, in the physiological range, the curve is essentially linear.](image)
Oxygen cascade

Oxygen levels fall further as it is unloaded into the tissues and diffuses to the mitochondria. Tissue oxygen content varies, depending on the distance travelled from the local capillary network. Some mitochondria continue to function at a PO$_2$ as low as 0.07 kPa (0.5 mmHg) (Fig. 10.6).

Mixed venous oxygen tension and saturation

Mixed venous oxygen tension (P$_{V\text{O}_2}$) is the partial pressure of oxygen in pulmonary arterial blood that has been thoroughly mixed in the right heart. Assuming $P_{a\text{O}_2}$ remains constant, both $P_{V\text{O}_2}$ and mixed venous oxygen saturation (S$_{V\text{O}_2}$) fall as more oxygen is extracted by tissues. Low S$_{V\text{O}_2}$ therefore indicates either inadequate oxygen delivery or a rise in tissue requirements beyond compensations in cardiac output. This may exacerbate pulmonary shunting; hence, worsening hypoxaemia does not necessarily indicate declining pulmonary function. Conversely, rises in venous oxygen content may reflect impaired tissue extraction due to microcirculatory abnormalities and/or reduced utilization due to mitochondrial dysfunction, as in severe sepsis or certain poisons (see later). Monitoring central venous oxygen saturation from the superior vena cava (S$_{\text{ScVO}_2}$) rather than the pulmonary artery is less invasive and approximates S$_{V\text{O}_2}$ to within around 5% in most situations, although this relationship becomes less predictable at the extremes of physiology (see p. 224).

Adaptation to hypoxia

Acute exposure to severe hypoxia may lead to sudden death if the immediate adaptive responses fail to maintain mitochondrial oxygen delivery. Chronic exposure to low oxygen tension, on the other hand, allows time for compensatory mechanisms to develop. Among the first is an increase in cardiac output, achieved primarily by increasing heart rate. Given the reciprocal relationship between the partial pressures of oxygen and carbon dioxide in the alveoli, as defined by the alveolar gas equation ($P_{a\text{O}_2}=P_{\text{O}_2}-P_{\text{aCO}_2}/R$, where R is the respiratory quotient (usually 0.8)), an increase in respiratory rate serves to decrease alveolar $P_{\text{CO}_2}$ and thereby increase alveolar $P_{\text{O}_2}$ (see also Fig. 10.4). Over time, increased erythropoietin production stimulates haemoglobin synthesis, leading to a marked increase in haematocrit. Over the longer term, capillary bed density in specific tissues adjusts to the physiological demand. In those residing at altitude over generations, the hypoxic ventilatory drive and pulmonary vasoconstrictor response evolve to maximize oxygen uptake. In 2007 a series of arterial blood samples were obtained by a group of critical care doctors on the summit of Mount Everest (see ‘Further reading’). The project included a 4-month acclimatization period at altitude and the samples were eventually obtained at an altitude of 8400 m while breathing air. The average $P_{a\text{O}_2}$ was 3.2 kPa (24.6 mmHg). These figures neatly demonstrate features of both acute (hyperventilation) and chronic (increased haematocrit) acclimatization to hypobaric hypoxia.

Further reading

Cardiac output

Cardiac output is the product of heart rate and stroke volume (Fig. 10.7). When the heart rate increases, the duration of systole is largely unchanged but diastole, and thus time for ventricular filling, progressively shortens and stroke volume eventually falls. In normal hearts this occurs at rates of more than about 160 beats per minute, but in those with cardiac pathology, particularly restricted ventricular filling (e.g. mitral stenosis), it may be seen at much lower rates. Tachycardia increases myocardial oxygen consumption and may precipitate ischaemia in areas with restricted coronary perfusion. Conversely, when heart rate falls, the compensatory increase in stroke volume eventually becomes insufficient and cardiac output falls. Furthermore, rhythm disturbances (e.g. atrial fibrillation, complete heart block) may prevent atrial augmentation of ventricular filling, exacerbating the fall in stroke volume.

Stroke volume

The volume of blood ejected in a single contraction is the difference between the ventricular end-diastolic volume (VEDV) and ventricular end-systolic volume (VESV) (i.e. stroke volume = VEDV – VESV). The ejection fraction describes the stroke volume as a percentage of VEDV (i.e. ejection fraction = (VEDV – VESV)/VEDV × 100%) and is an indicator of myocardial performance.

Three interdependent factors determine the stroke volume (see p. 1025).

Preload

This is defined as the tension of the myocardial fibres at the end of diastole, and is related to the degree of stretch of the fibres. As the end-diastolic volume of the ventricle increases, tension in the
myocardial fibres is increased and stroke volume rises (Fig. 10.8). Myocardial oxygen consumption \( (V_mO_2) \) increases only slightly with an increase in preload (produced, for example, by a ‘fluid challenge’, see later) and this is therefore the most efficient way of improving cardiac output.

**Myocardial contractility**

This refers to the ability of the heart to perform work, independent of changes in preload and afterload. The state of myocardial contractility determines the response of the ventricles to changes in preload and afterload. Contractility is often reduced in critically ill patients, as a result of either pre-existing myocardial damage (e.g. ischaemic heart disease) or the acute disease process itself (e.g. sepsis). Changes in myocardial contractility alter the slope and position of the Starling curve; worsening ventricular performance is manifested as a depressed, flattened curve (see Figs 10.8 and 30.5). Inotropic drugs are used to increase myocardial contractility (see later).

**Afterload**

This is defined as the myocardial wall tension developed during systolic ejection. In the case of the left ventricle, the resistance imposed by the aortic valve, the peripheral vascular resistance and the elasticity of the major blood vessels are the major determinants of afterload. Ventricular wall tension will also be increased by ventricular dilation, an increase in intraventricular pressure or a reduction in ventricular wall thickness.

Decreasing the afterload (through vasodilation due to exercise, sepsis or vasodilating agents) can increase the stroke volume achieved at a given preload (Fig. 10.9), while reducing \( V_mO_2 \). The reduction in wall tension also leads to an increase in coronary blood flow, thereby improving the myocardial oxygen supply/demand ratio. Excessive reductions in afterload will cause hypotension.

Increasing the afterload (vasoconstriction due to increased sympathetic activity, vasoconstrictor agents), on the other hand, can cause a fall in stroke volume and an increase in \( V_mO_2 \).

Right ventricular afterload is normally negligible because the resistance of the pulmonary circulation is very low but is increased in pulmonary hypertension. Unlike the left ventricle, the right is poorly tolerant of acute changes in this parameter and acutely elevated pulmonary vascular resistance may cause shock.

**Cardiovascular assessment and monitoring of critically ill patients**

Monitoring helps establish or confirm a diagnosis, gauge severity of a condition, follow its evolution, guide interventions and assess response to treatment. Invasive monitoring is usually indicated in critically ill patients and those unresponsive to initial resuscitation. These techniques carry a risk of significant complications, are costly and may lead to patient discomfort. They should be used only when potential benefits outweigh their dangers, and for the minimum time necessary.

**Assessment of tissue perfusion**

- **Pale, cold skin**, delayed capillary refill and the absence of visible veins in the hands and feet indicate poor perfusion. Although peripheral skin temperature measurements can help clinical evaluation, the earliest compensatory response to hypovolaemia or a low cardiac output, and the last to resolve after resuscitation, is splanchnic vasoconstriction.

- **Metabolic acidosis with raised lactate concentration** suggests that tissue perfusion is sufficiently compromised to cause cellular hypoxia and anaerobic glycolysis. Persistent, severe lactic acidosis is associated with a very poor prognosis. In addition to serving as a screen for cardiovascular insufficiency and poor tissue perfusion, lactate levels are frequently used to guide resuscitation. High lactate levels that do not respond to resuscitation suggest reduced splanchnic blood flow and bowel ischaemia. In sepsis, lactic acidosis can also be caused by metabolic disorders unrelated to tissue hypoxia and exacerbated by reduced clearance owing to hepatic or renal dysfunction, as well as the administration of adrenaline (epinephrine).

- **Urinary flow** is a sensitive indicator of renal perfusion and haemodynamic performance.

**Blood pressure**

Alterations in blood pressure are often interpreted as reflecting changes in cardiac output. However, if there is vasoconstriction with a high peripheral resistance, the blood pressure may be normal,
even when the cardiac output is low. Conversely, the vasodilated patient may be hypotensive, despite a very high cardiac output.

Hypotension jeopardizes perfusion of vital organs. The adequacy of blood pressure in an individual patient must always be assessed in relation to the pre-morbid value. Blood pressure is traditionally measured using a sphygmomanometer, but if rapid alterations are anticipated, continuous monitoring using an intra-arterial cannula is indicated (Box 10.2 and Fig. 10.10).

Central venous pressure

Assessment of central venous pressure (CVP) provides a fairly simple, but approximate, method of gauging the adequacy of a patient’s circulating volume and preload. The absolute value of the CVP is not as informative as its response to a fluid challenge (the infusion of 100–200 mL of fluid over a few minutes; Fig. 10.11). The hypovolaemic patient will initially respond to transfusion with little or no change in CVP but will exhibit some improvement in cardiovascular function (falling heart rate, rising blood pressure, increased peripheral temperature and urine output). As the normovolaemic state is approached, the CVP may rise slightly and reach a plateau, while other cardiovascular values begin to stabilize. At this stage, volume replacement should be slowed or even stopped. In cardiac failure, the venous pressure is usually high; the patient will not improve in response to volume replacement, which will cause a further, sometimes dramatic, rise in CVP.

However, the use of CVP to assess cardiovascular function is controversial and newer methods, particularly pulse contour analysis and oesophageal Doppler techniques, have largely replaced it (see later).

Central venous catheters are usually inserted via percutaneous puncture of the subclavian or internal jugular vein using a guidewire technique (Box 10.3; Figs 10.12 and 10.13). The objective is to place the tip of the catheter approximately at the junction of the superior vena cava and the right atrium. Usually, these catheters consist of more than one lumen, some of which may be used for drug or fluid administration. Central venous cannulæ may also be inserted via the femoral vein; when this route is used, the tip of the cannula will lie in the inferior vena cava. Guidewire techniques can also be employed for inserting double-lumen cannulæ for haemofiltration or pulmonary artery catheter introducers. The routine use of ultrasound to guide central venous cannulation reduces complication rates.

Box 10.2 Radial artery cannulation

**Technique**

1. Explain the procedure to the patient and, if possible, obtain consent.
2. Ask an assistant to support the patient’s arm, with the wrist extended. (Gloves should be worn.)
3. Clean the skin with chlorhexidine. Take sterile precautions throughout the procedure.
4. Palpate the radial artery where it arches over the head of the radius.
5. In conscious patients, inject local anaesthetic to raise a weal over the artery, taking care not to puncture the vessel or obscure its pulsation.
6. Make a small skin incision over the proposed puncture site.
7. Use a small, parallel-sided cannula (20 gauge for adults, 22 gauge for children) in order to allow blood flow to continue past the cannula.
8. Insert the cannula over the point of maximal pulsation and advance it in line with the direction of the vessel at an angle of approximately 30 degrees.
9. Look for ‘flashback’ of blood into the cannula, which indicates that the radial artery has been punctured.
10. To ensure that the shoulder of the cannula enters the vessel, lower the needle and cannula and advance them a few millimetres into the vessel.
11. Thread the cannula off the needle into the vessel and withdraw the needle.
12. Connect the cannula to a non-compliant manometer line filled with saline. Then connect this via a transducer and continuous flush device to a monitor, which records the arterial pressure.

**Possible complications**

- Thrombosis
- Loss of arterial pulsation
- Distal ischaemia, e.g. digital necrosis (rare)
- Infection
- Accidental injection of drugs – can produce vascular occlusion
- Disconnection – rapid blood loss

![Fig. 10.10 Percutaneous cannulation of the radial artery.](image-url)

![Fig. 10.11 The effects on the central venous pressure (CVP) of rapid administration of a ‘fluid challenge’ to patients with a CVP within the normal range.](image-url)
The CVP is usually displayed continuously using a transducer and bedside monitor but can also be recorded intermittently using a manometer system. It is essential for the recorded pressure always to be related to the level of the right atrium. Various landmarks are advocated (e.g. sternal notch with the patient supine; sternal angle or mid-axilla when the patient is at 45 degrees), but the choice is largely immaterial, provided the landmark is used consistently in an individual patient.

Left atrial pressure

In uncomplicated cases, careful interpretation of the CVP may provide a reasonable guide to the filling pressures of both sides of the heart. In some critically ill patients, however, there is a disparity in function between the two ventricles. Most commonly, left ventricular performance is worse, so that the left ventricular function curve is displaced downwards and to the right (Fig. 10.14). High right ventricular filling pressures, with normal or low left atrial pressures, are less common but occur with right ventricular dysfunction and with raised pulmonary vascular resistance (i.e. right ventricular afterload), such as in acute respiratory failure and pulmonary embolism.

Pulmonary artery pressures

A ‘balloon flotation catheter’ enables reliable catheterization of the pulmonary artery. These ‘Swan–Ganz’ catheters are inserted centrally (see Fig. 10.12). Passage of the catheter from the major veins, through the chambers of the heart into the pulmonary artery and into the wedge position, is monitored and guided by the pressure waveforms recorded from the distal lumen (Box 10.4 and Fig. 10.15). A chest X-ray should always be obtained to check the final position of the catheter (Fig. 10.16).

Once in position, the catheter measures pulmonary artery mean, systolic and end-diastolic pressures (PAEDP). The pulmonary artery

---

**Box 10.3 Internal jugular vein cannulation**

**Technique**

1. Explain the procedure to the patient and, if possible, obtain consent.
2. Place the patient head down to distend the central veins (this facilitates cannulation and minimizes the risk of air embolism, but may exacerbate respiratory distress and is dangerous in those with raised intracranial pressure).
3. Clean the skin with an antiseptic solution such as chlorhexidine. Take sterile precautions throughout the procedure.
4. Inject local anaesthetic (1% plain lidocaine) intradermally to raise a weal at the apex of a triangle formed by the two heads of sternomastoid with the clavicle at its base.
5. Make a small incision through the weal.
6. Insert the cannula or needle through the incision and direct it laterally, downwards and backwards, in the direction of the nipple, until the vein is punctured just beneath the skin and deep to the lateral head of sternomastoid. Ultrasound-guided puncture is recommended to reduce the incidence of complications.
7. Check that venous blood is easily aspirated.
8. Thread the cannula off the needle into the vein or pass the guidewire through the needle (see Fig. 10.13).
9. Connect the central venous pressure manometer line to a manometer/transducer.
10. Take a chest X-ray to verify that the tip of the catheter is in the superior vena cava and to exclude pneumothorax.

**Possible complications**

- Haemorrhage
- Accidental arterial puncture (carotid or subclavian)
- Pneumothorax
- Damage to thoracic duct on left
- Air embolism
- Thrombosis
- Catheter-related sepsis

---

**Fig. 10.13 Seldinger technique – insertion of a catheter over guidewire.** (1) Puncture vessel. (2) Advance guidewire. (3) Remove needle. (4) Dilate vessel. (5) Advance catheter over guidewire. (6) Remove guidewire. (7) Catheter in situ.
Cardiac output

The gold standard cardiac output monitor uses a modified pulmonary artery catheter that transmits low-energy heat from a heating element in the catheter into the surrounding blood. A ‘thermodilution curve’ is constructed by measuring dissipation of the heat using a thermistor located distal to the heating coil. The dissipation of heat is directly proportional to the cardiac output. These catheters also optically measure and continuously display $S_O_2$.

In general, pulmonary artery catheters may help the clinician to optimize cardiac output and oxygen delivery, while minimizing the risk of volume overload. They guide the rational use of inotropes and vasoactive agents, particularly in patients with pulmonary hypertension. The unselective use of this monitoring device in the absence of evidence-based haemodynamic goals does not, however, lead to improved outcomes, and less invasive techniques are preferred, except in the most complex cases (e.g. high-risk cardiac surgery).

Less invasive techniques for assessing cardiac function and guiding volume replacement

Arterial pressure variation as a guide to hypovolaemia

Systolic arterial pressure decreases during the inspiratory phase of intermittent positive pressure ventilation (see p. 227). The magnitude of this cyclical variability has been shown to correlate more closely with hypovolaemia than other monitored variables. Systolic pressure (or pulse pressure) variation during mechanical ventilation can therefore be used as a simple and reliable guide to the adequacy of the circulatory volume. The response to fluid loading can also be predicted simply by observing the changes in pulse pressure during passive leg-raising.

Oesophageal Doppler

Stroke volume, cardiac output and myocardial function can be assessed non-invasively using Doppler ultrasonography. A probe is passed into the oesophagus to monitor velocity waveforms from the descending aorta continuously (Fig. 10.17). Although reasonable estimates of stroke volume, and hence cardiac output, can be obtained, the technique is best reserved for trend analysis rather than for making absolute measurements. It is particularly valuable for perioperative optimization of the circulating volume and cardiac performance in the unconscious patient. It is contraindicated in patients with oropharyngeal/oesophageal pathology.

Arterial waveform analysis

Lithium dilution/pulse contour analysis does not require pulmonary artery catheterization or instrumentation of the oesophagus and is suitable for use in conscious patients. A bolus of lithium chloride is administered via a central venous catheter and the change in arterial plasma lithium concentration is detected by a lithium-sensitive electrode. This sensor can be connected to an existing arterial cannula via a three-way tap. The cardiac output determined in this way can be used to calibrate an arterial pressure waveform (‘pulse contour’) analysis program that will continuously monitor changes in cardiac output. Devices that employ uncalibrated pulse contour analysis to estimate cardiac output are also available.
Other devices utilize a thermodilution technique, where a small volume of cold fluid is injected into a large central vein and a temperature washout curve is detected via a sensor in a modified arterial line. Following this calibration, beat-to-beat cardiac output is generated by computer-based analysis of the arterial pressure waveform. As with pulse pressure variation, stroke volume variation, determined by oesophageal Doppler or arterial waveform analysis, can be used to guide fluid replacement.

Echocardiography

Focused echocardiography is increasingly used to provide immediate diagnostic information about cardiac structure and function (myocardial contractility, ventricular filling) in the critically ill patient. Although transoesophageal echocardiography (TOE) may be preferred because of its superior image clarity (Fig. 10.18), transthoracic echocardiography is non-invasive and more readily available.
DISTURBANCES OF ACID–BASE BALANCE

The physiology of acid–base control is discussed on page 196. Acid–base disturbances can be described in relation to Figure 9.14 (which shows $P_aCO_2$ plotted against arterial [H$^+$]). Both acidosis and alkalosis can occur, each of which is either metabolic (primarily affecting the bicarbonate component of the system) or respiratory (primarily affecting $P_aCO_2$). Compensatory changes may also be apparent. In clinical practice, arterial [H$^+$] values outside the 18–126 nmol/L (pH 6.9–7.7) range are rarely encountered.

Blood gas and acid–base values (normal ranges) are shown in Box 10.6. (For blood gas analysis, see p. 225.)

Respiratory acidosis

This is caused by retention of carbon dioxide. The $P_aCO_2$ and [H$^+$] rise. A chronically raised $P_aCO_2$ is compensated by renal retention of bicarbonate and the [H$^+$] returns towards normal. A constant arterial bicarbonate concentration is then usually established within 2–5 days. This represents a primary respiratory acidosis with a compensatory metabolic alkalosis (see p. 198). Common causes of respiratory acidosis include ventilatory failure and COPD (type II respiratory failure, where there is a high $P_aCO_2$ and a low $P_aO_2$; see p. 224).

Respiratory alkalosis

In this case, the reverse occurs and there is a fall in $P_aCO_2$ and [H$^+$], often with a small reduction in bicarbonate concentration. If hypocarbia persists, some degree of renal compensation may occur, producing a metabolic acidosis, although in practice this is unusual. A respiratory alkalosis may be produced, intentionally or unintentionally, when patients are mechanically ventilated; it may also be seen in patients with hypoaesthetic (type I) respiratory failure (see p. 224), those with spontaneous hyperventilation and those living at high altitudes.

Metabolic acidosis

Metabolic acidosis (see p. 198) may be due to excessive acid production, often lactic acid (lactic acidosis), as a consequence of anaerobic metabolism during an episode of shock or following cardiac arrest. A metabolic acidosis may develop as a consequence of chronic renal failure or in diabetic ketoacidosis. It can also follow the loss of bicarbonate from the gut or from the kidney in renal tubular acidosis. Respiratory compensation for a metabolic acidosis is usually slightly delayed because the blood–brain barrier initially prevents the respiratory centre from sensing the increased blood [H$^+$]. Following this short delay, however, the patient hyperventilates and ‘blows off’ carbon dioxide to produce a compensatory respiratory alkalosis. There is a limit to this respiratory compensation since, in practice, values for $P_aCO_2$ of less than about 1.4 kPa (11 mmHg) are rarely achieved. Spontaneous respiratory compensation cannot occur if the patient’s ventilation is controlled or if the respiratory centre is depressed: for example, by drugs or head injury.

Metabolic alkalosis

This can be caused by loss of acid – for example, from the stomach with nasogastric suction, or in high intestinal obstruction, or excessive administration of absorbable alkali. Over-zealous treatment with intravenous sodium bicarbonate is sometimes implicated. Respiratory compensation for a metabolic alkalosis is often slight, and it is rare to encounter a $P_aCO_2$ above 6.5 kPa (50 mmHg), even with severe alkalosis.

SHOCK, SEPSIS AND ACUTE DISTURBANCES OF HAEMODYNAMIC FUNCTION

Shock is the term used to describe acute circulatory failure with inadequate or inappropriately distributed tissue perfusion, resulting in generalized cellular hypoxia and/or an inability of the cells to utilize oxygen.
**Aetiology of shock**

Abnormalities of tissue perfusion can result from:
- failure of the heart to act as an effective pump
- mechanical impediments to forward flow
- loss of circulatory volume
- abnormalities of the peripheral circulation.

The causes of shock are shown in Box 10.7; see also page 154 for definitions of sepsis. Often, shock can result from a combination of these factors (e.g. in sepsis, distributive shock is frequently complicated by hypovolaemia and myocardial depression).

**Pathophysiology**

**The sympatho-adrenal response to shock**

Hypotension stimulates baroreceptors, and to a lesser extent chemoreceptors, causing increased sympathetic nervous activity with ‘spill-over’ of noradrenaline (norepinephrine) into the circulation. Later, this is augmented by the release of catecholamines (predominantly adrenaline (epinephrine)) from the adrenal medulla. The resulting vasoconstriction, together with increased myocardial contractility and heart rate, help to restore blood pressure and cardiac output (Fig. 10.19).

Reduced perfusion of the renal cortex stimulates the juxtaglomerular apparatus to release renin. This converts angiotensinogen to angiotensin I, which, in turn, is converted in the lungs and by the vascular endothelium to the potent vasoconstrictor angiotensin II. Angiotensin II also stimulates secretion of aldosterone by the adrenal cortex, causing sodium and water retention (see p. 1346). This helps to restore the circulating volume (see p. 173).

**The neuroendocrine response**

- **Release of pituitary hormones** includes adrenocorticotrophic hormone (ACTH), vasopressin (antidiuretic hormone, ADH) and endogenous opioid peptides. (In septic shock, there may be a relative deficiency of vasopressin.)
- **Release of cortisol** causes fluid retention and antagonizes insulin.
- **Release of glucagon** raises the blood sugar level.

**Fig. 10.19** The sympatho-adrenal response to shock. The effect of increased catecholamines is shown on the left, and the release of angiotensin and aldosterone on the right. Both mechanisms help to maintain cardiac output and blood pressure in shock.
Although absolute adrenocortical insufficiency (e.g. due to bilateral adrenal haemorrhage or necrosis in meningococcal infection) is rare, a blunted response to exogenous ACTH (so-called ‘relative’ or ‘occult’ adrenocortical insufficiency) has been observed in septic shock patients with impaired vasoconstrictor response to noradrenaline (norepinephrine). Steroid supplementation improves vasoconstrictor response with a rise in blood pressure but without mortality benefit.

**Release of immune mediators**

Severe infection (often with bacteraemia or endotoxaemia), the presence of large areas of damaged tissue (e.g. following trauma or extensive surgery), hypoxia or prolonged/repeated episodes of hypoperfusion can all trigger a dysfunctional immune response with alterations in leucocyte activation and release of a variety of potentially damaging ‘mediators’ (see also p. 57). Although an appropriate immune response is clearly beneficial, the disseminated, dysregulated response observed in some patients can lead to shock and organ failure. This immune response is complex, with upregulation and downregulation of both the innate and the adaptive immune pathways at different stages of the illness. Characteristically, the later phase is typified by a period of immune suppression, during which the patient is at increased risk of developing secondary infections.

**Microorganisms and their toxic products**

In sepsis/septic shock, the innate immune response (Fig. 10.20) and inflammatory cascade are triggered by the recognition of pathogen-associated molecular patterns (PAMPs), including bacterial and fungal DNA, cell-wall components (e.g. endotoxin) and/or exotoxins (antigenic proteins produced by bacteria such as staphylococci, streptococci and *Pseudomonas*) (see also p. 154).

*Endotoxin* is a lipopolysaccharide (LPS) derived from the cell wall of Gram-negative bacteria and a potent trigger of the immune response.

**Fig. 10.20** Induction of the innate immune response by the lipopolysaccharide–lipopolysaccharide-binding protein (LPS–LBP) complex. The intracellular events (simplified) initiated by Gram-negative and Gram-positive bacteria, which eventually lead to bacterial killing. IκB, inhibitory factor kappa B; IL, interleukin; LTA, lipoteichoic acid; MD2, a secreted protein involved in binding lipopolysaccharide with TLR4; MSR, macrophage scavenger receptor; MyD88, myeloid differentiation factor 88; NFκB, nuclear factor kappa B; NOD, nucleotide-binding oligomerization domain; PEPG, peptidoglycan-N; TIR, Toll-interleukin receptor; TIRAP, Toll-interleukin 1 receptor adaptor protein; TIRAP/Mal, an adaptor protein for TLR2 and TLR4; TLR, Toll-like receptors; TNF-α, tumour necrosis factor-alpha.
response. The lipid A portion of LPS is bound by a serum protein known as lipopolysaccharide-binding protein (LBP). The LBP–LPS complex attaches to the cell surface marker CD14 and, combined with a secreted protein (MD2), then binds to a member of the Toll-like receptor family (TLR4), which transduces the activation signal into the cell. Activation of these receptors promotes the synthesis of a wide variety of immune mediators. Gram-positive bacteria have cell-wall components that are similar in structure to LPS (e.g. lipoteichoic acid), and can also trigger an inflammatory response through similar pathways (see Fig. 10.20).

**Toxic products of tissue injury (surgery and trauma)**

Following traumatic or surgical tissue injury, inflammatory pathways may be triggered by damage-associated molecular patterns (DAMPs), such as DNA fragments. Of particular importance is circulating mitochondrial DNA (mtDNA), which is similar to bacterial DNA and can be ‘mistaken’ by the immune system for bacteria. This initiates an immune response identical to that observed following bacterial invasion. This is why distributive shock secondary to infection can be difficult to distinguish clinically from that caused by a ‘sterile’ insult such as severe trauma or surgery.

**Cytokines and other immune mediators**

An array of cytokines and chemokines (small proteins that orchestrate immune cell behaviour), prostaglandins, leukotrienes, heat shock proteins, adhesion molecules and endothelial derived vaso-active factors are induced, particularly during distributive shock. These include pro-inflammatory cytokines (tumour necrosis factor-alpha (TNF-α) and interferon-gamma (IFN-γ)), anti-inflammatory cytokines (interleukin 10 (IL-10)), mediators promoting extracellular extravasation (intracellular adhesion molecule 1 (ICAM-1), see Fig. 3.10) and vasodilation (inducible nitric oxide synthase (iNOS), Fig. 10.21). Although there was initial enthusiasm for treatments that dampened the immune response in septic shock (e.g. high-dose steroids and anti-TNF-α compounds), these strategies failed to improve survival and some worsened it (Box 10.8).

**Activation of the complement cascade**

Fragments of C3 act as opsonins and co-stimulatory molecules that assist lymphocytes with the adaptive immune response, while small peptides derived from C3, C4 and C5 cause leucocyte chemotaxis, release of cytokines and increased vascular permeability (see p. 44).

**Influence of genetic variation**

Individuals vary considerably in their susceptibility to infection, as well as their ability to recover from apparently similar infections, illnesses or traumatic insults; this is explained in part by genetic variations.

**Haemodynamic and microcirculatory changes**

The dominant haemodynamic feature of severe sepsis/septic shock is peripheral vascular failure with:

- vasodilation
- maldistribution of regional blood flow
- abnormalities in the microcirculation (Fig. 10.22):
  - ‘stop-flow’ capillaries (flow is intermittent)
  - ‘no-flow’ capillaries (capillaries are obstructed)
  - failure of capillary recruitment
  - increased capillary permeability with interstitial oedema.

Although these **vascular and microvascular abnormalities** may partly account for the reduced oxygen extraction seen in septic shock, there is also a primary defect of cellular oxygen utilization caused by mitochondrial dysfunction (see earlier). These changes may be associated with impaired oxygen consumption, a reduced arteriovenous oxygen content difference, an increased $S\text{PO}_{2}$ and a lactic acidosis (so-called ‘tissue dysoxia’). Similar vasodilation and increased vascular permeability also occur in anaphylactic shock.

The glycocalyx consists of a tight, negatively charged, extremely thin meshwork of proteoglycans on the luminal surface of the vascular endothelium. Oxidative stress, free radicals and endotoxaemia all have specific detrimental effects on the glycocalyx that promote

**Box 10.8 Some therapeutic strategies for sepsis tested in randomized, controlled, phase II/III trials**

- Granulocyte–monocyte colony stimulating factor
- Toll-like receptor/endotoxin antagonists
- Bactericidal permeability-increasing protein

- Soluble TNF receptors
- Interleukin-1 receptor antagonists
- Platelet-activating factor antagonists
- Nitric oxide synthase inhibition
- Antithrombin III
- Activated protein C
- Low-dose steroids
Critical care medicine

fluid movement into the tissues. Hence, ‘pitting’ peripheral oedema is often seen in the most seriously ill patients.

**Activation of the coagulation system**

The immune response to shock, tissue injury and infection is frequently associated with systemic activation of the clotting cascade, leading to platelet aggregation and widespread microvascular thrombosis, resulting in turn in reduced tissue perfusion.

Initially, the production of prostaglandin I₂ (PGI₂) by the capillary endothelium is impaired. Vascular endothelial injury leads to exposure to tissue factor (see p. 368), which triggers coagulation. In severe cases, these changes are compounded by impairment of fibrinolysis, as well as by deficiencies in physiological inhibitors of coagulation (including antithrombin, proteins C and S, and tissue factor-pathway inhibitor). This procoagulant state can lead to end-artery thrombosis and digital and mesenteric ischaemia. Following clot formation, plasminogen is converted to plasmin, which breaks down thrombus, liberating fibrin/fibrinogen degradation products (FDPs). These processes continue in parallel, leading to a ‘consumptive’ coagulopathy known as disseminated intravascular coagulation (DIC). Circulating levels of FDPs and D-dimers are therefore increased, the thrombin time, partial thromboplastin time (PTT) and prothrombin time (PT) are prolonged, and platelet and fibrinogen levels fall. Clinically, the patient will bleed from trivial venepuncture sites but, paradoxically, may still be at risk of thrombosis. The development of DIC is often associated with multiple organ failure. In some cases, a microangiopathic haemolytic anaemia develops. DIC is relatively uncommon but is associated particularly with septic shock, especially when due to meningococcal infection (see p. 545). Management targets the underlying cause, as well as supportive treatment with fresh frozen plasma, platelets and cryoprecipitate when fibrinogen levels are low and the patient is bleeding.

**Clinical features of shock and sepsis**

Although many clinical features are common to all types of shock, the causes may be distinguished by the associated haemodynamic changes (Box 10.9) and by examination.

**Hypovolaemic shock**

- *Inadequate tissue perfusion:*
  - Skin: cold, pale, slate-grey, slow capillary refill, ‘clammy’.
  - Kidneys: oliguria, anuria.
  - Brain: drowsiness, confusion and irritability.

  - *Increased sympathetic tone:*
    - Tachycardia, narrowed pulse pressure, ‘weak’ or ‘thready’ pulse.
    - Sweating.
    - Blood pressure: may be maintained initially (despite up to a 25% reduction in circulating volume if the patient is young and fit) but hypotension later supervenes.

- *Lactic acidosis:* compensatory tachypnoea.
  - Extreme hypovolaemia may be associated with bradycardia.

**Cardiogenic shock**

The signs in cardiogenic shock (see Box 10.28) are the same as those in hypovolaemic shock, with the addition of myocardial failure: for example, raised jugular venous pressure (JVP), pulsus alternans, ‘gallop’ rhythm, basal crackles and pulmonary oedema.

**Obstructive shock**

Again, the signs are as in hypovolaemic shock with the following additions:

- Elevated JVP
- Pulsus paradoxus and muffled heart sounds in cardiac tamponade
- Signs of pulmonary embolism (see p. 1003).

**Distributive shock: anaphylactic shock**

(See p. 65.)

- Signs of profound vasodilatation:
  - Warm peripheries
  - Low blood pressure
  - Tachycardia.
- Erythema, urticaria, angio-oedema, pallor, cyanosis.
- Bronchospasm, rhinitis.
- Oedema of the face, pharynx and larynx.
- Pulmonary oedema.
- Hypovolaemia due to vascular leak.
- Nausea, vomiting, abdominal cramps, diarrhoea.

Ideally, 10 mL of clotted blood should be taken within 45–60 minutes of the reaction for confirmation of the diagnosis by measurement of mast cell degranulation (tryptase levels). Immunology follow-up of these patients is essential.

**Distributive shock: sepsis and septic shock**

*Sepsis and septic shock* are defined on page 154. The Sequential Organ Failure Assessment score (SOFA), used to identify organ dysfunction, is shown in Box 8.2.
Symptoms and signs of sepsis include:
- pyrexia and rigors, or hypothermia (unusual, but more common in the elderly and associated with worse prognosis)
- nausea, vomiting
- vasodilation, warm peripheries
- bounding pulse
- rapid capillary refill
- hypotension, low diastolic pressure, widened pulse pressure
- occasionally, signs of cutaneous vasoconstriction
- other signs
  - jaundice
  - coma, stupor
  - bleeding due to coagulopathy (e.g. from vascular puncture sites, gastrointestinal tract and surgical wounds)
  - rash and meningism
  - hyperglycaemia; in more severe cases, hypoglycaemia.

The diagnosis of sepsis is easily missed, particularly in the elderly. Clues include mild confusion, tachycardia, tachypnoea, unexplained hypotension, a reduction in urine output, a rising plasma creatinine and glucose intolerance.

Sepsis and multiple organ failure (multiple organ dysfunction syndrome)

Sepsis is being diagnosed with increasing frequency and is now the most common cause of death in non-coronary adult ICUs. The estimated incidence of severe sepsis is 77–300 cases per 100,000 of the population. The most common cause is community-acquired pneumonia (Fig. 10.23). Mortality rates are high (between 20% and 60%) and are closely related to the severity of illness and the number of organs that fail. Although some early deaths are caused by cardiovascular collapse, advances in ICU care and supportive therapy have reduced early deaths, and most of those who die are overwhelmed by persistent or recurrent sepsis, with fever, intractable hypotension and failure of several organs.

Sequential failure of vital organs occurs progressively over days or weeks, although the pattern of organ dysfunction is variable. In many cases, the lungs are the first to be affected (acute respiratory distress syndrome, ARDS; see later) in association with cardiovascular instability and deteriorating renal function. Secondary pulmonary infection, complicating ARDS, frequently acts as a further stimulus to the immune response.

Liver dysfunction may develop later. Gastrointestinal failure, with an inability to tolerate enteral feeding and paralytic ileus, is common. Ischaemic colitis, acalculous cholecystitis, pancreatitis and gastrointestinal haemorrhage may also occur. Features of central nervous system dysfunction include impaired consciousness and disorientation, progressing to coma. Characteristically, these patients initially have a hyperdynamic circulation with vasodilatation and a high cardiac output, associated with an increased metabolic rate. Eventually, however, cardiovascular collapse supervenes. It is often possible to support such patients for weeks or months; most die following a decision to withdraw or not to escalate treatment (see p. 236).

Metabolic response to trauma, major surgery and severe infection

This is initiated and controlled by the neuroendocrine system and various cytokines (e.g. IL-6) acting in concert, and is characterized initially by an increase in energy expenditure (‘hypermetabolism’; Box 10.10 and see also p. 1253). Gluconeogenesis is stimulated by increased glucagon and catecholamine levels, while hepatic mobilization of glucose from glycogen is increased. Catecholamines inhibit insulin release and reduce peripheral glucose uptake. Combined with elevated circulating levels of other insulin antagonists such as cortisol, and downregulation of insulin receptors, these changes mean that the majority of patients are hyperglycaemic (‘insulin resistance’). Later, hypoglycaemia may be precipitated by depletion of hepatic glycogen stores and inhibition of gluconeogenesis. Free fatty acid synthesis is also increased, leading to hypertriglyceridaemia.

Protein breakdown is initiated to provide energy from amino acids, and hepatic protein synthesis is preferentially augmented to produce the ‘acute phase reactants’. The amino acid glutamine (which is indispensable in this situation) is mobilized from muscle for use as a metabolic fuel in rapidly dividing cells such as leukocytes and enterocytes. Glutamine is also required for hepatic production of the free radical scavenger glutathione. When severe and prolonged, this catabolic response can lead to considerable weight loss. Protein breakdown is associated with wasting and weakness of skeletal and respiratory muscle, prolonging the need for mechanical ventilation.

![Fig. 10.23 Bilateral pneumococcal pneumonia. Community-acquired pneumonia is the most common cause of sepsis requiring admission to intensive care. (From Hinds CJ, Watson JD. Intensive Care: A Concise Textbook, 3rd edn. Edinburgh: Saunders; 2008. Courtesy of Dr SPG Padley.)](image-url)
ventilation and delaying mobilization. Tissue repair, wound healing and immune function are also compromised.

**Management of shock and sepsis**

Delays in recognizing sepsis and initiating resuscitation and treatments (Fig. 10.24) (particularly antibiotics when infection is the underlying cause) are associated with substantially increased morbidity and mortality.

A patent airway must be maintained and oxygen given, as is standard for any acutely ill patient. Some may require endotracheal intubation and those with impending respiratory arrest will require immediate mechanical ventilation.

The underlying cause of shock should be sought and corrected where possible; for example, haemorrhage should be controlled or infection eradicated. In patients with septic shock, every effort must be made to identify the source of infection and isolate the causative organism. A thorough history, clinical examination and imaging (X-rays, ultrasonography or computed tomography (CT) scanning) should be undertaken. Appropriate samples (blood, urine, sputum, cerebrospinal fluid (CSF), pus drained from

---

**Fig. 10.24** Management of the critically ill, shocked or 'at-risk' patient. CRP, C-reactive protein; CSF, cerebrospinal fluid; CT, computed tomography; CVP, central venous pressure; ECG, electrocardiogram; ECMO, extracorporeal membrane oxygenation; FFP, fresh frozen plasma; Hb, haemoglobin; PCV, packed cell volume; WCC, white cell count.
Transfusion of whole blood has largely been replaced by that of red cell concentrates (see p. 363). The use of leucodepleted blood is considered to be safer in terms of immune-mediated transfusion reactions, disease transmission and immune suppression. Although red cell transfusion can augment oxygen-carrying capacity, and hence global oxygen delivery, transfusion of old stored red blood cells, which become spherical rather than biconcave, and poorly deformable with increased adhesiveness, can compromise microvascular flow. In the case of traumatic or intraoperative haemorrhagic shock, many now favour ‘hypotensive resuscitation’ with blood and blood products until surgical control of the bleeding has been achieved. This partial resuscitation has been shown to reduce the rate of bleeding and allows the surgeon a greater chance of achieving definitive haemostasis. Once the patient is stable, higher haemoglobin and blood pressure targets may be pursued.

The absolute haemoglobin target in critically ill patients has changed with increasing awareness of the subtle detrimental immune effects associated with transfusing blood. In patients not actively bleeding and without significant cardiovascular risk factors, it is usual to transfuse in order to achieve a target haemoglobin level of 70 g/L or more (‘restrictive transfusion strategy’). In patients with significant coronary artery disease or limited respiratory reserve, a target level of 90 g/L (‘liberal transfusion strategy’) may be more appropriate but remains controversial. Previously healthy individuals can tolerate haemoglobin levels as low as 40 g/L before displaying signs of cardiac ischaemia.

**Massive blood transfusion** can be defined as a volume of more than 8–10 units of red cells transfused within a 24-hour period, and **massive haemorrhage** as a loss of 50% or more of blood volume within 3 hours or a rate of blood loss exceeding 150 mL/min.

Complications of blood transfusion are discussed on page 359. Special problems arise as a result of massive transfusion:

- **Temperature changes**. Bank blood is stored at 4°C; transfusion may result in hypothermia, peripheral vasoconstriction and arrhythmias. Blood should be warmed during massive transfusion and in those at risk of hypothermia (e.g. prolonged major surgery with open body cavity).

- **Coagulopathy**. Stored blood has virtually no effective platelets or clotting factors. Massive blood transfusions are now accompanied by administration of fresh frozen plasma and platelet concentrates in a balanced ratio of 1:1:1, especially in the treatment of severe traumatic haemorrhage. Cryoprecipitate also plays a key role in securing haemostasis. Recombinant factor VIIa is rarely indicated in those with uncontrollable bleeding, and prothrombin complex concentrates have the advantage that they do not need to be crossmatched or thawed, but are expensive.

- **Hypocalcaemia**. Citrate is used to stop coagulation in stored blood by binding calcium ions. As a result, during large transfusion, total body ionized calcium levels often drop, causing myocardial depression and exacerbating coagulation defects. This is corrected by administering 10 mL of 10% calcium chloride intravenously.

- **Increased oxygen affinity**. In stored blood, the red cell 2,3-diphosphoglycerate (2,3-DPG) content is reduced, so that the oxyhaemoglobin dissociation curve is shifted to the left. The oxygen affinity of haemoglobin is therefore increased and oxygen unloading is impaired. Red cell levels of 2,3-diphosphoglycerate (2,3-DPG) are substantially restored within 12 hours of transfusion.

**Choice of fluid for volume replacement**

**Blood**

This is conventionally given for haemorrhagic shock as soon as it is available. In extreme emergencies, group-specific crossmatch can be performed in minutes (see p. 358). When available and not contraindicated, blood salvage may be employed for those with severe ongoing bleeding. Unmatched blood is frequently administered in trauma patients presenting *in extremis* to the emergency department.

**Preload and volume replacement**

Optimizing preload is the most efficient way of increasing cardiac output. Volume replacement is obviously essential in hypovolaemic shock but is also required in anaphylactic and septic shock because of vasodilatation, sequestration of blood, and loss of circulating volume because of vascular leak.

In obstructive shock, high filling pressures may be required to maintain an adequate stroke volume. Even in cardiogenic shock, careful volume expansion may, on occasion, lead to a useful increase in cardiac output. On the other hand, patients with severe cardiac failure, in whom ventricular filling pressures are markedly elevated, often benefit from measures to reduce preload (and afterload), such as the administration of vasodilators and diuretics (see later). Adequate perioperative volume replacement also reduces morbidity and mortality in high-risk surgical patients.

The circulating volume must be replaced quickly in order to reduce tissue damage and prevent acute kidney injury. Continuous observation of clinical signs, biochemical variables (acid–base and lactate levels) and stroke volume are vital for management and avoidance of volume overload. Pulmonary and peripheral oedema is more likely in seriously ill patients receiving large-volume fluid resuscitation because of a low colloid osmotic pressure (usually due to a low serum albumin), disruption of the alveolar–capillary membrane, microcirculatory changes and destruction of the endothelial glyocalyx.

Transfusion of whole blood has largely been replaced by that of red cell concentrates (see p. 363). The use of leucodepleted blood is considered to be safer in terms of immune-mediated transfusion reactions, disease transmission and immune suppression. Although red cell transfusion can augment oxygen-carrying capacity, and hence global oxygen delivery, transfusion of old stored red blood cells, which become spherical rather than biconcave, and poorly deformable with increased adhesiveness, can compromise microvascular flow. In the case of traumatic or intraoperative haemorrhagic shock, many now favour ‘hypotensive resuscitation’ with blood and blood products until surgical control of the bleeding has been achieved. This partial resuscitation has been shown to reduce the rate of bleeding and allows the surgeon a greater chance of achieving definitive haemostasis. Once the patient is stable, higher haemoglobin and blood pressure targets may be pursued.

The absolute haemoglobin target in critically ill patients has changed with increasing awareness of the subtle detrimental immune effects associated with transfusing blood. In patients not actively bleeding and without significant cardiovascular risk factors, it is usual to transfuse in order to achieve a target haemoglobin level of 70 g/L or more (‘restrictive transfusion strategy’). In patients with significant coronary artery disease or limited respiratory reserve, a target level of 90 g/L (‘liberal transfusion strategy’) may be more appropriate but remains controversial. Previously healthy individuals can tolerate haemoglobin levels as low as 40 g/L before displaying signs of cardiac ischaemia.

**Massive blood transfusion** can be defined as a volume of more than 8–10 units of red cells transfused within a 24-hour period, and **massive haemorrhage** as a loss of 50% or more of blood volume within 3 hours or a rate of blood loss exceeding 150 mL/min.

Complications of blood transfusion are discussed on page 359. Special problems arise as a result of massive transfusion:

- **Temperature changes**. Bank blood is stored at 4°C; transfusion may result in hypothermia, peripheral vasoconstriction and arrhythmias. Blood should be warmed during massive transfusion and in those at risk of hypothermia (e.g. prolonged major surgery with open body cavity).

- **Coagulopathy**. Stored blood has virtually no effective platelets or clotting factors. Massive blood transfusions are now accompanied by administration of fresh frozen plasma and platelet concentrates in a balanced ratio of 1:1:1, especially in the treatment of severe traumatic haemorrhage. Cryoprecipitate also plays a key role in securing haemostasis. Recombinant factor VIIa is rarely indicated in those with uncontrollable bleeding, and prothrombin complex concentrates have the advantage that they do not need to be crossmatched or thawed, but are expensive.

- **Hypocalcaemia**. Citrate is used to stop coagulation in stored blood by binding calcium ions. As a result, during large transfusion, total body ionized calcium levels often drop, causing myocardial depression and exacerbating coagulation defects. This is corrected by administering 10 mL of 10% calcium chloride intravenously.

- **Increased oxygen affinity**. In stored blood, the red cell 2,3-diphosphoglycerate (2,3-DPG) content is reduced, so that the oxyhaemoglobin dissociation curve is shifted to the left. The oxygen affinity of haemoglobin is therefore increased and oxygen unloading is impaired. Red cell levels of 2,3-diphosphoglycerate (2,3-DPG) are substantially restored within 12 hours of transfusion.

**Choice of fluid for volume replacement**

**Blood**

This is conventionally given for haemorrhagic shock as soon as it is available. In extreme emergencies, group-specific crossmatch can be performed in minutes (see p. 358). When available and not contraindicated, blood salvage may be employed for those with severe ongoing bleeding. Unmatched blood is frequently administered in trauma patients presenting *in extremis* to the emergency department.
Hyperkalaemia. Plasma potassium levels rise progressively as blood is stored. However, hyperkalaemia is rarely a problem, as rewarming of the blood increases red cell metabolism; the sodium pump becomes active and potassium levels fall.

Microembolism. Microaggregates in stored blood may obstruct the pulmonary capillaries. This process is thought by some to contribute to acute lung injury.

Immunity. Blood transfusion has subtle detrimental effects on the host immune system and has been implicated in a greater susceptibility to nosocomial infections and an increase in the risk of cancer recurrence.

Crystalloids and colloids
The choice of intravenous fluid for resuscitation and the relative merits of crystalloids or colloids have long been controversial. Crystalloid solutions are cheap and convenient to use. However, they are not completely free of side-effects, as large volumes of solutions with high chloride content, such as 0.9% saline, can cause a hyperchloremic acidosis and are associated with a greater risk of renal impairment. Balanced solutions, such as compound sodium lactate or Plasma-Lyte 148, may be preferred (see Box 9.10).

In critically ill patients, resuscitation with equivalent volumes of either 0.9% saline or the colloid 4% albumin has been shown to result in similar outcomes.

Polygelatin solutions have an average molecular weight of 35000, which is iso-osmotic with plasma. They are cheap and do not interfere with crossmatching. Clinically significant coagulation defects are unusual and renal function is not significantly impaired. However, because they readily cross the glomerular basement membrane, their half-life in the circulation is only approximately 4 hours and they can promote an osmotic diuresis. These solutions may be useful during the acute phase of resuscitation, especially when volume losses are continuing. Allergic reactions can, however, occur.

Hydroxyethyl starches (HES) are available as numerous preparations with differing half-lives. Elimination of HES occurs primarily via the kidneys following hydrolysis by amylase. HES are stored in the reticuloendothelial system, apparently without causing functional impairment, but skin deposits have been associated with persistent pruritus. HES, especially the higher-molecular-weight fractions, have anticoagulant properties, can increase the risk of acute kidney injury and have been associated with an increased mortality. HES should no longer be used in critically ill patients.

Human albumin solution (HAS) is a natural colloid that has been used for volume replacement in shock and burns, and for the treatment of hypoproteinaemia. HAS is not generally recommended for routine volume replacement because supplies are limited and other cheaper solutions are equally effective. It may have a role in the treatment of hepatorenal syndrome in patients with liver cirrhosis or low albumin.

Myocardial contractility and inotropic agents
Myocardial contractility can be impaired by many factors, such as hypoxaemia and hypocalcaemia, as well as by some drugs (e.g. beta-blockers, antiarrhythmics and sedatives).

Severe metabolic acidosis is conventionally said to depress myocardial contractility and limit the response to vasopressor agents. Attempted correction of acidosis with intravenous sodium bicarbonate, however, generates additional carbon dioxide, which diffuses across cell membranes, producing or exacerbating intracellular acidosis. Other disadvantages of bicarbonate therapy include sodium overload and a left shift of the oxyhaemoglobin dissociation curve. Ionized calcium levels may be reduced and, combined with the fall in intracellular pH, this may impair myocardial performance.

Treatment of lactic acidosis should therefore concentrate on correcting the cause. Bicarbonate should be administered only to correct extreme persistent metabolic acidosis (see p. 201).

If the signs of shock persist, despite adequate volume replacement, and perfusion of vital organs is jeopardized, inotropic/vasopressor agents should be administered to improve cardiac output and blood pressure. Vasopressor therapy may also be required to maintain perfusion in those with life-threatening hypotension, even when volume replacement is incomplete. All inotropes increase myocardial oxygen consumption, particularly if a tachycardia develops, and this can lead to an imbalance between myocardial oxygen supply and demand, with the development or extension of ischaemic areas. Inotropes should therefore be used with especial caution, particularly in cardiogenic shock following myocardial infarction and in known ischaemic heart disease.

Many of the most seriously ill patients become increasingly resistant to the effects of pressor agents, an observation attributed to ‘downregulation’ of adrenergic receptors and nitric oxide-induced ‘vasoplegia’ (see later).

All inotropic agents should be administered via a large central vein and their effects continually monitored (Box 10.11).

Adrenaline (epinephrine)
Adrenaline stimulates both α- and β-adrenergic receptors but β effects predominate at low doses. Heart rate and cardiac index increase, while peripheral resistance is reduced. If there is an associated increase in perfusion pressure, urine output may improve. Adrenaline at higher doses can cause excessive (α-mediated) vasoconstriction with reductions in splanchnic flow, and cardiac output may fall. Prolonged high-dose administration can cause peripheral gangrene and lactic acidosis. The minimum effective dose of adrenaline should therefore be used for as short a time as possible.

Noradrenaline (norepinephrine)
This is predominantly an α-adrenergic agonist. It is particularly useful in patients with hypotension and a low systemic vascular resistance, such as is seen in septic shock. There is a risk of producing excessive vasoconstriction with impaired organ perfusion and increased afterload, particularly if noradrenaline is administered when fluid resuscitation is inadequate, and the circulating volume is reduced.

Dopamine
The haemodynamic effects of dopamine are dose-dependent. At low doses, dopamine is a positive inotrope with vasodilator actions on the renal and splanchnic circulation. Higher doses may be complicated by tachycardia, arrhythmias and vasoconstriction. Dopamine may be used as an alternative to noradrenaline in patients with bradycardia and a low risk of tachyarrhythmia.

Dopexamine
Dopexamine is an analogue of dopamine that activates β2 receptors, as well as DA1 and DA2 receptors. Dopexamine is a weak positive inotrope but a powerful splanchnic vasodilator, reducing afterload and improving blood flow to vital organs, including the kidneys. It has been used as an adjunct to the perioperative management of high-risk surgical patients (see below).

Dobutamine
Dobutamine is closely related to dopamine and has predominantly β1 activity. Dobutamine has no specific effect on the renal vasculature but urine output often increases as cardiac
output and blood pressure improve. It reduces systemic vascular resistance, as well as improving cardiac performance, thereby decreasing afterload and ventricular filling pressures. Dobutamine is therefore useful in patients with cardiogenic shock and cardiac failure.

**Phosphodiesterase inhibitors (e.g. milrinone, enoximone)**

These agents have both inotropic and vasodilator properties. Because the phosphodiesterase type III inhibitors bypass the β-adrenergic receptor they cause less tachycardia and fewer arrhythmias than β agonists. They are useful in patients with receptor ‘downregulation’, those receiving beta-blockers, those being weaned from cardiopulmonary bypass and those with cardiac failure.

**Vasopressin**

Low-dose vasopressin can increase blood pressure and systemic vascular resistance in patients with vasodilatory septic shock and a high cardiac output unresponsive to other vasopressors (‘vasoplegia’). Low-dose vasopressin is sometimes added to conventional vasopressors in patients with septic shock.

**Levosimendan**

Levosimendan is a myofilament calcium sensitizer. Unlike other inotropes, levosimendan does not exert its action through increases in intracellular Ca\(^{2+}\) and, as a result, does not impair diastolic relaxation of the heart. Levosimendan has phosphodiesterase inhibitor actions but these are not thought to be clinically significant. The dose is usually infused over 24 hours but, significantly, a long-acting metabolite of levosimendan has similar calcium-sensitizing actions, maintaining the inotropic effect of levosimendan once an infusion is stopped. Adverse cardiovascular effects of levosimendan include tachycardia and hypotension; as a consequence, the addition of a vasopressor may be required.

**Summary for use of inotropic and vasopressor agents**

A combination of dobutamine and noradrenaline (norepinephrine) is used for the management of patients who are **shocked with a low systemic vascular resistance** (e.g. septic shock).

- Dobutamine is given to achieve optimal cardiac output.
- Noradrenaline, sometimes supplemented by vasopressin, is used for restoration of an adequate blood pressure by reducing vasodilation.

In **vasodilated septic patients** with an adequate cardiac output, noradrenaline can be used alone. There is evidence to suggest that adrenaline (epinephrine) may be equally safe and effective as a dobutamine/noradrenaline combination. Because of its potency, adrenaline is particularly useful in patients with **refractory hypotension**. Phosphodiesterase inhibitors can be used in the management of cardiac failure, especially when associated with pulmonary hypertension, and perioperatively in those undergoing cardiac surgery. Dobutamine is an alternative that is also used in septic patients with fluid overload or myocardial failure. Dopamine is used much less frequently than in the past. The role of levosimendan in the management of shock is less clear due to high cost and lack of mortality benefit, but it may be useful in resistant cardiogenic shock.
Targeting haemodynamics and oxygen transport

Although resuscitation has conventionally aimed at achieving normal haemodynamics, many of the critically ill patients that survive have raised values for cardiac output, $DO_2$ and $VO_2$. However, elevation of $DO_2$ and $VO_2$ to these ‘supranormal’ levels following admission to intensive care produces no benefit and may be harmful. Despite its initial promise, early goal-directed therapy to resuscitate patients in the emergency room, aimed at maintaining a central venous oxygen saturation of more than 70%, does not appear to improve outcome in patients with severe sepsis or septic shock.

High-risk surgical patients

These patients benefit from intensive perioperative monitoring and circulatory support in a critical care area (Box 10.12): in particular, maintenance of oxygenation, adequate circulating volume and blood pressure. Circulating volume replacement and administration of inotropes or vaspressors should be guided by monitoring of stroke volume/cardiac output. The value of the routine use of inotodilators such as dopexamine remains unclear.

Vasodilator therapy

In selected cases, afterload reduction is used to increase stroke volume and decrease myocardial oxygen requirements by reducing the systolic ventricular wall tension. Vasodilation (see p. 1075) also decreases heart size and the diastolic ventricular wall tension, so that coronary blood flow is improved. Vasodilators also improve microcirculatory flow.

Vasodilator therapy can be particularly helpful in patients with cardiac failure in whom the ventricular function curve is flat (see Figs 10.8 and 10.9), so that falls in preload have only a limited effect on stroke volume. This form of treatment, combined in selected cases with inotropic support, is therefore useful in the management of patients with cardiogenic shock and in those with cardiogenic pulmonary oedema or mitral regurgitation.

Nitroglycerine (NTG), at low doses, is predominantly a venodilator, but as the dose is increased it also causes arterial dilatation, thereby decreasing both preload and afterload. Nitrates are particularly useful in the treatment of cardiac failure with pulmonary oedema and are usually given in combination with intravenous furosemide. NTG reduces pulmonary vascular resistance, an effect that can be exploited in patients with a low cardiac output secondary to pulmonary hypertension.

Sodium nitroprusside (SNP) dilates arterioles and venous capacitance vessels as well as the pulmonary vasculature, by donating nitric oxide. SNP therefore reduces the afterload and preload of both ventricles and can improve cardiac output and the myocardial oxygen supply/demand ratio. The effects of SNP are rapid in onset and spontaneously reversible within a few minutes of discontinuing the infusion. Cyanide poisoning is a risk with high-dose, prolonged infusions.

Mechanical support of the myocardium

Intra-aortic balloon counterpulsation (IABCP) is the technique used most widely for mechanical support of the failing myocardium. It is discussed on page 1050. In specialized centres, ventricular assist devices and veno-arterial ECMO (see below) may be used in the treatment of cardiac failure.

RESPIRATORY FAILURE

(See also Chapter 28.)

Classification and aetiology

The respiratory system consists of a gas-exchanging organ (the lungs) and a ventilatory pump (respiratory muscles/thorax), either or both of which can fail and precipitate respiratory failure. Respiratory failure occurs when pulmonary gas exchange is sufficiently impaired to cause hypoxaemia with or without hypercarbia. In practical terms, respiratory failure is present when the $P_{a}O_2$ is below 8kPa (60mmHg) or the $P_{a}CO_2$ is above 7kPa (55mmHg). It can be divided into:

- type I respiratory failure, in which the $P_{a}O_2$ is low and the $P_{a}CO_2$ is normal or low
- type II respiratory failure, in which the $P_{a}O_2$ is low and the $P_{a}CO_2$ is high.

Type I or ‘acute hypoxaemic’ respiratory failure occurs with diseases that damage lung tissue. Hypoxaemia is due to right-to-left shunts or V/Q mismatch. Common causes include pneumonia, acute lung injury, cardiogenic pulmonary oedema, pulmonary embolism and lung fibrosis.

Type II or ‘ventilatory failure’ occurs when alveolar ventilation is insufficient to remove the volume of carbon dioxide being produced.
by tissue metabolism. Inadequate alveolar ventilation may be due to reduced ventilatory effort, inability to overcome an increased resistance to ventilation, failure to compensate for an increase in dead space and/or carbon dioxide production, or a combination of these factors. The most common cause is COPD. Other causes include chest-wall deformities, respiratory muscle weakness (e.g. Guillain–Barré syndrome) and depression of the respiratory centre (e.g. drug overdose).

Deterioration in the mechanical properties of the lungs and/or chest wall increases the work of breathing and the oxygen consumption/carbon dioxide production of the respiratory muscles. Respiratory muscle fatigue is a factor in the pathogenesis of respiratory failure.

Clinical features
A clinical assessment of respiratory distress should be made on the following criteria:
- the use of accessory muscles of respiration
- intercostal recession
- tachypnoea
- tachycardia
- sweating
- pulsus paradoxus (rarely present)
- inability to speak, unwillingness to lie flat
- agitation, restlessness, diminished conscious level
- asynchronous respiration (a discrepancy in the timing of movement of the abdominal and thoracic compartments)
- paradoxical respiration (abdominal and thoracic compartments move in opposite directions)
- respiratory alternans (breath-to-breath alteration in the relative contribution of the intercostal/accessory muscles and the diaphragm).

Investigations
Blood gas analysis should be performed to guide oxygen therapy and to provide an objective assessment of the severity of the respiratory failure. The most sensitive clinical indicator of increasing respiratory difficulty is a rising respiratory rate. Vital capacity is a better guide to deterioration, particularly in patients with respiratory inadequacy due to neuromuscular problems such as the Guillain–Barré syndrome or myasthenia gravis, in which the vital capacity decreases as weakness worsens. Measurement of forced expiratory volume in 1 second (FEV1) is useful in the assessment of patients suffering from acute asthma or COPD.

Monitoring
Pulse oximetry
Pulse oximeters applied to a finger or earlobe measure the changing amount of light transmitted through the pulsating arterial blood and provide a continuous, non-invasive measurement of arterial oxygen saturation (S\textsubscript{a}O\textsubscript{2}). These devices are reliable and easy to use, and do not require calibration.

Pulse oximetry is not a sensitive guide to changes in oxygenation. An S\textsubscript{a}O\textsubscript{2} within normal limits in a patient receiving supplemental oxygen does not exclude the possibility of hypventilation with carbon dioxide retention. Readings can be inaccurate in those with poor peripheral perfusion.

Blood gas analysis
Normal values of blood gas analysis are shown in Box 10.6. Disposable pre-heparinized syringes are available for blood gas analysis.
- The sample should be analysed immediately. Alternatively, the syringe should be immersed in iced water to prevent the continuing metabolism of white cells from causing a reduction in PO\textsubscript{2} and a rise in PCO\textsubscript{2}.
- Air almost inevitably enters the sample and air bubbles should be ejected immediately. The gas tensions within these air bubbles will equilibrate with those in the blood, thereby lowering the PCO\textsubscript{2} and usually raising the PO\textsubscript{2} of the sample.

Interpretation of the results of blood gas analysis can be considered in two separate parts:
- disturbances of acid–base balance (see p. 214)
- alterations in oxygenation.

Correct interpretation requires a knowledge of the patient’s clinical history and age, the inspired oxygen concentration, patient temperature and any other relevant treatment (e.g. the ventilator settings for those on mechanical ventilation or the administration of sodium bicarbonate). The oxygen content of the arterial blood is determined by the percentage saturation of haemoglobin with oxygen. The relationship between the latter and the PO\textsubscript{2} is determined by the oxyhaemoglobin dissociation curve (see Fig. 10.3).

\[ P_{\text{a}}O_2/F_{\text{IO}_2} \]

This calculated variable is a simple approximation to the \( P_{\text{a}}O_2 \) and can be used to assess the severity of respiratory failure, particularly in patients with ARDS (see p. 232). It is calculated by taking the arterial PO\textsubscript{2} in mmHg and dividing by the \( F_{\text{IO}_2} \) expressed as a fraction of 1.

Capnography
Continuous breath-by-breath analysis of the expired carbon dioxide concentration can be used to:
- confirm tracheal intubation
- continuously monitor end-tidal PCO\textsubscript{2}, which approximates to \( P_{\text{a}}CO_2 \) in normal subjects, and is used to assess effectiveness of ventilation
- detect acute airway problems, e.g. blocked or dislodged tracheal tube/tracheostomy, in all mechanically ventilated patients (essential when transporting the critically ill)
- detect acute alterations in cardiorespiratory function (e.g. a sudden fall in cardiac output).

Management
Standard management of patients with respiratory failure includes:
- administration of supplemental oxygen through a patent airway
- treatment for distal airways obstruction
- measures to limit pulmonary oedema
- control of secretions
- treatment of pulmonary infection.

The load on the respiratory muscles should be reduced by improving lung mechanics. Correction of abnormalities that may lead to respiratory muscle weakness, such as hypophosphataemia and malnutrition, is also necessary.

Oxygen therapy
Methods of oxygen administration
Oxygen is initially given via a face mask. In the majority of patients (except those with COPD with chronically elevated \( P_{\text{a}}CO_2 \)), the precise concentration of oxygen given is not vital and oxygen can therefore be delivered by a ‘variable performance’ device such as a simple face mask or nasal cannula (Fig. 10.25).

With these devices, the inspired oxygen concentration varies from about 35% to 55%, with oxygen flow rates of 6–10 L/min. Nasal cannulae are often preferred because they are less claustrophobic and do not interfere with feeding or speaking, but can cause ulceration of...
the nasal mucosa and the inspired oxygen concentration is diluted by mouth breathing. Higher concentrations of oxygen can be administered by using a mask with a reservoir bag attached (Fig. 10.25C). Fig. 10.25 should be compared with the fixed-performance mask shown in Fig. 10.26. The latter allows the oxygen concentration to be controlled and is used in patients with COPD and chronic type II failure who rely on their hypoxic drive to stimulate respiration. The hazards of reducing hypoxic drive can at times be overemphasized and are less dangerous when the patient is in a critical care unit. Remember, severe hypoxaemia is more dangerous than hypercapnia.
Oxygen toxicity

Hyperoxia can cause pulmonary damage due to increased oxygen free radicals and oxidative damage to the lung tissue. Although dangerous hypoxia through fear of pulmonary oxygen toxicity should never be tolerated, oxygen saturations between 90% and 92% are probably adequate for most patients and there is some suggestion that targeting higher oxygen saturations using greater concentrations of inspired oxygen may be detrimental (e.g. post myocardial infarction). Recent evidence suggests that even a brief period of hyperoxia may increase mortality compared with normoxia, even hyperoxia following emergency intubations for any cause in the emergency department.

Respiratory support

If, despite the above measures, the patient continues to deteriorate or fails to improve, the institution of some form of respiratory support is necessary (Box 10.13). Non-invasive ventilation via a mask or hood (see p. 230) can be used, but in many critically ill patients invasive ventilation through an endotracheal tube or tracheostomy is required.

Invasive mechanical ventilation (IMV) is achieved by intermittently inflating the lungs with positive pressure delivered by a mechanical ventilator through an endotracheal or tracheostomy tube, commonly carried out in the absence of spontaneous breaths. This is called intermittent positive pressure ventilation (IPPV) or controlled mechanical ventilation (CMV). However, technological development has meant that it is now more commonly carried out by augmenting the patient's own spontaneous breaths (see p. 229). This has the advantage of maintaining the patient's own respiratory muscle activity and function, thereby avoiding muscle atrophy.

Indications for mechanical ventilation

Acute respiratory failure, with signs of severe respiratory distress (e.g. respiratory rate >40 breaths/min, inability to speak, patient exhaustion) persisting despite maximal therapy, requires mechanical ventilation. Confusion, restlessness, agitation, a decreased conscious level, a rising $P_aCO_2$ (>8 kPa, >60 mmHg) and extreme hypoxaemia (<8 kPa, <60 mmHg), despite oxygen therapy, are further indications.

In acute ventilatory failure due, for example, to myasthenia gravis, Guillain–Barré syndrome or high spinal cord injuries, mechanical ventilation should usually be instituted when the vital capacity has fallen to 10 mL/kg or less. This will avoid complications such as atelectasis and infection, as well as preventing respiratory arrest. The tidal volume and respiratory rate are relatively insensitive indicators of respiratory failure in these conditions and change late in the course of the disease. A high $P_aCO_2$ (particularly if rising) is an indication for urgent mechanical ventilation.

Not all patients with respiratory failure and/or a reduced vital capacity require ventilation; clinical assessment of each individual case is essential. The patient's general condition, degree of exhaustion, level of consciousness and ability to protect the airway are often more useful than blood gas values.

Other indications include:

- postoperative ventilation in high-risk patients
- head injury: to avoid hypoxia and hypercarbia, which increase cerebral blood flow and intracranial pressure (see later)
- trauma: chest injury with lung contusions and high spinal cord injuries
- severe left ventricular failure with pulmonary oedema
- coma with airway compromise or breathing difficulties, e.g. following drug overdose.

Institution of invasive respiratory support

This requires tracheal intubation, which should be performed under anaesthesia only by experienced staff. If the patient is conscious, the procedure should be fully explained and consent obtained. The complications of tracheal intubation are given in Box 10.14.

Intubating a critically ill patient is very different to intubating a patient in the operating theatre for elective surgery. The patient is usually hypoxic and hypercarbic, with increased sympathetic activity; the stimulus of laryngoscopy and intubation can precipitate dangerous arrhythmias, bradycardia and even cardiac arrest. In extreme emergencies, it may be necessary to ventilate the patient by hand using a bag-valve mask (supplemented with high-flow oxygen) and an oropharyngeal airway or a laryngeal mask airway, until experienced help arrives.

The ECG and oxygen saturation should be monitored, and the patient pre-oxygened with 100% oxygen before intubation. Resuscitation drugs should be immediately available. If time allows, the circulating volume should be optimized and, if necessary, inotropes commenced before intubation is attempted. In some cases, it is appropriate to establish intra-arterial and CVP monitoring before instituting mechanical ventilation, although many patients will not tolerate the supine or head-down position. In some deeply comatose patients no sedation may be required, but in the majority a short-acting intravenous anaesthetic agent, usually with an opiate followed by muscle relaxation, will be necessary. Capnography must be used to confirm tracheal intubation.

Sedation, analgesia and muscle relaxation

Most critically ill patients require analgesia and many will receive sedatives. The combination of an opiate with a benzodiazepine or propofol is often used to facilitate mechanical ventilation. Heavy

sedation is indicated in those with severe respiratory failure, especially since ‘lung-protective’ ventilatory strategies (see later) are inherently uncomfortable. A few may require neuromuscular blockade. It is recognized, however, that minimizing sedation levels using ‘sedation scores’ and ‘daily wakening’, or even the avoidance of sedatives altogether, often in combination with spontaneous breathing modes of respiratory support (see later), is associated with reductions in the duration of mechanical ventilation and more rapid discharge from the ICU and hospital.

**Tracheostomy**

Tracheostomy may be required for long-term control of the airway in some patients with persistent reduced conscious state, to manage excessive bronchial secretions, facilitate respiratory weaning, reduce sedation requirements and improve patient comfort.

Tracheostomy is now performed most commonly on the ICU by the intensivist, adopting a percutaneous dilatational approach. This approach is quicker, less resource-intensive, safe and associated with a greatly reduced wound infection rate than surgical tracheostomy performed in the operating theatre. Surgical tracheostomy is reserved for when anatomical factors preclude a percutaneous approach or when there are concerns regarding abnormal coagulation that may require surgical haemostasis.

A life-threatening obstruction of the upper respiratory tract that cannot be bypassed with an endotracheal tube can be relieved by a **cricothyroidotomy**, which is safer, quicker and easier to perform than a formal tracheostomy.

Tracheostomy has a small but significant mortality rate. Complications associated with the technique are shown in **Box 10.15**.

**Complications associated with mechanical ventilation**

**Airway complications**

See **Boxes 10.14** and **10.15**.

**Disconnection, failure of gas or power supply, and mechanical faults**

These are unusual but dangerous. A method of manual ventilation, a face mask and oxygen must always be available by the bedside.

**Cardiovascular complications**

The application of positive pressure to the lungs impedes venous return and distends alveoli, thereby ‘stretching’ the pulmonary capillaries and causing a rise in pulmonary vascular resistance. Both of these mechanisms can produce a fall in cardiac output.

**Respiratory complications**

Mechanical ventilation can be complicated by a deterioration in gas exchange because of V/Q mismatch, fluid retention and collapse of peripheral alveoli. Traditionally, the latter was prevented by using high tidal volumes (10–12 mL/kg) but high inflation pressures, with over-distension of compliant alveoli, perhaps exacerbated by the repeated opening and closure of distal airways, can disrupt the alveolar–capillary membrane. There is an increase in microvascular permeability and release of inflammatory mediators, leading to ‘ventilator-associated lung injury’. This ‘barotrauma’ and ‘volutrauma’ can result in rupture of the alveoli and may be complicated by pneumomediastinum, subcutaneous emphysema, pneumothorax and intra-abdominal air. The risk of pneumothorax is increased in those with destructive lung disease (e.g. necrotizing pneumonia, emphysema), asthma or fractured ribs.

A **tension pneumothorax** can be rapidly fatal in ventilated patients. Signs include the development or worsening of hypoxia, hypercarbia, respiratory distress and an unexplained increase in airway pressure, as well as hypotension and tachycardia, sometimes accompanied by a rising CVP. Examination may reveal unequal chest expansion, mediastinal shift away from the side of the pneumothorax (deviated trachea, displaced apex beat) and a hyperresonant hemithorax. Although breath sounds are often diminished over the pneumothorax, this sign can be misleading in ventilated patients. If there is time, the diagnosis can be confirmed by chest X-ray. In a rapidly deteriorating patient with a high index of suspicion for a tension pneumothorax, a needle decompression into the second intercostal space in the mid-clavicular line may be indicated, followed by insertion of a definitive chest drain.

**Ventilator-associated pneumonia**

Hospital-acquired pneumonia occurs in as many as one-third of patients receiving mechanical ventilation and is associated with a significant increase in length of stay and mortality. The diagnosis can be controversial, as pyrexia and infiltrates on the chest X-ray that may not be infective in origin are common. Organisms commonly isolated are aerobic Gram-negative bacilli (e.g. *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, *Escherichia coli*, *Acinetobacter* spp.) and *Staphylococcus aureus*, including meticillin-resistant...
Box 10.15 Complications of tracheostomy

The complications for tracheal intubation shown in Box 10.14 plus:

**Early**
- Death
- Pneumothorax
- Haemorrhage
- Hypoxia
- Hypotension
- Cardiac arrhythmias
- Tube misplaced in pretracheal subcutaneous tissues
- Subcutaneous emphysema

**Intermediate**
- Mucosal ulceration
- Erosion of tracheal cartilages (can cause tracheo-oesophageal fistula)
- Erosion of innominate artery (occasionally leads to fatal haemorrhage)
- Stomal infection
- Pneumonia

**Late**
- Failure of stoma to heal
- Tracheal granuloma
- Tracheal stenosis at level of stoma, cuff or tube tip
- Collapse of tracheal rings at level of stoma
- Cosmetic factors

Staphylococcus aureus (MRSA). Deciding whether an organism that has been isolated is causing ventilator-associated pneumonia or is simply colonizing the respiratory tract can also be difficult. Leakage of infected oropharyngeal secretions past the tracheal tube cuff is thought to be largely responsible for ventilator-associated pneumonia and many ICUs now utilize endotracheal tubes with modern tube cuffs and subglottic aspiration ports to minimize the risk. Bacterial colonization of the oropharynx may be promoted by regurgitation of colonized gastric fluid and so the risk of ventilator-associated pneumonia can be reduced by nursing patients in the semi-recumbent position and by oropharyngeal decontamination. Treatment is with an appropriate broad-spectrum antibiotic, which can be modified if a causative organism is isolated.

Techniques for respiratory support

(See Box 10.13.)

**Controlled mechanical ventilation**

Controlled mechanical ventilation (CMV) is used when respiratory efforts are absent or have been abolished. It involves one of two types:

- **Volume-controlled ventilation.** The tidal volume and respiratory rate are preset on the ventilator. The airway pressure varies according to both the ventilator setting and the patient’s lung mechanics (airways resistance and compliance).

- **Pressure-controlled ventilation.** Both the inspiratory pressure and the respiratory rate are preset but the tidal volume varies according to the patient’s lung mechanics.

**Positive end-expiratory pressure**

A positive airway pressure can be maintained at a chosen level throughout expiration using a threshold resistor valve in the expiratory limb of the circuit. Positive end-expiratory pressure (PEEP) re-expands under-ventilated lung units, and redistributes lung water from the alveoli to the perivascular interstitial space, thereby reducing shunt and increasing PaO₂. The inevitable rise in mean intrathoracic pressure associated with the application of PEEP may, however, further impede venous return, increase pulmonary vascular resistance and reduce cardiac output. The fall in cardiac output can be ameliorated by expanding the circulating volume, although inotropic or vasopressor support is required in some cases. Thus, although arterial oxygenation is often improved by the application of PEEP, a simultaneous fall in cardiac output can lead to a reduction in total oxygen delivery.

Low levels of PEEP (5–8cmH₂O) are used in the majority of mechanically ventilated patients in order to maintain lung volume, as well as in those with basal atelectasis and in selected cases with airways obstruction.

**Continuous positive airway pressure**

The application of continuous positive airway pressure (CPAP) achieves for the spontaneously breathing patient what PEEP does for the ventilated patient. Oxygen and air are delivered under pressure via an endotracheal tube, a tracheostomy, a tightly fitting face mask or a hood (Fig. 10.27). Not only can CPAP improve oxygenation, but also the lungs become more compliant and the work of breathing is reduced.

An alternative is to use a very high flow of oxygen and air delivered via large-diameter nasal prongs to create a modest amount of CPAP. This high-flow nasal oxygen (HFNO) system is often better tolerated, as the patient is able to cough, expectorate, communicate and eat. Commencing therapy with HFNO in patients with type I respiratory failure may be equivalent to, and in some circumstances more effective than, non-invasive ventilation in preventing patient deterioration and avoiding subsequent invasive ventilation.

**Pressure support ventilation**

In pressure support ventilation (PSV), spontaneous breaths are augmented by a preset level of positive pressure (usually between 5 and 20cmH₂O), triggered by the patient’s spontaneous respiratory effort and applied for a given fraction of inspiratory time or until inspiratory flow falls below a certain level. Tidal volume is determined by the set pressure, the patient’s effort and pulmonary mechanics. The level of pressure support can be reduced progressively as the patient improves.
Intermittent mandatory ventilation

The intermittent mandatory ventilation (IMV) technique allows the patient to breathe spontaneously between the ‘mandatory’ tidal volumes delivered by the ventilator. These mandatory breaths are timed to coincide with the patient’s own inspiratory effort (synchronized intermittent mandatory ventilation, or SIMV). SIMV can be used with or without CPAP, and spontaneous breaths may be assisted with pressure support ventilation.

‘Lung-protective’ ventilation

This is an ideal method of mechanical ventilation that avoids overdistension of alveoli, as well as repeated energetic opening and closing of distal airway and alveoli. Alveolar volume is maintained with PEEP, and sometimes by prolonging the inspiratory phase, while tidal volumes are limited to 4–8 mL/kg ideal body weight (ideally, 6 mL/kg). Plateau pressures ($P_{\text{plat}}$) should not exceed 30 cmH$_2$O. Respiratory rate can be increased to improve CO$_2$ removal and avoid severe acidosis (pH >7.2), but permissive hypercapnia is common and acceptable. Ventilation with low tidal volumes has been shown to improve outcome in patients with ARDS (see later). Lung-protective ventilation should be used in almost all patients undergoing mechanical ventilation.

High-frequency oscillation

High-frequency oscillation (HFO) is administered using a purpose-designed ventilator. With HFO, there is no bulk flow of gas; rather, gas oscillates to and fro at rates of 4–15 Hz in a CPAP circuit set at a high mean airway pressure (often 20–30 cmH$_2$O). The mechanism of gas exchange is not fully understood but lung volume is well maintained and oxygenation may be improved. Recent evidence has shown, however, that HFO does not offer any mortality benefit in adults, and one trial suggested increased mortality.

Extracorporeal gas exchange

In patients with severe refractory respiratory failure, pumped, high-flow, veno-venous blood flow through an artificial lung is used in specialized centres to achieve adequate oxygenation and CO$_2$ removal (extracorporeal membrane oxygenation, ECMO; Fig. 10.28). Extracorporeal carbon dioxide removal (ECCO$_2$-R) is more easily administered, and uses lower blood flow rates to provide effective CO$_2$ removal but less efficient oxygenation. Both techniques have been used to reduce ventilation requirements, thereby minimizing further ventilation-induced lung damage and encouraging resolution of the lung injury.

Non-invasive ventilation

Non-invasive ventilation (NIV) is suitable for patients who are conscious, cooperative and able to protect their airway; they must also be able to expectorate effectively. Positive pressure is applied to the airways using a tight-fitting full-face/nasal mask or a hood. Modern ventilators are cheap, easy to use and flexible. They deliver bi-level positive airway pressure (BiPAP) with inspiratory (IPAP) and expiratory (EPAP) pressure levels, and times are set independently. Unrestricted spontaneous respiration is possible throughout the respiratory cycle. BiPAP can also be patient-triggered. There is a reduced risk of ventilator-associated pneumonia and improved patient comfort, with preservation of airway defence mechanisms, speech and swallowing (which allows better nutrition). Spontaneous coughing and expectoration are not hampered, permitting effective physiotherapy, and sedation is usually unnecessary. Institution of non-invasive respiratory support can rest the respiratory muscles, reduce respiratory acidosis and breathlessness, improve clearance of secretions and re-expand collapsed lung segments. The intubation rate, length of ICU and hospital stay, and, in some categories of patient, mortality may all be reduced. NIV is particularly useful in acute hypercapnic respiratory failure associated with COPD.
provided the patient is not profoundly hypoxic or obtunded. NIV is also valuable in immunocompromised patients with acute respiratory failure, and following extubation of hypercapnic patients with respiratory disorders to reduce the risk of subsequent respiratory failure and mortality. Box 10.16 lists some indications and contraindications for the use of NIV when standard medical treatment has failed.

Weaning

Weakness and wasting of respiratory muscles are inevitable consequences of the catabolic response to critical illness and the disuse atrophy that will occur as a result of mechanical ventilation. Often, abnormalities of gas exchange and lung mechanics persist. Not surprisingly, therefore, many patients experience difficulty in resuming unsupported spontaneous ventilation.

Neuromuscular weakness complicating critical illness

Polynuromyopathies have most often been described in association with persistent sepsis and multiple organ failure. Critical illness polyneuropathy is characterized by a primary axonal neuropathy involving both motor and, to a lesser extent, sensory nerves. Clinically, the initial manifestation is often difficulty in weaning the patient from respiratory support. There is muscle wasting, the limbs are weak and flaccid, and deep tendon reflexes are reduced or absent. Cranial nerves are relatively spared. Nerve conduction studies confirm axonal damage. The CSF protein concentration is normal or minimally elevated. These findings differentiate critical illness neuropathy from Guillain–Barre syndrome, in which nerve conduction studies nearly always provide evidence of demyelination and CSF protein is usually high.

The cause of critical illness polyneuropathy is not known and there is no specific treatment. Weaning from respiratory support and rehabilitation are likely to be prolonged. With resolution of the underlying critical illness, recovery can be expected after 1–6 months but weakness and fatigue frequently persist.

Critical illness myopathies can also occur, often in association with a neuropathy. A severe quadriplegic myopathy has been associated in particular with the administration of steroids and muscle relaxants to mechanically ventilated patients who have acute, severe asthma.

Criteria for weaning patients from mechanical ventilation

Clinical assessment is the best way of deciding whether a patient can be weaned from the ventilator. A key part of the assessment is deciding whether the precipitating need for mechanical ventilation is no longer present or has vastly improved, to allow a trial without ventilation. The patient’s conscious level and cardiovascular performance, as well as the effects of drugs, must all be taken into account. A subjective evaluation by an experienced clinician of the patient’s response to a short period of spontaneous breathing (spontaneous breathing trial) is the most reliable predictor of weaning success or failure. Objective criteria are based on an assessment of pulmonary gas exchange (blood gas analysis), lung mechanics and muscular strength.

Techniques for weaning

Patients who have received mechanical ventilation for less than 24–48 hours – after elective major surgery, for example – can usually resume spontaneous respiration immediately and no weaning process is required. This procedure can also be adopted for those who have been ventilated for longer periods but who tolerate a spontaneous breathing trial and clearly fulfil objective criteria for weaning.

Techniques of weaning include the following:

- The traditional method is to allow the patient to breathe entirely spontaneously for a short time, following which respiratory support is resumed. These periods of spontaneous breathing are gradually increased and the periods of respiratory support are progressively reduced. Initially, it is usually advisable to ventilate the patient throughout the night. This method can be stressful and tiring for both patients and staff, although it is sometimes successful when other methods have failed.
- SIMV (see earlier) involves a progressive reduction in the frequency of mandatory breaths. Spontaneous breaths are usually pressure-supported.
- Gradual reduction of the level of pressure support is thought to be the preferred technique.
- CPAP (see above) can prevent the alveolar collapse, hypoxaemia and fall in compliance that might otherwise occur when patients start to breathe spontaneously. It is therefore used during weaning with SIMV or pressure support, during spontaneous breathing trials and in spontaneously breathing patients prior to extubation.
- Tracheostomy is often used to facilitate weaning from mechanical ventilation.
- Non-invasive respiratory support (BiPAP, CPAP) can be used following extubation to prevent respiratory failure and re-intubation.

Extubation and tracheostomy decannulation

These should not be performed until patients can cough, swallow and protect their own airway, and are sufficiently alert to be cooperative. Patients who fulfil these criteria can be extubated, provided their respiratory function has improved sufficiently to sustain spontaneous ventilation indefinitely. Similar considerations guide the elective removal of tracheostomy tubes.

The ‘rapid shallow breathing index’ – the ratio of respiratory rate (in breaths/minute) to tidal volume (in litres) – can be used to predict successful extubation, provided all other preconditions have also been met. A score of less than 100 is a relatively good predictor of extubation success and represents a patient who breathes slowly and comfortably with adequate tidal volumes.

| Box 10.16 Indications for/contraindications to use of non-invasive ventilation |
|-------------------------------|----------------------------------|
| **Some indications**          | **Some contraindications**       |

ACUTE RESPIRATORY DISTRESS SYNDROME

Definition and aetiology

The acute respiratory distress syndrome (ARDS, Box 10.17) can be defined as follows:

- Respiratory distress.
- Stiff lungs: reduced pulmonary compliance resulting in high inflation pressures.
- Chest X-ray: new bilateral, diffuse, patchy or homogeneous pulmonary infiltrates.
- Non-cardiac origin: no apparent cardiogenic cause of pulmonary oedema (pulmonary artery occlusion pressure <18 mmHg, or normal echocardiogram and cardiac indices).
- Gas exchange abnormalities, all with a PEEP ≥5 cmH₂O (Berlin definition):
  - mild: : PₐO₂/FₐO₂ ratio 300–200 mmHg (40.26.6 kPa)
  - moderate: PₐO₂/FₐO₂ 200–100 mmHg (26.6–13.3 kPa)
  - severe: PₐO₂/FₐO₂ ratio <100 mmHg (<13.3 kPa).

ARDS can occur as a non-specific reaction of the lungs to a wide variety of direct pulmonary and indirect non-pulmonary insults. Approximately 10% of admissions to critical care fit the Berlin definition for ARDS, and the classifications above predict mortality which ranges from 27% in mild, 32% in moderate and 45% in severe ARDS. By far the most common predisposing factor is sepsis, and 20–40% of patients with severe sepsis will develop ARDS (see Box 10.17).

Pathogenesis and pathophysiology

ARDS can be viewed as an early manifestation of a generalized inflammatory response with endothelial dysfunction and therefore is frequently associated with the development of multiple organ dysfunction syndrome (MODS, see p. 219).

Non-cardiogenic pulmonary oedema

This is the cardinal feature of ARDS and is the first and clinically most evident sign of a generalized increase in vascular permeability, caused by the microcirculatory changes and release of immune mediators described earlier, with activated neutrophils playing a key role. The pulmonary epithelium is also damaged in the early stages, reducing surfactant production and predisposing to alveolar collapse.

Pulmonary hypertension

Pulmonary hypertension, sometimes complicated by right ventricular failure (see p. 1115), is a common feature of ARDS. Initially, mechanical obstruction of the pulmonary circulation may occur as a result of vascular compression by interstitial oedema, while local activation of the coagulation cascade leads to thrombosis and obstruction in the pulmonary microvasculature. Later, pulmonary vasoconstriction may develop in response to increased autonomic nervous activity and circulating substances such as catecholamines and thromboxane. Those vessels supplying alveoli with low oxygen tensions constrict (the ‘pulmonary hypoxic vasoconstrictor response’), diverting pulmonary blood flow to better-oxygenated areas of lung and thus limiting the degree of shunt.

Haemorrhagic intra-alveolar exudate

This exudate is rich in platelets, fibrin, fibrinogen and clotting factors, and may inactivate surfactant and stimulate inflammation, as well as promoting hyaline membrane formation and the migration of fibroblasts into the air spaces.

Resolution, fibrosis and repair

Within days of the onset of lung injury, formation of a new epithelial lining is under way and activated fibroblasts accumulate in the interstitial spaces. In some cases, there is progressive interstitial fibrosis. In those who recover the lungs are substantially remodelled.

Physiological changes

Shunt and dead space increase, compliance falls and there is evidence of airflow limitation. Although the lungs in ARDS are diffusely injured, the pulmonary lesions, when identified as densities on a CT scan, are predominantly located in dependent regions (Fig. 10.29). This is partly explained by the effects of gravity on the distribution of extravascular lung water and areas of lung collapse. Pleural effusions are common.

Clinical features

The first sign of the development of ARDS is often an unexplained tachypnoea, followed by increasing hypoxaemia and breathlessness. Fine crackles are heard throughout both lung fields. Later, the chest X-ray shows bilateral diffuse shadowing, interstitial at first, but subsequently with an alveolar pattern and air bronchograms (Fig. 10.30). The differential diagnosis includes cardiac failure and lung fibrosis.
overload by haemofiltration. The aim should be to achieve a consistently negative fluid balance.

**Prone position**

When the patient is changed from the supine to the prone position, lung densities in the dependent region are redistributed and shunt fraction is reduced. More uniform alveolar ventilation, caudal movement of the diaphragm, redistribution of perfusion and recruitment of collapsed alveoli all contribute to the improvement in gas exchange. Recent findings suggest that proning early in the course of the disease process and spending longer periods prone than supine are associated with substantial mortality benefits.

**Inhaled nitric oxide**

This vasodilator, when inhaled, may improve ventilation-perfusion matching by increasing perfusion of ventilated lung units, as well as reducing pulmonary hypertension. It has been shown to improve oxygenation in so-called ‘responders’ with ARDS but has not been shown to enhance survival.

**Aerosolized prostacyclin**

This appears to have similar effects to inhaled nitric oxide and is easier to deliver. As with inhaled nitric oxide, the response to aerosolized prostacyclin is variable: although it improves oxygenation, its effect on outcome is unclear.

**Steroids**

Administration of steroids to patients with persistent ARDS may improve lung function but does not appear to improve outcome. Their use remains controversial.

**Prognosis**

Mortality from ARDS has fallen over the last two decades, from around 60% to 20–40%, perhaps as a consequence of improved general care, lung-protective ventilation strategies, the increasing use of management protocols, and attention to infection control and nutrition. Prognosis is, however, still very dependent on aetiology. When ARDS occurs in association with intra-abdominal sepsis, mortality rates remain very high, whereas much lower mortality is to be expected in those with ‘primary’ ARDS (pneumonia, aspiration, lung contusion). Mortality rises with increasing age and failure of other organs. Most of those dying with ARDS do so as a result of MODS and haemodynamic instability rather than impaired gas exchange.

ACUTE KIDNEY INJURY

Acute kidney injury (AKI) is a common and serious complication of critical illness, and is strongly associated with increased morbidity and mortality. The presence and severity of AKI are now formally classified by relative increases in serum creatinine and/or a persistent reduction in urine output (see Box 36.30).

The importance of preventing renal injury with rapid and effective resuscitation, the avoidance of nephrotoxic drugs (especially non-steroidal anti-inflammatory drugs, NSAIDs), and control of infection cannot be overemphasized. While shock and sepsis are the most common causes of AKI in the critically ill, causes requiring specific treatment should be excluded, especially urinary tract obstruction and acute intrinsic renal disease such as rapidly progressive glomerulonephritis (see p. 1360).

Acutely, oliguria often accompanies shock and renal hypoperfusion, and should prompt attempts to optimize cardiovascular function by expanding the circulating volume and restoring blood pressure; restoration of urine output is a good indicator of successful resuscitation. However, when AKI is established, urine output is often normal or high due to impaired concentrating capacity, so that development of oliguria then implies almost complete loss of renal function; in this case, continued fluid resuscitation will be ineffective and potentially harmful.

There is no evidence to support specific pharmacological interventions to prevent or treat AKI; in particular, low-dose dopamine is ineffective for preventing or reversing renal impairment in sepsis (see p. 1390). Thus, treatment of those developing or at risk of AKI should focus on prompt resuscitation with fluid and/or vasopressor therapy, as well as treatment of the underlying causes of shock and sepsis. If these measures fail to reverse oliguria, loop diuretics such as furosemide (see p. 178) may be used to treat or prevent fluid overload. However, there is no evidence that diuretics alter the clinical course of AKI, and renal replacement therapy (RRT) should not be delayed if indicated.

In AKI, RRT is indicated for refractory fluid overload, major electrolyte disturbances (especially hyperkalaemia), severe acidosis and, less often, ureaemia. There is no evidence to support commencement of RRT for less severe AKI in the absence of these indications. Continuous renal replacement therapy (RRT, see p. 1398) is associated with greater haemodynamic stability and better control of fluid balance than intermittent haemodialysis, while use of peritoneal dialysis is unsatisfactory in critically ill patients (although this may be an option in resource-limited environments). Thus, continuous RRT is now the preferred method of renal support in the critically ill.

In critical illness complicated by AKI, if the underlying problems resolve, renal function usually recovers over a period of a few days to several weeks. However, there is good evidence to suggest that, after recovery, subtle defects in renal function persist, so that patients requiring RRT in the ICU have a significantly increased risk of developing chronic kidney disease in the months and years after critical illness.

NEUROCRITICAL CARE

Physiology
Neurones are particularly susceptible to acute ischaemic/hypoxic insults, as they have very limited capacity for anaerobic metabolism and are irreversibly lost when blood flow is restricted for as little as 3–8 minutes.

The intracranial contents – brain parenchyma, blood and CSF – are contained in the rigid skull vault. Intracranial pressure (ICP, pressure within the skull) is approximately 7–15 mmHg in a resting, supine adult. Changes in intra-abdominal and intrathoracic pressures, such as occur during coughing or a Valsalva manoeuvre, may result in transient increases in ICP that are of no consequence. The Monro–Kellie doctrine states that, because the intracranial volume is fixed, any increase in the volume of one of the intracranial constituents must be compensated by a decrease in volume of the others. As space-occupying lesions expand or brain tissue swells, the rise in ICP is limited by displacement of CSF and venous blood from the intracranial compartment. Once these compensatory mechanisms are exhausted, further increases in intracranial volume cause exponentially greater increases in ICP (Fig. 10.31).

In health, autoregulation maintains constant cerebral blood flow over a range of blood pressures. However, these mechanisms are lost following significant intracranial injury, and cerebral blood flow then becomes directly dependent on cerebral perfusion pressure (CPP). CPP is calculated as the MAP minus the ICP. Occasionally, a very high CVP, greater than the ICP, will also reduce CPP (Fig. 10.32).

Clinical features and investigations
The causes of coma are listed in Box 26.29. Conscious level should be documented regularly. The Glasgow Coma Scale (GCS) score (Box 26.28) is widely used as a semi-quantitative, yet crude, means of gauging the level of consciousness. Assessment of the airway is of particular importance. Patients with airway obstruction due to lary oopharyngeal musculature should be managed as discussed on page 220. Patients without a cough or gag reflex may need to be intubated in order to protect the airway. Pupillary size and reactivity is a crucial part of the assessment. A unilateral dilated pupil that reacts sluggishly or not at all is frequently a sign of increasing ICP. This is caused by compression of the IIIrd cranial nerve by herniating brain; if untreated, it can be rapidly fatal. Immediate measures to decrease ICP (see Box 10.18) are required while a CT scan of the brain is obtained. In some situations, patients may be taken directly to the operating theatre in order to alleviate the raised ICP and to remove expanding space-occupying lesions such as a haematoma. Small or pinpoint pupils

![Fig. 10.31 Intracranial compliance curve. ICP, intracranial pressure. (From Hinds CJ, Watson JD. Intensive Care: A Concise Handbook, 3rd edn. Edinburgh: Saunders; 2008, with permission.)](image-url)
may be a sign of mid-brain injury or opioid overdose. New focal neurological signs should be sought, such as cranial nerve palsies, limb weakness or hemiparesis. Seizures should be recognized and treated appropriately (see p. 856).

**Monitoring**

Regular clinical assessments by the bedside nurse are essential, including GCS score and pupillary size and reaction to light at least every hour. Neurological assessments are inevitably limited in patients requiring sedation and mechanical ventilation. In these individuals, invasive monitoring of ICP may be necessary.

**Invasive ICP monitoring devices** may be extradural, subdural, subarachnoid, intraparenchymal or intraventricular (Fig. 10.33). The external ventricular drain (EVD) is the most difficult to insert, particularly when increased ICP causes the ventricles to collapse. EVDs are normally placed through the non-dominant (usually right) hemisphere into the lateral ventricle in the operating theatre. Their main advantage over the other monitoring devices is that they can also be used to treat raised ICP by draining CSF from the ventricular system. They are more prone to infection, however.

**Multi-electrode electroencephalography (EEG) monitors** give both a waveform and an analogue display that can help in the diagnosis of non-convulsive seizures and are also useful in monitoring the depth of sedation.

**Oximeter-tipped catheters** can be placed via the internal jugular vein and advanced in a cranial direction to lie in the jugular bulb just external to the skull. These ‘jugular bulb oximetry’ catheters monitor venous saturation in blood leaving the brain and give an indication of the balance between cerebral oxygen supply and demand. Measurements can be interpreted similarly to the mixed venous oxygen content (see p. 208).

**Cerebral oximetry** uses near-infrared spectroscopy (NIRS) technology to estimate the oxygenation of a small portion of the cerebral cortex. Adhesive pads that both emit and capture near-infrared light waves are placed over the frontal cortex. Cerebral oximetry can provide an early warning of decreased cerebral oxygen delivery.

**Management**

Little can be done to reverse the immediate primary brain injury and irreversible loss of neurones that occur as a direct consequence of intracerebral haemorrhage, infarct or traumatic brain injury. ICU care is focused on minimizing secondary brain injury (Box 10.18). This commonly occurs as a result of increases in ICP and consequent decreases in CPP. Cerebral oedema, expanding mass lesions (e.g. haemorrhage), prolonged seizure activity and hypercarbia (which causes cerebral vasodilation) are all examples of mechanisms leading to secondary injury. Neurocritical care has therefore focused on monitoring ICP and maintaining CPP. The Brain Trauma Foundation (BTF) guidelines state that an ICP of 22 mmHg or less and a CPP of between 60 and 70 mmHg should be the aim, with vasopressors and fluid given as required in conjunction with supportive care; the latter should include airway protection, maintenance of normocarbia, reduction of the risk of nosocomial infections and prevention of thromboembolic complications.

OUTCOMES

Withholding and withdrawing treatment

(See also Ch. 7.)

For many critically ill patients, intensive care is undoubtedly life-saving and resumption of a normal lifestyle is to be expected. It is also widely accepted that the elective admission of high-risk patients into an ICU or HDU, particularly in the immediate post-operative period, can minimize morbidity and mortality and lower costs, as well as reducing the demands on medical and nursing personnel on general wards. In the most seriously ill patients, however, mortality rates are high, and a significant number die soon after discharge from the ICU. Mortality rates are particularly high in those who require readmission to intensive care. Moreover, patients surviving a prolonged ICU admission often do not regain their pre-morbid functional status, and longer-term mortality rates (for at least 10 years post discharge) remain higher than in a general population matched for age and illness severity.

Inappropriate use of intensive care facilities has other implications. The patient may experience unnecessary suffering and loss of dignity, while relatives may also have to endure considerable emotional pressures. In some cases treatment may simply prolong the process of dying, and in others the risks of interventions outweigh the potential benefits. Lastly, intensive care is expensive, particularly for those with the worst prognosis, and resources are limited.

To ensure both a humane approach to the management of critically ill patients and the appropriate use of limited resources, it is necessary to:

- avoid admitting patients who cannot benefit from intensive care
- limit further aggressive therapy when the prognosis is clearly hopeless.

Such decisions are extremely difficult; each case is assessed individually, taking into account previous health and quality of life, the patient’s expressed wishes, the primary diagnosis, medium- and long-term prognosis of the underlying condition, and survivability of the acute illness. Age alone should not be the sole consideration. When in doubt, active measures should continue but with regular review in light of response to treatment and any other changes.

Decisions to limit therapy, not to resuscitate or to withdraw treatment should be made jointly by the ICU medical staff, the primary physician or surgeon, nursing staff and, if possible, the patient, normally in consultation with the patient's family. Limitation of active treatment is not the cessation of medical or nursing care; rather, a caring approach must be adopted to ensure a dignified death, free of pain and distress, with support for family and friends (see p. 148).

Scoring systems

A variety of scoring systems have been developed to evaluate the severity of critical illness. Some include an assessment of the patient’s previous state of health and the severity of the acute disturbance of physiological function (acute physiology, age, chronic health evaluation, or APACHE; and the simplified acute physiology score, or SAPS). Other systems have been designed for particular categories of patient (e.g. the Injury Severity Score (ISS) for trauma victims).

The APACHE and SAPS scores are widely applicable and have been extensively validated. They can accurately quantify the severity of illness and predict the overall mortality for large groups of critically ill patients, and are therefore useful for defining the ‘case mix’ of patients when auditing a unit’s clinical activity, for comparing results nationally or internationally, and for characterizing groups of patients in clinical studies. Although the APACHE and SAPS methodologies can also estimate mortality risk, no scoring system has yet been devised that can predict with certainty the outcome in an individual patient. They must not, therefore, be used in isolation as a basis for limiting or discontinuing treatment.

Brain death and organ donation

Traditionally, death is thought of as cessation of breathing and the heartbeat. Brain death means ‘the irreversible loss of the capacity for consciousness combined with the irreversible loss of the capacity to breathe’. Both of these are essentially functions of the brainstem. With the advent of mechanical ventilation, it became possible to support such a dead patient temporarily, although, in all cases, cardiovascular failure eventually supervenes and progresses to asystole.

Before deciding on a diagnosis of brainstem death, it is essential for certain preconditions and exclusions to be fulfilled.

Preconditions

- The patient must be in apnoeic coma (i.e. unresponsive and on a ventilator, with no spontaneous respiratory efforts).
- Irremediable structural brain damage due to a disorder that can cause brainstem death must have been diagnosed with certainty (e.g. head injury, intracranial haemorrhage).

Exclusions

- The possibility that unresponsive apnoea is the result of poisoning, sedative drugs or neuromuscular blocking agents must be excluded.
- Hypothermia must be excluded as a cause of coma (core temperature >34°C).
- There must be no significant circulatory, metabolic or endocrine disturbance that could produce or contribute to coma or cause it to persist (including acid–base, electrolyte and glucose abnormalities).

Diagnostic tests for the confirmation of brainstem death

All brainstem reflexes are absent in brainstem death.

The following tests should not be performed in the presence of seizures or abnormal postures.

- The pupils are fixed and unresponsive to bright light. Both direct and consensual light reflexes are absent. The size of the pupils is irrelevant, although most often they will be dilated.
- Corneal reflexes are absent.
- There are no vestibulo-ocular reflexes on caloric testing (see p. 816).
- There is no motor response within the cranial nerve territory to painful stimuli applied centrally or peripherally. Spinal reflex movements may be present.
- There is no gag or cough reflex in response to pharyngeal, laryngeal or tracheal stimulation.
- Spontaneous respiration is absent. The patient should be ventilated with 100% O₂ for 10 minutes and then temporarily disconnected from the ventilator for 5 minutes. Oxygenation is maintained by insufflation with 100% oxygen via the endotracheal tube. The patient is observed for any signs of spontaneous respiratory efforts. A blood gas sample should be obtained during this period to ensure that the P₅CO₂ is sufficiently high to stimulate spontaneous respiration (starting P₅CO₂ ≥6.0kPa and pH <7.4, with P₅CO₂ rise of >0.5kPa after 5 minutes).
The examination should be performed and repeated by two senior doctors.

In the UK, it is not considered necessary to perform confirmatory tests, such as EEG or carotid and vertebral angiography. The primary purpose of establishing a diagnosis of brainstem death is to demonstrate beyond doubt that ongoing treatment is futile. In many jurisdictions, brainstem death is legally equivalent to cardiac death.

In suitable cases, and provided the assent of relatives has been obtained (easier if the patient is a registered organ donor), the organs of those in whom brainstem death has been established may be retrieved while the heart is still beating and be used for transplantation.

Organ donation may be possible in situations where ongoing life-sustaining treatment is deemed futile and a decision is reached in conjunction with the family (and, in rare circumstances, the patient) to withdraw treatments such as invasive ventilation and inotropes that are simply delaying an inevitable death. If the patient and family wish to consider organ donation, then withdrawal of life-sustaining therapies usually occurs in a planned fashion and often in the operating department suite. If death occurs relatively quickly, then organ retrieval may proceed immediately following cardiac death.

Both of these situations require rapport and trust to be established with the family. In the UK, there are separate teams of nurse specialists to help the families through these very difficult situations and coordinate organ retrieval. A local and regional transplant coordinator can help with the process, as well as providing information, training and advice about organ donation. The medical teams involved in the ICU care of the patient and those involved in the organ retrieval process must remain completely independent.

Bibliography

Significant websites

http://www.ficm.ac.uk Faculty of Intensive Care Medicine.
http://www.ics.ac.uk UK Intensive Care Society.
Around 313 million surgical procedures are carried out worldwide each year, though fewer than 6% of these procedures are performed in low- and low-middle income countries. Although local patterns vary, general surgeons tend to focus on surgical problems of the intra-abdominal organs, and typically subspecialize within fields such as colorectal, hepatobiliary, upper gastrointestinal or trauma surgery. Other major surgical specialties include orthopaedic, cardiothoracic, vascular, plastic and paediatric surgery, neurosurgery and urology.

Elective surgery is discussed and planned with patients in the outpatient setting and often carried out as a day-case procedure, with only major operations requiring an inpatient stay. Most general surgeons will participate in on-call work, in which patients presenting to hospital with surgical problems are admitted and treated on surgical wards, sometimes undergoing emergency surgery.

Keys skills to learn in surgery include:

- appreciating the benefits and risks of operative management compared with medical management in a range of conditions, and the patient factors that make different approaches appropriate in different situations
- understanding the physiological responses to surgery, and knowing how to instigate the appropriate anaesthetic and perioperative management to prevent harm
- recognizing common postoperative complications and understanding how to prevent and treat them.

Opportunities for learning surgery include observing operations and ‘scrubbing in’ to assist, attending surgical outpatient clinics to observe surgery being discussed with patients, pre-assessing patients on surgical day-stay units who are due to undergo elective surgery, and reviewing the role of surgical versus conservative management in patients on surgical assessment units who have presented with a range of acute surgical problems.

### History

A good history is the bedrock of diagnosis in the surgical patient, and along with a focused, diagnostic clinical examination, shapes and guides the subsequent investigations and management (Box 11.1).

### Examination

The general examination and a review of vital signs and systems are just as they are for any medical patient. However, the typical surgical patient often presents with a swelling or lump that benefits from a more surgical approach to examination, based on the time-tested methods of *inspection, palpation, percussion* and *auscultation* (Box 11.2).
Surgery

Box 11.1 Key elements in surgical history-taking

History of the presenting complaint
- A clear account of each problem experienced by the patient, including its duration
- The sequence of events leading up to the present illness or injury
Past medical and drug history
- Other medical problems
- Previous operations, including any reaction to anaesthesia
- Use of antiplatelet or anticoagulant medication
- Last menstrual period (LMP), always considering ectopic pregnancy in women of childbearing age

Fitness for surgery
- Time of last meal
- Social circumstances of patient, including baseline functional status:
  - How far can the patient walk along the flat on a good day?
  - Can they climb a flight of stairs?

Box 11.2 The surgical approach to examining a swelling or lump

LOOK (observe)
- Site or location of the lump
- Size, shape and number of lumps
- Surface and colour
- Prominent veins
- Visible expansive or transmitted pulsations
- Previous scars
- Cough impulse
- Pressure or infiltrative effects, including vascular or nerve involvement:
  - Oedema
  - Ischaemia
  - Muscular atrophy
- Lymph node enlargement

FEEL (palpate and percuss)
Always ask if the lump is painful BEFORE gently seeking to elicit tenderness!
- Consistency
- Fluctuation (suggests fluid content)
- Pulsations, thrills and compressibility (suggests vascular lesions)
- Cough impulse and reducibility (in possible hemias)
- Relationship/fixity of the lump to adjacent structures, including skin, muscle and bone
- Percuss for tympanic, resonant or dull notes
- Palpate the relevant draining lymph node groups

LISTEN (auscultate)
Auscultate over the lump or swelling for peristaltic sounds, bruits and murmurs
- High-pitched tinkling of trapped bowel suggests an obstructed hernia
- Sluggish or absent peristaltic sounds suggest paralytic ileus or generalized peritonitis
- Bruits and murmurs are suggestive of arteriovenous fistulae, arterial stenosis or aneurysms

Box 11.3 Preoperative investigation

Establishing the diagnosis
- Sometimes this is possible with simple or more complex imaging techniques, e.g. ultrasound, magnetic resonance imaging (MRI) or positron emission tomography (PET)
- Diagnostic angiography is minimally invasive and allows visualization of vascular pathology
- Often tissue samples are required for histological diagnosis: these may be obtained by a range of more or less invasive tests, including endoscopy, endoscopic retrograde cholangiopancreatography (ERCP), endoscopic ultrasound (EUS), fine needle aspiration (FNA) and Trucut core biopsy

Clarifying anatomy and guiding surgical approach
- Cross-sectional imaging, e.g. contrast-enhanced CT scanning allows excellent visualization of tissue pathology and is used to plan operative approaches, e.g. by assessing whether a tumour is resectable

Determining the fitness of the patient
- A basic surgical preoperative work-up could include a full blood count, serum creatinine and electrolytes, liver function tests, clotting profile, group and save/crossmatch anticipating possible transfusion requirements and urine testing, as well as electrocardiography (ECG) and chest X-ray
- Older people, or those with pre-existing co-morbidities, may also require echocardiography, cardiac stress tests, pulmonary function tests and cardiopulmonary exercise testing (CPET), to allow preoperative optimization of patients

Investigations
A thorough surgical history and examination are routinely supported by a variety of investigations and interventions performed for different purposes (Box 11.3).

Surgical pathology and nomenclature
These are described in (Box 11.4).
Abscess

- A collection of pus

Cyst

- A collection of fluid lined by epithelium
- May be complicated by bleeding, infection, rupture, local pressure effects and sometimes malignant change, e.g. thyroid, ovarian and liver cysts
- Pancreatic pseudocysts are collections of inflammatory pancreatic fluid lined by granulation tissue; they can cause all of the complications listed except malignancy, as a lining epithelium is absent

Sinus

- A blind-ending tract lined by epithelium
- Pilonidal sinuses, for example, are typically found in the internatal cleft and are prone to infection and abscess formation

Obstruction

- Blockage or occlusion of a hollow viscus or structure
- Obstruction can occur:
  - From within the lumen of any tubular structure, e.g. gallstones in the common bile duct causing jaundice, or a ureteric stone causing renal colic
  - From the wall or lining epithelium of a structure, e.g. an inflammatory stricture of the terminal ileum in Crohn’s disease, or malignant adenocarcinoma of the colon
  - From extrinsic pressure, e.g. a massive ovarian cyst causing pelvic vein congestion and bowel obstruction

Abscess

- A collection of pus

Cyst

- A collection of fluid lined by epithelium
- May be complicated by bleeding, infection, rupture, local pressure effects and sometimes malignant change, e.g. thyroid, ovarian and liver cysts
- Pancreatic pseudocysts are collections of inflammatory pancreatic fluid lined by granulation tissue; they can cause all of the complications listed except malignancy, as a lining epithelium is absent

Sinus

- A blind-ending tract lined by epithelium
- Pilonidal sinuses, for example, are typically found in the internatal cleft and are prone to infection and abscess formation

Obstruction

- Blockage or occlusion of a hollow viscus or structure
- Obstruction can occur:
  - From within the lumen of any tubular structure, e.g. gallstones in the common bile duct causing jaundice, or a ureteric stone causing renal colic
  - From the wall or lining epithelium of a structure, e.g. an inflammatory stricture of the terminal ileum in Crohn’s disease, or malignant adenocarcinoma of the colon
  - From extrinsic pressure, e.g. a massive ovarian cyst causing pelvic vein congestion and bowel obstruction

Fistula

- An abnormal communication between two epithelial surfaces
- Fistulae may be formed due to embryological, infective, inflammatory, traumatic and malignant processes; they persist because of undrained sepsis, distal obstruction, malignancy, high-volume throughput, epithelialization of the fistula tract, and presence of a foreign body
- They can heal with careful attention to fluid and electrolyte balance, nutrition, protection of surfaces, and optimally timed surgery to drain all pus, excise malignancy when feasible, remove foreign bodies and relieve obstruction
- Examples of intentionally permanent fistulae include arteriovenous fistulae, colostomies and ileostomies

Hernia

- An abnormal protrusion of part or all of a viscus through a defect in the wall of its containing cavity

Tumour

- Typically, a solid lump arising as a consequence of a neoplastic process
- Benign tumours may cause pain, bleeding, infection and obstruction
- Malignant tumours may also invade locally and metastasise

INTRODUCTION

Surgery is the branch of medicine that employs manual techniques to treat injury, deformity and disease. The word ‘surgery’ derives from the Greek kheirourgia, meaning ‘labour of the hands’. Diseased tissue or organs are removed, repaired, manipulated or replaced, and more so than anywhere else in medicine, patients commit their lives to surgeons’ hands, consenting to bodily incursion and placing their trust in the surgeon’s technical skills.

Performing an operation demands a particular mix of knowledge and skills: deep knowledge of anatomy, a profound respect for tissues, extreme task absorption, and the courage and confidence to be decisive but never arrogant – to know when to cut and when not to. Good surgical outcomes depend on many people working together to ensure that the right operation is performed in the right patient at the right time, with the right team and the right tools.

Surgery in high-income countries

Modern surgery continues to improve, innovate and evolve in exciting new ways. Surgical advances over the last 150 years have been facilitated by breakthroughs in medical science and technology: safe anaesthesia, aseptic technique and antibiotic therapy, cross-sectional imaging, minimal-access surgical instruments, endoscopy and robotics, three-dimensional printing, virtual and augmented reality simulation, and artificial intelligence. Where healthcare systems are well resourced, more and more complex and challenging operations can be undertaken with safer, life-enhancing outcomes for patients.

Technological advances in all aspects of surgery have inevitably required surgical specialization to permit the honing of technical skills and expertise within ever narrower fields of specialist focus. This move to subspecialization, however, must be tempered by the realization that individual surgical mastery is not sufficient to achieve exemplary outcomes of care. Success depends on the effectiveness of the wider healthcare team within which surgery is practised and, increasingly, surgeons are called on not just to refine their individual technical capabilities but also to develop insight into their own strengths and fallibility, and dependence on others. They must learn about safety, the science of clinical improvement and how to improve outcomes at the level of healthcare systems. They must provide clinical leadership and work effectively in multidisciplinary teams, supporting and empowering each team member to achieve the best possible outcomes for patients and their families.

Global provision of surgical care

The World Health Organization (WHO) estimates that 5 billion of the global population currently lack access to timely, safe and effective surgical care, which remains unaffordable for up to 90% of people in low-income countries. Changing demographics, ageing populations and variation in need and demand make access to safe surgery a major global public health concern. The health inequity and the global burden of suffering that arise from untreated surgical conditions in less wealthy regions of the world have substantial negative impacts on human health, welfare and economic development. The surgical challenge of the 21st century is to provide surgical healthcare for all that is high-quality, timely, safe and affordable.

THE PATHOPHYSIOLOGY OF SURGERY

The inflammatory and stress response

A major operation constitutes a significant injury to the body. The metabolic response is characterized by an acute inflammatory response mediated by:

- inflammatory cells, including macrophages, monocytes and neutrophils
- cytokines and other inflammatory mediators, such as tumour necrosis factor-alpha (TNF-α) and various interleukins
- activation of the endothelium with production of kinins, prostaglandins and nitric oxide, leading to vasodilation and increased vessel permeability
- release of stress hormones, mediated primarily via:
  - the sympathetic nervous system, through noradrenaline (nor-adrenaline) from sympathetic nerve endings and adrenaline (epinephrine) from the adrenal glands
  - activation of the hypothalamic–pituitary axis with release of antidiuretic hormone (ADH) and adrenocorticotrophic hormone (ACTH), leading to direct effects, as well as the subsequent release of other hormones such as glucagon and aldosterone.

Further aggravation of the injury may occur through ischaemia–reperfusion syndrome or superadded bacterial infection, which in turn may cause sepsis (see Chapter 8).

Fluid balance in surgical conditions

Significant fluid losses may result from surgery and trauma, and further complicate the physiological challenge to body homeostasis. These losses include:

- loss of blood (haemorrhage)
- direct loss of body fluids (through vomiting, diarrhoea, sweating, and exudative losses in drains and catheters)
- loss of fluid that is sequestered or shifted into ‘third spaces’, often as a result of increased capillary permeability due to the acute inflammatory response.

For example, in patients with bowel obstruction, large volumes of fluid can rapidly be secreted into the gut, causing intravascular hypovolaemia.

The metabolic response to surgery

The intra- and postoperative patient enters a catabolic state, proportional to the severity of injury or magnitude of surgery. This is characterized by:

- sodium and water retention mediated by ADH and the renin–angiotensin–aldosterone pathway
- an increase in carbohydrate, fat and protein catabolism, mediated by catecholamines and cytokines, with increased glucose and fat turnover
• the breakdown of adipose tissue and catabolism of skeletal muscle proteins to provide amino acids for both gluconeogenesis and acute-phase proteins by the liver
• hypercoagulopathy, typically in the first 24–48 hours after surgery and mediated via endothelial injury and activation, which increases the risk of thromboembolism.

**Wound healing**

**Stages of healing**

In simple terms, the body’s response to a breach in the integrity of an internal or external body surface follows three phases (Fig. 11.1).

**Haemostatic phase**

Vasoconstriction restricts rapid blood loss and a primary platelet plug forms. Secondary platelet/fibrin clot formation through activation of the coagulation pathway stops bleeding and plugs the breach in surface integrity within minutes.

**Inflammatory phase**

An inflammatory response is mediated primarily by scavenger macrophages and neutrophils, which swarm around the wound and release cytokines with 12–48 hours of injury. This causes the classic features of inflammation, including redness (rubor), heat (calor), swelling (tumor) and pain (dolor), with consequent restriction of function (functio laesa).

**Resolution phase**

Cytokines, including VEGF, PDGF and EGF, stimulate formation of granulation tissue from underlying mesoderm-derived connective tissue at the base of the wound. A matrix of new capillary networks is formed that nourishes and supports migratory myo-fibroblasts, which enable physiological wound contraction, collagen deposition and scar formation. Concurrent re-epithelialization occurs from the edges of the wound by epithelial cells derived from ectoderm or endoderm. The epithelium grows over the underlying granulation tissue scaffold and this continues until epithelial cover is established and the breach repaired.

**Surgical closure**

Surgical skin closure may be by primary, delayed primary and secondary intention, depending on the type of wound encountered. Closure by primary intention produces the best aesthetic and functional outcomes for the patient and is appropriate for most clean wounds (such as those made during an operation); closure by secondary intention or delayed primary intention is appropriate where a wound is contaminated or irregular, or where there is insufficient surrounding skin to allow closure by primary intention (Fig. 11.2).

**Further reading**

**MANAGEMENT OF THE PERIOPERATIVE PATIENT**

A systematic and evidence-based approach to the perioperative care of surgical patients has been brought together by international collaborators in Enhanced Recovery After Surgery (ERAS) protocols. These highlight the role of basic interventions before, during and after surgery that have been shown to improve patient outcomes. Implementation of these protocols has been shown to reduce complication rates, length of stay and re-admission rates after surgery, as well as the costs of treatment.

**Fluid and electrolyte balance**

All patients undergoing surgery require careful attention to their fluid and electrolyte balance (see Ch. 9). Appropriate management requires:

- relevant maintenance fluids for patients who are ‘nil by mouth’ ahead of surgical procedures
- prediction of likely shifts in body fluids in response to the particular disease process, e.g. where ‘third space’ fluid sequestration (see earlier) can be predicted to occur in conditions such as

---

**Fig. 11.1** The stages of wound healing. (A) Haemostatic phase with formation of a platelet plug followed by secondary platelet/fibrin scab. (B) Inflammatory phase with proliferation of macrophages and fibroblasts, leading to the classic features of inflammation. (C) Resolution phase with neovascularization, myo-fibrocyte activity, collagen deposition and scar formation from the base on the wound. Re-epithelialization occurs from the wound margins.
• **Recognition of increased insensible fluid losses** in all febrile and catabolic patients
• **Careful assessment of the patient’s fluid status** through clinical examination (see p. 170)
• **Review of fluid input and output charts**, noting urine output, and fluid losses from surgical drains and nasogastric tubes, and calculating cumulative fluid balance (total input minus total output), which should generally be positive by about 500 mL over a 24-hour period to allow for insensible losses
• **Blood tests** to monitor renal function and electrolyte levels.

**Nutrition**

The majority of surgical patients admitted to an acute hospital either present with evidence of protein-energy malnutrition or leave with a degree of malnutrition or weight loss. Patients may have depleted reserves because of prior infection, anorexia, starvation or malignancy. They may then experience further exacerbation through poor nutrition in hospital related to restricted intake or to intestinal malabsorption from obstruction, inflammation or short gut syndrome; typically, they have increased catabolic rates.

Nutrition can be formally assessed using composite measures that include body mass index (BMI), skinfold (subcutaneous fat) thickness, skeletal muscle wasting, and biochemical parameters such as pre-albumin and 24-hour urinary urea excretion. In routine practice, the Malnutrition Universal Screening Tool (MUST) is widely used for screening inpatients at risk of malnutrition (see p. 1233).

Daily energy and protein requirements after surgery vary between 30 and 40 kcal/kg per day and 1 and 2 g/kg per day respectively, depending on whether the surgery is uncomplicated or complicated. Dietician and nutrition team input is invaluable in the care of the surgical patient.

Malnutrition has adverse effects on patients’ mood, mobility and postoperative wound healing, may predispose to wound infection and pneumonia, and may increase the length of stay. Where patients are unable to meet their energy requirements through oral intake, enteral nutrition is most appropriate in the first instance and may be delivered via nasogastric or nasojejunal tubes, or a percutaneous feeding-tube jejunostomy. Total parenteral nutrition (TPN), through peripheral or central venous lines, is typically indicated only in patients with significant gut dysfunction and is associated with a range of complications, including central venous catheter infection, that lead to higher morbidity and mortality than those associated with enteral nutrition.

The use of preoperative nutritional supplementation in the weeks prior to major surgery, and carbohydrate preloading the night before, delivered as part of the ERAS programme, have accounted for some of the significant improvements in surgical outcomes after major surgery in recent decades.
Coagulation, bleeding and transfusion

Massive blood transfusion is defined as the replacement of the equivalent of the circulating blood volume (4.5–6L) by transfusion within 24 hours. It is not uncommonly required in major surgical emergencies, including major exsanguinating trauma, massive gastrointestinal bleeding and obstetric complications. Blood transfusion and its complications are covered comprehensively on pages 357–362.

Blood is a precious resource, dependent on the good will of voluntary donors, meaning that every effort must be made to avoid unnecessary transfusions. In the elective setting, triggers for transfusion include a haemoglobin level of <70 g/L (or 90 g/L in patients with cardiovascular disease). Transfusion in the context of a haemoglobin level >100 g/L is unjustified. Transfusion requirements may be reduced by:

- **preoperative use of erythropoietin and intravenous iron** to raise haemoglobin concentrations prior to elective surgery
- **preoperative blood donation** by healthy patients in advance of their own surgery, which can then be ‘given back’ as required during or after surgery
- **acute normovolaemic haemodilution**, where whole blood is removed from patients immediately prior to surgery and replaced with the same volume of other intravenous fluids; surgery then takes place with a normal blood volume containing a reduced red cell mass, and the stored blood is restored to the patient postoperatively
- **meticulous intraoperative haemostasis**, based on good surgical technique, use of diathermy and other energy devices, antifibrinolytics such as tranexamic acid and aprotinin, and fibrin sealants and other topical haemostats
- **intraoperative red cell salvage**, where medical devices operated by the surgeon retrieve, wash and then re-infuse a patient’s own blood that has been lost during a procedure.

In the future, synthetic or biologically engineered blood substitutes may become available.

Trauma

The Advanced Trauma and Life Support (ATLS) guidelines provide a systematic approach to patients presenting after major trauma, and pay careful attention to the relative immediacy of threats to life. The ‘ABCDE’ approach used in critically ill patients elsewhere in medicine is adapted to trauma, recognizing the physiological consequences of different types of traumatic injury:

- **The airway** is assessed while also **protecting the cervical spine**, which may have been injured during the incident that led to the trauma.
- **Breathing** may be compromised by massive haemothorax or tension pneumothorax, requiring urgent chest drain insertion.
- **Circulatory compromise** from haemorrhagic shock or cardiac tamponade may occur, and **haemorrhage control** is undertaken before proceeding to further evaluation.
- **Disability** may occur from traumatic brain or spine injury.
- **Exposure and environmental control** is carried out to exclude other injuries not immediately obvious on initial assessment, and steps are taken to warm the patient and prevent hypothermia.

The metabolic response to injury is aggravated in major trauma by what has been termed an ‘unholy triad’ of **hypothermia, acidosis** and **coagulopathy**. Together, these can have devastating consequences for a rapidly exsanguinating, severely injured patient. While massive blood transfusion is often required, emergency surgery to achieve control of a catastrophic bleed and ‘**turn off the tap**’ is an immediate and life-saving intervention. Studies have revealed that a degree of hypotension can be permitted until surgical control can be achieved, in order to limit the loss of blood. Excessive crystalloid resuscitation must be avoided in the severely injured patient and this may exacerbate coagulopathy; instead, use of antifibrinolytics such as tranexamic acid, and transfusion of packed cells, fresh frozen plasma, platelets and cryoprecipitate in 1:1:1 ratios, form part of major transfusion protocols in trauma.

Care has been revolutionized by a focus on early transfusion in the management of massive haemorrhage in trauma, in combination with damage control surgery. The availability of less invasive but equally effective radiological angio-embolization techniques has facilitated a more conservative approach to blunt trauma in particular. The outcomes for severely injured patients continue to improve. The key principles of major trauma are based around the principle of **damage control** – operating early to avert life-threatening complications, leaving definitive surgical management until the patient is more stable (**Box 11.5**).

The critically ill surgical patient

Surgical patients may be critically ill at the time of presentation to hospital (e.g. if suffering from a life-threatening surgical emergency such as intestinal perforation, ruptured aortic aneurysm or necrotizing fasciitis), or may become critically ill as a consequence of major surgery or its complications.

Shock is characterized by inadequate tissue perfusion and oxygenation. If uncorrected, shock will lead to cellular dysfunction and organ damage, and eventually irreversible organ failure and death. Causes of shock in the surgical patient include haemorrhage or hypovolaemia, sepsis and anaphylaxis. Prompt recognition and resuscitation (see p. 203), along with early management with blood products or intravenous antibiotics, is critical.

Early transfer to the high-dependency/intensive care unit may improve outcomes. This allows intensive physiological monitoring (including intra-arterial blood pressure and invasive cardiac monitoring), as well as the institution of isotropic support using agents such as noradrenaline (norepinephrine), adrenaline (epinephrine) and vasopressin. Respiratory support, including artificial ventilation and renal replacement therapy (haemofiltration), may be required to help patients survive critical illness, and often high-risk individuals are moved directly to critical care units for intensive monitoring and treatment directly after major surgery.

**Box 11.5 Key principles of treatment for major trauma**

- **Haemorrhage control** by surgical or radiological intervention, combined with rapid use of appropriate blood products and antifibrinolytics
- **Elimination of contamination** by thorough washout of wounds and repair of perforated gut
- **Limited surgery** initially, doing only what is necessary to achieve the objectives above, while seeking to limit operative duration
- **Temporary abdominal closure or laparostomy**, where the abdominal cavity is left open and protected using a vacuum device, in order to reduce the risk of abdominal compartment syndrome and allow easy access for repeat surgery
Cancer

Cancer is a pathological condition that is characterized by the proliferation of neoplastic cells, which display unregulated growth and resistance to programmed cell death (see also Ch. 6). Cancers can directly invade adjoining organs and tissues, or may metastasize. Metastasis occurs in one of several ways:
- via lymphatics to draining lymph nodes
- haematogenously via veins and arteries to distant sites
- along the nerves (perineurally)
- across body cavities such as the peritoneum (transcoelomic spread).

Cancer results in general systemic symptoms, including anorexia and weight loss, as well as local symptoms. The latter may include specific surgical pathology (Box 11.6).

Most cancers can be TNM-staged according to:
- the size of the tumour (T)
- the extent of lymph node involvement (N)
- the presence or absence of distant metastases (M) (see Box 6.12).

Surgery remains the only potentially curative therapeutic option for the majority of solid and hollow organ cancers, and complete cure is often possible only in the early stages. The key principle of oncologically curative surgery is to ensure that the cancer has been excised completely: that is to achieve an ‘R0’ resection. If microscopic tumour remains at the pathology excision margins (R1) or is macroscopically present (R2), then cancer recurrence is either highly likely (R1 resection margins) or inevitable (R2).

All patients being considered for cancer treatment must be discussed in multidisciplinary meetings where radiologists, pathologists, oncologists, palliative physicians, surgeons and allied health professionals with cancer expertise are present to plan optimal therapy. Survival outcomes for patients undergoing cancer surgery have been immensely enhanced over the last few decades, through improvements in surgery and anaesthesia, progress in understanding tumour biology and genetics, and related advances in medical oncology and radiotherapy. Surgery in potentially curable disease is often supplemented by chemotherapy and radiotherapy, provided by clinical oncologists. This may be:
- neoadjuvant (preoperative), to reduce tumour mass prior to resection
- adjuvant (postoperative), to kill any remaining cancer cells and prevent recurrence.

Surgery, alongside other interventional techniques including interventional radiology and endoscopy, also has a role to play in the palliation of cancer. For example, large-volume tumours causing symptoms as a result of mass effect may be ‘debulked’, or expandable stents may be inserted into obstructed hollow viscera such as the duodenum or the biliary tract.

THE PATIENT JOURNEY IN SURGERY

The patient journey through surgical treatment is best understood in terms of three phases: preoperative, intraoperative and postoperative. Surgery may be elective, expedited, urgent or immediate (Box 11.7). For example, a patient with colon cancer could present with life-threatening haemorrhage (requires immediate surgical intervention), perforation and peritonitis (requires urgent surgery), impending bowel obstruction (requires expedited surgery), or for a planned colonic resection of the tumour (elective surgery).

An increasing number of minor and intermediate-complexity elective procedures, and even some emergency operations, are being carried out in the day surgery or short overnight-stay setting. Inpatient stays are reserved for more major procedures or for patients with more complex co-morbidity.

Preoperative phase

Fitness for surgery

One of the aims of the preoperative assessment is to evaluate a patient’s fitness for surgery, often graded using the American Society of Anesthesiologists (ASA) criteria (Box 11.8). Once risk has been estimated, a second focus is to optimize a patient’s physical state in terms of nutrition and pre-existing medical conditions, in order to minimize this risk.

The preoperative assessment seeks to:

- establish the status of known pre-existing co-morbidities, e.g. respiratory and cardiovascular disease
- screen for undiagnosed conditions, e.g. diabetes and hypertension
- identify drug allergies
- document current medications and identify the need for these to be modified perioperatively, e.g. withholding anticoagulants and antiplatelet drugs that could increase bleeding risk
- note previous anaesthesia history and any related problems
- identify modifiable risk factors, e.g. smoking, alcohol use and obesity.

If there are factors that are not modifiable in the necessary timescale, and that place the patient at high risk of operative or anaesthetic complications, assignment of an appropriate postoperative high-dependency/intensive care setting is critical.

Preoperative ERAS principles include optimization of nutritional status: for example, by using dietary supplements, intensive physiotherapy and pre-habilitation (‘pre-hab’) for deconditioned patients with poor functional reserves undergoing major surgery.

Patients must be appropriately fasted for expedited/elective procedures, taking no food for 4–6 hours and no liquids for 2 hours prior to the procedure. Appropriate premedication, as determined by the anaesthetist, may be administered to alleviate anxiety and pain.

Deciding when to operate

A critical skill in surgery is judging whether or not to operate on a patient. A simple series of questions can facilitate sensible decision-making.

Is the patient willing?

The surgeon must ensure that the patient is willing to have the surgery and has sufficient mental capacity to make an informed decision (see p. 83). The patient must have an understanding of the rationale for the operation; the likely benefits in terms of recovery of function, quality of life, survival and prognosis; and the predicted risks in terms of morbidity and mortality. Operative risk can be quantified using scoring systems such as the Preoperative Risk Calculator (PoRC) and Physiological and Operative Severity Score for the enUmeration of Mortality and morbidity (POSSUM). Patients should be aware of alternative treatment options, the role of non-intervention and the likely outcomes of different approaches. They must be given an idea of what they can expect in the immediate postoperative period, including the likelihood of an intensive care/high-dependency unit stay, and should be warned about postoperative drains, vascular access lines, catheters and the predicted course of recovery. Patients should be offered a second opinion, and indeed encouraged to seek one, particularly for complex major interventions.

Is the patient fit enough?

The preoperative physiological reserve of the patient who is to undergo the proposed surgery must be determined and optimized, both in elective and emergency situations, to minimize surgical risk (see earlier). The expertise of colleagues in other specialties such as anaesthesia, intensive care and cardiovascular, respiratory, renal, metabolic and geriatric medicine, as well as the input of allied health professionals, including physiotherapists and nutritionists, should be sought, in order to mitigate against pre-existing illness and deconditioning.

Is the operation doable?

The operation must be technically feasible. For example, a proposed cancer resection must be capable of accomplishing satisfactory resection margins if it is to achieve its curative intent.

Who is the right person to do the operation?

The operating surgeon has the responsibility to ensure that they have the necessary skills to perform the operation to the highest possible standard. The team and the organization in which they operate must ensure that the patient is in the right hands, and that the operation is appropriate for the patient and surgeon. The rapid growth of surgical specialization means that the breadth of experience in a particular surgical specialty is often considerably narrower than it was in previous decades. It is essential to consider that the appropriate expertise may be outside one’s immediate surgical family.

work must be similarly equipped. Where appropriate, patients with complex problems ought to be referred elsewhere, if greater expertise is available. Surgical outcomes improve based on the number of particular procedures performed by the surgeon each year, and so uncommon procedures may be best performed in tertiary referral centres where experience can be pooled.

Is it sensible to proceed?
Having confirmed all of the above, the surgeon must still make a holistic judgement in partnership with the patient on the overall wisdom of proceeding with surgery.

Intraoperative phase

Anaesthesia
Anaesthesia seeks to achieve three goals for a patient undergoing surgery:
- hypnosis
- analgesia
- muscle relaxation.

The phases of general anaesthesia include induction, maintenance and recovery. Anaesthetists make use of induction agents, muscle relaxants, analgesics and inhalational anaesthetic agents to allow endotracheal intubation, mechanical ventilation and complete muscle relaxation during major surgery. Depending on the type of surgery, regional anaesthesia using a spinal, epidural or regional nerve block can be used, or procedures may be performed under local anaesthesia. Avoiding a general anaesthetic can be important where a patient’s co-morbidity or lack of physiological reserve mean that sedation, ventilation and the subsequent haemodynamic fluctuations that they entail could carry significant risk.

Operating theatre safety
The successful outcome of any surgical procedure relies on constant attention to patient safety. The five-step surgical checklist published by the WHO in 2008 (Box 11.9) has been shown to reduce 30-day mortality after emergency abdominal surgery by 38% in a study carried out in 58 different countries.

Operative technique
Meticulous intraoperative attention to surgical technique is required to ensure optimal outcomes for the surgical patient. Good pre- and postoperative care cannot compensate for intraoperative surgical failures. Although all operations differ, some basic techniques are common to almost all procedures.

Access
Accurate placement of an appropriate surgical incision, based on relevant anatomical considerations, is critical to the success of any open surgical procedure. Similar principles remain valid for laparoscopic and robotic surgery, as laparoscope port placement can determine both the ease and the success of minimally invasive procedures.

Visibility
This is critical for safe surgery. High-quality theatre lighting enables the surgeon to see the key organs and structures clearly and to determine relevant anatomy in open surgery. Laparoscopic and robotic surgery is dependent on high-quality light sources and laparoscopic camera systems of increasing sophistication.

Haemostasis
Achieving meticulous surgical control of bleeding throughout a procedure, aided by sophisticated modern electrocautery and other energy devices, can reduce transfusion requirements, enable a smooth postoperative recovery and prevent complications.

Respect for tissues
Gentle handling of all tissue by the surgeon is vital, with the utmost care being required to respect anatomical planes, avoid bruising, prevent crushing, tension and ischaemia, and minimize the need for surgical drains where possible. These steps reduce postoperative infection and ensure better surgical outcomes.

Postoperative phase
Postoperative care is informed by ERAS principles and requires excellent analgesia, careful attention to fluid and electrolyte balance, early mobilization of the patient, early fluids and feeding (as soon as tolerated by the patient), and removal of drains, tubes and

catheters as soon as safely possible, with nutritional support and post-habilitation if required.

Postoperative care has:
- an ‘immediate phase’ within the recovery room, where the focus is on ensuring safe and full return of consciousness with careful attention to airway, breathing and circulation
- a ‘return to surgical ward care’ phase (unless transfer to the high-dependency or intensive care unit is indicated)
- a possible ‘late rehabilitation/convalescence’ phase, depending on the pre-morbid status of the patient, the magnitude of surgery and the development of related complications.

Direct complications of surgery
Some complications arise directly as a result of the surgical procedure and may require further surgical intervention:

Haemorrhage
This can occur during the operation (‘primary haemorrhage’); or within 24 hours or so of surgery when it is often due to a dislodged surgical tie or displacement of a diathermy eschar or clot when the waking patient’s blood pressure rises (‘reactive haemorrhage’); or in the later period of recovery, often 7–10 days after the operation and frequently caused by infection and erosion of a blood vessel (‘secondary haemorrhage’). Haemorrhage often requires an immediate return to the operating theatre for control, although radiological intervention may also be employed.

Anastomotic leaks
Leaks from breakdown of surgically created anastomoses, typically related to gastrointestinal surgery, can lead to gastric, biliary, pancreatic, small intestinal and colonic contents leaking into the peritoneum. This can cause sepsis and peritonitis, and the formation of abscesses and fistulae.

Wound infections
These may progress to cause superficial or deep wound dehiscence and subsequent incisional herniation.

Paralytic ileus
This commonly occurs after intraperitoneal surgery as a result of significant displacement and handling of bowel. Patients present with symptoms that are similar to those of bowel obstruction, including constipation, vomiting, abdominal discomfort and bloating. Management is conservative, with nasogastric drainage, antiemetics, intravenous fluids, and a slow and gradual introduction of oral feeding.

Pain
Pain at the operative site is common after surgery. Standard analgesia using paracetamol, non-steroidal anti-inflammatory drugs (NSAIDs), and weak and strong opiates can sometimes be supplemented with local interventions at the site of surgery, such as transversus abdominis plane (TAP) block after abdominal surgery.

Medical complications in the postoperative patient
Other complications arise indirectly as a result of surgery but are common and potentially life-threatening. Typically, surgical teams identify these problems and commence initial management, calling on the expertise of relevant physicians where appropriate.

Venous thromboembolic disease
Venous thromboembolic disease (including deep vein thrombosis and pulmonary embolus) is common in the postoperative period, especially after abdominal or lower limb orthopaedic surgery. Prophylaxis with low-molecular-weight heparin is almost always indicated (see p. 1006).

Pulmonary complications
These include lower lobe atelectasis and pneumonia, which are common following surgery and are often a result of under-breathing caused by pain and sedation. Good analgesia and the use of incentive spirometry to encourage deep breathing and re-expansion of basal lung segments can help to prevent these complications.

Cardiac complications
Cardiac complications, including acute myocardial infarction, can be seen postoperatively, often complicating pre-existing cardiac disease.

Delirium
This is common after surgery, especially in elderly patients or those with pre-existing cognitive impairment. Contributory factors include pain, constipation and use of opiate analgesia. Careful management uses the principles outlined on page 310, and in many hospitals geriatric physicians provide a surgical liaison service to help manage the medical needs of elderly patients undergoing surgical procedures.

Acute kidney injury
This is common in the postoperative period and can be multifactorial, causes including fluid losses, sepsis, use of NSAID analgesia and urinary retention. Monitoring of urine output is crucial in the postoperative period, and oliguria should prompt an assessment of fluid status and current medications. Abrupt anuria often indicates urinary retention, a common complication of spinal and general anaesthesia.

Surgical Ethics, Consent and the Law

The four principles of clinical ethics are crucial in ensuring that surgery is performed in a patient’s best interests through shared decision-making (see also p. 82).
- **Autonomy** is typically reflected in the critical importance of obtaining properly informed patient consent before surgery, and providing information about different courses of action and their likely outcomes to allow patients to make their own choice of treatment.
- **Non-maleficence** manifests as a commitment to patient safety, driving clinical improvement to avoid causing unnecessary harm.
- **Beneficence** requires on-going surgical commitment to the highest quality of surgical outcomes, improving patient experience and encouraging continuous surgical quality improvement.
- **Justice** demands a surgical understanding of equity and fairness in terms of access and allocation of finite resources for healthcare and health.
Consent in surgery

Consent must be understood as a process, not merely the one-off signing of a document. Through the consent process, a surgeon empowers, enables and assists the patient to make a fully informed decision regarding treatment by providing all necessary information in a comprehensible way, including a description of all the available alternatives to surgery, such as medical treatment or non-intervention.

Where patients lack mental capacity to consent to a procedure, emergency surgery (to save ‘life or limb’) is often carried out on the basis of a surgical decision that it is in a patient’s best interests. When elective or non-urgent procedures are contemplated, a careful safeguarding process is followed, where views expressed by the patient are weighed alongside surgical opinions about a patient’s best interests, and other opinions: for instance, those of family members or carers. Sometimes, independent advocates or even the courts can be required to make decisions. These principles are explained more fully in Chapter 5.

Surgical audit and quality improvement

Surgical outcomes should be monitored in an attempt to provide continuous quality improvement. Both the performance of individual surgeons, and hospital or departmental surgical outcomes in terms of complications and mortality should be tracked. Local ‘mortality and morbidity’ meetings allow lessons to be learned where avoidable harm has been done to patients, and local surgical outcomes should be contributed to relevant national specialty audits to benchmark local services against national or international equivalents.

Further reading

All doctors need to learn how to prescribe medications safely and effectively. This requires mastery of the principles in the first half of this chapter, which cover key concepts including pharmacokinetics, pharmacodynamics, drug interactions and adverse drug reactions. Pharmacists play a critical role in helping doctors make safe and effective choices when prescribing.

The second half of the chapter covers poisoning: a significant global health problem most commonly seen in the context of deliberate self-harm, but with a substantial proportion of inadvertent poisoning globally. Patients who have taken a drug overdose, a substance of abuse or who have been accidentally poisoned will usually present to a hospital emergency department. Fortunately most can be managed with supportive care alone, although a few require critical care admission. Poisoning with rare agents may require the expertise of clinical toxicologists in a specialist poisons unit.

Key skills related to prescribing, therapeutics and toxicology include:

- developing a systematic approach to prescribing, using key pharmacological principles to select and administer an appropriate drug, avoiding interactions and anticipating or preventing toxicity
- understanding treatment algorithms for patients poisoned by one of the ‘top ten poisons’ described in this chapter.

There are many practical ways to learn prescribing skills: reviewing patients’ medication charts on ward rounds, rewriting medication charts under supervision, observing annual medication reviews in primary care, reporting adverse drug reactions (e.g. using the ‘Yellow Card’ scheme in the UK), or working with pharmacists reviewing inpatient or outpatient prescriptions. The initial assessment and management of patients who have been poisoned, either intentionally or accidentally, is best observed in the emergency department. Subsequent management may be observed in the intensive care setting or on medical wards.
Prescribing, therapeutics and toxicology

**INTRODUCTION**

Prescribing a medicine is the most common healthcare intervention performed by doctors and hence the correct choice of medication and the act of prescribing are key skills required by all doctors. The 1984 ‘Nairobi Declaration’ emphasized that prescribing should be to the right patient with the right drug at the right dose, and at an affordable cost. Thus, the prescription of a medicine needs to take into account the potential benefits and harms of that medicine, and ensure that every step is taken to maximize the benefit:harm ratio. The key principles of prescribing are described in Box 12.1.

**WHY DO PATIENTS NEED DRUGS?**

There are many reasons for prescribing drugs to patients. These are as follows:

- **Disease treatment.** A reliable diagnosis is crucial before starting treatment to ensure that a patient is not exposed unnessarily to the hazards of a particular intervention (ratinal). However, a prior diagnosis may not be possible in every circumstance. For example, in sepsis, the initiation of blind (empirical) antimicrobial therapy is justified, as delay would expose a patient to serious hazard (see p. 159).

**Box 12.1 Key principles of prescribing**

- **Be clear about the reasons for prescribing.** Obtain an accurate diagnosis and have clear aims of what the benefits will be from prescribing the drug
- **Obtain an accurate drug history.** Patients should be asked about their current medications, over-the-counter herbal medicines, and illicit drug usage. A past history of intolerances, including true allergic reactions, is also required.
- **Obtain an accurate history of other factors that might affect the benefit:harm ratio of drugs.** Take note of liver and renal impairment, age, whether patient is pregnant or breast-feeding, and co-morbidities.
- **Establish what the patient expects from the drug, and deal with any concerns.** Provide good information for the patient and answer any questions clearly.
- **Select the most clinically effective, cost-effective and safe medicine for the patient, based on an assessment of the individual.** Optimize the benefit:harm balance by choosing the right dose and frequency, and the right drug, in the best formulation, route of administration and duration of treatment. Prescribe within the licence of the medicine, except when no alternative is available.
- **Adhere to guidelines and local and national formularies.** Based on the needs of the individual patient, use the most reliable information to identify the medicine most suited to the patient.
- **Write prescriptions legibly using the correct documents, or prescribe electronically, depending on availability.** Take care to avoid medication errors.
- **Monitor the patient for both efficacy and safety after starting the drug.** This is essential to optimize dose, identify adverse reactions, and determine when to stop the medicine. Report adverse reactions using spontaneous reporting schemes, if appropriate.
- **Communicate clearly with other healthcare professionals and patients about the reasons for prescribing decisions.** Communication is essential to optimize the benefit:harm ratio of drugs, particularly when there are multiple prescribers for a single patient.
- **Prescribe within your competencies.** Prescribing should be within the limits of your knowledge and experience. Do not be afraid to ask for advice and ensure that complex prescriptions are checked (e.g. when calculating doses).

**THE CHOICE OF DRUG**

The choice of the drug often depends on clinical factors (such as age of the patient, comitant disease and concurrent therapy), pharmaceutical factors (the availability of other medicines and relative cost-effectiveness) and, increasingly, individual (host) factors.

Selecting the right drug (therapeutics) involves three elements:

- the drug’s clinical efficacy for the proposed use
- the balance between the drug’s efficacy and safety
- patient preference.

The most common approach to assessing a drug’s efficacy is the randomized controlled trial (RCT) (Box 12.2), although other approaches can be informative (see Ch. 4). Although common

Adapted from British Pharmacological Society. [https://www.bps.ac.uk/education-engagement/teaching-pharmacology/ten-principles-of-good-prescribing](https://www.bps.ac.uk/education-engagement/teaching-pharmacology/ten-principles-of-good-prescribing).
adverse reactions are usually identified in early-phase drug development studies and RCTs, rare (often serious) adverse reactions are often only discovered after drugs are licensed by post-marketing surveillance studies (pharmacovigilance) (see Box 12.2). All patients should be offered the opportunity to be involved in making decisions about their medical treatment, including those about medications, so-called shared decision-making (see p. 11). Patients’ own preferences should be discussed to enable them to be equal partners in decision-making about whether, and how, they wish to be treated. This approach improves ‘concordance’ with treatment regimens.

THE DOSE

The dose administered to the patient is crucial in determining both efficacy and safety of medicines. Appropriate drug dosages will usually have been determined from the results of so-called ‘dose-ranging’ studies during the drug development programme (see Box 12.2).

In some cases, drug doses are fixed, with all patients being given the same dose: for example, levonorgestrel for emergency contraception (see p. 1489). However, these situations are unusual. Although most patients take 75 mg aspirin daily, doses of up to 300 mg daily have been used for the secondary prevention of myocardial infarction (see p. 1086).

More commonly, doses are titrated. For many drugs, there are wide inter-individual variations in response. As a consequence, while a particular dose may, in one person, lack any therapeutic effect, the same dose in another may cause serious toxicity. This is because the concentration of drug reaching the systemic circulation – that is, exposure – varies between individuals even for the same dose, and it is exposure that determines the response to drugs, in terms of both efficacy and safety. Pharmacokinetic factors (including differences in the rates of drug absorption, metabolism and excretion) are the main determinants of such variability in exposure between individuals.

Variability in response, at an equivalent exposure, can also be due to pharmacodynamic factors, where there are differences in the sensitivity of the drug target that generally fall into the categories of receptors, enzymes, ion channels, transporters, DNA or transcription factors.

Because it is not easy to measure exposure, we use the dose as a proxy. Furthermore, it is not always possible to predict pharmacodynamic variability. For these two reasons, prescribers should thus start most drugs at a low dose and titrate to the lowest effective dose. This can help overcome the inter-individual variability in the dose (concentration)–response curve, whereby there is an increase in response with an increase in dose, until a plateau effect is reached (Fig. 12.1).

Pharmacokinetics

Pharmacokinetics is the study of what the body does to a drug. This can be divided into four different processes: absorption, distribution, metabolism and excretion. Age, body weight, renal and hepatic function, concomitant drugs, co-morbidities, diet, smoking and alcohol are all known to affect the pharmacokinetics and so increase inter-individual variation in required drug dose. Genetic factors affecting drug pharmacokinetics also play a role in determining how individuals respond to drugs.

Absorption

Drugs can be administered by various different routes (Box 12.3) but oral administration is the most common. The main determinants of a drug’s plasma concentration after oral administration are its bioavailability (Box 12.4) and its rate of systemic clearance (by hepatic metabolism or renal excretion). A drug’s oral bioavailability depends on the extent to which it is:

- **Destroyed in the gastrointestinal tract**, especially by gastric acid.
- **Unable to cross the gastrointestinal epithelium**. Drugs can cross either by passive diffusion or by active uptake by gut epithelial transporters. Transporters can generally be divided into influx transporters, which increase uptake of drug (e.g. the PEPT1 influx transporter is required for the uptake of penicillins), and efflux transporters, which limit the absorption of a drug (e.g. P-glycoprotein is an efflux transporter that limits digoxin absorption).
- **Metabolized by the liver** before reaching the systemic circulation (‘first-pass’ metabolism). First-pass metabolism can be avoided by non-enteral routes.

Distribution

This is the process by which drugs are distributed from the bloodstream to organs and cells. Most drugs will circulate in the bloodstream bound to plasma proteins, most commonly albumin. Free drug, which is the active drug, is usually in dynamic equilibrium with protein-bound drug, with the latter being released as the free drug concentration decreases.

Metabolism

Metabolism takes place in many different organs, the liver being the most common site. Drug metabolism converts lipid-soluble drugs to water-soluble drugs for excretion by the kidneys. Metabolism usually inactivates a drug, but in some cases, it can convert a pro-drug into an active drug (e.g. enalapril to enalaprilat) or lead to the formation of toxic metabolites (N-acetyl-para-benzoquinoneimine in paracetamol overdose). Drug metabolism occurs in two stages:

Box 12.4 Key pharmacokinetic parameters

- **Area under the curve**: a plasma concentration time curve and a measure of the actual body exposure to a drug after administration of a dose of the drug; expressed in mg·L⁻¹·h⁻¹.
- **Bioavailability**: the fraction or proportion of a drug that enters the systemic circulation. Thus, while intravenous formulations have 100% bioavailability, administration via other routes will have <100% bioavailability.
- **Clearance**: the volume of plasma cleared of the drug per unit time.
- **Cmax**: peak plasma concentration after drug administration.
- **Concentration**: the amount of drug in a given volume. Even when the dose is similar, concentrations (and thus exposure) will vary between individuals.
- **Dose**: the amount of drug administered. This may be micrograms, milligrams or grams. Occasionally, drugs are administered per body weight or body surface area.
- **Loading dose**: an initial larger dose to achieve immediate therapeutic plasma or tissue drug concentration. It is usually reserved for medical emergencies, but can also be used for drugs with long half-lives, which would otherwise take a long time to reach desired therapeutic steady-state concentration.
- **Phase I**: oxidation, reduction or hydrolysis. This is largely undertaken by a family of isoenzymes known as the cytochrome P450 system. Inhibition or induction of cytochrome P450 isoenzymes is a major cause of drug–drug interactions (see p. 259).
- **Phase II**: conjugation with glucuronate, sulphate or other substances. This renders drugs more water-soluble.

Variability in the genes that encode drug-metabolizing enzymes (Box 12.5) is a major determinant of the inter-individual differences in the therapeutic and adverse responses to drug treatment. One-quarter of all licensed medicines are substrates for a single P450 isoenzyme, CYP2D6. The poor metabolizer (reduced function) CYP2D6 phenotype increases the risk of toxicity, for example, with those antidepressants (e.g. selective serotonin reuptake inhibitors, SSRIs) or antipsychotics (e.g. risperidone) that undergo CYP2D6 metabolism.

Reduced conversion of a prodrug to active metabolite may also compromise efficacy in some patients; for example, poor metabolizers of CYP2D6 do not experience analgesic benefit with codeine, which is a prodrug converted to morphine by CYP2D6. In individuals with more than two copies of the normal CYP2D6 gene (ultra-rapid metabolizers), there is increased drug metabolism and therapeutic failure at conventional doses. Ultra-rapid metabolism can also lead to increased toxicity with prodrugs such as codeine, because there is increased conversion of morphine, thereby increasing the risk of respiratory depression at therapeutic doses, particularly in children with upper airways obstruction, for example with enlarged tonsils/adenoids.

Warfarin is predominantly metabolized by CYP2C9. Up to 10% of most populations have reduced CYP2C9 activity. Such individuals metabolize warfarin more slowly, leading to higher plasma levels, a greater risk of bleeding, and require lower doses if the international normalized ratio (INR) is to be maintained appropriately. When combined with the genetic polymorphisms in the vitamin K epoxide reductase complex (VKORC1) genes (a pharmacodynamic variation), and age and body mass index (BMI), over 50% of the variation in individual daily-dose requirement can be predicted. Pre-prescription genotyping for CYP2C9 and VKORC1 has been shown to improve anticoagulation control.

Individual differences in the activity of thiopurine methyltransferase (TPMT), a phase II enzyme, are used to determine safe dosing of the immunosuppressants, mercaptopurine and azathioprine. TPMT inactivates these drugs and testing for TPMT activity is therefore undertaken routinely to determine appropriate starting doses to reduce the risk of bone marrow suppression associated with these drugs.
The dose

Excretion

Excretion of drugs and their metabolites occurs most commonly via the kidneys, although faeces, breath and sweat represent other routes of excretion. In the kidney, free drug is filtered through the glomerulus and excreted in the urine as long as it is water-soluble. Lipid-soluble drugs are usually reabsorbed in the renal tubules. Some drugs, such as benzylpenicillin, are actively excreted by cells in the proximal convoluted tubule. Renal impairment reduces the elimination of water-soluble drugs, and thus reduction of the maintenance dose must be undertaken to avoid toxicity.

Pharmacodynamics

Pharmacodynamics is the study of what the drug does to the body. Pharmacodynamic sources of variation in drug action can be due to changes in the expression of the drug target, their affinity or their selectivity. This can be caused by genetic factors and also by disease. For example, in hepatic impairment, pharmacodynamic factors can determine the sensitivity to a drug, adding to changes in pharmacokinetics.

Genetic factors affecting drug pharmacodynamics also play a role in determining how individuals respond to drugs. For example, variation in the β2-adrenoceptor gene can affect response to the most common bronchodilator (salbutamol) in asthma. Glucose-6-phosphate dehydrogenase deficiency, the most common enzyme deficiency, can predispose patients to acute red cell haemolysis with certain drugs such as primaquine, dapsone, sulphonamides and rasburicase. The biggest clinical advances in this area have occurred in two therapeutic areas: targeted cancer therapies and drug safety. Sequencing the cancer genome has identified novel driver mutations, leading to the development of targeted therapies. These have seen remarkable success, for instance, trastuzumab is only of value in women with breast cancer whose malignant cells express the HER2 epidermal growth factor receptor. Some immune-mediated reactions involving the skin and liver can now be predicted by genotyping for certain human leucocyte antigen (HLA) polymorphisms. For example, pre-prescription genotyping for HLA-B*57:01 has largely eliminated hypersensitivity to the anti-human immunodeficiency virus (HIV) drug abacavir. Similarly, HLA-B*15:02 predisposes patients from South-east Asia to Stevens–Johnson syndrome with carbamazepine.

As we learn more about the human genome, and the fact that many drugs undergo metabolism via many pathways and act on a number of targets, most of which show polymorphic expression, it may be possible in the future to utilize this information to personalize drug therapy to improve both efficacy and safety of drugs. The prospect for personalized prescribing will be enhanced when the interplay between pharmacokinetics and pharmacodynamics is better understood, which will then permit drug selection and dosing to become much more precise. With the advent of national programmes to increase the availability of whole genome sequencing in routine clinical practice (such as Genomics England 100,000 Genomes Project), this represents a key component of the drive towards personalized medicine.

PRESCRIBING IN SPECIAL POPULATIONS

Most medications are evaluated in clinical trials, and therefore licensed for use, in adult patients. Therefore, healthcare professionals need to consider the specific issues relating to prescribing in other special populations.

For example, the use of drugs in young people poses special problems. Young people have different drug pharmacokinetics:

- **Absorption**: reduced intestinal motility, gastric emptying and acidity.
- **Distribution**: increased total body water (and relative less body fat) increases the volume of distribution for water-soluble drugs; immature blood–brain barrier.
- **Metabolism**: immature hepatic metabolic pathways (up to 1 year old).
- **Excretion**: immature renal excretory pathways (up to 6 months old). Thus, extrapolating from adult dosage regimens, merely adjusting for weight, can lead to excessive (and potentially toxic) prescribing.

Other issues pertinent to prescribing in young people include administration:

- **Oral**: unreliable in ill newborn babies due to slow gastric transit, while precise oral dosing on liquids may be difficult due to refusal/spitting out.
- **Intramuscular** (IM): reduced muscle mass may lead to slower absorption from IM injections.
- **Intravenous** (IV): risk of volume overload, need for slow infusion rates.

In addition, many treatments have never been subject to formal trials in either children or adolescents and therefore their benefits and risks have not been appropriately assessed in these age groups. Adverse effect profiles of medicines may be different in children compared with adults for example Reye’s syndrome in children given aspirin or suicidal ideas in depressed adolescents treated with SSRIs (see p. 780).

Pregnant women

Four in five pregnant women use an over-the-counter or prescribed medicine while pregnant. There is little published evidence for the safety of most drugs in pregnancy. Clinicians should be extremely cautious about prescribing drugs to pregnant women and only essential treatments should be given. There are significant changes in maternal physiology that have consequences for the prescribing of medications.

**Pharmacokinetics**

- **Absorption**: decreased intestinal motility and gastric emptying, increased gastric reflux and emesis.
- **Distribution**: increased total plasma volume (up to 40% higher), increased total body fat, decreased albumin.
- **Metabolism**: no major changes.
- **Excretion**: increased glomerular filtration rate (GFR) (up to 50% higher).

There is also significant drug transfer to the fetal circulation. Blood flow to the placenta increases 1000% over the last 6 months of gestation. Total placental surface (and therefore drug transfer) is greatest at term. Drugs that are small (<1 kDa) can cross the placenta and the main determinant of fetal drug concentration is maternal drug concentration.

Up to 1% of fetal malformations may be due to drug effects. In addition to the pharmacokinetic and pharmacodynamic differences in a young person (see p. 256), additional issues are encountered when there is significant fetal in utero drug exposure. Organ structure and function is most susceptible to perturbation during gestation, especially during organogenesis between 2 and 14 weeks’ gestation, which may include a period where the woman is unaware of being pregnant. Many drugs are known to cause developmental abnormality, known as teratogenesis (Box 12.6). Furthermore, there is increased exposure to drugs that are renally excreted in the amniotic fluid as this is reswallowed and recirculated in the fetus in utero.

When a known teratogen is needed during pregnancy (e.g. an anticonvulsant drug or lithium), the potential adverse effects should be discussed with the parents, preferably before conception. Teratogens are best known for causing structural malformations; for example, congenital heart disease. However, teratogens can also lead to neurodevelopmental problems without any obvious structural damage. For example, exposure to sodium valproate in utero can lead to developmental neurotoxicity, which is manifested as cognitive and behavioural problems. The relevant drug literature should be consulted when prescribing for pregnant women.

**Note:** All drugs should be avoided in pregnancy unless benefit clearly outweighs the risk.
Breast-feeding women

Although most drugs can be detected in breast milk, the quantity is generally small. This is because, for most drugs, the concentration in milk is in equilibrium with plasma water (i.e. the non-protein-bound fraction). A few drugs (e.g. aspirin, carbimazole, methotrexate) may, however, cause harm to the infant if ingested in breast milk. This is especially the case for drugs that cause idiosyncratic reactions where there is little or no concentration–effect relationship (type B adverse events (see p. 258). The relevant drug literature should be consulted when prescribing for nursing mothers.

Prescribing in old age

Prescribing in old age has additional considerations. Old age alters drug pharmacokinetics:

- **Absorption**: diminished due to reductions in intestinal motility and blood flow.
- **Distribution**: reduced total body water affects the volume of distribution for water-soluble drugs; increased total body fat affects volume of distribution of fat-soluble drugs.
- **Metabolism**: decreased hepatic blood flow and enzyme function.
- **Excretion**: renal function declines with age at the rate of approximately 1 mL/min after the age of 40 years.

Old age alters pharmacodynamics:

- **Exaggerated pharmacodynamic effects** of drugs acting on the central nervous, cardiovascular and gastrointestinal systems are common.

Examples of common problems encountered in the use of drugs among older people are shown in **Box 12.7. Extrapolation of drug dosages** from those appropriate in younger adults may therefore lead to toxic plasma levels in older patients.

Additional considerations include:

- **Co-morbidity**, often associated with polypharmacy, leads to increased opportunities for disease–drug and drug–drug interactions.
- **Concordance with treatment regimens** diminishes as the number of prescribed drugs increases and is especially poor in the face of cognitive impairment (see p. 315).

Patients with renal disease

Prescribing drugs that require renal excretion as a major form of drug clearance can be problematic in patients with coexisting chronic kidney disease.

In chronic kidney disease there is less glomerular filtration of drugs leading to reduced renal clearance, enhanced drug half-life and potential for drug accumulation. As well as these significant pharmacokinetic considerations, patients with chronic kidney disease appear to be more susceptible and sensitive to adverse drug effects. Furthermore, some medications, such as thiazide and thiazide-like diuretics, work from the luminal side of the collecting duct, and therefore are ineffective in advanced chronic kidney disease.

The level of renal function below which the dose of a drug must be reduced depends on the proportion of the drug eliminated by renal excretion and its toxicity. For many drugs with only minor or no dose-related side-effects very precise modification of the dose regimen is unnecessary and a simple scheme for dose reduction is sufficient. For more toxic drugs with a small safety margin or patients at extremes of weight, dose regimens based on renal function should be used. When both efficacy and toxicity are closely related to plasma drug concentration, dosage must be adjusted according to clinical response and plasma drug concentration.

Renal function can be measured in different ways. Renal function varies with age. Term infants have 30% of adult renal capacity and adult function is reached by 9–12 months. From the fourth decade onwards, GFR decreases by approximately 1 mL/min per year. Serum creatinine is a simple measure of renal function but is dependent on muscle mass and is only elevated once 50% of renal function is lost. Estimates of GFR are better, as they take into account age and sex (and some formulas take into account other factors such as weight and ethnicity). Most drug adjustments are recommended to use estimated GFR (eGFR) or creatinine clearance (usually calculated by the Cockcroft-Gault formula). Although there is a good correlation between these two measures, at the extremes of weight there can be significant differences and so the relevant drug literature should be checked when prescribing for patients with chronic kidney disease to be sure which measure is recommended.

Various patterns of drug-induced nephrotoxicity can occur:

- **Pre-renal**: diuretics (volume), angiotensin-converting enzyme (ACE) inhibitors (renal perfusion), antihypertensive medications (hypotension).
- **Intrinsic**: glomerular (non-steroidal anti-inflammatory drugs, NSAIDs), immune (PPIs), tubular (lithium).
- **Post-renal**: drug crystallization (aciclovir), oxalate crystallization (allopurinol).

It is good practice to advise avoidance where possible of nephrotoxic drugs, especially over-the-counter drugs such as NSAIDs, in patients with chronic kidney disease.

Patients with liver disease

Prescribing drugs that require hepatic metabolism as a major form of drug clearance can be problematic in patients with coexisting chronic liver disease.

In chronic liver disease, there is less first-pass metabolism. In addition, there are often portosystemic shunts. Therefore, after oral dosing these combine to increase the proportion of drug that enters the systemic circulation, increasing drug exposure for a fixed-given dose.
However, some drugs require hepatic metabolism for efficacy (prodrugs, such as clopidogrel). For prodrugs, the presence of chronic liver disease and/or portosystemic shunts reduces the proportion of orally ingested drug that undergoes hepatic activation and therefore there is relatively less circulating active drug per oral dose.

The assessment of severity of chronic liver disease that requires dose-adjustment is more nebulous than when dose adjusting in renal failure. Although there are validated scoring systems for predicting outcome in chronic liver disease, such as Child–Pugh and MELD (see p. 1290), these have not been routinely used to make decisions on drug-dose adjustment. Holistic clinical assessment is preferred and the relevant drug literature should be consulted when prescribing for patients with chronic liver disease.

Drugs can cause liver injury in various patterns, for example:

- **hepatitis**: paracetamol, amiodarone, azathioprine
- **fatty change**: tetracyclines
- **cholestatics**: co-amoxiclav, nifedipine.

Therefore, for patients with chronic liver disease, avoid hepatotoxins if possible or reduce doses. For example, it is common to restrict paracetamol dosing to 2 g/day in chronic liver disease, compared with 4 g/day in patients without liver injury.

### MONITORING DRUG THERAPY

The combination of pharmacokinetic and pharmacodynamic causes of variability makes monitoring of the effects of treatment essential. Three approaches are used:

- **Pre-treatment dose selection.** In patients who have known, or suspected, impaired renal or liver function, it is usually possible to predict dose requirements from their eGFR (see p. 1346) or clinical assessment of severity of chronic liver disease (see p. 1268).

- **Measuring plasma drug concentrations (therapeutic drug monitoring).** For a few drugs, dosages can be effectively monitored by reference to their plasma concentrations (Box 12.8). This technique, however, is useful only if both of the following criteria are fulfilled:
  - There is a reliable and available drug assay.
  - Plasma concentrations correlate well with both therapeutic efficacy and toxicity.

  **Therapeutic drug monitoring** refers to the individualization of dosage by maintaining plasma or blood drug concentrations within a target range (therapeutic range, therapeutic window). Using this pharmacokinetic approach, therapeutic drug monitoring is used in two major situations:
  - when drugs are used prophylactically to maintain the absence of a condition, such as seizures, cardiac arrhythmias, depressive or manic episodes, asthma relapses or organ rejection
  - to avoid serious toxicity, as with the aminoglycoside antibiotics which, unlike most antibiotics, have a narrow therapeutic range.

### Measuring drug effects

For many drugs, dosage adjustments are made in line with patients’ responses (pharmacodynamics approach). Monitoring can involve dose titration against a therapeutic end-point or a toxic effect. Objective measures (such as monitoring antihypertensive therapy by measuring blood pressure, or cytotoxic therapy with serial white blood cell counts) are most helpful, but subjective ones are necessary in many instances (as with antipsychotic therapy in people with schizophrenia). Pharmacodynamic tests can be used in clinical practice to target therapy or to avoid undue sensitivity. Examples are use of the INR or prothrombin time to titrate warfarin dosage to find the targeted level of anticoagulation for different diseases (see p. 1006).

### ADVERSE DRUG REACTIONS

Adverse drug reactions (ADRs), defined as ‘the unwanted effects of drugs occurring under normal conditions of use’, are a significant cause of morbidity and mortality. The burden of ADRs is huge in both adults and children: ADRs account for about 6.5% of hospital admissions, affecting 15% of adult inpatients. In addition, about 1 in 4 patients in primary care will have an adverse reaction but fortunately these are mild in most cases. Unwanted effects of drugs are 5–6 times more likely in the elderly than in young adults, and the risk of an ADR rises sharply with the number of drugs administered. ADRs are also more common in women than in men.

### Classification

Two types of ADR are recognized: type A (augmented) reactions and type B (idiosyncratic) reactions (Box 12.9).

### Diagnosis

All ADRs mimic some naturally occurring disease, and drawing a distinction between an iatrogenic aetiology and an event unrelated to the drug is often difficult. The patient should be asked not only about prescription drugs but also about over-the-counter medicines, herbal medicines and illicit drugs. Although some effects are obviously iatrogenic (e.g. acute anaphylaxis occurring a few minutes after intravenous penicillin), many are less so.

Causality assessment of a suspected ADR can be difficult, particularly in patients on multiple drugs. The temporal relationship between drug exposure and suspected adverse events should be
appropriate, and other causes of the suspected adverse events should be excluded. Rechallenge with the suspected drug and dechallenge (i.e. stopping the suspected drug to see if the adverse effect disappears) may be appropriate in certain circumstances. Some ADRs are so typical, such as cough or angio-oedema following initiation of ACE inhibitors, that identification of such as an ADR is likely.

Management
As a general rule, type A reactions can usually be managed by a reduction in dosage, while type B reactions almost invariably require the drug to be withdrawn (and never re-instituted). Most ADRs resolve spontaneously when the drug is withdrawn, but specific therapy is sometimes required for ADRs that cause acute patient harm (see p. 64). For example, bleeding with anticoagulants is actively reversed (vitamin K and prothrombin complex can be used for warfarin) and drug-induced anaphylaxis is a medical emergency, such that patients are given their own supply of adrenaline (epinephrine) to self-inject in such cases. When a patient suffers an ADR, this should be reported to the regulatory agency; for example, through the UK’s Yellow Card reporting scheme to the Medicines Healthcare Products Regulatory Agency. The criteria for reporting vary across the world but, in general, all ADRs to new drugs or drugs used outside their licence should be reported, while only the serious ADRs to established drugs (i.e. those that have been on the market for usually more than 2 years) should be reported.

DRUG INTERACTIONS

Drugs can interact with each other (drug–drug interactions, DDIs), with food (drug–food interactions) and with herbal medicines (drug–herbal interactions) (Box 12.10). These interactions, in general, can be either pharmacokinetic (affecting the processes of absorption, distribution, metabolism and excretion), pharmacodynamic (synergistic or antagonistic or mixed). Approximately 1% of all ADRs that lead to hospital admission are due to DDIs. A major risk factor for DDIs is polypharmacy, which is becoming more common because of the co-morbidities associated with an ageing population (see p. 305). About 57% of patients above the age of 65 years are on more than five drugs, with 12% being on more than ten drugs.

Food–drug interactions are also becoming increasingly recognized. A common example is grapefruit juice that inhibits CYP3A4 in the intestinal wall, increasing the bioavailability of drugs metabolized by CYP3A4 (see Box 12.10), resulting in higher exposure and toxicity.

Herbal medicines are taken by almost 20% of the population but are rarely asked about when a patient’s clinical history is taken. Many different herbal–drug interactions have been described, the best recognized of which is with St John’s Wort (SJW), which is an inducer of P450 enzymes and drug transporters, such as P-glycoprotein. SJW can lead to increased drug metabolism, reduction in drug concentration, and failure of therapeutic effect. An example is interaction with immunosuppressants such as prednisolone and ciclosporin, where the use of SJW has led to allograft rejection.

Reliable sources of information (see next section) must be used when prescribing new drugs to patients who already are taking other medications to ensure that no significant DDI exist.

INFORMATION SOURCES

Pharmacotherapy moves at a very rapid pace and it is impossible for anyone to keep up with contemporary advances. Reliable prescribing advice can be found in:

- The Summary of Product Characteristics (SmPCs) produced by manufacturers and vetted by drug regulatory authorities.
- The relevant national formulary. Many countries have their own formularies: e.g. the UK has the British National Formulary (BNF).
- Guidance produced by national health technology agencies such as the UK’s National Institute for Health and Care Excellence (NICE).

INTRODUCTION

In developed countries, poisoning is responsible for approximately 10% of acute hospital medical presentations and 1% of admissions. Most cases involve self-administration of prescribed or over-the-counter medicines, and/or illicit drugs.

- **Poisoning in children** aged <6 months is usually iatrogenic. Children between 8 months and 5 years of age may ingest poisons accidentally (due to inappropriate storage of prescribed or illicit medicines intended for use by an older family member/carer). Drugs may also be administered deliberately to cause harm (abuse by proxy).

- **Self-poisoning in adults** is commonly a ‘cry for help’, particularly among females <35 years old who are otherwise in good physical health. The overdose is taken in circumstances where they are likely to be found, often in the presence of others. In the over-55s, there is a preponderance of men who are suffering from mental and/or physical ill health.

- **Occupational poisoning** due to dermal or inhalational exposure to chemicals is more common in the developing world.

- Poisoning may be iatrogenic, and common in drugs with a narrow therapeutic window, e.g. lithium, digoxin, theophylline or phenytoin.

- The **type of agent** taken in overdose is influenced by availability and culture. In the UK, paracetamol poisoning remains the most common drug taken, whereas in Sri Lanka, for example, the agents ingested are more often pesticides (e.g. organophosphorus insecticides) or plants (e.g. oleander). In addition, ingestion of heating fuels, antimalarials, anti-tuberculous drugs and traditional medicines are common in the developing world. Poisoning from snake venoms is also a problem in rural areas.

Most patients taking an overdose reach for a drug, or a combination of drugs, that is easily available. To this end, Box 12.11 lists some significant aspects of poisoning prevention. Acute overdoses often involve more than one agent, particularly alcohol. There is often a poor correlation between the patient’s history (which itself may change over time) and subsequent analytical findings.

The majority of patients do not require intensive medical management, but all require a sympathetic and caring approach, with a psychiatric and social assessment. Fatalities in the UK are due predominantly to antidepressants, paracetamol, or analgesic combinations containing paracetamol and an opioid, heroin, methadone or cocaine. In North America there has been a substantial increase in recent years in fatal poisonings from prescription and illicit opioids (including fentanyl).

**CLINICAL APPROACH TO THE POISONED PATIENT**

**History**

More than 80% of adults are conscious on arrival at hospital and the diagnosis of self-poisoning can usually be made from the history (Box 12.12). Acute poisoning should be considered in the differential diagnosis of any patient presenting with impaired consciousness.

**Examination**

Box 12.13 provides a quick examination guide. The ‘cluster of features’ on presentation may be distinctive and diagnostic; for example, sinus tachycardia, fixed dilated pupils, exaggerated tendon reflexes, extensor plantar responses and coma suggest tricyclic antidepressant poisoning (Box 12.14).
Box 12.11 Prevention of self-poisoning

Patients usually take what is readily available at home:
- Only small amounts of drugs should be sold
- Foil-wrapped drugs are less likely to be taken in overdose
- Drugs should always be kept in a safe place
- Drugs and liquids should be kept in their original containers

- Child-resistant drug containers should be used
- Care should be taken in prescribing all drugs
- Prescriptions for any susceptible patient (e.g. the depressed) must be monitored
- Household products should be labelled and kept safely away from children

Box 12.12 History-taking in poisoning (record in notes)

- Obtain history (if possible) from patient, relatives, friends, paramedics, witnesses
- Seek evidence of overdose
- Establish whether suicide note was left
- Ascertain what drugs/poisons were taken
- Establish time/route taken

- Ask about additional drugs, e.g. alcohol
- Seek details from GP, e.g. prescribed medicines
- Assess suicide risk
- Assess capacity to make decisions
- Record a general history – past history, allergies, family history, social history

Box 12.13 Quick examination guide for the poisoned patient

- A B C D E (see p. 833)
- Level of consciousness (Glasgow Coma Scale; see p. 832)
- Ventilation – pulse oximetry
- Blood pressure and pulse rate

- Pupil size and reaction to light
- Temperature
- Head injury complicating poisonings
- If patient is unconscious, check cough and gag reflex

PRINCIPLES OF MANAGEMENT OF POISONING

Most people with self-poisoning require only general care and support of the vital systems (Box 12.15). However, for a few poisons additional therapy is required.

Care of the unconscious patient

(See also page 833.) In all cases, the initial priority is to ensure that basic resuscitative measures are instituted promptly, establishing a clear airway and supporting breathing as necessary. Remember that pulse oximetry alone will not detect hypercapnia. Loss of the cough or gag reflex is the prime indication for intubation. In many severely poisoned patients, the reflexes are depressed sufficiently to allow intubation without the use of sedatives or relaxants.

Immediate catheterization of the bladder is not usually required. Insertion of a venous cannula is usual, but administration of intravenous fluids is unnecessary unless the patient has been unconscious for more than 12 hours, is dehydrated or is hypotensive.

Cardiovascular support

Severe hypotension and shock are unusual in the acutely poisoned patient but may be caused by:
- a direct cardio-depressant action of the poison (e.g. beta-blockers, calcium-channel blockers, tricyclic antidepressants)
- vasodilation and venous pooling in the lower limbs (e.g. ACE inhibitors, phenothiazines)
- a decrease in circulating blood volume because of gastrointestinal losses (e.g. profuse vomiting), increased sweating, increased renal losses and/or increased capillary permeability. Hypotension may be exacerbated by coexisting hypoxia, acidosis and dysrhythmias. Volume expansion with intravenous crystalloids is usually sufficient to restore blood pressure. Volume replacement and the use of inotropes are discussed on pages 221–222. All patients with cardiogenic shock should have electrocardiographic (ECG) monitoring. Systemic hypertension may occur in poisoning with drugs such as amfetamines and cocaine. If this is mild and associated with agitation, treatment with a benzodiazepine may suffice. In more severe cases there may be a risk of arterial rupture, particularly intracranial. To prevent this, intravenous nitrites such as glyceryl trinitrate are given, starting at a dose of 1–2 mg/h, gradually increasing the dose to a maximum of 12 mg/h until blood pressure is controlled. Calcium antagonists, such as verapamil 240–480 mg daily in divided doses, are an alternative second-line therapy. Sodium nitroprusside 0.5–1.5 μg/kg/min (to a maximum of 8 μg/kg/min) is an option for patients with increased blood pressure when there is no evidence of cardiac ischaemia, but caution is required as it may cause a rapid fall in blood pressure.

Arrhythmias can occur, such as tachyarrhythmias following ingestion of a tricyclic antidepressant, or bradyarrhythmias with digoxin poisoning. Known arrhythmogenic factors, such as hypoxia, acidosis and hypokalaemia, should be corrected.
Box 12.15 Management strategy in acute poisoning

### Immediate decisions
- Supportive treatment
- Is an antidote appropriate? (see Box 12.16)
- Is it appropriate to try to reduce poison absorption?
- Is it appropriate to perform toxicological investigations?
- Is it appropriate to try to enhance elimination?

### Practical points – contact with poison

**Eyes**
- Remove contact lenses
- Wash eyes with 0.9% saline or water for about 15 min
- Assess corneal damage (if necessary) with slit lamp and fluorescein stain

**Skin**
- Remove clothing
- Wash thoroughly with soap and water if, e.g., chemical exposure

**Other problems**

**Hypothermia**
A rectal temperature below 35°C is a recognized complication of poisoning, especially in older patients or in those who are comatose. The patient should be covered with a ‘space blanket’ and, if necessary, given intravenous fluids at normal body temperature. The administration of heated (37°C), humidified oxygen delivered by face mask is also useful.

**Hyperthermia**
Body temperature can, rarely, increase to being potentially fatal after poisoning with central nervous stimulants such as cocaine, and amphetamines, including ‘ecstasy’ (MDMA) and the weight-loss/body-building agent dinitrophenol (DNP). Muscle tone is often increased and convulsions and rhabdomyolysis are common. Cooling measures, sedation with diazepam and, in severe cases, intravenous dantrolene (a skeletal muscle relaxant) 1 mg/kg body weight should be given.

**Skin blisters**
Skin blisters may be found in poisoned patients who are, or have been, unconscious and do not move. Such lesions are not diagnostic of specific poisons but are sufficiently common in poisoned patients (and sufficiently uncommon in patients unconscious from other causes) to be of diagnostic value.

**Rhabdomyolysis**
Rhabdomyolysis can occur from pressure necrosis in drug-induced coma, or it may complicate poisoning in the absence of coma, such as in ecstasy (MDMA) abuse. People with rhabdomyolysis are at risk of developing acute kidney injury from myoglobinemia, particularly if they are hypovolaemic and have a metabolic acidosis. Severe rhabdomyolysis may lead to the development of a compartment syndrome (see p. 427), which can cause serious tissue damage if not treated promptly.

**Convulsions**
These may occur in poisoning from many drugs, including tricyclic antidepressants, mafenamic acid and opioids. Usually seizures are short-lived but, if they are prolonged, intravenous diazepam 10–20 mg or lorazepam 4 mg should be administered. Persistent fits must be controlled rapidly to prevent severe hypoxia, brain damage and laryngeal trauma. If diazepam or lorazepam in repeated dose is ineffective, second-line treatments include intravenous phenytoin (loading dose 20 mg/kg at not more than 50 mg/min) or intravenous phenobarbital sodium (10 mg/kg at not more than 100 mg/min). Phenytoin is contraindicated in cases of poisoning with sodium channel-blocking drugs (such as tricyclic antidepressants) and is relatively contraindicated in all cases of poisoning with cardiotoxic drugs.

**Stress ulceration and bleeding**
An intravenous PPI should be given to prevent stress ulceration of the stomach in the elderly and patients with a previous history of ulceration.

### Body ‘packers’ and body ‘stuffers’

**Body ‘packers’** (sometimes called ‘mules’ or ‘swallowers’) are those who swallow a substantial number of packages containing illicit drugs as a means of smuggling. Heroin used to be the drug of choice but this has been superseded by cocaine. Although each package contains a potentially lethal amount of drug, packets are now usually machine-manufactured using a material that does not leak. Body packers may ingest up to 100–200 packages.

**Body ‘stuffers’** swallow a small number of packages containing an illicit drug, usually heroin, cocaine, cannabis or an amphetamine, in an unplanned attempt to conceal evidence when on the verge of being arrested. These drugs are usually either unpackaged or poorly packaged and, as a consequence, leakage may occur over the ensuing 3–6 hours and cause significant symptoms. Some also hide illicit drug packages in their rectum or vagina with the same intent (these are sometimes known as body ‘pushers’).

The role of imaging is usually confined to body packers; imaging has little role in the care of body stuffers or pushers. Ultrasound is of similar accuracy to abdominal X-ray in locating packages but is less accurate than computed tomography (CT). A urine screen for drugs of misuse should be performed. A screen that is positive for one or more drugs of misuse suggests that either the patient has used the drug in the previous few days, or at least one packet is leaking. A negative screen strongly suggests that no packet is leaking. Screens should be repeated daily, or immediately if the patient develops features of intoxication, to confirm the diagnosis.

### Management
Packages can be removed most expeditiously in body stuffers by employing whole-bowel irrigation (see p. 263). Indications for urgent surgery in body packers include evidence of acute intestinal obstruction, radiological confirmation of many packets and clinical or analytical evidence to suggest package leakage, particularly if the drug involved is cocaine.

Packets in the vagina can usually be removed manually.
### Specific management of the poisoned patient

#### Antidotes
Specific antidotes are available for a small number of poisons only (Box 12.16).

Antidotes may exert a beneficial effect by:

- **forming an inert complex** with the poison (e.g. desferrioxamine, dicobalt edetate, digoxin-specific antibody fragments, dimercaprol, HI-6, hydroxocobalamin, obidoxime, pralidoxime, sodium calcium edetate, succimer (dimercaptosuccinic acid; DMSA), Unithiol (dimercaptopropanesulphonate; DMPS))
- **accelerating detoxification** of the poison (e.g. acetylcysteine, sodium thiosulphate)
- **reducing the rate of conversion** of the poison to a more toxic compound (e.g. ethanol, fomepizole)
- **competing with the poison** for essential receptor sites (e.g. oxygen, naloxone, phytomenadione)
- **blocking essential receptors** through which the toxic effects are mediated (e.g. atropine)
- **bypassing the effect** of the poison (e.g. oxygen, glucagon).

#### Gut decontamination
Although it seems logical to assume that removal of unabsorbed drug from the gastrointestinal tract will be beneficial (gut decontamination), the efficacy of gastric lavage and syrup of ipecacuanha (to induce vomiting) remains unproven and efforts to remove small amounts of non-toxic drugs are clinically not worthwhile or appropriate.

**Gastric lavage** should only be performed if a patient has ingested a potentially life-threatening amount of a poison, e.g. iron, and the procedure can be undertaken within 60 minutes of ingestion. Ensure the airway is protected. Lavage is contraindicated if a hydrocarbon with high aspiration potential or a corrosive substance has been ingested.

**Syrup of ipecacuanha** to induce vomiting should not be used, as the amount of drug recovered is highly variable and diminishes with time; there is no evidence that it improves outcome.

**Single-dose activated charcoal** can adsorb a wide variety of compounds. Exceptions are strong acids and alkalis, ethanol, ethylene glycol, iron, lithium, mercury and methanol. In studies in volunteers given 50 g activated charcoal, the mean reduction in absorption was 40%, 16% and 21%, at 60 min, 120 min and 180 min, respectively, after ingestion. Administration of oral activated charcoal (50 g for an adult, 1 g/kg for a child) should be considered following ingestion of a potentially toxic amount of a poison (except those listed above) if this is possible with in 1 hour of ingestion. There are insufficient data to support or exclude its use after 1 hour. There is no evidence that administration of activated charcoal improves clinical outcome.

**Cathartics** have no role in the management of the poisoned patient.

**Whole-bowel irrigation** requires the insertion of a nasogastric tube into the stomach and the introduction of polyethylene glycol electrolyte solution 1500–2000 mL/h in an adult, which is continued until the rectal effluent is clear. Whole-bowel irrigation may be used for potentially toxic ingestions of sustained-release or entericoated drugs, or to remove illicit drug packets.

#### Increasing poison elimination

**Multiple-dose activated charcoal (MDAC)** involves the repeated administration of oral activated charcoal to increase elimination of a drug that has already been absorbed. Most absorbed drugs re-enter the gut from the villi capillaries by passive diffusion (a few by an active process) if the concentration in the gut is lower than that in the blood (this is called the entero-enteric circulation). Some drugs are also secreted in the bile (enterohepatic circulation). Activated charcoal will bind any drug that is in the gut lumen, so keeping the concentration in the gut low and favouring further diffusion from blood to gut lumen.

Elimination of drugs with a small volume of distribution (<1 L/kg), low pKa (which maximizes transport across membranes), low binding affinity and prolonged elimination half-life following overdose is particularly likely to be enhanced by MDAC. MDAC also improves total body clearance of the drug when endogenous processes are compromised by liver and/or renal failure.

Although MDAC has been shown to increase drug elimination significantly, it has not reduced morbidity and mortality in controlled studies. At present, MDAC should be used only in patients who have ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine or theophylline.

In adults, charcoal should be administered in an initial dose of 50–100 g and then at a rate of not less than 12.5 g/h, preferably via a nasogastric tube; usually, 200 g is sufficient. Intravenous ondansetron 4–8 mg is an effective antiemetic and facilitates MDAC administration if vomiting is a problem.
**Urine alkalization** enhances elimination of salicylate, phenobarbital and chlorophenoxyl herbicides (e.g. 2,4-dichlorophenoxyacetic acid) by mechanisms that are not clearly understood. Urine alkalization is a metabolically invasive procedure requiring frequent biochemical monitoring and medical and nursing expertise. Advice should be sought from those familiar with the procedure before urine alkalization is commenced. Plasma volume depletion, electrolytes (notably plasma potassium since sodium bicarbonate exacerbates pre-existing hypokalaemia) and metabolic abnormalities should be corrected first. Sufficient bicarbonate is then administered to ensure that urine pH is over 7.5 and preferably close to 8.5. In one study, sodium bicarbonate 225 mmol was the mean amount required initially. This can be administered intravenously as 225 mL of an 8.4% solution (1 mmol bicarbonate/mL) over 1 hour but great care must be taken to avoid extravasation if given via a peripheral line.

**Haemodialysis and haemodiafiltration** are of little value in patients poisoned with drugs that have large volumes of distribution (e.g. tricyclic antidepressants) because the plasma contains only a small proportion of the total amount of drug in the body. These methods are indicated in patients with severe clinical features and high plasma concentrations of ethanol, ethylene glycol, isopropanol, lithium, methanol and salicylate: that is, drugs with small volumes of distribution.

**Lipid emulsion therapy** involves the intravenous administration of 20% Intralipid (fractionated soya oil) 1.5 mL/kg, followed by 0.25–0.5 mL/kg per minute for 30–60 minutes to an initial maximum of 500 mL. Use of lipid emulsion as an antidote for severe poisoning with highly lipid-soluble drugs is based on experience of its efficacy in local anesthetic poisoning. It is believed to increase the intravascular lipid phase, so creating a ‘lipid sink’ to reduce the amount of active drug in plasma. Other proposed mechanisms of benefit include increasing myocardial fatty acid energy substrate and improving the function of cell membrane-bound ion channels (particularly Ca2+ and Na+). The role of Intralipid in the management of poisoning with highly lipid-soluble drugs is not well defined but case reports suggest some benefit in life-threatening cardiotoxicity that is resistant to other measures.

### Investigations

**Box 12.17** (and see also Box 12.20) sets out investigations that may be helpful in poisoned patients. On admission, or at an appropriate time post overdose, a timed blood sample should be taken if it is suspected that aspirin, digoxin, ethylene glycol, iron, lithium, methanol, paracetamol, paraquat, quinine or theophylline has been ingested (Box 12.18). The determination of the concentrations of these drugs will be valuable in management. Drug screens on blood and urine are occasionally indicated in severely poisoned patients in whom the cause of coma is unknown. A poison information service will advise.

**Box 12.17 Investigations that may be helpful in poisoned patients**

- Serum creatinine and electrolytes, estimated glomerular filtration rate
- Creatine kinase activity
- Acid–base assessment (arterial gas, unless no concern regarding ventilation)
- Blood for specific poisons (see later)
- Electrocardiography (see p. 265)
- Urine saved (plain tube) for possible drug screen
- Radiology (see p. 265)

Some routine investigations (Box 12.19) are of value in the differential diagnosis of coma or the detection of poison-induced hypokalaemia, hyperkalaemia, hypoglycaemia, hyperglycaemia, hepatic or renal failure or metabolic acidosis (Box 12.20). Measurement of carboxyhaemoglobin, methaemoglobin and cholinesterase activities are of assistance in the diagnosis and management of cases of poisoning due to carbon monoxide, methaemoglobin-inducing agents, such as nitrates, and organophosphorus insecticides, respectively.

**ECG**

Routine ECG is of limited diagnostic value, but continuous ECG monitoring should be undertaken in those ingesting potentially cardiotoxic drugs; for example, sinus tachycardia with prolongation of the PR and QRS intervals in an unconscious patient suggests tricyclic antidepressant overdose. QT interval prolongation is an adverse effect of several drugs (e.g. quetiapine).

### Box 12.18 Laboratory analysis for toxins

- Carbon monoxide (carboxyhaemoglobin) concentrations are available on most blood gas analysers
- Ethanol (when monitoring treatment in glycol and methanol poisoning)
- Ethylene glycol
- Iron
- Lithium
- Methanol
- Paracetamol
- Salicylate
- Theophylline

### Box 12.19 Relevant non-toxicological investigations with examples

Radiology
Routine radiology is of little diagnostic value. It can confirm ingestion of metallic objects (e.g. coins, button batteries) or injection of globules of metallic mercury. Some enteric-coated or sustained-release drugs or ingested packets of illicit substances may be seen on plain abdominal X-rays. Radiology can confirm complications of poisoning, such as aspiration pneumonia, non-cardiogenic pulmonary oedema (salicylates) and acute respiratory distress syndrome (ARDS).

SPECIFIC POISONS

- All patients must be reviewed by senior medical staff.
- All patients should have relevant blood tests and monitoring when appropriate.
- The general principles of management of self-poisoning outlined earlier will always need to be applied.

In this section, only the specific treatment regimens are outlined. The first section covers the ‘top ten’ drug types encountered in poisoning; paracetamol, NSAIDs, opiates/opioids, antidepressants, benzodiazepines, stimulants (including cocaine), ethanol, neuroleptics, cannabis/synthetic cannabinoids and anticonvulsants. All doctors working in an acute setting should be familiar with the clinical presentation and principles of management of poisoning with these agents.

The top ten

Paracetamol (acetaminophen)
In therapeutic doses, paracetamol is conjugated with glucuronide and sulphate. A small amount of paracetamol is metabolized by mixed-function oxidase enzymes to form a highly reactive toxic compound (N-acetyl-p-benzoquinoneimine; NAPQI), which is then immediately conjugated with glutathione and subsequently excreted as cysteine and mercapturic conjugates.

In overdose, large amounts of paracetamol are metabolized by oxidation because of saturation of the sulphate conjugation pathway. Liver glutathione stores become depleted so that the liver is unable to deactivate NAPQI. Paracetamol-induced kidney injury probably results from a mechanism similar to that responsible for hepatotoxicity.

Clinical features
Following the ingestion of an overdose of paracetamol, patients usually remain asymptomatic for the first 24 hours or, at the most, develop anorexia, nausea and vomiting. Liver damage is not usually detectable by routine liver function tests until at least 18 hours after ingestion of the drug. Liver damage usually reaches a peak, as assessed by measurement of alanine transferase (ALT) activity and prothrombin time (INR), at 72–96 hours after ingestion. Without treatment, a small percentage of patients will develop fulminant hepatic failure. Acute kidney injury due to acute tubular necrosis occurs in 25% of patients who have severe hepatic damage and in a few without evidence of serious disturbance of liver function.

Management
Acetylcysteine is an effective protective agent, provided that it is administered within 8–10 hours of ingestion of the overdose. It acts by replenishing cellular glutathione stores, though it may also repair oxidation damage caused by NAPQI. The treatment regimen is shown in Box 12.21.

There are now two main approaches to treatment worldwide. In the UK, following a decision by the Medicines and Healthcare products Regulatory Agency (MHRA) in 2012 to abandon a detailed risk assessment in the decision to treat, it is deemed that patients with concentrations above a ‘treatment line’ starting at 100 mg/L 4 hours after ingestion (Fig. 12.2) should be given treatment with acetylcysteine. In most other countries, a parallel line starting at 150 mg/L 4 hours after ingestion is used, though some still follow the original treatment line starting at 200 mg/L 4 hours after ingestion. The treatment lines (see Fig. 12.2) are uncertain if the patient presents 15 hours or more after ingestion or has taken a modified-release preparation of paracetamol. Although these lines are often extended to 24 hours (dotted lines), the concentrations are not based on clinical trial data.

A summary of single acute paracetamol overdose management at different times post ingestion is given in Box 12.22. Note that patients whose paracetamol overdose is staggered over more than 1 hour or who take repeated therapeutic excess are at greater risk of liver damage, and decisions to treat are generally based on the dose ingested/24 hours. In the UK, treatment with acetylcysteine is considered if more than 75 mg/kg has been ingested in 24 hours.

Up to 15% of patients treated with intravenous acetylcysteine develop a rash, angio-oedema, hypotension and/or bronchospasm. These reactions, which are histamine-mediated and related to the initial bolus, are seldom serious and discontinuing the infusion is usually all that is required. In more severe, adult cases, intravenous chlorphenamine 10–20 mg should be given.

If liver or renal failure ensues, this should be treated conventionally, although there is evidence that a continuing infusion of acetylcysteine (continue 16-h infusion until recovery) will improve the morbidity and mortality. Liver transplantation has been performed successfully in patients who have paracetamol-induced acute hepatic failure (see Box 34.13).

Non-steroidal anti-inflammatory drugs
Self-poisoning with non-steroidal anti-inflammatory drugs (NSAIDs), other than salicylates, has increased, particularly now that ibuprofen is available without prescription, over the counter, in many countries. Poisoning with salicylates is considered on page 271.
**Box 12.22 Summary of management of single acute paracetamol overdose**

**All patients**
- Clarify date, time, formulation and dose of paracetamol taken
- Weigh the patient
- Calculate the paracetamol dose ingested in mg/kg

**Patients presenting 0–8 hours since last paracetamol ingestion**
- Wait until 4 h post ingestion then take venous blood for plasma paracetamol concentration, serum creatinine and electrolytes, bicarbonate, liver function and INR
- If the blood results will not be available until after 8 h post ingestion AND patient has ingested >150 mg/kg, commence acetylcysteine immediately
- When the plasma paracetamol concentration is available, assess need for antidotal treatment with acetylcysteine using the treatment nomogram (see Fig. 12.2)
- Administer acetylcysteine if required. If already commenced but not required, acetylcysteine can be discontinued at this stage
- Seek specialist advice if plasma paracetamol concentration is below the treatment line but LFTs or clotting are abnormal
- At end of acetylcysteine course take venous blood for serum creatine and electrolytes, liver function and INR
- Consider need for further acetylcysteine if post-treatment bloods are abnormal

**Patients presenting between 8 h and 24 h after paracetamol ingestion**
- Take venous blood for urgent measurement of plasma paracetamol concentration, serum creatinine and electrolytes, bicarbonate, liver function, INR
- Commence acetylcysteine immediately if ingested paracetamol dose is >150 mg/kg
- If ingested dose <150 mg/kg, await blood results and assess need for acetylcysteine using treatment nomogram
- Administer acetylcysteine if required. If already commenced but not required, acetylcysteine can be discontinued at this stage
- BEWARE that for patients presenting >12 h after ingestion, the plasma paracetamol concentration at which treatment is required may be close to the laboratory’s limit of detection. If borderline, treat with acetylcysteine
- Seek specialist advice if plasma paracetamol concentration is below the treatment line but LFTs or clotting are abnormal
- At end of acetylcysteine course take venous blood for serum creatine and electrolytes, bicarbonate, liver function and INR
- Consider need for further acetylcysteine if post-treatment bloods are abnormal

**Patients presenting more than 24 h post overdose**
- Commence acetylcysteine if the patient is jaundiced or has hepatic tenderness
- Measure the plasma paracetamol concentration (before NAC is administered if possible), serum creatinine and electrolytes, bicarbonate, LFTs, glucose, FBC and INR
- Treat with acetylcysteine if the ALT is above the upper limit of normal, OR INR is >1.3 (in the absence of another cause, e.g. warfarin) OR paracetamol concentration is detectable
- If the paracetamol concentration is not detectable, the INR and ALT are normal, and the patient is asymptomatic, no treatment with an antidote is indicated. If acetylcysteine has been started it may then be discontinued
- At end of acetylcysteine course take venous blood for serum creatine and electrolytes, bicarbonate, liver function and INR
- Consider need for further acetylcysteine if post treatment bloods are abnormal

**ALT,** alanine transferase; **FBC,** full blood count; **LFTs,** liver function tests; **INR,** international normalized ratio; **NAC,** N-acetyl cysteine.
Clinical features and management
In most cases, minor gastrointestinal disturbance is the only feature but, in more severe cases, coma, convulsions and acute kidney injury have occurred. Transient renal impairment is common after ibuprofen overdose. Poisoning with mefenamic acid commonly results in convulsions, though these are usually short-lived.

Treatment is symptomatic and supportive.

Opiates and opioids
Clinical features
Cardinal signs of opiate poisoning are pinpoint pupils, reduced respiratory rate and coma. Hypothermia, hypoglycaemia and convulsions are occasionally observed in severe cases. Non-cardiogenic pulmonary oedema has been reported in severe heroin overdose. See page 141 for more information about the worldwide opioid crisis.

Management
Intravenous naloxone will reverse respiratory depression and coma, at least partially. In severe poisoning, an initial dose of 1.2 mg is likely to be required and repeat doses necessary. Lower doses (0.4–0.8 mg) may suffice in less severe cases and if precipitating opioid withdrawal is a concern. The duration of action of naloxone is often less than the drug taken in overdose; for example, methadone, which has a very long half-life. For this reason, an infusion of naloxone is often required. Non-cardiogenic pulmonary oedema should be treated with mechanical ventilation.

Antidepressants: tricyclics and selective serotonin reuptake inhibitors
Tricyclic antidepressants block the reuptake of monoamines (e.g. norepinephrine (noradrenaline) and serotonin) into peripheral and intracerebral neurones, thereby increasing the concentration of these neurotransmitters in these areas. They also have antimuscarinic actions and class 1 antiarrhythmic (quinidine-like) sodium-channel-blocking activity.

Selective serotonin reuptake inhibitors (SSRIs) (e.g. citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine and sertraline) lack the antimuscarinic and sodium-channel-blocking actions of tricyclic antidepressants.

Clinical features
Tricyclic antidepressants. Mild poisoning commonly causes drowsiness, sinus tachycardia, dry mouth, dilated pupils, urinary retention (all antimuscarinic effects), and increased reflexes and extensor plantar responses. Severe intoxication leads to coma, convulsions and, occasionally, divergent strabismus. Plantar, oculocephalic and oculovestibular reflexes may be abolished temporarily. An ECG will often show a wide QRS interval and there is a reasonable correlation between the width of the QRS complex and the severity of poisoning. Life-threatening arrhythmias may ensue. Metabolic acidosis and cardiorespiratory depression are observed in severe cases.

SSRIs. Even in large overdoses, SSRIs appear to be relatively safe unless potentiated by ethanol. Most patients will show no signs of toxicity but drowsiness, nausea, diarrhoea and sinus tachycardia have been reported. Rarely, junctional bradycardia, seizures and hypertension have been encountered and influenza-like symptoms may develop.

Serotonin syndrome occasionally occurs (see p. 781). Venlafaxine is a serotonin norepinephrine reuptake inhibitor (SNRI) with a similar toxicity profile to the SSRIs but with greater risk of cardiac arrhythmias and convulsions. Mirtazapine, an antidepressant that acts via presynaptic alpha blockade to increase central serotonin release, is probably the safest antidepressant in overdose, causing mainly only sedation.

Management
The majority of patients recover with supportive therapy alone (adequate oxygenation, control of convulsions and correction of acidosis), although a small percentage who ingest a tricyclic will require assisted ventilation for 24–48 hours. The onset of supraventricular tachycardia and ventricular tachycardia should be treated with intravenous sodium bicarbonate (8.4%) 50 mmol, even if there is no acidosis present; a second bolus may be required.

Benzodiazepines
Benzodiazepines are commonly taken in overdose but rarely produce severe poisoning, except in the elderly or those with chronic respiratory disease.

Clinical features
Benzodiazepines produce drowsiness, ataxia, dysarthria and nystagmus. Coma and respiratory depression develop in severe intoxication.

Management
If respiratory depression is present in patients who have severe benzodiazepine poisoning, intravenous flumazenil 0.5–1.0 mg is given in an adult and this dose often needs repeating. Flumazenil use often avoids the need for assisted ventilation. It is relatively contraindicated in patients with mixed proconvulsant (e.g. tricyclic antidepressants)/benzodiazepine poisoning and those with a history of epilepsy because it may cause convulsions.

Stimulants
The most commonly abused stimulants are the amphetamines, cocaine and the synthetic cathinones.

Amphetamines are central nervous system (CNS) and cardiovascular stimulants. These effects are mediated by increasing synaptic concentrations of adrenaline (epinephrine) and dopamine. The N-methylated derivative, metamfetamine (the crystalline form of this salt is known as ‘crystal meth’ or ‘ice’), and 3,4-methylenedioxymetamfetamine (MDMA), known as ecstasy, are common examples.

Cocaine hydrochloride (‘street’ cocaine, ‘coke’) is a water-soluble powder or granule that can be taken orally, intravenously or intranasally (‘snorting’). ‘Freebase’ or ‘crack’ cocaine comprises crystals (‘rocks’) of relatively pure cocaine without the hydrochloride moiety. Crack cocaine is more suitable for smoking in a pipe or mixed with tobacco; it can also be heated on foil and the vapour inhaled (approximately 35 mg of drug per ‘line’ or a ‘rail’). The effects of cocaine are experienced almost immediately after intravenous administration or smoking, about 10 minutes following intranasal administration and 45–90 minutes after ingestion. The effects start to resolve in about 20 minutes but may last up
to 90 minutes. In severe poisoning, death occurs in minutes, and death rarely occurs more than 3 hours after exposure.

Cocaine blocks the reuptake of biogenic amines:
- Inhibition of dopamine reuptake is responsible for psychomotor effects.
- Blockade of noradrenaline (norepinephrine) reuptake produces tachycardia.
- Inhibition of serotonin reuptake induces hallucinations.
- CNS arousal is enhanced by potentiating the effects of excitatory amino acids.
- Cocaine is a powerful local anaesthetic and vasoconstrictor.

Cathinone (khat) is a naturally occurring stimulant derived from the plant Catha edulis. The drug is released during prolonged chewing of plant leaves. An increasing number of synthetic cathinone derivatives are available, the best-known of which is methedrone (4-methyl methcathinone). While typically sold as ‘plant foods’ or ‘bath salts’, these ‘legal highs’ are purchased for their recreational abuse potential. Synthetic cathinones may be taken by mouth, nasal insufflation or injection.

Clinical features
Stimulants cause dilated pupils, tachycardia and hypertension, sweating, euphoria, extrovert behaviour, and a lack of desire to eat or sleep. More severe intoxication is associated with agitation, paranoid delusions, hallucinations and violent behaviour. Convulsions, rhabdomyolysis, hyperthermia, metabolic acidosis and cardiac arrhythmias may develop. Rarely, dissection of the aorta, myocarditis, myocardial infarction, dilated cardiomyopathy, subarachnoid haemorrhage, or cerebral haemorrhage or infarction may occur and can be fatal. Disseminated intravascular coagulation and acute kidney injury are recognized. If a young person presents with a stroke or myocardial infarction, poisoning with a stimulant should be considered in the differential diagnosis.

Management
Agitation is best controlled by intravenous diazepam 10–20 mg. Hypertension and tachycardia also usually respond to sedation but if hypertension persists, consider intravenous glyceryl trinitrate starting at 1–2 mg/h and gradually increase the dose (maximum 12 mg/h) until the blood pressure is controlled. The peripheral sympathomimetic actions of amphetamines can be antagonized by β-adrenoceptor-blocking drugs but these are rarely required. The use of β-blockers in cocaine poisoning is controversial. Active external cooling should be employed for hyperthermia and if uncontrolled, intravenous dantrolene 1 mg/kg body weight should be considered (see p. 262). Early use of a benzodiazepine is often effective in relieving stimulant-associated non-cardiac chest pain. Myocardial ischaemia/infarction should be treated conventionally.

Ethanol
Ethanol is commonly ingested in beverages and deliberately with other substances in overdose. It is also present in many cosmetic and antiseptic preparations. Following absorption, ethanol is oxidized to acetaldehyde and then to acetate. Ethanol is a CNS depressant and the features of ethanol intoxication are generally related to blood concentrations (Box 12.23).

Clinical features
In children in particular, severe hypoglycaemia may accompany alcohol intoxication due to inhibition of gluconeogenesis. Hypoglycaemia is also observed in those who are malnourished or who have fasted in the previous 24 hours. In severe cases of intoxication, coma and hypothermia are often present, and lactic acidosis, ketoacidosis and acute kidney injury have been reported.

Management
Supportive care is paramount. Intravenous glucose may be required to treat hypoglycaemia. Haemodialysis should be considered if the blood ethanol concentration exceeds 7500 mg/L and if a severe metabolic acidosis (see p. 198) is present, which has not been corrected by fluids and intravenous bicarbonate.

Neuroleptics and atypical neuroleptics
Neuroleptic (antipsychotic) drugs are thought to act predominantly by blockade of dopamine D2 receptors. The first-generation neuroleptics include the phenothiazines (chlorpromazine), the butyrophenones (benperidol, haloperidol) and the substituted benzamides (sulpiride). More selective second-generation (or ‘atypical’) antipsychotics include amisulpride, aripiprazole, clozapine, olanzapine, quetiapine and risperidone.

Clinical features
These include impaired consciousness, hypotension, respiratory depression, hypothermia or hyperthermia, antimuscarinic effects such as tachycardia, dry mouth and blurred vision, occasionally seizures, rhabdomyolysis, cardiac arrhythmias (both atrial and ventricular) and ARDS. Extrapyramidal effects, including acute dystonic reactions, occur but are not dose related. Most ‘atypical’ antipsychotics have less profound sedative actions than the older neuroleptics.
Clinical features of poisoning

Most frequent: drowsiness, lethargy, coma, ataxia, nystagmus, myoclonus, facial grimacing, nystagmus, respiratory depression.

Management

Intravenous procyclidine 5–10 mg in an adult can occasionally be required for the treatment of dyskinesia and oculogyric crisis. After acidosis has been corrected with sodium bicarbonate, the preferred treatment for arrhythmias caused by antipsychotic drugs (including torsades de pointes) is intravenous magnesium (see p. 1065) or cardiac pacing (p. 1049).

Cannabis (marijuana) and synthetic cannabinoids

Cannabis is usually smoked but may be ingested as a ‘cake’, made into a tea or injected intravenously. The major psychoactive constituent is 6-11-tetrahydrocannabinol (THC). THC possesses activity at the benzodiazepine, opioid and cannabinoid receptors.

Synthetic cannabinoids emerged onto the drug scene around 2009, initially sold as herbal incense or ‘spice’. There are now hundreds of derivatives and most are considerably more potent than THC.

Clinical features

Cannabis intoxication initially causes euphoria followed by distorted and heightened images, colours and sounds, altered tactile sensations and sinus tachycardia. Visual and auditory hallucinations and acute psychosis are particularly likely to occur after substantial ingestion in naive users. Heavy users suffer impairment of memory and attention, and poor academic performance. There is an increased risk of anxiety and depression. Regular users are at risk of dependence. Cannabis use results in an overall increase in the relative risk for later schizophrenia and psychotic episodes (see p. 793). Cannabis smoke is probably carcinogenic.

The clinical features observed following intoxication with synthetic cannabinoids are variable, reflecting the numerous derivatives available. Tachycardia and agitation are the most consistent effects but psychosis, seizures, respiratory failure, coma, acute kidney injury, stroke and myocardial infarction have all been reported and fatalities have occurred.

Management

Reassurance is usually the only treatment required, although sedation with intravenous diazepam (10–20 mg in an adult) or intramuscular or oral haloperidol (2–5 mg in an adult) is sometimes required if agitation is severe. Occasionally, agitation is sufficiently severe for patients to require sedation in a critical care environment.

Anticonvulsants

Clinical features

The clinical features of poisoning with anticonvulsant drugs are summarized in Box 12.24.

Management

Elimination of carbamazepine can be significantly increased by multiple-dose activated charcoal.

If hepatotoxicity and encephalopathy develop in severe valproate poisoning, early intravenous supplementation with L-carnitine will reduce the formation of ammonia and other toxic metabolites of valproic acid. Haemodialysis increases the elimination of valproate and should be instituted if severe hyper-ammonaemia and electrolyte and acid–base disturbances occur.

Other drugs of importance in poisoning

For ease of reference these are arranged in alphabetical order and include antidiabetic drugs, antimalarial drugs, beta-blockers, calcium-channel blockers, digoxin, iron salts, lithium salts and salicylates.

Antidiabetic drugs

Insulin (if injected but not if ingested) and sulphonylureas cause hypoglycaemia. This is not seen with metformin, since its mode of action is to increase glucose utilization, but lactic acidosis is a potentially serious complication of metformin poisoning.

Clinical features

Features of severe hypoglycaemia include drowsiness, coma, convulsions, depressed limb reflexes, extensor plantar responses and cerebral oedema. Hypokalaemia also occurs. Cranial (neurogenic) diabetes insipidus and persistent vegetative states are possible long-term complications if hypoglycaemia is prolonged.

Management

The blood or plasma glucose concentration should be measured urgently and intravenous glucose given, if necessary. Glucagon
produces only a slight rise in blood glucose, although it can reduce the amount of glucose required (see p. 717).

Severe insulin poisoning
A continuous infusion of 10–20% glucose (with K⁺ 10–20 mmol/L) is required, together with carbohydrate-rich meals, though there may be difficulty in maintaining normoglycaemia.

Sulphonylurea poisoning
The administration of glucose increases already high circulating insulin concentrations. Intravenous octreotide (50 μg), which inhibits insulin release, should be given as well as glucose.

Antimalarials
Chloroquine
Severe poisoning may present with hypotension, cardiac failure, pulmonary oedema and cardiac arrest. Agitation, acute psychosis, convulsions and coma may occur. Hypokalaemia is common and is due to chloroquine-induced potassium-channel blockade. Bradycardia and tachyarrhythmias are common, and ECG conduction abnormalities are similar to those seen in quinine poisoning.

Quinine
Cinchonism (tinnitus, deafness, vertigo, nausea, headache and diarrhoea) is common. In more severe poisoning, convulsions, hypotension, pulmonary oedema and cardiorespiratory arrest are seen (due to ventricular arrhythmias that are often preceded by ECG conduction abnormalities, particularly QT prolongation). Quinine cardiotoxicity is due to sodium-channel blockade. Patients may also develop ocular features, including blindness, which can be permanent.

Primaquine
The main concern is primaquine’s propensity to cause methaemoglobinaemia and haemolytic anaemia.

Management
Multiple-dose oral activated charcoal increases quinine and probably chloroquine clearance. Hypokalaemia should be corrected. Intravenous sodium bicarbonate 50–100 mmol is given if the ECG shows QRS prolongation but it will exacerbate hypokalaemia, which should be corrected first. Mechanical ventilation, the administration of an inotrope (see p. 222) and high doses of diazepam (1 mg/kg as a loading dose and 0.25–0.4 mg/kg per hour maintenance) may reduce the mortality in severe chloroquine poisoning. Overdrive pacing may be required if torsades de pointes (see p. 1065) occurs in quinine poisoning and does not respond to intravenous magnesium sulphate (see p. 1065). If clinically significant methaemoglobinemia (generally above 30%) develops in primaquine poisoning, methylythioninium (methylene blue) 1–2 mg/kg body weight should be administered.

Beta-adrenoceptor-blocking drugs
In mild poisoning, sinus bradycardia is the only feature, but if a substantial amount has been ingested, coma, convulsions and hypotension develop. Less commonly, delirium, hallucinations and cardiac arrest supervene. Bronchospasm and hypoglycaemia are rare complications.

Management
Glucagon 50–150 μg/kg (typically 5–10 mg in an adult), followed by an infusion of 5–10 mg/h, is the most effective agent. It acts by bypassing the blocked beta-receptor, thus activating adenyl cyclase and promoting formation of cyclic adenosine monophosphate (cAMP) from adenosine triphosphate (ATP); cAMP, in turn, exerts a direct beta-stimulant effect on the heart. Intravenous atropine 0.6–1.2 mg can be used to treat bradycardia but is usually less effective. High-dose insulin (initial intravenous bolus of 1.0 IU/kg, followed by 1–10 IU/kg per hour) with hypertonic glucose to avoid hypoglycaemia, has been shown to improve myocardial contractility and systemic perfusion.

Calcium-channel blockers
Calcium-channel blockers all act by blocking voltage-gated calcium channels. Dihydropyridines (e.g. amiodipine, felodipine, nifedipine) are predominantly peripheral vasodilators, while verapamil (a phenylalkylamine) and diltiazem (a benzothiazepine) also have significant cardiac effects. Poisoning, particularly with verapamil and diltiazem, causes heart block and hypotension; in severe poisoning, there is a substantial fatality rate. When a sustained-release preparation has been ingested, the onset of severe features is delayed, sometimes for more than 12 hours. Overdose with even small amounts can have profound effects.

Clinical features
Hypotension occurs due to peripheral vasodilation, myocardial depression and conduction block. The ECG may progress from sinus bradycardia through first, then higher, degrees of block, to asystole. Cardiac and non-cardiac pulmonary oedema may ensue in severely poisoned patients. Other features include nausea, vomiting, seizures and a lactic acidosis.

Management
Intravenous atropine 0.6–1.2 mg, repeated as required, should be given for bradycardia and heart block. The initial dose can be repeated every 3–5 min, but if there is no response in pulse rate or blood pressure after three doses, it is unlikely that further boluses will be helpful. The response to atropine is sometimes improved following intravenous 10% calcium chloride, 5–10 mL (at 1–2 mL/min). If there is an initial response to calcium, a continuous infusion is warranted as 10% calcium chloride, 1–10 mL/h.

Cardiac pacing has a role if there is evidence of atrioventricular conduction delay but failure to capture occurs.

Hypotension that persists despite volume replacement may respond to IV glucagon, which activates myosin kinase independent of calcium. An initial bolus of 50–150 μg/kg can be repeated as necessary or an infusion of 5–10 mg/h can be commenced.

Insulin–glucose euglycaemia has been shown to improve myocardial contractility and systemic perfusion, and should be considered in cases of resistant hypotension. Insulin is given as a bolus dose of 1 IU/kg, followed by an infusion of 1–10 IU/kg per hour with hypertonic glucose and frequent monitoring of blood glucose and potassium.

Digoxin
Toxicity occurring during chronic administration is common, though acute poisoning is infrequent.

Clinical features
These include nausea, vomiting, dizziness, anorexia and drowsiness. Rarely, confusion, visual disturbances and hallucinations occur. Initial sinus bradycardia may be followed by supraventricular arrhythmias with or without heart block, ventricular premature beats and ventricular tachycardia. Hyperkalaemia occurs due to inhibition of the sodium–potassium activated ATPase pump.
Management

- **Intravenous atropine** 1.2–2.4 mg is given to reduce sinus bradycardia, atrioventricular block and sinoatrial standstill.
- **Digoxin-specific antibody fragments** (digoxin-Fab) should be given intravenously for significant hyperkalaemia, marked arrhythmias (usually severe bradycardia compromising the cardiac output) and asystole. In both acute and chronic poisoning, only half the estimated dose required for full neutralization (calculated from amount of drug taken or serum digoxin concentration) need be given initially; a further dose is given if clinically indicated.

Iron salts

Unless more than 60 mg of elemental iron per kg of body weight is ingested (a ferrous sulfate tablet contains 60 mg of iron), features are unlikely to develop. As a result, poisoning is seldom severe but deaths still occur. Iron salts have a direct corrosive effect on the upper gastrointestinal tract.

Clinical features

Initial features include nausea, vomiting (the vomit may be grey or black in colour), abdominal pain and diarrhoea. Severely poisoned patients develop haematemesis, hypotension, coma and shock at an early stage. Usually, however, most patients suffer only mild gastrointestinal symptoms. A small minority deteriorate 12–48 hours after ingestion and develop shock, metabolic acidosis, acute tubular necrosis and hepatocellular necrosis. Rarely, up to 6 weeks after ingestion, intestinal strictures occur due to corrosive damage. The serum iron concentration should be measured some 4 hours after ingestion; if the concentration exceeds the predicted normal iron-binding capacity (usually >5 mg/L; 90 μmol/L), free iron is circulating and treatment with desferrioxamine should be considered.

Management

The majority of patients ingesting iron do not require desferrioxamine therapy. If a patient develops coma or shock, desferrioxamine should be given without delay in an intravenous dose of 15 mg/kg per hour (the total amount of infusion usually not to exceed 80 mg/kg in 24 h). If the recommended rate of administration is continued for several days, adverse effects, including pulmonary oedema and ARDS (see p. 232), have been reported.

Lithium salts

Lithium poisoning usually results from impaired renal elimination in an individual on lithium therapeutically; that is, chronic toxicity rather than deliberate self-poisoning (acute toxicity). Lithium has a narrow therapeutic index (target plasma range 0.8–1.2 mmol/L).

Clinical features

Features of intoxication include diarrhoea and vomiting, tremor, thirst, polyuria and, in more serious cases, impairment of consciousness, hypertension and convulsions; irreversible neurological damage may occur. Measurement of the serum lithium concentration confirms the diagnosis. However, in chronic poisoning the plasma lithium concentration may not be markedly above the upper end of the therapeutic range despite the presence of severe neurological features (which are due to accumulation of lithium in the CNS). Conversely, acute massive overdose may produce high plasma concentrations with few toxic features.

Management

The plasma lithium concentration must always be interpreted in association with the clinical features present. Since lithium is eliminated unchanged via the kidneys, diuresis with sodium chloride 0.9% is effective in increasing clearance. Haemodialysis is far superior and is used if neurological features are present and/or if renal function is impaired. It is employed particularly in cases of chronic toxicity.

Salicylates

**Aspirin** is metabolized to salicylic acid (salicylate) by esterases present in many tissues, especially the liver, and subsequently to salicylicuric acid and salicyl phenolic glucuronide (Fig. 12.3); these two pathways become saturated, with the consequence that the renal excretion of salicylic acid increases after overdose; this excretion pathway is extremely sensitive to changes in urinary pH.

Clinical features

Salicylates stimulate the respiratory centre, increase the depth and rate of respiration, and induce a respiratory alkalosis. Compensatory mechanisms, including renal excretion of bicarbonate and potassium, result in a metabolic acidosis. Salicylates also interfere with carbohydrate, fat and protein metabolism, and disrupt oxidative phosphorylation, producing increased concentrations of lactate, pyruvate and ketone bodies, all of which contribute to the acidosis.

Common features of poisoning include tachypnoea, sweating, vomiting, epigastric pain, tinnitus and deafness. Respiratory alkalosis and metabolic acidosis supervene and a mixed acid–base disturbance is typical. Rarely, in severe poisoning, non-cardiogenic pulmonary oedema, coma and convulsions ensue.

The severity of salicylate toxicity is dose-related.

Management

Fluid and electrolyte replacement are required with prompt correction of dehydration and hypokalaemia. Mild cases of salicylate poisoning are managed with parenteral fluid and electrolyte replacement only. Patients whose plasma salicylate concentrations are in excess of 500 mg/L (3.6 mmol/L) should receive urine alkalinization (see p. 264). Haemodialysis is the treatment of choice for severely poisoned patients (plasma salicylate concentration >700 mg/L; >5.1 mmol/L), particularly those with coma and metabolic acidosis.
Poisoning with chemicals

Included in this section, in alphabetical order, are arsenic, carbamate insecticides, carbon monoxide, copper sulfate, corrosives, cyanide, ethylene glycol, household agents, lead, mercury, methanol, nerve agents, organophosphorus insecticides and phosphides.

Arsenic

Arsenic poisoning worldwide is commonly caused by contamination of the ground water by inorganic arsenates, particularly in Asia. Occasionally, arsenic is found in Chinese and Indian traditional remedies.

Clinical features

*Acute ingestion* causes abdominal pain, vomiting and diarrhoea. Hypovolaemic shock and acute tubular necrosis occur in severe cases.

*Chronic exposure* to lower doses produces gastrointestinal effects, accompanied by skin changes (hyperkeratosis of palms and soles, ‘raindrop’ pattern of hyperpigmentation and alopecia), neurological features (headache, sensorimotor neuropathy), abnormal liver biochemistry (non-cirrhotic portal hypertension is recognized), peripheral vascular arteriosclerosis and haematological abnormalities (pancytopenia).

Management

The identification of, and removal from, the source of exposure to arsenic is vital. Chelation therapy with oral DMSA 30 mg/kg per day or intravenous DMPS 30 mg/kg per day may be indicated.

Carbamate insecticides

Carbamate insecticides inhibit acetylcholinesterase but the duration of this inhibition is comparatively short-lived in comparison with organophosphorus insecticides (see p. 275), since the carbamate–enzyme complex tends to dissociate spontaneously.

Clinical features

Although carbamate insecticide poisoning is generally less severe than organophosphorus insecticide poisoning, acute poisoning with a carbamate can be severe and fatal. Cholinergic symptoms usually develop within a few minutes. In the most severe cases, muscle twitching, profound weakness, profuse sweating, incontinence, mental confusion and progressive cardiac and respiratory failure ensue. In less severe cases, cholinergic symptoms are usually evident within 2 hours and typically resolve within 24 hours. Seizures are relatively uncommon, since carbamate penetration into the CNS is limited.

Management

Mild cases require no specific treatment other than the removal of soiled clothing. Intravenous atropine 2 mg should be given every 3–5 minutes, if necessary, to reduce increased secretions, rhinorrhea and bronchorrhoea. If this measure fails, the patient should be intubated and mechanical ventilation instituted. Since carbamates have a shorter duration of action than organophosphorus insecticides, pralidoxime should be used only rarely in carbamate poisoning. If intoxication is life-threatening, give intravenous pralidoxime chloride 30 mg/kg body weight over 5–10 minutes, followed by an infusion of 8–10 mg/kg per hour.

Carbon monoxide

The most common source of carbon monoxide is an improperly maintained and poorly ventilated heating system. In addition, inhalation of methylene chloride (found in paint strippers) may also lead to carbon monoxide poisoning, as methylene chloride is metabolized *in vivo* to carbon monoxide. Carbon monoxide has a greater affinity for haemoglobin and forms carboxyhaemoglobin (COHb), thereby reducing the oxygen-carrying capacity. The affinity of the remaining haem groups for oxygen is increased. This shifts the oxyhaemoglobin dissociation curve to the left, impairing liberation of oxygen to the cells and leading to tissue hypoxia. In addition, carbon monoxide also inhibits cytochrome oxidase a3.

Clinical features

Symptoms of mild to moderate exposure to carbon monoxide may be mistaken for a viral illness.

- A peak COHb concentration of <10% is not normally associated with symptoms.
- A peak COHb concentration of 10–30% usually causes headache and mild exertional dyspnoea.
- Higher concentrations of COHb are associated with coma, convulsions and cardiorespiratory arrest. Metabolic acidosis, myocardial ischaemia, hypertension, extensor plantar responses, retinal haemorrhages and papilloedema also occur.

Neuropsychiatric features may develop after apparent recovery from carbon monoxide exposure.

Management

In addition to removing the patient from carbon monoxide exposure, high-flow oxygen should be administered using a tightly fitting face mask (see p. 230). Endotracheal intubation and mechanical ventilation are required in those who are unconscious. Several controlled studies of hyperbaric oxygen have been published but none has shown long-term clinical benefit.

Copper sulphate

Copper sulphate is used in fungicides, algicides, electroplating, dyes, inks, disinfectants and wood preservatives.

Clinical features

Ingestion causes vomiting, abdominal pain, diarrhoea, headache, dizziness and a metallic taste. Gastrointestinal haemorrhage, intravascular haemolysis, methaemoglobinemia, rhabdomyolysis, coma, convulsions and hepatoportal failure may ensue and fatalities have occurred. Body secretions may be blue/green.

Management

Treatment is supportive with replenishment of lost fluids/blood. Blood copper concentrations correlate with the severity of poisoning; a copper concentration of >8 mg/L is indicative of severe poisoning. Early endoscopy (or CT scan with contrast if endoscopy is not possible) is recommended if corrosive damage is suspected. Methylaminobenzenaemia of >30% should be treated with intravenous methylthioninium chloride 1-2 mg/kg. Renal failure may require extracorporeal support.

Corrosive agents

Strong acids and alkalis cause chemical burns. Inorganic acids such as hydrochloric and sulphuric acid are generally more toxic than organic acids such as acetic acid. Hydrofluoric acid is considered separately (see p. 273). Some household products, such as water-sterilizing tablets, are strong alkalis. Following corrosive ingestion, the vital aspects of management are early (within 24 h) assessment
of the severity of injury (ideally with endoscopy, or alternatively with CT imaging) and prompt surgical intervention to remove necrotic tissue, if indicated.

**Cyanide**
Cyanide and its derivatives are used widely in industry. Hydrogen cyanide is also released during the thermal decomposition of polyurethane foams, such as that in mattresses. Cyanide reversibly inhibits cytochrome oxidase \( a_3 \), so that cellular respiration ceases.

**Clinical features**
Inhalation of hydrogen cyanide produces symptoms within seconds and death within minutes. By contrast, the ingestion of a cyanide salt may not produce features for 1 hour. After exposure, initial symptoms are non-specific and include a feeling of constriction in the chest and dyspnoea. Coma, convulsions and metabolic acidosis may then supervene.

**Management**
Oxygen should be administered and, if it is available, dicobalt edetate 300 mg should be administered intravenously; the dose is repeated in severe cases. Dicobalt edetate (and the free cobalt contained in the preparation) complexes free cyanide. An alternative but expensive antidote is intravenous hydroxocobalamin (5 g), which enhances endogenous cyanide detoxification; a second dose may be required in severe cases. If these two antidotes are not available, intravenous sodium thiosulphate 12.5 g, which acts by enhancing endogenous detoxification, and intravenous sodium nitrite 300 mg should be administered. Sodium nitrite produces methaemoglobin; methaemoglobin combines with cyanide to form cyanmethaemoglobin.

**Ethylene glycol**
Ethylene glycol is found in a variety of common household products, including antifreeze, windshield washer fluid, brake fluid and lubricants. The features observed in poisoning are due to metabolites predominantly, not the parent chemical. Ethylene glycol (Fig. 12.4) is metabolized to glycolate, the cause of the acidosis. A small proportion of glyoxylate is metabolized to oxalate. Calcium ions chelate oxalate to form insoluble calcium oxalate, which is responsible for renal toxicity.

**Clinical features**
Initially, the features of ethylene glycol poisoning are similar to those of ethanol intoxication (though there is no ethanol on the breath). Coma and convulsions follow and a variety of neurological abnormalities, including nystagmus and ophthalmoplegias, are seen. Severe metabolic acidosis, hypocalcaemia and acute kidney injury are well-recognized complications.

**Management**
If the patient presents early after ingestion, the priority is to inhibit metabolism using either intravenous fomepizole or ethanol; the former does not require monitoring of blood concentrations.

- **Fomepizole**: 15 mg/kg body weight should be administered, followed by four 12-hourly doses of 10 mg/kg, then 15 mg/kg every 12 h until glycol concentrations are not detectable. Following a substantial ingestion, haemodialysis or haemodiafiltration should be employed to remove the glycol and metabolites. If dialysis is used, the frequency of fomepizole dosing should be increased to 4-hourly because fomepizole is dialysable.
- **Ethanol**: alternatively, a loading dose of ethanol 50 g can be administered, followed by an intravenous infusion of ethanol 10–12 g/h to produce blood ethanol concentrations of 500–1000 mg/L (11–22 mmol/L). The infusion is continued until the glycol is no longer detectable in the blood. If haemodialysis is employed, the rate of ethanol administration will need to be increased to 17–22 g/h, as ethanol is dialysable. Supportive measures to combat shock, hypocalcaemia and metabolic acidosis should be instituted.

**Household products**
The agents most commonly involved are bleach, cosmetics, toiletries, detergents, disinfectants, and petroleum distillates such as paraffin and white spirit. Ingestion of household products is usually accidental and is most common among children less than 5 years of age.

**Clinical features**
If ingestion is accidental, features very rarely occur, except in the case of petroleum distillates where aspiration is a recognized complication because of their low surface tension. Powder detergents, sterilizing tablets, denture cleaning tablets and industrial bleaches (which contain high concentrations of sodium hypochlorite) are corrosive to the mouth and pharynx if ingested. Nail polish and nail polish remover contain acetone, which may produce a coma if ingested in substantial quantities. Inhalation by small children of substantial quantities of talcum powder has occasionally given rise to severe pulmonary oedema and death.

**Hydrofluoric acid and hydrogen fluoride**
Hydrofluoric acid, a solution of hydrogen fluoride in water, is a colourless, fuming liquid that is widely used in industry. It is particularly dangerous because of its unique ability among acids to penetrate tissue.

**Clinical features**
*Dermal exposure* to hydrofluoric acid results in rapid liquefactive necrosis and erosion of bone. If more than 1% of the body surface area is contaminated with a 50% or higher solution of hydrofluoric acid, there is a high risk of hypocalcaemia from the formation of calcium fluoride. This may lead to cardiac conduction disturbances, notably QT interval prolongation and an increased risk of ventricular arrhythmias, particularly torsades de pointes (see p. 1065).

*Fig. 12.4 The metabolism of ethylene glycol.* Fomepizole and ethanol inhibit ADH, ADH, alcohol dehydrogenase; ALDH, aldehyde dehydrogenase; AO, aldehyde oxidase; GO, glycolate oxidase; LDH, lactate dehydrogenase.
Ingestion of hydrofluoric acid causes severe corrosive injury to the gastrointestinal tract.

Inhalation of hydrogen fluoride causes irritation of the eyes and nose, with sore throat, cough, chest tightness, headache, ataxia and confusion. Dyspnoea and stridor due to laryngeal oedema may follow, depending on the concentration of hydrogen fluoride. Haemorrhagic pulmonary oedema with increasing breathlessness, wheeze, hypoxia and cyanosis may take up to 36 hours to develop.

Management
- **Dermal exposure**. Immediate irrigation of the skin with copious volumes of water is the priority, followed by the prompt application of calcium gluconate gel to reduce pain and limit skin damage.
- **Ingestion**. This is a medical emergency with the need for immediate assessment for surgery after endoscopy or CT.
- **Inhalation**. If the patient has clinical features of bronchospasm after inhalation, then treat conventionally with nebulized bronchodilators and steroids. Treat pulmonary oedema and/or ARDS (see p. 232) with continuous positive airway pressure (CPAP) or, in severe cases, with intermittent positive pressure ventilation (IPPV).

Lead
Exposure to lead occurs occupationally, children may eat lead-painted items in their homes (pica), and the use of lead-containing cosmetics or ‘drugs’ has also resulted in poisoning.

Clinical features
Mild intoxication may result in no more than lethargy and occasional abdominal discomfort, though abdominal pain, vomiting, constipation and encephalopathy (seizures, delirium, coma) may develop in more severe cases. Encephalopathy is more common in children than in adults but is rare in the developed world. Typically, though very rarely, lead poisoning results in foot drop attributable to peripheral motor neuropathy.

Anaemia (normally normochromic normocytic) occurs due both to inhibition by lead of several enzymes involved in haem synthesis and to haemolysis. The latter results from damage to the red cell membrane by aggregates of RNA that accumulate owing to inhibition by lead of pyrimidine-5-nucleotidase, causing characteristic ‘basophilic stippling’ of erythrocytes.

Management
The social and occupational dimensions of lead poisoning must be recognized. Simply giving patients chelation therapy and then returning them to a contaminated environment is of no value.

The decision to use chelation therapy is based not only on the blood lead concentration but also on the presence of symptoms. Parenteral sodium calcium edetate 75 mg/kg per day or oral succimer (DMSA) 30 mg/kg per day is of similar efficacy. At least 5 days’ treatment is usually required. As chelation of zinc may occur with sodium calcium edetate, serum zinc concentrations should be checked.

Mercury
Mercury is the only metal that is liquid at room temperature. It exists in three oxidation states (elemental/metallic Hg⁰, mercurous Hg⁰²⁺ and mercuric Hg²⁺) and can form inorganic (e.g. mercuric chloride) and organic (e.g. methylmercury) compounds. Metallic mercury is very volatile; when spilled, it has a large surface area so that high atmospheric concentrations may be produced in enclosed spaces, particularly when environmental temperatures are high. Thus, great care should be taken in clearing up a spillage. If ingested, metallic mercury will usually be eliminated per rectum, though small amounts may settle in the appendix and remain there for years. Mercury salts are well absorbed following ingestion, as is mercury vapour following inhalation.

Clinical features
Acute inhalation of mercury vapour causes headache, nausea, cough, chest pain and, occasionally, a chemical pneumonitis. Proteinuria and nephrotic syndrome are observed rarely.

Ingestion of inorganic or organic mercury compounds causes an irritant gastroenteritis. Mercurous (Hg⁰²⁺) compounds are less corrosive and less toxic than mercuric (Hg²⁺) salts.

Systemic accumulation of mercury from any source and by any route of exposure leads to characteristic neurological features, including a fine tremor, lethargy, memory loss, insomnia, personality changes and ataxia. Peripheral nerve damage has also been observed, as has renal tubular damage.

Management
Unithiol (DMPS) is the antidote of choice and is given in an intravenous dose of 30 mg/kg per day. At least 5 days’ treatment is usually required.

Methanol
Methanol is used widely as a solvent and is found in antifreeze solutions. Methanol is metabolized to formaldehyde and formate (Fig. 12.5). The concentration of formate increases greatly and is accompanied by accumulation of hydrogen ions, leading to metabolic acidosis.

Clinical features
Methanol causes inebriation and drowsiness. After a latent period, coma supervenes. Blurred vision and diminished visual acuity occur due to formate accumulation. The presence of diluted pupils that are unreactive to light suggests that permanent blindness is likely to ensue. A severe metabolic acidosis may develop and be accompanied by hyperglycaemia and a raised serum amylase activity. A blood methanol concentration of 500 mg/L (15.6 mmol/L) confirms severe poisoning. The mortality correlates well with the severity and duration of metabolic acidosis. Survivors may show permanent neurological sequelae, including parkinsonian-like signs as well as blindness.

Management
Treatment is similar to that of ethylene glycol poisoning (see p. 273) with the addition of intravenous folic acid 30 mg 6-hourly for 48 hours, which accelerates formate metabolism, thereby reducing ocular toxicity.

Nerve agents
Nerve agents are related chemically to organophosphorus insecticides (see below) and have a similar mechanism of toxicity but a much higher mammalian acute toxicity, particularly via the dermal route of exposure.
route. In addition to inhibition of acetylcholinesterase, a chemical reaction known as ‘ageing’ also occurs rapidly and more completely than in the case of insecticides. This makes the enzyme resistant to spontaneous reactivation or treatment with oximes (pralidoxime, obidoxime or HI-6).

Several classes of nerve agent are recognized: G agents (named after Gerhard Schrader, who synthesized the first agents) and V agents (V allegedly standing for venomous). G agents include tabun, sarin, soman and cyclosarin. The V agents, for example VX, were introduced later. The G agents are both dermal and respiratory hazards, whereas the V agents, unless aerosolized, are contact poisons. The latest class of nerve agents to receive notoriety are the Novichok agents, which are potent contact poisons.

Clinical features
Systemic features include increased salivation, rhinorrhoea, bronchorrhoea, miosis (which is characteristic) and eye pain, abdominal pain, nausea, vomiting and diarrhoea, involuntary micturition and defecation, muscle weakness and fasciculation, tremor, restlessness, ataxia and convulsions. Bradycardia, tachycardia and hypertension occur, depending on whether muscarinic or nicotinic effects predominate. Death occurs from respiratory failure within minutes but individuals with mild or moderate exposure usually recover completely. Diagnosis is confirmed by measuring the erythrocyte cholinesterase activity.

Management
The administration of intravenous atropine 2 mg repeated every 3–5 min as necessary to patients presenting with rhinorrhoea and bronchorrhoea may be lifesaving. In addition, an oxime should be given to all those requiring atropine as soon as possible after exposure before ‘aging’ has occurred; for example, intravenous pralidoxime chloride 30 mg/kg, followed by an infusion of pralidoxime chloride 8–10 mg/kg per hour. Alternatively, boluses of pralidoxime chloride 30 mg/kg may be given 4- to 6-hourly. Intravenous diazepam 10–20 mg, repeated as required, is useful in controlling apprehension, agitation, fasciculation and convulsions.

Organophosphorus insecticides
Organophosphorus (OP) insecticides are used widely throughout the world and are a common cause of poisoning, leading to thousands of deaths annually in the developing world. Intoxication may follow ingestion, inhalation or dermal absorption. OP insecticides inhibit acetylcholinesterase, causing accumulation of acetylcholine at central and peripheral cholinergic nerve endings, including neuromuscular junctions. Many OP insecticides require biotransformation before becoming active and so the features of intoxication may be delayed.

Clinical features
Poisoning is characterized by anxiety and restlessness, which is typically followed by nausea, vomiting, abdominal colic, diarrhoea (particularly if exposure is by ingestion), tenesmus, sweating, hypersalivation and chest tightness. Respiratory failure will ensue in severe cases and is exacerbated by the development of bronchorrhoea and pulmonary oedema. Miosis is characteristic. Muscle fasciculation and flaccid paresis of limb muscles, and, occasionally, paralysis of extraocular muscles is observed. Coma and convulsions occur in severe poisoning.

Diagnosis is confirmed by measuring the erythrocyte acetylcholinesterase activity; plasma cholinesterase activity is less specific but may also be depressed.

The intermediate syndrome usually becomes established 1–4 days after exposure, when the symptoms and signs of the acute cholinergic syndrome are no longer obvious. The characteristic features of the syndrome are weakness of the muscles of respiration (diaphragm, intercostal muscles and accessory muscles, including neck muscles) and of proximal limb muscles. Accompanying features often include weakness of muscles innervated by some cranial nerves.

Delayed polyneuropathy is a rare complication of acute exposure to some OP insecticides not marketed in most countries. It presents with glove and stocking paraesthesiae some 1–4 weeks after exposure, followed by an ascending motor polyneuropathy in many cases. It is initiated by phosphorylation, and subsequent ageing, of at least 70% of an esterase – neuropathy target esterase (NTE) – in peripheral nerves. Most mild cases improve with time but severe cases can be left with an upper motor neurone syndrome and permanent disability.

Management
Mild cases require no specific treatment other than the removal of soiled clothing. Intravenous atropine 2 mg should be given every 3–5 minutes if necessary, to reduce increased secretions, rhinorrhoea and bronchorrhoea.

Symptomatic patients should also be given an oxime (pralidoxime, obidoxime) to reactivate inhibited acetylcholinesterase; for example, pralidoxime chloride 30 mg/kg by slow intravenous injection, followed by an infusion of pralidoxime chloride 8–10 mg/kg per hour. There is no specific treatment for the intermediate syndrome apart from supportive care, including prolonged ventilation, though a prospective trial suggested that early treatment with oximes could reduce the likelihood of the syndrome developing. Most patients recover in 2–3 weeks.

Phosphides
Aluminium and zinc phosphides are used as rodenticides and insecticides. They react with moisture in the air (and the gastrointestinal tract) to produce phosphine, the active pesticide. Acute poisoning with these compounds may be direct, due to ingestion of the salts, or indirect, from accidental inhalation of phosphine generated during their approved use.

Clinical features
Ingestion causes vomiting, epigastric pain, peripheral circulatory failure, severe metabolic acidosis, acute kidney injury and disseminated intravascular coagulation, in addition to the features induced by phosphine.

Exposure to phosphine causes lacrimation, rhinorrhoea, cough, breathlessness, chest tightness, dizziness, diplopia, headache, nausea, drowsiness, intention tremor and ataxia. Acute pulmonary oedema, hypertension, cardiac arrhythmias, convulsions and jaundice have been described in severe cases.

Management
Treatment is symptomatic and supportive. Gastric lavage should not be used, as it can speed up the rate of disintegration of the product ingested and increase toxicity. Activated charcoal may bind metal phosphides. The mortality is high, despite supportive care.
Poisons in the natural world

Numerous biological organisms produce or contain substances that are toxic to humans, including animals (snakes, insects, spiders and marine creatures), and some species of plants and fungi. Space precludes discussion of all of these poisons and toxins here, where only snake bite is covered because of its relatively high prevalence and potential severity. An online supplement covers these other naturally occurring poisons in detail, alongside much more detailed description of the treatment of different subtypes of snake envenomation.

Venomous snakes

Approximately 15% of the 3000 species of snake found worldwide are considered to be dangerous to humans. Snake bite is common in some tropical countries; rural areas of West Africa, Southeast Asia, the Indian subcontinent, New Guinea and the Amazon region are particularly affected. Bites by venomous snakes cause more than 100,000 deaths and many permanent sequelae each year (some 460,000 people are killed each year in India alone).

There are three main groups of venomous snakes, representing some 200 species, which have in their upper jaws a pair of enlarged teeth (fangs) that inject venom into the tissues of their victim. These are:

- **Viperidae** (with two subgroups: Viperinae – European adders and Russell’s vipers; and Crotalinae – American rattlesnakes, moccasins, lance-headed vipers and Asian pit vipers)
- **Hydrophiidae** (sea snakes).

In addition, some members of the family Colubridae are mildly venomous (mongoose snake).

Clinical features

The main effects of envenoming are:

- local swelling, bruising, blistering, regional lymph node enlargement and necrosis
- anti-haemostatic defects: consumption coagulopathy and spontaneous systemic bleeding from gums, nose, skin, gut, genitourinary tract and intracranial haemorrhage
- shock (hypotension) and myocardial damage
- descending paralysis: progressing from ptosis and external ophthalmoplegia to bulbar, respiratory muscle and total flaccid paralysis
- generalized rhabdomyolysis with myoglobinuria
- intravascular haemolysis
- acute kidney injury.

**Viperidae (Viperinae and Crotalinae)**

Russell’s viper causes most of the snake-bite mortality in India, Pakistan and Myanmar. There is local swelling at the site of the bite, which may become massive. Local tissue necrosis may occur. Evidence of systemic involvement (envenomation) occurs within 30 minutes, including vomiting, shock and hypotension. Haemorrhage due to incoagulable blood can be fatal. Envenomation by European adders (*Vipera berus*) is rarely fatal.

**Elapidae**

There is not usually any swelling at the site of the bite, except with Asian cobras and African spitting cobras; in these cases, the bite is painful and is followed by local tissue necrosis. Vomiting occurs first, followed by shock and then neurological symptoms and muscle weakness, with paralysis of the respiratory muscles in severe cases. Cardiac muscle can be involved.

**Hydrophiidae**

Envenomation produces muscle involvement, myalgia and myoglobinuria, which can lead to acute kidney injury. Cardiac and respiratory paralysis may occur.

Management

Following a snake bite, all efforts should be made to transport the patient quickly to a hospital or dispensary. Traditional methods should be discouraged, as they are often ineffective and may harm the patient. Arterial tourniquets should not be used, and incision or excision of the bite area should not be performed.

As a first aid measure, a firm pressure bandage should be placed over the bite and the limb immobilized, as this may delay the spread of the venom. Local wounds often require little treatment. If necrosis is present, antibiotics should be given. Skin grafting may be required later. Anti-tetanus prophylaxis must be given. The type of snake should be identified, if possible.

In about 50% of cases, no venom has been injected by the bite but, nevertheless, careful observation for 12–24 hours is necessary in case envenomation develops. General supportive measures should be carried out, as necessary. These include intravenous fluids with volume expanders for hypotension and diazepam for anxiety. Treatment of acute respiratory, cardiac and kidney injury is instituted as necessary.

Antivenoms are not generally indicated unless envenomation is present, as they can cause severe allergic reactions. Antivenoms can rapidly neutralize venom, but only if an amount in excess of the amount of venom is given. Large quantities of antivenom may be required; as antivenoms cannot reverse the effects of the venom, they must be given early to minimize some of the local effects and may prevent necrosis at the site of the bite. Antivenoms should be administered intravenously by slow infusion, the same dose being given to children and adults.

Allergic reactions are frequent, and adrenaline (epinephrine) 1 in 1000 solution should be available. In severe cases, the antivenom infusion should be continued even if an allergic reaction occurs, with subcutaneous injections of adrenaline being given as necessary. Some forms of neurotoxicity, such as those induced by the death adder, respond to anticholinesterase therapy with neostigmine and atropine.

Marine animals

Amnesic shellfish (domoic acid) poisoning
The syndrome should be known more accurately as domoic acid poisoning because amnesia is not always present. In one outbreak, the first symptoms were experienced between 15 minutes and 38 hours after mussel consumption. There are now legal limits on the domoic acid concentrations allowed in mussels.

Clinical features and management
The most common symptoms are nausea, vomiting, abdominal cramps, headache, diarrhoea and short-term memory loss. Axonal sensory motor neuropathy, seizures, coma and death have also been reported. Treatment is symptomatic and supportive.

Diarrhoiec shellfish (okadaic) poisoning
Okadaic poisoning occurs worldwide, often after eating bivalve molluscs such as mussels and scallops. Okadaic acid is produced by dinoflagellates belonging to the genus Dinophysis. It inhibits the activity of the protein phosphatases 1 and 2a. As a result, increased phosphorylation of intestinal transport proteins, with increased permeability to solutes, leads to diarrhoea.

Clinical features and management
The predominant symptoms are diarrhoea, nausea, vomiting and abdominal pain. Symptoms tend to occur between 30 minutes and a few hours after shellfish consumption, with patients recovering within 2–3 days. Treatment is symptomatic and supportive.

Neurotoxic shellfish (brevetoxin) poisoning
Neurotoxic shellfish poisoning is caused by brevetoxins produced by the dinoflagellate Gymnodinium breve. Brevetoxin opens voltage-gated sodium ion channels in cell walls and enhance the inward flow of sodium ions into the cell.

Clinical features and management
The symptoms of neurotoxic shellfish poisoning occur within 30 minutes to 3 hours and last a few days; they include nausea, vomiting, diarrhoea, chills, sweats, reversal of temperature sensation, hypotension, arrhythmias, numbness, tingling, paraesthesiae of the lips, face and extremities, cramps, bronchoconstriction, paralysis, seizures and coma. Treatment is symptomatic and supportive.

Paralytic shellfish (saxitoxin) poisoning
This is caused by bivalve molluscs being contaminated with neurotoxins, including saxitoxin, produced by toxic dinoflagellates on which the molluscs graze. Saxitoxin blocks voltage-gated sodium channels in nerve and muscle cell membranes, thereby blocking nerve signal transmission.

Clinical features and management
Symptoms develop within 30 minutes. The illness is characterized by paraesthesiae of the mouth, lips, face and extremities, and is often accompanied by nausea, vomiting and diarrhoea. In more severe cases, dystonia, dysphagia, muscle weakness, paralysis, ataxia and respiratory depression occur. In one outbreak involving 187 cases, there were 26 deaths. Treatment is symptomatic and supportive.

Ciguatera fish poisoning
Over 400 fish species have been reported as ciguatoxic (cigua is Spanish for poisonous snail), though barracuda, red snapper, amberjack and grouper are most commonly implicated. Ciguatera fish contain ciguatoxin, maitotoxin and scaritoxin, which are lipid-soluble, heat-stable compounds that are derived from dinoflagellates such as Gambierdiscus toxicus. Ciguatoxin opens voltage-sensitive sodium channels at the neuromuscular junction and maitotoxin opens calcium channels of the cell plasma membrane.

Clinical features and management
The onset of symptoms occurs from a few minutes to 30 hours after ingestion of toxic fish. Typically, features appear between 1 and 6 hours, and include abdominal cramps, nausea, vomiting and watery diarrhoea. In some cases, numbness and paraesthesiae of the lips, tongue and throat occur. Other features described include malaise, dry mouth, metallic taste, myalgia, arthralgia, blurred vision, photophobia and transient blindness. In more severe cases, hypotension, cranial nerve palsies and respiratory paralysis have been reported. Treatment is symptomatic and supportive. Recovery takes from 48 hours to 1 week in the mild form, and from 1 to several weeks in the severe form. The mortality in severe cases may be as high as 12%.

Scombroid fish poisoning
This is due to the action of bacteria such as Proteus morgani and Klebsiella pneumoniae in the decomposing flesh of fish such as tuna, mackerel, mahi-mahi, bonito and skipjack stored at insufficiently low temperatures. The spoiled fish can contain excessively high concentrations of histamine (muscle histidine is broken down by the bacteria to histamine), though the precise role of histamine in the pathogenesis of the clinical syndrome is uncertain.

Clinical features and management
Clinically, the mean incubation period is 30 minutes. The illness is characterized by flushing, headache, sweating, dizziness, burning of the mouth and throat, abdominal cramps, nausea, vomiting and diarrhoea; it is usually short-lived, the mean duration being 4 hours. Treatment is symptomatic and supportive. Antihistamines may alleviate the symptoms.

Stings from marine animals
Several species of fish have venomous spines in their fins. These include the weaver fish, short-spine cottus, spiny dogfish and stingray. Bathers and fishermen may be stung if they tread on or handle these...
species. The immediate result of a sting is intense local pain, swelling, bruising, blistering, necrosis and, if the poisoned spine is not removed, chronic sepsis (although this is uncommon). Occasionally, systemic symptoms, including vomiting, diarrhoea, hypotension and tachycardia, occur. Treatment by immersing the affected part in hot water may relieve local symptoms, as this denatures the thermolabile toxin.

**Jellyfish stings**

Most of the jellyfish found in North European coastal waters are non-toxic, as their stings cannot penetrate human skin. A notable exception is the ‘Portuguese man-o’-war’ (*Physalia physalis*), whose sting contains a toxic peptide, phospholipase A, and a histamine-liberating factor. Toxic jellyfish are found more frequently in Australia and some, notably the box jellyfish, *Carukia barnesi*, cause the Irukandji syndrome (see below).

**Clinical features and management**

Local pain occurs, followed by myalgia, nausea, gripping abdominal pain, dyspnoea and even death. The cluster of severe systemic symptoms that constitute the Irukandji syndrome occur some 30 minutes after the jellyfish sting. The symptoms include severe low back pain, excruciating muscle cramps in all four limbs, abdomen and chest, sweating, anxiety, restlessness, nausea, vomiting, headache, palpitations, life-threatening hypertension and cardiogenic pulmonary oedema.

Adhesive tape may be used to remove any tentacles still adherent to the bather. Local application of 5% acetic acid is said to prevent stinging cells adherent to the skin discharging. Local analgesia and antihistamine creams provide symptomatic relief. Other features should be treated symptomatically and supportively.

**Venomous snakes**

Contributed by C. Ariaranee Gnanathasan and Rezvi Sheriff

University of Colombo, Sri Lanka

Praveen Aggarwal

All India Institute of Medical Sciences, New Delhi, India

Venomous snakes are found in most parts of the world except in very cold regions such as Antarctica and islands such as Ireland, Iceland, New Zealand and most islands of the Western Mediterranean, Caribbean and Pacific. Sea snakes (Fig. E12.1) inhabit the Indian and Pacific Oceans between latitudes 30°N and 30°S.

Two families of venomous snakes are of major medical importance:

- **Elapidae**: African and Asian cobras (Fig. E12.2), Asian kraits (Figs E12.3 and E12.4), African mambas, American coral snakes, most Australo-Papuan venomous snakes and sea snakes
- **Viperidae**: i.e. vipers (Fig. E12.5), adders, pit vipers (Fig. E12.6) and rattlesnakes.

**Insect stings and bites**

Insect stings from wasps and bees, and bites from ants, produce pain and swelling at the puncture site. Following the sting or bite, patients should be observed for 2 hours for any signs of evolving urticaria, pruritus, bronchospasm or oropharyngeal oedema. The onset of anaphylaxis requires urgent treatment (see p. 64).

**Scorpions**

Scorpion stings are a serious problem in North Africa, the Middle East and the Americas. Scorpion venoms stimulate the release of acetylcholine and catecholamines, causing both cholinergic and adrenergic symptoms.

**Clinical features and management**

Severe pain occurs immediately at the site of puncture, followed by swelling. Signs of systemic involvement, which may be delayed for 24 hours, include vomiting, sweating, piloerection, abdominal colic and diarrhoea. In some cases, depending on the species, cardiogenic shock, respiratory depression and pulmonary oedema may develop.

Local infiltration with anaesthetic or a ring block will usually alleviate local pain, though systemic analgesia may be required. Specific antivenom, if available, should be administered as soon as possible.

**Spiders**

The black widow spider (*Latrodectus mactans*) is found in North America, Australia, the tropics and, occasionally, in Mediterranean countries.
The burden of snake-bite envenoming has the highest impact on populations and healthcare systems in sub-Saharan Africa, South and South-east Asia, Latin America and Oceania. It is estimated that as many as 4.5 million bites occur worldwide each year, with about 90,000 deaths and a staggering 400,000 limb amputations. A large number of victims survive with permanent sequelae of envenoming, both physical and psychological (e.g. post-traumatic stress disorder).

Snake venom is not a single toxin. It is a complex mixture of more than 100 different components. More than 90% of the dry weight is protein, comprising a variety of enzymes, non-enzymatic polypeptide toxins and non-toxic proteins. Non-protein components include carbohydrates and metals (often part of glycoprotein metalloproteinase enzymes), lipids, free amino acids, nucleosides and biogenic amines such as serotonin and acetylcholine.

- Proteinases act as cytotoxins, causing severe local swelling and tissue damage in the region of the bite.
- Neurotoxins interfere with neuromuscular transmission.
- Some phospholipase A2 toxins also directly damage myocytes and red blood cells (causing rhabdomyolysis and haemolysis).
- Some venoms contain haemorrhagins (metalloproteinases) that damage the vascular endothelium, causing systemic haemorrhage.
Components of venom can act at many different sites in the coagulation pathways, resulting in anticoagulant or procoagulant effects.

Venom components can also act directly on platelets. Snake venoms are capable of producing adverse effects in one or more systems of the body. Most have multisystem effects. There are qualitative or quantitative variations in the chemistry of venoms in different snake species of the same family. Such differences may also occur within a species, depending on their geographical distribution.

Clinical features

The clinical effects of snake-bite envenoming will vary with the species of snake, its age, size and geographical origin, the quantity of venom injected, the route of injection, the age, size and previous health of the victim, and past exposure to venom. Accurate identification of the biting species, ideally by examination of the dead snake, is crucial. Care should be taken, however, when examining a dead snake, as a reflex bite can still occur. Careful clinical evaluation of the patient is necessary before treatment is administered because bites by venomous species do not always result in envenoming (‘dry bite’).

Envenoming may cause both local and systemic effects. Elapid snakes (kraits, cobras) most commonly cause neurotoxicity whereas viperine snakes (vipers, pit vipers, rattlesnakes, adders) cause local tissue damage and coagulopathy. However, this distinction may be blurred; for example, Australasian elapids may cause both neurotoxicity and coagulopathy.

Local effects

- **Oedema** at the site of the bite, which may spread to involve the whole limb.
- **Tissue necrosis** at the site of the bite (Fig. E6.7).
- **Painful regional lymph node enlargement** – a common early sign of envenoming.

Systemic effects

- **Coagulopathy and haemorrhage** include bleeding from the gums and other sites (Fig. E12.8). Bleeding may occasionally be life-threatening.
- **Shock** may occur as a result of loss of fluid into a limb or haemorrhage.
- **Neurological involvement** classically causes progressive descending paralysis. Ptosis (Fig. E12.9) occurs initially; this progresses with involvement of bulbar muscles and, ultimately, paralysis of the diaphragm.
- **Skeletal muscle necrosis** leads to painful myopathy, myoglobinuria and paralysis. This complication is especially seen following envenoming by sea snakes.
- **Renal failure** occurs due to envenoming by several species, such as Russell’s vipers.
Management

First aid

• Reassurance should be given, as even the most venomous species often bite without injecting enough venom to be harmful.
• Immobilization of the patient, especially of the bitten limb, is the most important component of first aid.
• Pressure immobilization can reduce systemic spread of large-molecular-weight neurotoxins and delay the onset of life-threatening neurotoxicity. The technique requires training and the appropriate equipment. The entire limb is bandaged ‘as tightly as for a sprained ankle’, starting around the fingers or toes and finishing at the axilla or groin using stretch bandages, crepe and a splint. Pressure immobilization should be used in all cases unless the snake has not been identified or it is clear that the patient was bitten by a large viper, as development of severe local swelling may compromise the circulation.
• Transport of the victim to a medical centre should take place as quickly, safely and passively as possible.
• Traditional methods, such as incision, suction, tourniquet, electroshock, cryotherapy, instillation of chemicals and snake stones, are useless and harmful.
• Avoidance of aspirin and non-steroidal anti-inflammatory drugs is important, as they may aggravate bleeding.
• The biting snake is valuable evidence but should not be pursued or handled carelessly.

Hospital treatment

Hospital treatment involves rapid clinical assessment, resuscitation and administration of antivenom, the only specific treatment for envenoming. Wherever possible, the priority is to assess critically and stabilize vital systems. Attention to airway, breathing and circulation should take priority.

Diagnosis

There are three principal diagnostic questions:
• Is this a snake bite?
• If it is, is there significant envenoming?
• What snake species was responsible?
  In the history, three preliminary questions should be asked of the victim:
• Which part of your body was bitten?
• How long ago were you bitten?
• Have you brought the snake along, and if not, can anyone describe it?
  Look for circumstantial evidence if the answers are not clear.
  Immunodiagnostic tests that can identify the offending species by detecting specific snake venom antigens in wound swabs, serum, urine or other body fluids are not widely available.

Investigations

The white blood count is commonly elevated and thrombocytopenia is often seen, particularly in patients with coagulopathy. Renal function should be assessed. Creatine kinase levels are elevated when myotoxicity occurs. The 20-minute whole-blood clotting test (20 WBCT) is a good bedside indicator of envenoming by species that cause coagulopathy. Blood left in a clean, dry, glass tube is examined after 20 minutes to see whether clotting has occurred. The test may also be used to assess response to treatment with antivenom.

Antivenom

Antivenom is indicated for the treatment of systemic or severe local envenoming. A delay in administration reduces its efficacy, but antivenom may remain useful for as long as signs of systemic envenoming persist. The antivenom used depends on the biting species. In many parts of the world, polyspecific antivenoms covering locally occurring snake species are employed. This is because the biting species is only rarely identified. Monospecific/monovalent antivenoms can be used only if the snake has been positively identified, either by direct identification if the offending snake is brought to hospital or by detection of venom antigens in body fluids using immunodiagnostic tests. Indications for antivenom include:
• spontaneous systemic bleeding
• incoagulable blood based on the 20 WBCT or other laboratory tests (e.g. international normalized ratio, INR)
• shock, indicated by low or falling blood pressure or cardiac arrhythmia
• ptosis, diplopia, neck muscle weakness, paralysis of limb muscles, respiratory paralysis, altered sensorium
• black urine positive for blood/haemoglobin/myoglobin (indicating rhhabdomyolysis or intravascular haemolysis)
• local swelling involving more than half the bitten limb, swelling after bites on the fingers and toes, or swelling after bites by species likely to cause necrosis.

Antivenom should be administered by slow intravenous infusion. The appropriate dose is dictated by local experience. The initial dose of antivenom depends on the type of antivenom, the offending snake species and the severity of envenoming. Children require the same dose as adults. Reactions to some preparations of antivenoms are common and include life-threatening anaphylaxis. Test doses of antivenom do not reliably predict these reactions and have no role in management. Adrenaline (epinephrine) must be kept available whenever antivenom is administered, to treat possible anaphylactic reactions.

Antivenom only neutralizes circulatory venom, and will not neutralize or combine with venom once the venom is attached to target organs: that is, platelets, red blood cells, vascular endothelium, renal tubules, muscles or neuromuscular receptors. Effective antivenom treatment should halt the progression of symptoms and reverse coagulopathy within 6 hours of administration. The dose of antivenom should be repeated if life-threatening bleeding, shock or paralysis persists a few hours after the first infusion, or if the blood remains incoagulable when retested after 6 hours. Most postsynaptic neuromuscular junction neurotoxins (cobra and krait) are neutralized by antivenom, but presynaptic neurotoxins (krait) are less responsive and may need supportive therapy.

Supportive treatment and treatment of complications
• Shock usually results from hypovolaemia (extravasation of blood into the bitten limb), and should be corrected with intravenous fluids.
• Respiratory failure from respiratory muscle paralysis should be treated with assisted ventilation (common in krait bite).
• Paralysis due to postsynaptic neurotoxicity may respond to anticholinesterases such as neostigmine.
• Tetanus prophylaxis should be given as per requirement.
• Acute renal failure may need dialysis (common after Russell’s viper bites).
• Surgical complications include necrotic tissue, which should be debrided and split skin grafts should be applied. Compartment syndrome is uncommon. Fasciotomy is seldom necessary, even when there is severe oedema, the only indication being raised intra-compartmental pressure. Surgery should not be performed until coagulopathy has been corrected.

Prevention
Avoid contact with snakes, even harmless or apparently dead ones. Wear protective clothing (boots not open sandals, socks, long trousers) when walking in the undergrowth or deep sand, and carry a light at night. Avoid blindly putting hands or feet into termite holes, crevices in trees, bushes and under logs. Sleep off the ground and ideally under a mosquito net to prevent nocturnal bites (kraits). Fishermen should not handle sea snakes trapped in fishing nets.

Further reading

Plants
Life-threatening poisoning from plant ingestion is rare, though many plants contain potentially toxic substances. These include antimuscarinic agents, calcium oxalate crystals, cardiogenic glycosides, pro-convulsants, cyanogenic compounds, mitotic inhibitors, nicotine-like alkaloids, alkylating agent precursors, sodium channel activators and toxic proteins (toxalbumins). While many plants contain gastrointestinal toxins, these rarely give rise to life-threatening sequelae. In contrast, other botanical poisons may cause specific organ damage, and death may occur from only small ingestions of yew (genus: Taxus), oleander (Thevetia peruviana and Nerium oleander) and cowbane (Cicuta).

Atropa belladonna
Atropa belladonna (deadly nightshade) contains hyoscyamine and atropine. It causes antimuscarinic effects – a dry mouth, nausea and vomiting – leading to blurred vision, hallucinations, confusion and hyperpyrexia.

Cicuta species
Cicuta spp. (water hemlock) and the related genus Oenanthe contain cicutoxin, a potent CNS stimulant that produces violent seizure activity. The CNS effects of cicutoxin are similar to those of picrotoxin, a known inhibitor of GABA. Severe gastrointestinal symptoms, diaphoresis, salivation and skeletal muscle stimulation may precede the seizure activity.

Conium maculatum
Conium maculatum (poison hemlock) contains a variety of volatile piperidine alkaloids, which have a toxic activity similar to that of nicotine. Large doses produce non-polarizing neuromuscular blockade, which may result in respiratory depression and death.

Datura stramonium
Datura stramonium (jimsonweed) and other Datura spp. contain L-hyoscyamine and atropine. These alkaloids are potent antagonists of acetylcholine at muscarinic receptors and produce the anticholinergic syndrome. While morbidity is significant, fatalities are rare and are the consequence of hyperthermia, seizures and/or arrhythmias.

Digitalis purpurea, Nerium oleander, Thevetia peruviana (yellow oleander)
Ingestion of Digitalis purpurea or the common (Nerium oleander) or yellow (Thevetia peruviana) oleander can produce a syndrome similar to digoxin poisoning (see p. 270). A randomized controlled trial has shown that digoxin-specific antibody fragments can rapidly and safely reverse yellow oleander-induced arrhythmias, restore sinus rhythm and rapidly reverse bradycardia and hyperkalaemia. The administration of multiple doses of activated charcoal is used but the effect on survival is debated.

Mushrooms
Poisoning due to mushrooms is usually accidental, though ingestion of hallucinogenic (‘magic’) mushrooms is invariably intentional.
**Cytotoxic mushrooms**
Cytotoxic mushroom poisoning is caused by amatoxins and orellanin. Amatoxins are found in *Amanita phalloides*, *A. virosa* and *A. verna*, and in some *Galerina* and *Lepiota* spp. Amatoxins inhibit transcription from DNA to mRNA by the blockade of nuclear RNA polymerase II; this results in impaired protein synthesis and cell death.

**Clinical features and management**
Intense watery diarrhoea starts 8–24 hours after ingestion and persists for 24 hours or longer. Patients often become severely dehydrated. Signs of liver damage appear during the second day and hepatic failure may ensue. Impaired kidney function is often seen both because of fluid loss and as a result of direct kidney injury. In all patients, fluid, electrolyte and acid–base disturbances should be corrected and renal and hepatic function supported. The value of silibinin and benzylpenicillin is not proven. Occasionally, liver transplantation is necessary.

**Gyromitrin poisoning**
Gyromitrin is found in *Gyromitra* spp., including in particular the false morel (*Gyromitra esculenta*) and *Cudonia circinans*. Gyromitrin decomposes in the stomach, to form hydrazines that inhibit pyridoxine kinase and thus produce functional pyridoxine deficiency. GABA deficiency ensues since pyridoxine is an essential co-factor in GABA synthesis. Seizures may result. Hydrazines also cause haemolysis, methaemoglobin formation and hepatorenal toxicity.

**Clinical features and management**
Vapours from the mushrooms are irritating to the eyes and respiratory tract. Gastrointestinal symptoms appear 5–8 hours after exposure. Vertigo, sweating, diplopia, headache, dysarthria, incoordination, ataxia and seizures may follow. Symptomatic and supportive care is required. Pyridoxine 25 mg/kg as an infusion over 30 minutes should be given if severe CNS toxicity develops; repeat doses may be required.

**Hallucinogenic mushroom poisoning**
Psilocybin produces pharmacological effects similar to those of LSD and is found in *Psilocybe* and *Panaeolus* spp.

**Clinical features and management**
Symptoms occur within 20–60 minutes. Effects include altered time and space sense, depersonalization, hallucinations, derealization and euphoria. Symptoms are usually maximal within 2 hours and disappear within 4–6 hours, though ‘flashbacks’ may recur after weeks or months. Anxiety and agitation should be treated with diazepam, 10–20 mg i.v., repeated as necessary.

**Isoxazole poisoning**
Isoxazoles (e.g. ibotenic acid, muscimol, muscazone) occur in *Amanita muscaria* and *A. pantherina*, and act as GABA agonists.

**Clinical features and management**
Nausea, vomiting, inebriation, euphoria, confusion, anxiety, visual disturbances and hallucinations occur often within 30 minutes. Drowsiness is common and a coma-like state may ensue. Severe agitation and violent behaviour are seen occasionally. Other features include myoclonic jerks, muscle fasciculation and seizures. Symptomatic and supportive care should be given as necessary. Diazepam 10–20 mg i.v., repeated as required, should be administered for anxiety, agitation and seizures.

**Neurotoxic mushroom poisoning**
Muscarine is found in, for example, *Inocybe* spp., *Clitocybe* spp. and *Mycena pura*. Muscarine stimulates cholinergic receptors in the autonomic nervous system.

**Clinical features and management**
Diarrhoea, abdominal pain, diaphoresis, salivation, lacrimation, miosis, bronchorrhoea, bronchospasm, bradycardia and hypotension occur. Atropine 0.6–2 mg i.v. should be given to manage the cholinergic syndrome.

**Orellanin poisoning**
Orellanin is a potent nephrotoxin found in, for example, *Cortinarius orellanus* and *C. speciosissimus*. A metabolite of orellanin inhibits protein synthesis in the kidneys.

**Clinical features and management**
Symptoms are typically delayed for 2–4 days. Some patients suffer a mild gastrointestinal disturbance before developing signs of renal impairment, headache, fatigue, intense thirst, chills, myalgia and abdominal, lumbar and flank pain. Transient polyuria with proteinuria, haematuria and, characteristically, leucocyturia is followed by oliguria and then anuria. Renal function may recover only partially; chronic kidney disease is reported in about 10–40% of cases. Management involves careful monitoring and haemodialysis/haemofiltration if renal failure supervenes. Renal transplantation may be required.

CORE SKILLS AND KNOWLEDGE

Global health can be defined as ‘an area of study, research and practice that places a priority on improving health and achieving equity in health for all people worldwide’. It recognizes that health is determined by challenges that transcend national boundaries, and looks at healthcare needs across the world as well as within individual nations. Such needs are complex, may be triggered by natural disasters or armed conflict, and must be addressed using a multiprofessional approach.

Efforts to improve global health are championed by non-governmental organizations such as the World Health Organization (WHO), the United Nations Children’s Fund (UNICEF) and the World Food Programme, alongside individual charities and local government health systems, and interventions are often directed by international targets such as the United Nations’ Sustainable Development Goals.

Opportunities for developing an understanding of global health include:
• engaging actively in debates about the global economic and political determinants of health
• considering the evidence for community-level interventions in improving health outcomes
• travelling to see medicine being practised in a radically different context (e.g. as part of a medical school elective, see p. 283), and reflecting on the successes and ongoing challenges of local healthcare provision.

INTRODUCTION

Complex individual and community health needs are present in high-, as well as low- and middle-income countries (LMICs), but may be particularly acute in times of crisis, for example during or after armed conflict. Effective delivery of global health (GH) requires multiprofessional collaboration between healthcare workers, politicians, economists and scientists in pursuit of both individual wellbeing and population-based prevention and care.

Examples of successful interventions include campaigns for the provision of vaccines by the Global Alliance for Vaccines and Immunization (GAVI) and initiatives to reduce the economic exploitation of child labour. The African Programme for Onchocerciasis Control (APOC) has transformed the lives of millions of people by the administration of a single, annual dose of the drug ivermectin. Similarly, the use of praziquantel by the Schistosomiasis Control Programme, funded by many organizations, has in many areas significantly reduced the prevalence of schistosomiasis (bilharzia), one of the most common but neglected tropical diseases.

The scale of the problem worldwide

Although global life expectancy has increased by 5.5 years since 2000 (mean 69.8 years in males and 74.2 years in females; WHO 2017/18), several unacceptable facts remain:
• Around 5.4 million children under the age of 5 die each year.
• Preterm birth (before 37 weeks’ gestation) accounts for >1 million deaths per year.
• Each day, 830 women die from preventable causes related to pregnancy and childbirth.
• Cardiovascular diseases are the leading cause of death globally.
• Some 36.9 million people are living with human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS), and 65% of deaths from HIV/AIDS occur in the WHO African region.
• Mental health disorders, e.g. depression, are among the 20 leading causes of disability worldwide.
• Tobacco use kills more than 7 million people each year and 80% of users live in an LMIC.
• More than 1.9 billion adults, 41 million children below 5 years of age and 340 million children and adolescents (aged 5–19 years) were obese or overweight in 2016.
Approximately 1.6 million deaths were due to diabetes mellitus in 2016. The number of people living with diabetes increased from 108 million in 1980 to 422 million in 2014.

Nearly 1.35 million people die from road traffic collisions every year.

MILLENNIUM AND SUSTAINABLE DEVELOPMENT GOALS

In 2000, world leaders from 189 countries adopted a series of goals, the Millennium Development Goals (MDGs), to be achieved by 2015. Several of these goals aimed to reduce poverty, improve the health of women and children, and combat HIV/AIDS, malaria and other diseases. The MDGs were only partially achieved and were succeeded by a new set of Sustainable Development Goals (SDGs) in the 2030 United Nations Agenda for Sustainable Development. The 17 SDGs (Fig. 13.1) cover a vast area for improvement and emphasize the fact that achievement of the good health and wellbeing goal (SDG 3) is inextricably linked to other major areas such as politics, economics and agriculture. SDG 3 now also includes non-communicable diseases, mental health, road accident injuries and universal health coverage (Box 13.1).

GLOBAL BURDEN OF DISEASE

There is a gross global mismatch in the use of funds, research and development with the majority (90%) going to high-income countries (Fig. 13.2), which only have 10% of the disease burden (2006). The Global Burden of Disease (GBD) Study 2010 provided critical data for guiding prevention and other interventions by retrospectively reviewing and updating data using the same methodology. This gives an accurate understanding of health trends and future health priorities for the global community and for individual countries.

The 2010 GBD study introduced a new metric that gave a single measure to quantify the burden of diseases, injuries and risk factors. This disability-adjusted life year (DALY) metric allowed the comparison of burden across diseases, both treated and untreated, mortality, morbidity, disability, injuries and risk factors. DALYs measure health gaps, as opposed to health expectancies. They are derived from the calculation of the years of life lost due to early death (YLL) and years lived with disability (YLD).

\[
\text{DALY} = \text{YLL} + \text{YLD}
\]

Unfortunately, this GBD equation has some limitations: for example, it does not incorporate rapid demographic changes such as changing age, causes of death and disability. Any change in DALYs can be a useful indicator of health outcomes but must be interpreted with care. Both a decrease and an increase in DALYs may reflect improved outcomes. A decrease in DALYs for maternal and neonatal deaths can be accounted for by better education, nutrition or obstetric facilities. However, an increase in DALYs is seen when an ageing population requires treatment for chronic ill health, despite a reduction in mortality.

POVERTY

In 2018, nearly half of the world population lived on less than US$ 5.50 per day (compared with US$ 2.50 in 2003). Extreme poverty (defined as <US$ 1.90) was seen in 385 million children, and in 2015 only 10% of the world population lived in extreme poverty (compared with 33% in 1990). Poverty is on the rise in sub-Saharan Africa and in conflict-affected states. Efforts continue to reduce the incidence of extreme poverty to less than 3% by 2030. SDGs 1, 2, 12, 13 and 15 (see Box 13.1) relate to this ambition.

Poverty, hunger, agriculture and climate change

These issues are inextricably interdependent. Food production is compromised when agricultural land is directed towards alternative priorities, such as industrial development. Astonishingly, 25%
of food is wasted in LMICs by crop deterioration due to deficiencies in transport and storage. Globally, one-third of all food produced, equivalent to 1.3 billion tonnes, is wasted each year.

In 2009, the UCL-Lancet Commission on ‘Managing the health effects of climate change’ called climate change ‘the biggest global threat of the 21st century’. Changes in climate pose major threats to human health either directly (heatwaves, floods, fires, droughts) or indirectly (agricultural losses, mass migration); for example, a 1°C rise in mean temperature in India would result in the loss of 7 million tons of wheat (Fig. 13.3). The 2015 Paris accord, ratified by 195 parties, agreed to target a reduction in global temperature rise to below 2°C by 2100. The 2018 report of the Intergovernmental Panel on Climate Change (IPCC) emphasized the urgent need to further reduce global warming by reporting the beneficial effects in combating climate change of a lower, 1.5°C rise in global temperatures (Fig. 13.4).

Chronic illness and disease in LMICs cause much pain and suffering due to the incurred massive expenditure, accentuated by food shortages and dramatic changes in climate. In 2010, 808 million people experienced catastrophic health spending (where health spending exceeded 10% of household consumption).

WATER AND SANITATION

Poor water and sanitation are major causes of early mortality, particularly in children. More than 800 children under the age of 5 years die each day as a result of diarrhoea caused by poor water and sanitation. In 2018, 848 million people still lacked access to safe drinking water, and 1 billion people had access to very basic drinking water services. A total of 892 million people were forced to defecate outside in the open. The MDG target to halve the proportion of people without sustainable access to safe drinking water and sanitation by 2015 was not met and is now in SDG 6. Water is usually collected by women, often from distant sources; this can be a hazardous journey, as the women are unprotected and open to abuse. A secondary effect of improved access to water is that the time saved in collecting water can be spent on income generation, food production, education, and activities that lead to social and health benefits.

ORGANIZATIONS AND THE GLOBAL HEALTH AGENDA

International support for GH initiatives may be directed at disease-specific projects (vertical care models) or allied to national health system development. A vast number of organizations (Box 13.2) cover the key areas for health development and infrastructural support, including the response to emergency situations (war and natural disasters). The areas encompass service delivery, patient care, education and training, research, equipment, medicines and human
Investment in healthcare systems promotes public health benefits by the provision of vaccination, hygiene and sanitation, as well as major infrastructural projects including technology and communications, such as building roads.

Empowering the local population to help themselves by delivering locally appropriate education and training is of paramount importance.

EDUCATION

Education has a major impact on the health of a nation. The more years that are spent in schooling, the better the health outcomes. Literacy and, in particular, health literacy can have a major impact on nutrition and the control of disease: for example, by the simple process of hand washing. Education helps to promote healthier lifestyles, both by improving nutrition and development, and by reducing the risks associated with infectious diseases. As a result, unemployment falls while family and community wellbeing is improved.

Women have a crucial role in the welfare of their families and the development of a nation's good health. Although women may have a lower social status in some societies, they have a major impact on the health of a family by looking after the household and caring for the children, elderly and sick. Approximately 25% of girls in 'developing countries' become mothers before the age of 18. These pregnancies have a high rate of deaths from complications of pregnancy and childbirth (see Chapter 30). The cost to a country’s economy of adolescent pregnancy, as a share of gross domestic product (GDP), can be as high as 30%. The education and welfare of women should be major issues in any developing society.

Further reading
Infections in children under 5 years of age are mainly concentrated in malaria. Almost 50% of these deaths are linked to malnutrition and preterm complications, birth asphyxia, diarrhoea, pneumonia and malaria. Deaths in children under 5 years of age are mainly concentrated in South-east Asia and in sub-Saharan Africa, where children are 15 times more likely to die in comparison to children in HICs. In the rest of the world, mortality figures in children dropped from 12.6 million in 1990 to 5.4 million in 2017 and so there remains a need for global and concerted action to improve the survival chances for children.

**Vaccination**

The World Health Assembly produced a framework to prevent millions of deaths by more equitable access to vaccines and developed a ‘Decade of Vaccines Global Vaccine Action Plan 2011–2020’. GAVI plays a critical role in this area by financing and facilitating the delivery of vaccine platforms, and by 2017 85% of infants worldwide had received the diphtheria–tetanus–pertussis vaccine.

**Child labour**

The global number of children engaged in child labour declined by 38% between 2012 and 2017 (246 million dropping to 152 million). Some 48% of these children (73 million) were engaged in hazardous work, mainly in agriculture.

**Child nutrition**

Improving child nutrition remains a global imperative as nearly half of the deaths in children under 5 years of age are attributable to malnutrition.

According to data from UNICEF (2017), stunting affects 151 million children under 5 years of age. This problem can be mitigated by appropriate interventions during maternal pregnancy and increased access to food before the child is 2 years old.

UNICEF Data. Malnutrition in Children. [https://data.unicef.org/topic/nutrition/malnutrition/](https://data.unicef.org/topic/nutrition/malnutrition/)

**MENTAL HEALTH**

Mental health (including psychological and neurological problems) or substance abuse disorders affect 15.5% of the global population.
population. Mental health is thus the second leading cause of long-term disability.

Depression and anxiety disorders remain major clinical challenges with approximately 600 million sufferers worldwide. Additionally, it is estimated that suicide will account for 1.5 million deaths each year by 2020, with a further 15–30 million people attempting suicide.

Globally, the incidence of dementia is rising. In 2017, 50 million people were living with dementia worldwide and this is predicted to increase to 152 million by 2050; 60% of people with dementia live in LMICs. All of these data represent a major worldwide social and financial burden, especially for poorer countries.

ACCIDENTS AND TRAUMA

We are currently in the midst of a global trauma epidemic. It is estimated that 5.8 million people die each year as a result of injury and trauma. At least 2 million of these deaths are potentially avoidable.

Injuries are a significant and increasing cause of mortality and morbidity; more than 90% of injury-related deaths occur in LMICs. Around 5 billion people do not have access to safe and affordable surgical and anaesthesia care when needed, especially in LMICs. Many of those who do access care risk personal financial ruin. The WHO estimates that, by 2030, trauma from road traffic accidents will be the third most common cause worldwide of both mortality and disability (as measured in DALYs).

The Guidelines for Essential Trauma Care (WHO 2004) established a core list of 11 essential trauma services (Box 13.3). Although the implementation of these recommendations has been hampered by deficiencies in planning and infrastructure that need to be addressed by national governments, recent (2018) evaluation of these guidelines suggests that they remain appropriate recommendations for trauma system development.

CONFLICT AND CATASTROPHE

Recent years have seen a number of natural disasters; examples include earthquakes in Nepal (2015) and Indonesia (2018), tsunamis

Box 13.3 International guidelines for essential trauma care (‘rights of the injured’)

- Obstructed airways cleared and maintained
- Impaired breathing supported until the injured person is self-ventilating
- Pneumothorax and haemothorax promptly relieved
- Bleeding stopped promptly
- Shock recognized and treated with intravenous fluid replacement
- Traumatic brain injury treated with timely decompression of space-occupying lesions
- Intestinal and other abdominal injuries promptly addressed
- Disabling extremity injuries corrected
- Unstable spinal cord injuries managed appropriately with early immobilization
- Appropriate rehabilitative services available
- Medications for the above and for pain control readily available

Funding for initiatives in the GH development of LMICs (also known as Development Assistance for Health, DAH) has, historically, originated from multiple sources (see Box 13.3). While these initiatives may have been beneficial for specific diseases like malaria (see p. 563), tuberculosis (p. 967) and HIV/AIDS (p. 1425), health systems development has frequently lagged behind such high-profile schemes. The consequences of this were seen in the slow response of the WHO and others to the 2014 outbreak of Ebola virus in Africa.

Improvements in healthcare result in economic growth. For example, a 10% reduction of malaria in endemic areas is associated with a 0.3% increase in GDP. Treatment of HIV-positive patients with anti-retroviral drugs results in net economic benefit through increased productivity and a reduction in the costs of medical care. Any failure to invest in health and health systems is a threat to future global prosperity, particularly in poor countries. Transnational collaboration is especially necessary in the face of pandemic threats.

Surgical care is currently a neglected component of the health systems in many countries (see p. 242). The cumulative loss of economic productivity between 2015 and 2030, in the absence of a significant scaling up of global surgical services, is estimated at US$12.3 trillion.

Political decisions regarding investment in healthcare and health systems also need to focus on infrastructure, including food and agriculture, the environment and human rights issues, especially the rights of women. In essence, the pursuit of ‘pro-poor’ policies that place the poor at the centre of development policy is essential for future global prosperity.

HUMAN RIGHTS AND THE VALUE OF ENGAGEMENT IN GLOBAL HEALTH

The Universal Declaration of Human Rights (1948), while not legally binding, serves as a ‘common standard for all peoples and all nations’. It has given rise to two new legally binding covenants: the International Covenant on Civil and Political Rights and the International Covenant on Economic, Social and Cultural Rights.

The WHO is a specialized agency of the United Nations with a remit for international public health. Its constitution enshrines the highest attainable standard of health’ as a fundamental right of every human being. The right to health contains four elements: availability (of programmes of public health), accessibility (of health facilities and services in a non-discriminatory fashion), acceptability (ethical and cultural requirements), and good-quality care.

SOCIAL DETERMINANTS OF HEALTH

The drivers of health inequities reside in the social, economic and political environments. The WHO (2008) defined the social determinants of health as ‘the conditions in which people are born, grow, work, and age. These circumstances are shaped by the distribution of money, power and resources at global, national and local levels.’

The social gradient of health follows the socioeconomic pattern from the top to the bottom: that is, the lower the individual is within their socioeconomic position, the worse their health. This is seen globally in HICs, as well as in LMICs. The socioeconomic status of a person is their social position in society, which is determined by their education, income and occupation.

There is now clear evidence to justify national policies that aim to reduce health inequity and the health divide across all countries. It has also been suggested that reduction in health inequities should become one of the main criteria used to assess the effectiveness of health systems and governments as a whole.

HUMAN RIGHTS AND THE VALUE OF ENGAGEMENT IN GLOBAL HEALTH

The Universal Declaration of Human Rights (1948), while not legally binding, serves as a ‘common standard for all peoples and all nations’. It has given rise to two new legally binding covenants: the International Covenant on Civil and Political Rights and the International Covenant on Economic, Social and Cultural Rights.

The WHO is a specialized agency of the United Nations with a remit for international public health. Its constitution enshrines the highest attainable standard of health’ as a fundamental right of every human being. The right to health contains four elements: availability (of programmes of public health), accessibility (of health facilities and services in a non-discriminatory fashion), acceptability (ethical and cultural requirements), and good-quality care.

The healthcare workforce

There is a worldwide shortage of healthcare workers from all disciplines (Fig. 13.5). Current estimates suggest that an additional 40 million healthcare workers will be required by 2030 to meet global demand. Engagement in GH challenges helps to promote patterns of behaviour that benefit healthcare workers and their recipients. These behaviours include altruism, team-working and appreciation of cultural diversity.

Medical electives

Many medical students and doctors undertake periods of time visiting and working in unfamiliar environments, whether in their home

![Fig. 13.5 Worldwide shortage of healthcare workers. There are 57 countries with a critical shortage of 2.4 million health service providers (doctors, nurses and midwives). Africa has 25% of the world’s healthcare burden and 1.3% of the providers. (From Crisp N, Cheng L. Global supply of health professionals. N Engl J Med 2014; 370:950–957 [Figure 1], with permission.)](image-url)
country or abroad. This is mutually beneficial to all participants, provided that a culture of shared learning is embraced. All such visits, commonly termed ‘medical electives’, should have clear objectives and measurable educational outcomes. They promote altruistic behaviours and should not compromise the working arrangements for host organizations. Pre-departure preparation should include consideration of culture, ethical challenges and security issues. All visitors must work within their approved competencies, be appropriately supervised and comply with national guidance on good medical practice. Maximum benefit from medical electives is achieved when there is a mutual commitment to long-term partnership.

**Bibliography**

INTRODUCTION

When viewed on a population level, health is a broad concept. Social determinants of health are numerous and varied, stretching from climate change through to health behaviours. The Alma Ata (World Health Organization (WHO) conference) declaration of 1978 stated that ‘health, which is a state of complete physical, mental and social wellbeing, and not merely the absence of disease or infirmity, is a fundamental human right’ and that ‘the attainment of the highest possible level of health is a most important worldwide social goal whose realization requires the action of many other social and economic sectors in addition to the health sector’. It goes on to assert the key importance of addressing inequalities. Those working in public health strive to bring about change at a scale that will maximize benefit, while reducing inequalities in health.

The origins of public health lie in the big cities of industrialized nations in the mid-nineteenth century, where pioneers such as John Snow began studying patterns of transmissible disease and intervening to prevent the spread of infection. The development of germ theory, the discovery of means to prevent communicable diseases (such as vaccination and sanitation), and epidemiological insights into key causes of non-communicable diseases (such as smoking) allowed public health teams to attain a crucial position in improving the health of the whole population. Latterly, healthcare public health has brought academic rigour to the study of aspects of healthcare delivery and to ensuring that maximum benefit is derived at a population level from healthcare services.

Public health and global health

This chapter focuses primarily on public health in higher-income countries. Public health issues more commonly associated with low- to middle-income countries, such as communicable and nutritional diseases, are covered in Chapter 13 (‘Global health’). However, non-communicable diseases, such as cardiovascular disease and cancer, are now the leading cause of death globally (Global Burden of Disease 2017), meaning that the contents of this chapter are relevant for all settings.

INTRODUCTION

Factors that influence health stretch from climate change through to health behaviours. A multiprofessional approach, incorporating the epidemiological study of disease alongside practical health interventions, is required to address these complex and high-level challenges. When John Snow analysed cases of cholera in 1854, he not only mapped the distribution of cases and the possible link to a water pump, but also dealt with the source of the outbreak by removing the pump.

The core workforce includes doctors within the medical specialty of public health, working alongside epidemiologists, analysts, commissioners, nurses, health visitors and environmental health officers. Clinicians in other specialties often take a population approach too, especially in primary care.

Key to understanding public health is recognizing that many patients have had their health adversely affected by social, environmental or behavioural factors. The three pillars of public health intervene to address these:

- **health improvement**: implementing interventions to prevent ill-health and improve population health
- **health protection**: preventing, controlling and monitoring infectious, environmental, chemical and radiological hazards to population health
- **healthcare public health**: maximizing the benefits of healthcare interventions and reducing inequalities, using tools such as screening and health economics.

Skills required in public health can be developed by critically appraising relevant articles in journals, by undertaking local quality improvement projects, and by seeking out opportunities to work with national or local groups focusing on health or sustainability. Many public health departments in local authorities will be happy to discuss public health or arrange placements.
Public health is defined as the number of years that a person can expect to live in a good health condition (Stevens and Raftery 1997).

Real healthcare needs must be distinguished from either demand (what individuals may wish to buy or use) or supply (current provision).

Health Needs Assessments (HNAs) aim to determine healthcare needs systematically and to compare them with current service provision in order to identify gaps. A health need (whenever individuals are not completely well) and a healthcare need (if there is an ability for them to benefit from care) should be differentiated: that is, if an evidence-based intervention has been shown to improve the health of the individuals with the condition in question, as not all diseases are amenable to treatment.

Three techniques for producing HNAs have been described (Stevens and Raftery 1997):

- **epidemiological** – summarizing data on healthcare needs from a range of sources by time, place and person

**Box 14.1** John Snow and the Broad Street pump

In 1854, an outbreak of cholera struck Soho in central London. Dr John Snow was a local physician who had written a paper theorizing about the transmission of cholera 5 years previously. Snow began to investigate the outbreak, reviewing local hospital records, talking to local residents and mapping the cases he identified. He noted that within 250 yards of the spot where Cambridge Street joins Broad Street there were upwards of 500 fatal attacks of cholera in 10 days. I suspected some contamination of the water of the much-frequented street-pump in Broad Street. Snow proceeded to remove the handle of the water pump to prevent future cases, translating epidemiology into the practice of public health.

**Box 14.2** Public health teams

Public health is increasingly a multidisciplinary specialty, accessible not only to doctors but also to applicants who can demonstrate suitable academic attainment and experience working in the field. Public health specialty registrar training in the UK has been multidisciplinary since 2003 and around half of public health trainees are doctors, the rest being graduates from backgrounds that include epidemiology, health policy, biostatistics or behavioural science. Public health teams exist at local, regional and national levels; depending on the context, they may work closely with local or national government, the emergency services, education professionals, policy experts and advocates, healthcare academics and other local medical services.

**Box 14.3** Bradford Hill criteria

Causality is more likely if:
- the effect size is large (strength)
- findings are reproducible across different samples (consistency)
- the association is demonstrable in only a specific population (specificity)
- the effect occurs after the cause (temporality)
- greater exposure leads to greater incidence of the effect (biological gradient)
- there is a feasible mechanism for the association (plausibility)
- the proposed causal relationship is not at odds with previous research (coherence)
- the effect varies measurably following a change to the causal factor (experiment)
- the effects could be proposed to be similar to other situations (analogy).

**KEY CONCEPTS IN PUBLIC HEALTH**

**Epidemiology and causality**

Epidemiology is the study of how often diseases occur in different groups of people, and why. It is central to the discipline and practice of public health medicine. Understanding the patterns of disease distribution in a population can reveal factors that may be associated with that disease. For example, the demonstration of a link between smoking and lung cancer by Sir Richard Doll and Sir Austin Bradford Hill in 1950 is a seminal piece of epidemiological research. If epidemiological associations are causal, then working to reduce or mitigate identified causes may provide an opportunity to prevent future disease. Bradford Hill laid out nine criteria to be considered when judging whether an association is likely to be causal (Box 14.3).

**Health needs assessments**

Health Needs Assessments (HNAs) are key tools used in public health medicine to drive improvement in health within a population. HNAs aim to determine healthcare needs systematically and to compare them with current service provision in order to identify gaps. A health need (whenever individuals are not completely well) and a healthcare need (if there is an ability for them to benefit from care) should be differentiated: that is, if an evidence-based intervention has been shown to improve the health of the individuals with the condition in question, as not all diseases are amenable to treatment. Real healthcare needs must be distinguished from either demand (what individuals may wish to buy or use) or supply (current provision) (Fig. 14.1).

Three techniques for producing HNAs have been described (Stevens and Raftery 1997):

- **comparative** – comparing needs, as well as service provision and service usage, between different populations
- **corporate** – consulting with stakeholders, such as healthcare professionals, commissioners and patients, to identify priorities

**Life expectancy and quality of life**

*Life expectancy at birth* is defined as the number of years that a newborn could be expected to live if current mortality rates continue. Life expectancy has generally been rising across the world, although an Organisation for Economic Co-operation and Development (OECD) report from 2019 notes that the rate of improvement has slowed in several European countries since 2011, including France, Germany, Sweden, the Netherlands and the UK, and life expectancy has fallen in the USA in recent years.

*Healthy life expectancy*, defined as the number of years lived in self-assessed good health, adds a quality of life component to estimates of life expectancy. While healthy life expectancy in many countries is generally rising, it is doing so at a lower rate than life expectancy. This means that although people in most countries are living longer, they are experiencing more years in poor health. There is also a strong link to deprivation. For example, individuals living in the most deprived areas of England spend more of their life in poor health, in comparison to those in areas of lesser deprivation (Fig. 14.2).
Key concepts in public health

Health inequalities

Health inequalities are differences in health status between groups of individuals, which differ based on gender, ethnicity, disability, area of residence, socioeconomic status or other factors. Health differences arising from such characteristics often represent an injustice, especially if they are potentially avoidable and thus inequitable (inherently unjust and unfair). One of public health’s fundamental principles is to strive to reduce such inequalities and to make health outcomes fairer for the population (Fig. 14.3 and Box 14.4). However, this is often complicated by Tudor Hart’s inverse care law, which states that the availability of good healthcare often varies inversely with need, particularly where market forces are operating.

Deprivation

Examples of health inequalities that are amenable to change are those associated with deprivation. Deprivation can be measured by a basket of indicators within defined geographical areas. One example is the Index of Multiple Deprivation, which uses data across seven domains to compare relative deprivation across small areas in England. The domains encompass:

- income levels
- employment levels
- education and skills within a population
- levels of chronic ill-health and disability
- crime
- barriers to housing and local services
- the living environment.

A number of poor health outcomes have been found to correlate with deprivation. For example, it has been shown that children living in deprived areas have a higher prevalence of dental caries than those in less deprived areas. Water fluoridation is a public health intervention that improves oral health across the population but has been shown to have the most impact in those who are more deprived, thereby reducing health inequality. Other adverse outcomes associated with deprivation extend throughout the life-course, and include
low birth weight, higher infant mortality, increased chronic disease and premature death. Data suggest that inequalities in health due to deprivation are widening. In the UK, official statistics from 2014–16 demonstrate that life expectancy in the 10% least deprived areas of England and Wales was 9 years longer for males and 7 years longer for females than in the 10% most deprived areas, and that these gaps are widening.

**Politics and advocacy**

The WHO defines health advocacy as ‘a combination of individual and social actions designed to gain political commitment, policy support, social acceptance and systems support for a particular health goal or programme’. It is a key component of health promotion, as detailed within the WHO’s Ottawa Charter for Health Promotion, and requires the collective efforts of medical professionals, professional bodies, patient groups and charities. Targets of advocacy might be to change the law, to improve access to healthcare services, to improve standards in the food industry or to change attitudes in society towards healthy behaviours. Overcoming the powerful opposition of large corporations and/or governments is often a requirement of effective public health advocacy.

All major strategies should be assessed – not just those within the health sector, but also those in other areas such as transport or housing – to understand their impact on health and health inequalities. Such health impact assessments can be used to maximize the positive health consequences and minimize the adverse ones (both indirect and direct), together with reducing health inequalities. Examples of successful health advocacy include smoking bans and reduction of salt intake.

**Smoking bans**

A number of countries have introduced bans on smoking in the workplace and in public spaces; a few (such as New Zealand and Finland) have announced a target to be ‘tobacco-free’ by a designated point in the future. International data from the USA and Europe have revealed a variety of improved health outcomes since the introduction of smoking bans, including reductions in preterm births, childhood hospital admissions for asthma, and emergency admissions for myocardial infarction. Despite unequivocal evidence of public health benefits, opponents of smoking bans have suggested they are examples of governments acting as a ‘nanny state’, or have expressed concern over the potential for a shift in smoking behaviour into private homes (which does not seem to have occurred). However, in general, smoking bans received public support, including among smokers, and much of the opposition came from large tobacco companies.

**Reduction of daily salt intake**

Regularly exceeding the maximum amount of salt recommended for daily consumption is common across the world.
and is strongly associated with hypertension, cardiovascular disease and premature mortality. Health advocacy efforts have been based on public education campaigns, clear labelling of the salt content of foods, and salt reduction targets for the food industry. Most salt in Western diets is found in processed food, and an approach based on purely individual behaviour change is widely regarded as insufficient to tackle the problem. To make stronger gains, the food industry needs to reduce salt further within prepared food in supermarkets and food outlets. Such widespread change requires government commitment, with imposed targets and incentives for reducing salt within the food industry.

PILLARS OF PUBLIC HEALTH

Although models of public health provision vary in different countries, services are often delivered at the level of local government or regional health authorities. National bodies, such as the Centers for Disease Control and Prevention (CDC) in the USA or Public Health England (PHE), are responsible for collation of health statistics, support for national vaccination programmes and advice to government on other aspects of health policy.

The work of public health services can be described according to the three pillars of public health:

- health improvement
- health protection
- healthcare public health.

Health improvement

While it might seem self-evident that preventing a disease is better than dealing with the consequences, there is also strong economic evidence to support the case for prevention. For example, a number of studies have demonstrated that smoking cessation services both improve population health and reduce healthcare costs overall. When considering approaches to prevention, they can be classified as primary, secondary or tertiary (Box 14.5).

Wider determinants of health

Wider determinants of health (WDHs) are the broader social, economic, political and environmental circumstances that influence health outcomes throughout life. Dahlgren and Whitehead (1991), subsequently modified by Barton and Grant (2006), developed an influential model of the main determinants of health, in which, at the core, are constitutional factors such as sex, age and genetics; overlapping layers represent individual lifestyle factors, followed by the WDHs (Fig. 14.4). The core attributes are relatively fixed but, as the layers of influence extend outwards, the determinants are amenable to change:

- The first layer represents individual lifestyle behaviours, such as diet, physical activity, smoking and alcohol consumption.
- The second layer represents the communities in which individuals live – social networks that influence health and the health behaviours we exhibit.
- Next, living and working conditions have an impact on health, for example, the quality of an individual’s employment, housing and education.
- Finally, the prevailing socioeconomic, cultural and environmental conditions affect the health of the whole population, and these are influenced by local, regional, national and international factors. These overlapping layers exert an influence over each other and there is a complex interplay between them.

Air pollution

Air pollution is an example of a WDH, representing a huge environmental health risk globally. Poor air quality has a range of short- and long-term health impacts, including but not limited to cardiovascular and respiratory disease, emergency hospital admissions and death. One of the first demonstrations of these effects was during the ‘great smog of London’ in 1952, which contributed towards a large number of deaths. This led to the Clean Air Act of 1956, which limited the burning of solid fuel for heating in urban areas.

A range of pollutants are known to be harmful to health, including particulate matter and nitrogen dioxide. Although tackling air pollution requires individual efforts, the problem cannot be adequately addressed without local, national and international policy change. Examples of interventions for tackling air pollution include:

- setting objectives and limits for different pollutants
- encouraging use of active transport instead of cars

### Box 14.5 Levels of prevention of disease

<table>
<thead>
<tr>
<th>Primary</th>
<th>Secondary</th>
<th>Tertiary</th>
</tr>
</thead>
<tbody>
<tr>
<td>Involves reduction in exposure to risk factors, focusing either on the whole population or on high-risk subgroups</td>
<td>Involves detecting disease at an early stage and undertaking prompt intervention to reduce the disease’s impact</td>
<td>Aims to reduce or mitigate long-term complications of a disease and maximize functioning</td>
</tr>
<tr>
<td>Examples include healthy lifestyle interventions for the prevention of cardiovascular disease, or workplace-based interventions to reduce asbestos exposure</td>
<td>Examples include screening programmes, or prescription of statins for hypercholesterolaemia to reduce the likelihood of myocardial infarction or stroke</td>
<td>Examples are HbA&lt;sub&gt;1c&lt;/sub&gt; monitoring in diabetes mellitus to minimize long-term micro- and macrovascular complications, or neuro-rehabilitation after head injury</td>
</tr>
<tr>
<td>Focusing on the whole population may result in Rose’s prevention paradox – such strategies may have a relatively small impact at an individual level, despite large benefits at a population level or for those at highest risk</td>
<td></td>
<td></td>

</tbody>
</table>
Public health

• encouraging manufacturers to produce cleaner vehicles, and industry to adopt greener technologies
• introducing ultra-low emissions zones in urban areas and ‘no-idling zones’ around schools.

Poor air quality affects the whole population, but also represents a significant health inequality in that more vulnerable members of society have higher exposure (for example, those living in more deprived areas) or are more susceptible to harm (such as young children or the elderly). Thus it is imperative to ensure that any interventions aimed at tackling air pollution also aim to address such inequalities.

Behaviour change

Behaviour change provides a crucial opportunity to improve health significantly. However, unhealthy behaviours are often complex and deeply ingrained. For example, the COM-B model recognizes that the interrelated components of capability, opportunity and motivation must all be addressed before behaviour will be changed. At a population level, instigating change requires holistic and sustained interventions across a range of policy types. Interventions may be classified as individual, structural, fiscal or legal (Fig. 14.5), although there may be significant overlap between these: for instance, structural and fiscal approaches are often enshrined in legislature.

The determinants of health and wellbeing in our neighbourhoods

- macro-economy, politics, culture, global forces
- other neighbourhoods
- other regions
- age, sex & hereditary factors
- diet, physical activity
- work-life balance
- social networks
- living, playing, learning
- streets, routes
- air, water, land
- buildings, places
- working, shopping, moving
- wealth creation
- social capital
- resilient markets
- community
- local economy
- built environment
- activities
- natural environment
- global ecosystem
Individual interventions

Clinical consultations can be a prime setting in which to encourage individual-level behavioural change. The ‘Making Every Contact Count’ initiative seeks to encourage clinicians, and a broader range of professionals, to consider how they can build health promotion into their routine patient or client interactions. For example, professionals working in education or in the emergency services may identify issues of poor mental or physical health, isolation or violence. They may have an initial conversation about the issues they have identified, before signposting to a range of other local services that may provide further support.

While brief advice is unlikely to instigate long-term change if delivered in isolation, it may raise the idea of change higher up the patient’s agenda, particularly if delivered during a ‘teachable moment’ when an individual becomes especially aware of their health, such as during an unexpected hospital admission. There are several models to describe individual-level behaviour change, such as Prochaska and DiClemente’s 1983 Stages of Change model (Fig. 14.6). Individual-level behaviour change therapies have been found to be highly cost-effective: for example, brief advice given to adult patients in primary care about increasing their physical activity has been shown to cost £1730 per quality-adjusted life-year (QALY) gained. A commonly used threshold for determining the cost-effectiveness of a healthcare intervention is £20 000–£30 000 per QALY gained.

Structural interventions

Structural approaches to behaviour change may be achieved through ‘nudging’ individuals to default to healthier choices. The nudge theory of behavioural economics rose to prominence in 2008 with the publication of ‘Nudge: Improving Decisions about Health, Wealth and Happiness’ by Richard Thaler and Cass Sunstein, leading to Thaler being awarded the 2017 Nobel Prize for Economics. Nudge theory proposes that small tweaks to frame a choice more favourably or render an option easier are often sufficient to increase its uptake, and that decisions are not based purely on underlying rationale. A Cochrane review in 2015 concluded that individuals consistently eat more food when offered large portions or use larger items of tableware. Promoting package and portion size reductions could be a tool to reduce weight gain.

Fiscal interventions

Fiscal measures may also encourage behaviour change, through either the taxation of potentially harmful choices to render them less attractive, or the subsidization of healthy ones to make them more favourable. The WHO encourages countries to tax sugary drinks, and many have implemented such legislation. Measures to improve healthy eating by subsidizing school dinners or offering free vitamin supplements to children and pregnant women may enhance health outcomes and also reduce inequality (Box 14.6). These measures often operate at a national level through the introduction of governmental policy, which may be associated with new legislation.

Legal interventions

In addition to the introduction of taxes, legislative approaches to encourage behaviour change may include the regulation or prohibition of unhealthy activities. It was estimated in 2008 in the UK that

### Box 14.6 Fiscal measures to improve diet and nutrition

**Taxing harmful behaviours**
- Poor oral health, including the presence of dental caries, is the most prevalent condition worldwide (Global Burden of Disease 2017). Reducing sugar consumption is predicted to improve oral health, as well as tackle obesity.
- An excise tax on sugar-sweetened beverages (‘sugar tax’) is an example of a fiscal policy that aims to encourage manufacturers to reduce the sugar content of their products, as well as dissuading individuals from consuming products with high sugar levels.
- Such a tax has been introduced in a number of jurisdictions over recent years and initial results are promising. In the UK the government introduced a Soft Drinks Industry Levy in 2018 and it is estimated that half of manufacturers reformulated their drinks to avoid it. An evaluation of a similar tax in Berkeley, California, found that it was associated with a 21% decrease in sugar-sweetened beverages in low-income neighbourhoods, indicating that the policy has the potential not only to improve health, but also to reduce health inequalities.

**Subsidizing healthy behaviours**
- It has been estimated that 1 billion people globally have vitamin D deficiency, and there has been a rise in cases of rickets in some countries.
- This can be prevented by eating a diet rich in vitamin D and calcium, or by taking vitamin D supplements.
- The Healthy Start vitamins scheme was introduced in the UK in 2006 and provides free vitamin supplements (including vitamin D) for pregnant women and young children in low-income families.
over the previous 25 years since the wearing of seatbelts became compulsory, at least 60,000 lives had been saved and 600,000 severe injuries had been prevented. Legal approaches to behaviour change are often used once other methods have been tried without adequate success, since they may be perceived as paternalistic, attracting political controversy and significant lobbying from industry.

Further reading

Health protection

Health protection involves anticipating and controlling infectious, environmental, chemical and radiological hazards to public health. There are three main areas of activity: prevention, control and monitoring (surveillance).

Prevention

Prevention within health protection is concerned with reducing the risk of transmission of infectious diseases. Two key examples of this are hand hygiene and vaccination.

Hand hygiene

This is one of the simplest yet most effective public health (prevention and control) measures. Basic hand-washing in communities minimizes the spread of infection (e.g. reducing the risk of Escherichia coli infection in petting zoos, or disrupting the transmission of norovirus in schools), but is also the main way of combating hospital-acquired infections and preventing the spread of antimicrobial resistance. The WHO recognizes the significant impact that such a simple measure can have in saving lives through its Clean Care is Safer Care campaign, which aims to promote good hand hygiene globally.

Vaccination

Vaccination has had a huge impact on the burden of infectious disease, second only to clean water provision. Vaccination programmes confer benefit to the individual and to the population as a whole (especially its most vulnerable members) through herd immunity, whereby a high proportion of population immunity reduces person-to-person transmission. The basic reproduction number ($R_0$) is the number of secondary infections produced by a typical infection in a totally susceptible population. For diseases with a high $R_0$ (e.g. measles), higher coverage is required to attain herd protection.

Vaccination programmes are tailored to the national prevalence of particular diseases. Selective vaccination programmes aim to protect those at highest risk of certain diseases (e.g. for travellers or healthcare workers), while mass vaccination programmes aim to contain (control), eliminate or eradicate disease (Box 14.7). Some vaccines provide protection after exposure in some cases (e.g. the measles, mumps and rubella (MMR) vaccine), which can be used to help limit the spread of a measles outbreak by immunizing previously unvaccinated contacts of a known case, (Box 14.8).

Box 14.7 Control, elimination and eradication

- **Control** is defined as when the amount or impact of a disease within a population has reduced to a locally acceptable level.
- **Elimination** is when the disease incidence within a defined area is zero.
- **Eradication** occurs when the disease incidence is zero worldwide and no environmental reservoir exists. This has been achieved only for smallpox.

Box 14.8 Notification of suspected measles cases

Recent outbreaks of measles in Europe and the USA have been seen primarily among individuals who have not received the measles, mumps and rubella (MMR) vaccination. Post-exposure prophylaxis (PEP), if delivered promptly, can prevent contacts of known sufferers from developing measles, or may attenuate their symptoms if they go on to develop the disease.

PEP can be delivered in two ways:

- **Using a dose of MMR vaccine to induce active immunity.** However, MMR is a live vaccine and should not be administered to immunocompromised individuals or pregnant women, and is inappropriate for some infants.
- **Using immunoglobulin to provide passive immunity.** This is recommended for groups who cannot receive the MMR vaccine for the reasons listed above, who are often at greatest risk of morbidity and mortality from measles infection.

Therefore, risk assessments for notifications of suspected measles cases involve not only the provision of infection control (isolation) advice, but also contact tracing to identify those who stand to benefit from PEP.

Control

Control of infectious diseases

Rapid response to outbreaks of disease requires timely notification of new cases to the relevant public health authorities. The International Health Regulations (IHR) 2005 signify an agreement between 196 countries to build their capacities to detect, assess and report public health events, and to notify the WHO of any event that may constitute a ‘public health emergency of international concern’. In England, the most recent national legislation lists 32 diseases and 60 causative organisms as notifiable, and other infections not included on this list should also be notified if they could present significant harm to human health (such as emerging or new infections). Cases are notified on the basis of clinical suspicion to the local health protection team, and notification should not be delayed while awaiting confirmation.

Health protection teams will then perform a risk assessment for each notification they receive, and will introduce control measures specific to the disease and the context to mitigate identified risks, working in conjunction with environmental health officers from the local authority. Control measures may include:

- provision of infection prevention and control advice
- isolation of infected individuals
- post-exposure prophylaxis.

Control of environmental hazards

Public health services are also notified of local environmental, chemical or radiological hazards that threaten the health of the public. These threats are wide-ranging and include air pollution, drinking water contamination and exposure to radiation. Public health professionals work with the relevant experts, emergency services, local government and industry to identify and mitigate these hazards.
Box 14.9 Middle East respiratory syndrome coronavirus (MERS-CoV)

- In 2015, MERS-CoV was reported to be one of the top emerging pathogens likely to cause severe outbreaks.
- It is a viral respiratory disease first reported in Saudi Arabia in 2012 and thought to be associated with bat coronaviruses.
- MERS-CoV has also been found in camels, and the WHO advises that individuals with co-morbidities should avoid contact with camels, refrain from drinking raw camel milk and not eat undercooked camel meat.
- Patients may develop severe pneumonia and renal failure, and there is high mortality in 30–40% of cases.
- Thus far, all cases have been associated with countries in or near the Arabian Peninsula, and spread has been reported via close contact with infected cases or in healthcare settings.

Box 14.10 Escherichia coli outbreak investigation using whole-genome sequencing (WGS)

WGS is increasingly used in infectious disease surveillance. The identification of highly similar bacterial genomes can link individuals to the same outbreak, when there may not otherwise have been obvious similarities between cases. For example, in 2017, Public Health England surveillance identified an outbreak of 12 cases of E. coli O157 occurring within a 6-week window and carrying the same WGS. The cases lived across England, had no other known common features and would not have been investigated collectively, were it not for WGS results. Using a detailed questionnaire, epidemiologists identified burgers from a particular retailer as a potential link. In collaboration with the supermarket and the Food Standards Agency, supermarket loyalty card records belonging to the affected individuals were analysed to identify the specific burger brand. The product was recalled and the supermarket contacted those known to have bought the burgers, advising them to be returned for a refund.

Monitoring (surveillance)

‘Emerging infectious diseases’ (EIDs) is a term that encompasses newly emerging pathogens, pathogens whose incidence is increasing and/or that are appearing in new populations, and pathogens that are re-emerging in different forms (e.g. multidrug-resistant (MDR) and extensively drug-resistant (XDR) tuberculosis). Many of these EIDs are zoonoses (of animal origin), including, for example, human immunodeficiency virus (HIV) and Middle East respiratory syndrome coronavirus (MERS-CoV, Box 14.9). Other recent examples of EIDs include Zika virus associated with microcephaly, Ebola virus disease associated with outbreaks in West Africa and the Democratic Republic of Congo, and SARS-CoV2, responsible for the global COVID-19 pandemic which continues to unfold at the time of publication.

The reasons why new infections appear and old ones return are multifactorial and include:
- **population movement** to new geographical areas, e.g. displacement following war or natural disasters
- **a rise in global trade and travel**
- **ecological changes**, such as those driven by climate change or severe weather events (which can, for example, have an impact on vectors implicated in the transmission of pathogens); or changes in agricultural practices (which can, for example, alter the likelihood of coming into contact with sources of infection)
- **technologies in healthcare**, e.g. xenotransplantation or increased antibiotic use (associated with the development of antimicrobial resistance).

Well-developed surveillance mechanisms are key in the early detection of new and emerging pathogens that may represent a significant future threat to health. This monitoring facilitates outbreak investigations (Box 14.10), as well as informing broader infection prevention policy (Box 14.11).

Box 14.11 Pertussis vaccination in pregnancy

Pertussis infection (whooping cough) is a significant infectious cause of morbidity and mortality in infants, particularly among those too young to have been protected by vaccination. After UK surveillance data identified that, during a 2012 pertussis outbreak, the highest incidence of disease was among infants under 3 months of age, the Department of Health introduced an antenatal vaccination programme. Intrauterine transfer of maternal antibodies confers passive immunity, protecting infants until they are old enough for active immunity with routine vaccination. The antenatal programme has been shown to be effective, with a reduction in infant pertussis incidence (Fig. 14.7).

Healthcare public health

Healthcare public health is the final of the three domains of public health, defined as being concerned with maximizing population benefits from healthcare interventions and reducing health inequalities. It involves the prioritization of limited resources, the prevention of disease and the improvement of healthcare outcomes via ‘design, access, utilisation and evaluation of effective and efficient health and social care interventions, settings and pathways of care’ (Faculty of Public Health 2017).

Screening

Screening aims to reduce the harm caused by a disease and its complications by detecting the disease or its risk factors at an early enough stage for it to have a beneficial impact on outcome.
Screening tests do not diagnose disease; they determine who should be investigated further for diagnosis and treatment. Screening can be:

- opportunistic, e.g. assessment of smoking status during a primary care visit
- part of a coordinated programme, with quality assurance and programme monitoring.

Although screening programmes are commissioned and delivered to improve health outcomes, screening has the potential to do harm, and so the benefits and risks need to be carefully considered, and screening should be implemented only when certain criteria are met (Boxes 14.12 and 14.13). In the UK, there are currently 11 population screening programmes (Box 14.14).

### Screening for prostate cancer

An example of uncertainty around implementation of screening programmes is prostate cancer. This is a common cancer, although rates vary across countries. Some men have slow-growing asymptomatic tumours that may never require treatment, whereas others present with aggressive metastatic disease. Prostate-specific antigen (PSA) is a glycoprotein that can be detected in blood and is associated with a range of conditions affecting the prostate, including but not limited to prostate cancer. For example, elevated PSA levels are also found with benign prostatic enlargement, increasing age, inflammation and after ejaculation. Additionally, some medications may lower PSA levels.

#### Wilson and Jungner criteria for screening tests

Wilson and Jungner (1968) developed the classical screening criteria to determine whether or not a condition/disease should be subject to screening:

- The condition should represent an important health problem.
- There should be an accepted treatment.
- Diagnostic and treatment facilities should be available.
- There should be a recognizable latent or early symptomatic stage.
- There should be an appropriate test or examination.
- The test should be acceptable to the population.
- The natural history of the condition should be well understood.
- There should be agreement on who to treat.
- The cost of case-finding should be economically balanced in relation to possible expenditure on medical care as a whole.
- Case-finding should be a continuous process.

#### Screening test performance

Negative screening tests do not necessarily confirm the absence of disease. Screening test performance can be evaluated by assessing the disease status against the test result.

- **False positives** occur when individuals with no disease test positive.
- **False negatives** occur when individuals with disease test negative.
- Sensitivity and specificity describe how well the screening test performs against a gold standard (criterion) test:
  - **Sensitivity** is the ability of the test to detect all cases of disease.
  - **Specificity** is the ability of the test to detect all disease-free cases.
- Both positive and negative predictive values are dependent on the population disease prevalence:
  - **Positive predictive value (PPV)** is the probability of having the disease, given a positive test result.
  - **Negative predictive value (NPV)** is the probability of not having the disease, given a negative test result.

<table>

### UK screening programmes

#### Antenatal and newborn

- Sickle cell and thalassaemia
- Fetal anomaly
- Infectious diseases in pregnancy
- Newborn and infant physical examination
- Newborn blood spot
- Newborn hearing

#### Adult

- Diabetic eye (from 12 years of age)
- Abdominal aortic aneurysm
- Breast cancer
- Cervical cancer
- Bowel cancer

A systematic review in 2018 demonstrated that PSA screening resulted in a possible small reduction in disease-specific mortality over 10 years but no reduction in overall mortality. The authors estimated that this equates to 1 less death from prostate cancer per 1000 men screened, but that the harms of such an approach would include 1 man hospitalized for sepsis, 3 experiencing urinary incontinence and 25 experiencing erectile dysfunction from the same 1000 screened. There is concern that population-level PSA screening would result in overdiagnosis and overtreatment, further complicated by the fact that optimum treatment is not always clear and treatment often has side-effects. As a result, many European countries have no population-wide screening programme, but in the UK asymptomatic men over 50 years who request PSA testing are given advice regarding the risks and benefits of testing so that they can make an informed choice about whether to undergo screening.

### Antimicrobial resistance

This occurs when microorganisms develop resistance to commonly used antimicrobial drugs and are not suppressed by pharmacological agents that would normally inhibit their growth or kill them (see Chapter 8). Examples include meticillin-resistant *Staphylococcus aureus* (MRSA), XDR tuberculosis and carbapenemase-producing Enterobacteriaceae (CPE). These multiply-drug-resistant organisms are an emerging cause of hospital-acquired infections, which can result in outbreaks, are associated with high morbidity and mortality,
and have the potential to develop into even more drug-resistant strains (Box 14.15).

The cornerstones of prevention of the spread of antimicrobial resistance include:

- **Early case recognition** using robust surveillance mechanisms, e.g. screening new admissions to hospital for asymptomatic carriage of some organisms.
- **Antimicrobial stewardship**:
  - Antibiotics are prescribed only when clinically indicated.
  - Local prescribing guidelines are adhered to.
  - Use of broad-spectrum antibiotics is minimized.
  - Dose, route and length of administration are monitored.
  - Antibiotics are stopped or switched promptly, as appropriate (see p. 159).
- **Public education campaigns** to reduce antibiotic demand.
- **Good hand hygiene** on the part of healthcare workers.
- **Reduction of agricultural antibiotic use**.
- **Promotion of vaccination**.
- **Research** to develop new classes of antimicrobial agent.

### Health economics

Demand for healthcare often exceeds the finite resources available to deliver it. These finite resources include not only money but also the availability of space and appropriately trained staff. As not all demands for healthcare can be met, the concept of **opportunity cost** arises: if resource is used for one intervention, less will be available to do something else. The benefits gained from the chosen option should be greater than the benefits foregone by not choosing the alternative. Opportunity cost may be minimized by resourcing interventions with maximal cost-effectiveness.

### Measuring outcomes

A prerequisite for maximal cost-effectiveness is maximal efficiency. Efficiency describes using the minimum resource to produce the same output, or alternatively, maximizing the output gained from using the same resource. When comparing interventions that produce the same output, such as an antihypertensive that, on average, reduces blood pressure by the same extent, the intervention that is cheaper will be most efficient (this is known as cost minimization). If the interventions produce different types of output, then a common measure of health is needed to permit comparison: if both treatments are being used for the same disease, then a disease-specific measure may be used.

Comparing treatments between completely different diseases requires a generic measure of the amount of health gained (termed ‘utility’). The most commonly used measures of utility are the **quality-adjusted life year (QALY)** and the **disability-adjusted life year (DALY)**. A QALY is 1 year of life in perfect health, whereas a DALY is the inverse: 1 year of healthy life that has been lost due to premature death. The aim is to maximize the number of QALYs gained or minimize the number of DALYs lost.

### Measuring cost-effectiveness

When the interventions being compared involve both different outputs and different costs, then a measure of utility in comparison to cost is produced. These cost-utility analyses produce an **incremental cost-effectiveness ratio (ICER)**, which can then be compared by policy-makers to make funding decisions across the healthcare system (Box 14.16). The threshold at which interventions are deemed to be cost-effective depends on the resources available in a particular setting. For example, in England, funding recommendations are made by the National Institute for Health and Care Excellence (NICE), and a threshold of between £20,000 and £30,000 per QALY gained is currently used to determine whether an intervention should be recommended by NICE.

### The ethics of funding decisions

Health economics does not only concern cost-effectiveness. The use of funds, and particularly of public funds, should be fair, as well as representing good value. The determination of ‘fairness’ is an ethical one, and contextual to the society in which the health system is operating. It is commonly said that the benefit of using QALY’s is that they are uniform across conditions (‘a QALY is a QALY is a QALY’), but whether this should be applied in all circumstances is debatable. For example:

- Is extending life by 1 month when a patient is only expected otherwise to live for 1 month the same as extending life by 1 month when a patient can be expected otherwise to live for 20 years?
- Should the amount a funder is willing to pay per QALY be the same for all diseases, when it is recognized that treatments for rare diseases are more expensive (to allow pharmaceutical companies to cover their research and development costs among a smaller sales volume)?

In the UK, specific rules have been introduced with respect to end-of-life treatments and to rare diseases in an attempt to answer these questions.

### Service delivery

Research has shown that active consideration of the needs of patient groups when planning how and where interventions are to be delivered has the potential to improve patients’ health at a population level. Tailoring service design to patient needs can be observed in the use of outreach services for areas with high numbers of hard-to-reach individuals, to increase accessibility. For example, homelessness is a risk factor for tuberculosis, but individuals who are homeless may be less likely to present to healthcare services with symptoms and so may remain undiagnosed; once diagnosed, they may also be less likely to complete courses of treatment. Novel outreach services run to engage homeless people in the wider community have been described that use mobile X-ray diagnostic units to provide tuberculosis screening in the community.

### Centralization

Where the volumes of patients with a particular condition are low, the quality of care that patients receive may be improved by service centralization, which ensures that they are seen by teams dealing with sufficient numbers of cases to make their care routine, not unusual. Services may be delivered using a ‘hub-and-spoke’ model, whereby problems of lower complexity are dealt with in local...
Public health

Box 14.16 Cost–utility calculations

**Treatment A**
- In comparison to current treatment, treatment A would extend patients’ lives by a further 3 years, each at half the ‘perfect’ quality of life
- Net QALYs gained = 3 × 0.5 = 1.5
- Treatment A costs £45,000 per patient (one-off sum) more than the current treatment
- Cost–utility = 45,000 / 1.5 = £30,000 per QALY

**Treatment B**
- In comparison to current treatment, treatment B would not prolong patients’ lives, but it would improve their quality of life from 30% to 50% (with a life expectancy from treatment of 10 years)
- Net QALYs gained = 10 × 0.2 = 2
- Treatment B costs £1,600 per patient per year (ongoing)
- Cost–utility = (1,600 × 10) / 2 = £8000 per QALY

Therefore, treatment B is more cost-effective than treatment A.

hospitals and problems of higher complexity or acuity are referred to a tertiary centre. For example, in London, city-wide stroke services were reorganized in 2010 with the introduction of eight ‘hyper-acute’ stroke units where emergency care, including thrombolysis, is delivered; these are supported by a number of other local stroke units, to which patients are subsequently ‘stepped down’ for rehabilitation. A 2013 evaluation concluded that this service reorganization was associated with significantly improved patient survival and reduced healthcare costs.

Centralization has a number of benefits, including:
- allowing investment in specialized healthcare professionals and equipment
- helping to ensure that clinicians remain up to date with current evidence
- reducing unwarranted variation between units.

However, any centralization is a trade-off against increased travel time for patients (which might reduce accessibility, potentially inequitably), and may be politically controversial if there is a perception that local hospitals are being undermined.

**Further reading**
Geriatric medicine focuses on the medical care of older people. Increasingly, the criteria for specialist geriatric care are defined by the presence of multiple problems and/or frailty rather than chronological age. Medical care is provided within a multidisciplinary team.

Geriatricians cover the range of general medicine in older adults, in both acute hospital settings (the emergency department and specialist wards) and the community (rehabilitation wards or patients’ homes). Geriatricians support other specialists with specific issues such as the management of multimorbidity, polypharmacy or complex discharge planning. Subspecialty work includes falls, orthogeriatrics, stroke medicine and Parkinson’s disease, along with evolving areas such as oncogeriatrics.

Key skills in geriatric medicine include:

1. managing the complexity inherent in ageing physiological systems and interacting diseases and treatments
2. making pragmatic and holistic decisions for individual patients in the face of uncertainty, including understanding and individualizing the evidence base
3. working with allied health professionals to address patients’ challenging social circumstances
4. caring and advocating for the most vulnerable and frail of adult patients.

INTRODUCTION

There have been incredible changes in human life expectancy over the last 200 years, with increasing numbers of people enjoying fulfilling lives up until their nineties and beyond. These changes reflect numerous factors, ranging from improved sanitation and nutrition to the development of antibiotics. Preventative measures, such as reductions in cardiovascular disease through blood pressure control, can postpone the onset of disease. Increasingly, many diseases are treatable or even curable, including numerous cancers and chronic infections such as human immunodeficiency virus (HIV). In turn, many people are living with one or more chronic conditions, which may require ongoing treatment and intervention to reduce any negative impact on the individual’s quality of life. These interventions may have their own side-effects, and ageing itself has an impact on the body and its function, requiring a specific approach.

In the 1960s, Bernard Isaacs described four ‘Geriatric Giants’:
1. incontinence
2. immobility
3. intellectual impairment
4. instability
5. iatrogenesis.

More recently, ‘5Ms’ have been proposed by Mary Tinnetti (Box 15.1).

Presentations of illnesses often differ in older age. For example, the physical symptoms and signs associated with depression are common, and difficult to differentiate from those of organic disease. A diagnosis of depression may be signalled by reduced social interaction and by the fact that the patient does not leave their home when this is unexplained by any co-morbidities or physical disability.

Investigation and interpretation of results must also be balanced against pragmatic considerations. For example, finding a pulmonary nodule in a frail person should prompt the questions, ‘If this were malignant, what would the patient want? Are they fit for surgery or chemo- or radiotherapy? Will their present co-morbidities and disabilities allow them to tolerate further investigations?’ Another common scenario is a person who is experiencing postural hypotension due to antihypertensives. It may be prudent to accept a higher blood pressure than guidelines would suggest in order to reduce the risk of falling. These decisions must be discussed with patients as part of shared decision-making, but finding a balance can prove difficult for patient and clinicians alike. At its heart, geriatric medicine is the interplay between the patient, the medical teams and the declining physiology of the ageing process.
AGEING

Ageing is a progressive physiological decline associated with living beyond roughly the age of 30. Bernhard Strehler defined ageing as:

• **Universal**: the process must happen to all members of a species.
• **Intrinsic**: it takes place via endogenous processes, i.e. it must not depend on external factors.
• **Progressive**: changes leading to ageing must occur progressively throughout a person’s lifespan.
• **Deleterious**: it is bad for the individual.

Virtually all physiological functions lose efficiency with ageing, and individuals lose the capacity to maintain homeostasis when faced by external challenges. Where a younger person stumbling over a kerb would have the strength and reflexes to adjust and maintain their balance, an older person is more likely to fall.

Ageing happens at differing rates between individuals. Some aspects are easily apparent, such as the hair turning grey. Other aspects are less obvious, such as accumulation of atheroma (plaque) within blood vessels. Ageing will eventually occur in everyone, but can be influenced by a number of factors, such as genetic make-up, activity levels and environment. Some factors are associated with accelerated ageing, such as smoking and diabetes. Others are protective and slow the ageing process, such as a balanced diet and regular exercise.

Why do we age?

Theories of ageing can broadly be split into two: those concerned with the limited replication of cells and those related to evolution.

**Theories related to limited cell replication**

**Telomere shortening**

Telomeres protect the ends of chromosomes from errors in DNA during replication. With each cell replication, a small piece of the telomere is removed until it eventually becomes too short to provide this protective effect, which may lead to clinical problems associated with ageing including an increased risk of cancers.

**Damage accumulation theory**

Ageing is a result of fault accumulation at cellular and molecular levels due to a limitation of maintenance and repair mechanisms. The primary problems do not lie with the cells themselves, but with the regulation of mechanisms keeping the cell division process efficient and safe.

**Free radical theory**

Free radicals, derived from chemical reactions involving oxygen molecules (oxidation), occur more frequently in older cells. Species with high levels of free radicals have shorter life expectancies. Free radicals are balanced by antioxidants, which protect against oxidative damage to elements within cells, such as proteins, DNA and lipids — all of which are vital for normal cell function. The mitochondrial theory of free radicals in ageing suggests that damage by reactive oxygen species (ROS) causes oxidative stress that overwhelms the antioxidant cellular defences, leading to *cellular senescence* (see later). Chronic oxidative stress throughout the lifespan plays a critical role in ageing overall. There is some evidence that antioxidants can reduce this damage but no clinically relevant outcomes have been observed.

**Theories related to evolution**

Evolutionary theories are based on the idea that the biological processes associated with ageing provide an advantage earlier in life in terms of reproduction and survival of the species. As humans now regularly survive beyond reproductive age, individual negative biological impacts later in life may be seen as payback for this group advantage.

**Disposable soma theory**

This suggests that an organism must budget for the limited energy available to it and preferentially focus on reproduction rather than maintaining the mature body, leading to inefficiencies in cell replication later in life.

**Mutation accumulation theory**

This theory supports the disposable soma idea by asserting that DNA mutations taking place after reproductive age cannot affect future generations, meaning that there is no evolutionary imperative to correct them or develop protection against consequent defects.

**Antagonistic pleiotropy theory**

This theory takes the idea one step further, suggesting that genes that are protective or beneficial in early life become detrimental later in life. An example is sickle cell disease, which is protective against malaria in earlier life.

**Calorie restriction**

Calorie restriction is thought to prolong life expectancy, mediated through reduction of oxidative damage and anti-inflammatory benefits. This is supported by animal studies, and by the example of the population of the Japanese island of Okinawa, who, through cultural calorie restriction, boast the highest prevalence of centenarians worldwide.

**Cell senescence**

Cell senescence, when cells stop dividing but remain metabolically active, leads to a pro-inflammatory state. It is different from apoptosis, which is programmed cellular death followed by removal of the cell from the system in an organized way. Cells with senescent properties are seen in the tissues of those with age-related diseases, such as osteoarthritis, pulmonary fibrosis, atherosclerosis and Alzheimer’s disease. Exactly what the mechanism is that leads from one to the other is unclear.

Senescence is not just seen in the context of ageing. Another example is wound healing. Once a wound is healed, the myofibroblast cells go into acute senescence to prevent excessive fibrosis at the site. Senescence also occurs when the blood supply for an embryo is being built. In these circumstances, it is a programmed process, triggered by specific stimuli and targeting specific types of cell. In ageing, the process appears unscheduled and more random. Clearance of aged cells that have undergone senescence is much less efficient. This may be due to the reduced immune function associated with ageing.
Applied anatomy and physiology of ageing

One of the key aspects of providing medical care for older people is distinguishing between normal ageing and disease. Ageing affects each organ differently. Presentations that probably arise as single-organ pathology in younger adults are likely to have more than one cause in older adults. For example, anaemia in a young woman is likely to be related to menstrual bleeding. In an older woman the anaemia might represent chronic disease, such as myelofibrotic bone marrow that is unable to respond quickly to increased demand for red cells, exacerbated by a poor nutritional state with low iron and folate levels. Older adults need to have their physical conditions assessed and managed alongside their functional and social circumstances.

What commonly differentiates people with the same apparent condition(s) is the ability of their whole system to balance these conditions in a way that keeps the person functioning. This difference is usually accounted for by the presence of frailty as an underlying physiological process.

As we age, our organs function less well, with the percentage function of each individual system reducing by the order of 0.5–1% per organ system per year from the age of 30. Fig. 15.1 is based on a large international cohort. Similar graphs can be drawn for maximum usage of oxygen (VO₂ max), cardiac output, maximum heart rate or renal function.

INVESTIGATIONS IN OLDER ADULTS

Normal ranges stated by laboratories account for the values expected for the majority of the population, but older adults (like children) are outliers compared with the whole population. The altered anatomy and physiology in older adults mean that routine investigations need to be interpreted with this in mind (Boxes 15.2 and 15.3).

TAKING A HISTORY

When symptoms can be non-specific and many conditions present in an atypical manner, it can be difficult knowing where to start. Asking open questions like ‘What is your biggest concern today?’ can help. In those with confusion, timelines of presentation may not be reliable, but you can usually get a feel for immediate concerns, such as pain or breathlessness. Do not be afraid to ask about difficult issues (e.g. bladder and bowel dysfunction, death and dying); patients often want to explore these areas but are hesitant to bring them up themselves.

A key aspect of geriatric medicine is the ability to think in detail about the current issue while maintaining a longer-term, bigger picture of the person and their life. Geriatricians often manage patients with interacting multimorbidity, polypharmacy and physiological decline. They need the ability to focus on those aspects that might be troubling the patient (e.g. constipation or a dry mouth) while being aware of overall progressive decline, reservations about interventions and the potential need for advanced care-planning.

MULTIMORBIDITY, SARCOGENIA AND FRAILTY

Multimorbidity

Older people are more likely to have multiple medical issues. By 2035, around two-thirds of people over 65 years of age will have multimorbidity. Within the UK, for example, such patients currently account for 50% of general practitioner consultations, 55% of hospital admissions and 80% of prescriptions. Each condition often requires a number of medications, with treatments potentially interacting adversely. This can lead to prescribing cascades, whereby medications are given for one condition and then further medications are required to counter the side-effects (e.g. the co-prescription of aspirin with a proton-pump inhibitor).

Sarcopenia

Sarcopenia is closely related to frailty (Box 15.4). It is a progressive and generalized muscle disorder associated with an increased risk

of adverse outcomes, including falls and fractures. Muscle fibres reduce in number, the fast-twitch type II muscle fibres in particular. The result is loss of their explosive power, which is needed for functions such as sprinting, standing from a chair or even coughing.

In sarcopenia, VO\textsubscript{2} max within muscle reduces, as does gait speed. Reduction in physical activity leads to a reduction in energy usage; when coupled with the relative anorexia of ageing, this leads to an energy deficit. With this energy deficit, cells that are predetermined to undergo apoptosis do not have sufficient free adenosine triphosphate (ATP) to allow this process to occur. Instead, the cell undergoes necrosis, which uses more ATP and worsens the energy deficit. When this occurs in muscle tissue, it leads to worsening sarcopenia and development of the cycle of frailty (Fig. 15.2).

**Frailty**

Frailty is ‘a state of increased vulnerability to stressors due to age-related declines in physiologic reserve across neuromuscular, metabolic, and immune systems’. It is the effect of systemic ageing (the underlying process) rather than chronological age. It is possible to be chronologically old and not frail, likewise to be young and very frail. As an individual organ’s ability to react to a physiological stressor reduces with age, the impact of a given illness on that organ system will have a greater effect. A minor infection (e.g. an uncomplicated urinary tract infection, UTI) will have little impact on

a young and fit patient but may cause serious delirium and morbidity in the cognitively impaired, especially when combined with frailty or serious multimorbidity.

Frailty, multimorbidity and disability are distinct entities that often co-exist. The difference is important in the management of patients.

- **Frailty** is a risk of a deterioration when faced with a physiological stressor.
- **Multimorbidity** involves two or more medical conditions that may or may not interact.
- **Disability** is physical or mental impairment that has a ‘substantial’ and ‘long-term’ negative effect on a person’s ability to carry out normal daily activities.

**Identifying frailty**

A number of models have been developed to describe frailty and the manner in which it evolves. Frailty is relatively simple to recognize when it is severe but more challenging when mild. Its recognition ensures that patients are managed according to their functional level rather than their chronological age.

Frailty recognition is an effective way of identifying people who may be at greater risk of future hospital admission, care home placement or death; those with severe frailty have more than a four times greater annual risk for these outcomes. Interventions targeted at actively managing frailty around a stressor, such as elective surgery, show better outcomes.

The key benefits to patients of a definition of frailty and an active search for it are twofold:

†Three or more define frailty. (From Fried LP, Tangen CM, Walston J et al., Cardiovascular Health Study Collaborative Research Group, Frailty in older adults: evidence for a phenotype, Gerontol A Biol Sci Med Sci 2001; 56(3):M146–156.)

- It prompts an objective assessment of patients (Comprehensive Geriatric Assessment, CGA; see later) to identify those who might benefit from optimization.
- It acts as a trigger for the point at which medicine stops following standardized protocols and becomes a balance between the two questions that Edmund Pellegrino termed ‘prudential’: ‘What can be done for the patient?’ and ‘What should be done for the patient?’

Identification and stratification of population-level frailty could assist in planning for future demands on health and social care while allowing targeted interventions to help people age well. Upskilling of all those working with older adults is a priority. This runs in parallel with Geriatrics teams supporting specialist services, from perioperative care to specific patient populations, in areas such as oncogeriatrics and HIV medicine.

Two main theories can also be used to identify frailty: frailty as a phenotype and frailty as an accumulation of deficits.

**Frailty phenotype**

In 2001, Linda Fried published her model of frailty (including the frailty cycle described earlier), and demonstrated that becoming frail was associated with negative outcomes in terms of length of life and institutionalization (Box 15.5).

**Frailty Index – accumulation of deficits**

The Frailty Index (FI) defines frailty from a list of medical conditions, physiological parameters, and observations on factors that become more common with increasing age and are associated with negative health outcomes. This method has been used largely in research but now, with the development (in the UK) of the e-Frailty Index, it can be run on routinely collected data from GP records.

**The Clinical Frailty Scale (CFS)**

The Clinical Frailty Scale (CFS) correlates with the more in-depth FI. It uses clinical descriptors and images to stratify older adults according to level of vulnerability. It has been validated in a number of clinical settings but only after a CGA has been carried out. It is increasingly being employed for identification purposes, however, due to its ease of use (Fig. 15.3).

**Further reading**

**COMPREHENSIVE GERIATRIC ASSESSMENT**

Once a patient is identified as being frail, what can be done to help them? There is no single treatment to cure frailty. Inaction is likely to result in worsening frailty, functional decline and disability. Therefore, a proactive assessment of each of the potential clinical and subclinical deficits is needed.
Comprehensive Geriatric Assessment (CGA) is not something that is just delivered by doctors; it is a multidimensional, interdisciplinary diagnostic process focused on determining a person’s medical, psychological and functional capability in order to develop a coordinated and integrated plan for treatment and long-term follow-up. As such, it is firmly rooted in the biological, psychological and sociological approach to thinking about patients and their conditions. CGA involves exploring a number of domains (Box 15.6). The further roles of the multidisciplinary team (MDT) are explored later.

In older adults with frailty there is often a large overlap between symptoms caused by disease, by treatment of disease, by normal ageing and by accelerated ageing. More practically, CGA can be thought of as a process of good holistic care delivered by a focused MDT, which goes above and beyond simply managing the acute problem with which the person has presented. If an older person is not managed in this way, care becomes reactive to a series of acute problems, rather than a proactive problem-solving process.

Compared to those given ‘usual’ care, those who undergo CGA during an acute admission have favourable outcomes. At 6 and 12 months, respectively, the number needed to treat (NNT) is 20 and 25 to prevent institutionalization and 17 for unnecessary death. By comparison, the NNT for many medications is in the hundreds to thousands range.

One area that remains to be fully explored is how best to identify patients who would benefit from a CGA who are not in an acute hospital. The proactive assessment of patient frailty is one means of doing this. Once patients are identified as frail (or becoming frailer), then a proactive CGA, in either the community or a day hospital setting, would seem to be a pragmatic approach.

AF, atrial fibrillation; CPR, cardiopulmonary resuscitation; DNACPR, do not attempt cardiopulmonary resuscitation; STOPP-START, Screening Tool of Older People’s potentially inappropriate Prescriptions-Screening Tool to Alert doctors to Right Treatments.
In order to deliver true CGA, geriatricians need to work as part of an expert MDT. Communication between the whole of the MDT is essential to ensure that patient care plans are discussed and developed together. Each team member’s specialist skills are better utilized, making for a more egalitarian approach to care, rather than the traditional hierarchical one with the senior doctor as the leader (Box 15.7). Learning about geriatric medicine therefore requires an understanding not only of the role of the doctor in delivering CGA, but also of the roles of each member of the MDT.

### ADVANCE CARE PLANNING

Advance care planning (ACP) involves discussing the approach to a patient’s future care, often prior to their becoming unwell (see p. 84). ACP is a continuous process of communication between patients, their loved ones and healthcare professionals. It is not always possible or appropriate to cover everything in one conversation. Patients may want to think through often complex issues and discuss their plans with their loved ones. Plans should also be subject to regular review in case patients have changed their mind.

One of the most common decisions concerns resuscitation status. Many older people recognize that they are coming towards the end of their lives. Even though they are in good health, many would like to be allowed a natural death in the event of a cardiorespiratory arrest. Others may want to live for as long as possible and ask for all that medicine can do to prolong their lives. Events that may precede resuscitation should be planned for too, such as hospitalization for treatment of infections.

ACPs often focus on the dying phase but can be expanded to include what constitutes living well. Statements of wishes and preferences can range from where a person lives (e.g. in their own home or in a care home) to their favourite foods.

ACP discussions can be started at any time if the patient is willing and ready. They should be specifically considered in patients diagnosed with progressive conditions, such as neurodegenerative diseases, where there is the potential for capacity to be lost in the latter stages. Any agreed outcomes should be documented and available to all who need access to them, including the patient and their family, ambulance staff, GPs, community teams and hospital teams. This can also be a good time to highlight the importance of ensuring that wills and power of attorney are considered.

CGA, Comprehensive Geriatric Assessment.
The most common issues in older people

Polypharmacy

Prescribing in older people
While prescribing for older people is largely the same as for younger people, there are some key differences. The approach should be based around the patient’s physiological rather than chronological age. There are numerous mechanisms behind the altered pharmacokinetics in older people (Box 15.8) but the net result is that older patients tend to suffer increased side-effects from their medications.

Drug interactions
One-third of patients over 65 living in the UK take six or more medications, with 5% taking more than ten. Polypharmacy leads to increased drug interactions and increased potential for drug–drug interactions (e.g. cholinesterase inhibitors and anticholinergics) and drug–disease interactions (e.g. non-steroidal anti-inflammatory drugs worsening hypertension). Polypharmacy accounts in part for up to 6.5% of all iatrogenic hospital admissions.

Patient choice
Polypharmacy may leave patients unhappy with their medication burden, which can lead to poor concordance overall (Box 15.9). Many prefer to take fewer medicines, accepting an increased risk of further events and potentially shortened life expectancy (e.g. forgoing a statin after an acute coronary syndrome). A patient’s priorities of care (what is most important to them) often rate immediate symptom control over preventative interventions. When prescribing, clarifying the goals and educating patients about the benefits of treatment are key to supporting them in making treatment choices.

Evidence base
Few clinical trials involve patients over 80 years old, and those who are included tend to be fitter than those encountered in clinical practice, especially those in secondary care. Reported levels of benefit and risk of harm from medications studied in younger, non-frail, non-co-morbid groups cannot therefore be assumed to be the same as in older, frailer cohorts with higher levels of co-morbidity. Research that includes frailer populations with multimorbidity is inherently very difficult due to the confounding issues seen in such cohorts and the practicalities of obtaining consent or attending follow-up visits. However, it would be wrong to deny patients the benefits of treatment on the grounds that there is no evidence base: the absence of an evidence base is not the same as the absence of benefit.

Benefits of therapy
The levels of benefit from interventions differ between age groups. For example, there is increasing evidence in older diabetic patients treated with insulin that tighter target HbA1c levels of <50mmol/mol (<6.7%) are associated with worse outcomes (increased mortality, increased weight gain) than in those patients with a more relaxed target HbA1c of 47.5–57.4 mmol/mol (6.5–7.4%). In older people with diabetes, the avoidance of immediate complications (e.g. hypoglycaemic events) should be prioritized over prevention

**Box 15.8 Reasons for altered pharmacokinetics in older people**

<table>
<thead>
<tr>
<th>Reason</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Drug absorption</strong></td>
<td></td>
</tr>
<tr>
<td>Gastric pH gradually increases with age (exacerbated by medications such as proton-pump inhibitors)</td>
<td></td>
</tr>
<tr>
<td>Gastric emptying slows</td>
<td></td>
</tr>
<tr>
<td><strong>Drug distribution</strong></td>
<td></td>
</tr>
<tr>
<td>Increased body fat and decreased body water (as a proportion of total body weight)</td>
<td></td>
</tr>
<tr>
<td>Increased volume of distribution for fat-soluble drugs, and so medications may accumulate due to an increased elimination half-life; this means that their effects may continue despite the drug being stopped</td>
<td></td>
</tr>
<tr>
<td>Decreased volume of distribution for water-soluble drugs, and so drugs such as digoxin need a reduced loading dose</td>
<td></td>
</tr>
<tr>
<td><strong>Drug metabolism</strong></td>
<td></td>
</tr>
<tr>
<td>Altered permeability of the blood–brain barrier, and so the brain of an older adult can be exposed to higher levels of medication, causing adverse effects</td>
<td></td>
</tr>
<tr>
<td>Reduced hepatic blood flow and hence clearance of medications that have high hepatic excretion ratio, e.g. amitriptyline</td>
<td></td>
</tr>
<tr>
<td><strong>Elimination/ kidneys</strong></td>
<td></td>
</tr>
<tr>
<td>With age, there is a reduction in renal mass and renal blood flow; eGFR decreases by 0.5% per year after the age of 20</td>
<td></td>
</tr>
<tr>
<td>Affects clearance of water-soluble drugs such as diuretics, NSAIDs and digoxin</td>
<td></td>
</tr>
</tbody>
</table>

*N.B.* In older adults, a ‘normal’ creatinine may be associated with significant renal impairment.

eGFR, estimated glomerular filtration rate; NSAIDs, non-steroidal anti-inflammatory drugs.

**Box 15.9 Optimizing compliance and concordance**

**Understand what medications are and are not being taken**
- The patient may be taking certain medications only; exercise caution when increasing medications without understanding this, to avoid causing iatrogenic complications.
- Why might the patient not want particular medications?
- Review side-effects (e.g. diuretics causing incontinence).
- Review aims of treatment (see later).

**Understand problems around taking the medications**
- Dysphagia: is there a liquid or patch alternative?
- Dexterity: can the patient take the medication from the packaging? Aids are available for inhalers and eye drops.
- Cognition: is the patient forgetting to take the medication, or taking a second dose of one already taken? Are they managing complicated instructions, e.g. for oral bisphosphonates, or variable-dosing medications such as insulin or warfarin?
- Visual impairment: consider large-font labelling.

**Simplify regimens**
- Is a particular time of day better to take the medications?
- Consider once-a-day, modified-release preparations.
- Reduce inappropriate polypharmacy.
- Agree which medications the patient wishes to take.
- Use blister packs to reduce the need to coordinate multiple medications and aid monitoring of compliance.

**Review care needs**
- Is supervision or prompting required?
of longer-term consequences, which may take decades to develop. Similarly, while targets for blood pressure tend to be around 130/80 mmHg in younger patients, outcomes for older patients are better with a higher target: there is a U-shaped curve with an optimum of 160/90 mmHg (i.e. there is an increased risk of adverse events and mortality when blood pressure is significantly higher or lower than this). Some of these adverse events relate to the side-effects of antihypertensives, such as orthostatic hypotension, falls, and associated morbidity and mortality.

**Clinical decision-making**

Many tools exist to aid clinical decision-making with respect to polypharmacy. They aim to summarize the evidence for a given medication in older adults and allow a negotiated approach between patient and clinician regarding the stopping and starting of medications. Examples include the Beers Criteria, Screening Tool of Older People’s potentially inappropriate Prescriptions-Screening Tool to Alert doctors to Right Treatments (STOPP-START), Anti-Cholinergic Burden (ACB) Scale and the Scottish polypharmacy app (see Box 15.6). Figure 15.4 shows the potential hierarchy of utility for medications that might be considered when undertaking a polypharmacy review.

**Falls (instability)**

Most of us take for granted the amazing complexity of the process that maintains an upright posture. High levels of functioning are needed across multiple systems, including musculoskeletal, neurological and cardiovascular. While anyone of any age can fall, it is said that ‘young people trip, old people fall’. For many older or frail adults there are numerous, cumulative risk factors for falling that, individually, would be unlikely to produce major instability (Boxes 15.10 and 15.11). Assessment of falls is one of the most complex areas for geriatricians and can take significant time. Asking about falls should nevertheless be part of routine practice for all professionals working with older people.

Approximately 5% of fallers over 65 years of age will sustain an injury that is serious enough to limit normal activities. Most falls occur during the daytime, when people are most active, and only around 20% take place overnight. Risk factors include cognitive impairment, medications, alcohol excess and a change of environment, such as being admitted to hospital or moving to new accommodation.

Breaking down the contributing risk factors helps provide some structure for assessing and developing a management plan for a person who has fallen (Box 15.12 and Fig. 15.5), and for targeting those risk factors that are reversible. An approach to the assessment of falls is summarized in Box 15.13.

Loss of consciousness is a worrying symptom but of those patients who do actually lose consciousness, over 30% are unaware that this occurred. Often patients try to rationalize what has happened, stating ‘I must have tripped.’ Normally, people will put their arms out when falling to protect themselves. Be suspicious of syncopal falls where this has not happened and there are facial injuries. Items to check include lying and standing blood pressure, electrocardiogram (ECG), and medications such as antihypertensives or diuretics. Management of syncope is largely the same at all ages (see p. 1029).

**Box 15.12 Some risk factors for falls with possible management strategies**

[Continued]
Consequences of falls
Most falls result in minor or no injuries. However, consequences can include fractures and trauma.

Fear of falling
Even after minor falls, patients can develop a fear of falling. This is characterized by anxiety around mobilizing and is associated with an increasing loss of confidence and hesitant gait (see Box 15.11). As a result, people often reduce the amount of walking they do and stop going out of the house. In turn, they develop reduced muscle strength and an increased risk of falling. There is also a danger of social isolation and depression.

Fragility fractures
Fragility fractures occur following an injury from a standing height or lower, and range from vertebral fractures (where there may even be no fall) to wrist, proximal humeral, pubic rami and neck of femur fractures. Most of these are associated with osteoporosis and enquiry should be made about:

- previous fractures, including site, history and age at the time
- age of menopause for female patients
- history of previous osteoporosis treatment.

Sometimes there is no history of trauma. These atraumatic fractures can be due to severe osteoporosis but other causes should be considered, particularly malignancy (e.g. breast, prostate, myeloma, lung), and investigated accordingly. Long-term anti-resorptive bone therapy (i.e. bisphosphonates, denosumab) can cause bones to become unnaturally brittle, especially if it is given as a parenteral treatment or at high doses for malignancy. This can result in unusual fractures, often atraumatic ones, such as fractures of the femoral shaft.

Neck of femur fractures
In England, there are approximately 60,000 neck of femur fractures per year, accounting for 15% of all fragility fractures (Fig. 15.6). They represent a significant injury for an older person:

- They account for 1.8 million inpatient bed days per year.
- Some 20% of patients suffering a neck of femur fracture require transfer to long-term care within 1 year.
- Mortality is 5% at 30 days and 30% at 1 year.

In a number of countries there has been a drive to develop geriatric liaison services to deliver CGA for patients with hip fractures. The geriatrician’s role in perioperative care covers the issues outlined in Box 15.13 and includes:

The most common issues in older people

- pain management
- management of venous thrombotic risk
- recognition and management of delirium
- management of bowels and bladder
- assessment and management of bone health and osteoporosis.

In the UK the widespread establishment of orthogeriatric services has led to a halving of 1-month mortality for hip fractures (from around 10% to around 5%).

In the UK the widespread establishment of orthogeriatric services has led to a halving of 1-month mortality for hip fractures (from around 10% to around 5%).

**Institutionalization**

Falls and their consequences contribute to approximately 40% of admissions to care homes. The fact of being in a care home does not in itself improve gait or remove the risk of falling; indeed, the risk of falling may initially increase on moving into a care home. However, it does mean that there are people on hand to help reduce the risk and to assist if someone does fall.
**Postural hypotension**

Cerebral autoregulation is responsible for maintaining stable blood flow through the brain. In old age, this becomes less well controlled, causing the brain to become more vulnerable to changes in systemic blood pressure and, in turn, to postural instability and falls. The prevalence of postural (orthostatic) hypotension in the community is 1 in 5 older adults.

On standing, normal physiological responses should result in maintenance of a normal blood pressure. This requires:
- normal plasma volume, i.e. the person must not be dehydrated (younger people compensate well for this)
- intact baroreceptors and reflexes
- venomotor tone, the ability of blood vessels to respond to changes in blood flow.

Symptoms of postural hypotension (Box 15.14) typically occur on or soon after standing; they are rare when a person is sitting or lying down, unless they have been lying for a long period and then attempt to sit upright or stand. Some definitions of ‘significant drop’ are provided in Box 15.15.

**Aetiology**

Acute postural hypotension is seen with a reduced intravascular volume, e.g. decreased oral intake, excessive diuresis or excessive fluid losses as in diarrhoea, vomiting or haemorrhage.

Chronic causes are principally:
- **Medications**: classically, diuretics, beta-blockers and other anti-arrhythmics, antihypertensives and vasodilators.
- **Autonomic dysfunction**: associated with diabetes mellitus, Parkinson’s disease and multisystem atrophy (medications for Parkinson’s disease may exacerbate this further). Some autoimmune conditions can also cause autonomic dysfunction.
- **Poor vascular compliance**: seen in ageing blood vessels due to a reduction in elasticity and increased calcification.

**Management**

The evidence base behind management of postural hypotension is poor and only a couple of medications are licensed for use. The goal is to minimize symptoms and improve standing time, in order to enable activities of daily living through improvement of standing blood pressure without excessive supine hypertension (Box 15.16).

**Delirium**

Delirium (sometimes called acute intellectual impairment or acute confusional state) is a common neuropsychiatric syndrome characterized by disturbed consciousness, cognitive function or perception. The characteristic feature is a lack of ‘attention’. It has an acute onset (1–2 days) and fluctuating course. It is the most common psychosis seen in hospital, occurring in 20–30% of medical and 50% of orthogeriatric patients.

Delirium occurs for a large number of reasons; anything that causes a physiological stress can be a trigger. One useful way of thinking about delirium is to consider its predisposing and precipitating factors (Box 15.17).

As a person becomes more cognitively frail (or has significant predisposing risk factors), there is less physiological and cerebral reserve, and so smaller precipitants may trigger delirium. Delirium can be thought of as an acute brain failure. Patients admitted to hospital with delirium have:

**Box 15.14 Measurement of postural blood pressure**

1. Ensure that you are able to stand the patient up, getting help beforehand if necessary.
2. Use a manual sphygmomanometer, ideally.
3. Lie the patient down for 5 min.
4. Measure blood pressure.
5. Stand the patient up and measure blood pressure in the first minute.
6. Repeat at 3 min.
7. If blood pressure is still dropping, repeat and keep checking until it resolves.
8. Repeat if symptoms change at any point.

(Adapted from Royal College of Physicians: https://www.rcplondon.ac.uk/projects/out-puts/measurement-lying-and-standing-blood-pressure-brief-guide-clinical-staff)

**Box 15.15 Definitions of a ‘significant’ drop in blood pressure**

- **Classical**: reduction of 20/10 mmHg within 3 min of standing
- **Initial**: reduction of 40/20 mmHg in first 15 sec – a beat-to-beat recording is required
- **Delayed**: no agreed definition but occurring >3 min
- **In hypertensive patients**: reduction of 30 mmHg systolic – variability higher in this group

- an increased length of stay by an average of 8 days
- worse physical and cognitive recovery at 6 and 12 months
- an increased need for institutional care
- a 1.5-fold increase in mortality risk in the year following admission.

Delirium is characteristically fluctuant and may follow a hyperactive, hypoactive or mixed picture (Box 15.18).

Screening tools to aid recognition of delirium include the Confusion Assessment Method (CAM, Box 15.19) and the 4AT test (Alertness, Attention, four-question Abbreviated Mental Test (AMT4) and Acute change). A key feature is the recognition of a change in cognitive state. This has led to the development of the Single QUestion in Delirium (SQUID): ‘Do you think this patient has been more confused lately?’

**Assessment and management**

History and examination, including collateral information from family or carers, should aim to establish the duration and nature of any cognitive change and then focus on what altered for the patient in the hours or days prior to that change. There are a number of easy-to-use and swift screening tools (e.g. the 4AT test) that can aid the identification of delirium in clinical practice. Some types of dementia can have a fluctuating course, such as Lewy body disease, though the duration and pattern can help differentiate this. Patients may be worse by late afternoon or early evening; this is known as ‘sundowning syndrome’. Management approaches are summarized in Box 15.20.

**Pharmacological management**

Sedatives and antipsychotics can be used to treat delirium, but only when a person is a risk to themselves or others and conservative measures have failed. There is no evidence that these interventions treat (as opposed to sedate) delirium at a physiological level. The drugs themselves are deliriogenic and can lead to a perpetuation of delirium. When necessary, the lowest dose to control symptoms should be used (e.g. risperidone 0.25 mg, lorazepam 0.5 mg, haloperidol 0.5 mg).
The most common issues in older people

Prognosis

Usually, delirium clears within a week or two but full cognitive recovery often takes longer: up to 3 months. Rarely, it may never resolve. Those with more marked underlying cognitive impairments are less likely to regain their previous level of cognition. Delirium is both inflammatory and toxic to the cerebrum, and pathological studies show that the length of time for which delirium lasts correlates with the increased neuropathological changes commonly associated with dementia. Those who experience delirium are more likely to be diagnosed with dementia in the subsequent 1–2 years.

Urinary tract infections

UTIs are common in older adults. However, they are also commonly misdiagnosed or over-diagnosed without clear evidence. This can result in potentially dangerous overuse of antibiotics and overlooking (or missing) the actual cause of the patient’s presentation. Recurrent UTIs in particular should be questioned. Often evidence is lacking and alternative diagnoses, such as vulvovaginal atrophy, should be investigated.

A diagnosis of UTI is likely with a short history of new-onset dysuria alone, or two or more of:
Geriatric medicine, frailty and multimorbidity

Delirium subtype | Characteristics | Notes |
--- | --- | --- |
Hyperactive | Agitation | Patients receive medical attention as they identify themselves. May need pharmacological intervention if safety at risk. |
Paranoia | |
Anxiety | |
Hallucinations (may reach out, trying to pluck things from air) | |
Disorientation | |
Starting easily | |
Carphologia or floccillation (limt-picking movements) | |
Restlessness | |
Wandering; associated risk of falls | |
Hypoactive | Quiet, sleepy | Patients do not often disturb staff and so are easily missed. Poorer prognosis. |
Little psychomotor agitation | |
May have paranoia and anxiety | |
Reduced oral intake | |
Increased pressure sore risk | |
Mixed | A mixture of both the above subtypes | Most common subtype |
May be present at same time or alternate |

Box 15.19

Management of delirium

This is mostly centred around multifactorial interventions:
1. Identify underlying precipitants, e.g. constipation, new medications, pain, electrolyte imbalance, infection.
2. Address treatable causes.
3. Minimize sensory impairments, e.g. hearing aids, glasses.
4. Reduce sensory distractions, e.g. closing of some curtains, reduction of loud noises, consistent staff, gentle lighting.
5. Re-orientate (where not distressing to do so):
   - Clock/calendar
   - Radio
   - Personal objects
   - Family photos
   - ‘REACH out to me’/’This is me’ documents – can be used to structure background information that will help in management and care.
6. Social support and family presence – encourage and allow family members to be present. Any delusions and hallucinations should be neither endorsed nor challenged.
7. Pharmacological measures are of limited benefit.

Box 15.20

Urine dipsticks in the diagnosis of urinary tract infection

- In conjunction with symptoms, dipsticks have a sensitivity of around 77%.
- In the absence of symptoms (e.g. as a screen in a patient with confusion), sensitivity falls to 44%.
- The frequency of positive urine dips in institutional care is very high: up to 50% of females in nursing homes have asymptomatic bacteriuria. In non-care-home residents the figure is lower, ranging from 6% to 16% in females aged 65–90.
- The negative predictive value of dipsticks is 100% for nursing home residents.
- In the presence of long-term catheters, dipsticks will almost always be positive (colonization).

Asymptomatic bacteriuria is bacterial colonization without active infection in the urinary tract. It can cause false positives on urine dipsticks and raised white cell counts on MSU samples.

Management
- In the absence of systemic features of sepsis (see p. 156), treat with empirical antibiotics when a UTI is suspected.
- Review with MSU sensitivities when available.
- Change the catheter as soon as possible if it has been present for more than 7 days before antibiotics, if it is clinically safe to do so.

Recurrent UTIs
- Hold off antibiotics if possible and send 2–3 MSU samples.
- Consider alternative diagnoses if MSUs are repeatedly negative, including vulvovaginal atrophy in peri- and postmenopausal women, sexually transmitted infections, urethritis and prostatitis.
- Ensure that non-specific symptoms are not being inappropriately attributed to UTIs.
- In truly recurrent UTIs, specific management is often required (Box 15.22).

Box 15.21

Urinary incontinence

Up to 50% of women will be incontinent at some time in their life. For men, urinary tract symptoms and difficulty passing urine...
are also common but less well studied. Incontinence is under-recognized and undertreated. Many people will not volunteer their symptoms; even if asked directly, not everyone will be comfortable talking about it.

Incontinence has a huge impact on a person’s quality of life and often on their relationships with partners and family. Poorly controlled urinary incontinence is a common reason for admissions to residential care due to carer strain. It is independently associated with falls and is a modifiable risk factor for them. For those who are bedbound, incontinence can cause local irritation in areas prone to pressure damage, increasing the risk of breakdown of skin integrity.

There are four main types of urinary incontinence but there is often overlap between them.

**Stress incontinence**

Urine leaks from the bladder due to higher pressures than the pelvic muscles are able to contain. This is commonly due to weakness or damage to the pelvic floor muscles, and previous pregnancy is a risk factor. A typical history with this kind of incontinence is for it to occur on coughing, laughing or straining.

Management may be conservative or surgical. Conservative measures can cure stress incontinence and so are first-line treatment (Box 15.23). If they fail, surgical referral should be considered. Surgery aims to support the pelvic floor either through suspension of the bladder higher up from the external sphincter or by bulking the pelvic floor itself.

**Urge incontinence (overactive bladder)**

In this type, the bladder becomes irritable, causing the person to feel that they urgently need to empty it when it is not actually full. Symptoms include frequency, urgency and nocturia. If these are of new onset, the trigger may be a UTI. Other precipitants include medications (e.g. anticholinergics) and constipation. Symptoms include difficulty initiating micturition, poor stream and terminal dribbling, and urge incontinence can lead to renal failure due to obstructive uropathy. Catheterization may be required, either in the short or long term, to alleviate the obstruction.

**Functional incontinence**

This involves the patient being unable to reach the toilet, rather than there being a primary urogenital problem. For example, someone with poor mobility may be unable to get to the toilet in time but would otherwise be continent if their mobility improved. In states of impaired cognition, such as delirium or advanced dementia, the signals for micturition are no longer interpreted normally, resulting in the passing of urine without conscious processing and thus in incontinence. Management requires CGA to address any modifiable components, such as pain control, to allow improved mobilization. This can include environmental adaptations, which may make toileting easier. Regular toileting can be helpful for those with advanced dementia and good mobility; this involves prompting the person to go to the toilet at regular intervals, before they need to go urgently, to minimize the risk of incontinence.

**Older adult abuse and safeguarding**

Abuse of older adults is defined as a single or repeated act that causes harm or distress to an older person, or lack of appropriate action. It can take place within any relationship where there is an expectation of trust. There are a number of different types of abuse (Box 15.24) and it is quite common for a number of these to occur simultaneously.

Older people are particularly vulnerable to abuse. Worldwide, the World Health Organization (WHO) has found that approximately...

Box 15.25 Risk factors for abuse

**Patient factors**
- Frailty or any serious health condition
- Physical or sensory disability, e.g. reduced mobility, poor vision
- Memory problems or dementia; other mental health problems; learning disability
- Previous episodes of abuse
- Low income or socioeconomic status

**Social factors**
- Substance misuse by abuser
- Mental health problems in abuser

**Care provider factors**
- Shared living situation
- Abuser’s dependency on the older person (often financial)
- Difficult family relationships
- Social isolation

1 in 10 older people experience abuse each month. They also found that two-thirds of older people with dementia have been abused. Obtaining clear data is very difficult, and there is concern that these figures are under-estimates. Some risk factors for abuse are shown in Box 15.25.

Older people are often afraid to talk about cases of abuse to family, friends or the authorities, with fewer than 1 in 20 cases being reported. Even where abuse is recognized, many victims are unwilling to discuss or pursue complaints, especially if family are involved.

Cognitive impairment is a major risk factor for abuse, where recall of specific issues around the abuse is patchy and unreliable, making clarification of concerns difficult. The key point is to be aware of the issue and to have a low threshold for escalating possible concerns.

While older men have the same risk of abuse as women, older females are at higher risk of neglect and financial abuse in some cultures where women have unequal social status, particularly when they are widowed. Women may also be at higher risk of more persistent and severe forms of abuse and injury.

**Management**
Safeguarding is the protection of people’s health and wellbeing, enabling them to live safely and free from neglect or abuse in conjunction with their own wishes and beliefs. Preventative strategies include:
- clear support, education and guidance for patients and care-givers
- education at an institutional level, and clear guidelines on the management of specific conditions, e.g. behavioural and psychological symptoms of dementia (BPSD)
- involvement of patients and advocates in the development of policies and guidelines
- external assessments, e.g. Care Quality Commission

Recognizing abuse can be difficult. There should be a low threshold for escalating concerns to the relevant specialists, who can then investigate and act where necessary. Often, this will be led by social services.
Rehabilitation

Rehabilitation is a multidisciplinary process through which an individual's functional level is optimized, including physical, psychological and social aspects of function. It can take place anywhere, from the patient's home to acute inpatient settings; even on the intensive care unit, there are interventions to help longer-term function. Rehabilitation is dependent on working closely with the patient and the wider MDT, including (where relevant) community and hospital-based services.

While the emphasis is on returning patients to their pre-morbid level of function, a limitation of functional regain, such as after a major stroke, must be recognized. In such cases, helping the patient adjust to the new functional level is a fundamental aspect of the process.

Most commonly, we think of rehabilitation occurring after an acute illness, such as a stroke or pneumonia. However, it also plays a key part in chronic conditions, such as Parkinson's disease and reduced mobility. Increasingly, its role in preparing people for interventions such as surgery is being recognized; this is known as 'pre-habilitation' and aims to expedite recovery and improve longer-term outcomes.

A number of factors affect the likely outcome from rehabilitation:

- **Premorbid status.** A frailer patient is less likely to improve as much as those who are stronger prior to their acute illness.
- **Reasons for deterioration.** An acute injury or illness, from which full or nearly full recovery might be expected, should be compared with progressive underlying illness, such as cancer or motor neurone disease, in which it is possible to achieve short-term gains but patients will deteriorate over the longer term.
- **Co-morbidities.** Where possible, these should be addressed through CGA. Areas that bring particular benefit include pain management (e.g., in arthritis of the knee), blood pressure (too low can increase falls risk) and Parkinson's disease (timing sessions to periods of the day when control is better).
- **Cognitive impairment.** This may reduce the patient's ability to follow instructions in the intervals between sessions. However, significant improvements may occur and cognition alone should not preclude rehabilitation. The clinician should also be aware that recognizing and treating pain in patients with dementia can be difficult but that poor control will have an impact on progress.
- **Depression.** Be suspicious when patients fail to progress as expected. Trying to discriminate between depression and an adjustment reaction following an acute illness (e.g., loss of function following a stroke) can be difficult, and monitoring over a period of weeks is often necessary.
- **Motivation.** Rehabilitation takes effort on the part of the patient and there is great variability in how much individuals are willing to engage.

A distinction should be made between patients who have a realistic chance of making a meaningful improvement and those who have no realistic chance of seeing a significant change. One of the key principles of rehabilitation is goal-setting, with clear and achievable targets over appropriate timescales. For example, in a patient needing a Zimmer frame and assistance from two people to transfer between bed and chair, rather than the goal being 'To improve transferring', a better target would be 'To develop to transferring with one person and a Zimmer frame within 1 week'.

Complex discharge planning

Discharge planning can be a complex balance of managing risk, expectations and resources. It requires close multidisciplinary working across primary and secondary care to fit best with a patient's wishes. The discharge destination from an acute hospital can be directly to home or to an intermediate care facility for further rehabilitation or convalescence. A number of factors affect a patient's discharge and destination (Box 15.26).

Typically, when patients are preparing for discharge, assessments are carried out in hospital; however, this may involve exploring the patient's mobility in a place where distances may be significantly greater than at home, and kitchen assessments take place in an unfamiliar environment. Occupational therapy home visits evaluate a patient’s ability to function within their home environment, and people often do significantly better there. Some schemes, such as Discharge to Assess (D2A), complete all assessments in the patient’s home, with essential equipment and care being put in place on the same day. This can reduce time spent in hospital and often results in lower care needs than were predicted from hospital-based assessments.

Managing risk is a crucial part of discharge planning. Risk cannot be removed completely from any discharge; the aim is to recognize predictable risks, minimize them, and then make further decisions with the person involved.

Besides patients’ own homes, there are alternative options for older people. The most common ones available in the UK are outlined in Box 15.27.

Carer strain

A widely accepted definition of a carer is someone who provides unpaid, informal support to family or friends who could not manage without this help. In the UK, there are around 5 million unpaid carers. Many may struggle with the demands of their role. They may lose their sense of self and their own wellbeing, or experience an enhanced level of anxiety and stress, particularly if they are subject to:

- increased physical or verbal abuse
- being woken during the night.

Other factors that have a major impact include depression in the patient and incontinence, with faecal incontinence being particularly difficult for carers to manage. Carers may, in addition, have medical issues of their own. Assumptions should not be made regarding a carer’s capacity or willingness either to start taking responsibility or to continue to care for a person. Carers should be actively involved in decisions surrounding a patient’s care.

Ways to help reduce carer strain include:

- recognition and appreciation of what the carer is doing
- financial support, e.g. a carer or attendance allowance
- maximizing performance status, e.g. making transfers easier
- addressing co-morbidities, e.g. treating depression
- periods of respite, e.g. day centres, where the carer can take some time off; a sitting service; rolling respite, where the patient spends 1–2 weeks every 2 months, for example, in a care home; and asking friends and family to help for periods, either regularly or on a more ad hoc basis
- holidays, provided by companies who specialize in holidays for people with health conditions, with carers on site; often, patient and carer will travel together.
As people age and experience associated disability and frailty, their personal world may progressively shrink — in some cases to a single room. This is commonly associated with an increase in social isolation and loneliness. Approximately 50% of the population over 75 years of age in the UK live alone, with around 10% of older people reporting loneliness. There are two main facets to loneliness:

- **emotional** — stemming from the absence of an intimate relationship or a close emotional attachment (e.g. a partner or a best friend)
- **social** — stemming from the absence of a broader group of contacts or an engaging social network (e.g. friends, colleagues and people in the neighbourhood).

Loneliness may be regarded as a new ‘geriatric giant’ and is linked with numerous negative health outcomes. The negative impact of loneliness on health equates to smoking 15 cigarettes a day, and people who suffer a high degree of loneliness are twice as likely to develop Alzheimer’s disease. Conversely, people taking part in health-maintaining and independence-maintaining behaviours are less likely to feel isolated and more likely to feel that their community is a good one to grow old in. Loneliness has complex causes and the most effective schemes to deal with it take a broad view, targeting higher-risk groups including those from lower socioeconomic backgrounds, the widowed, the physically isolated, people who have given up driving and those with sensory impairment.

**Further reading**

characterized by, for example, relapses in chronic conditions, the consequences of a fall, a breakdown in social care or functional difficulties, including a decrease in mobility. These changes in the nature of emergency and acute care reflect the fact that in many ways medicine is achieving its fundamental goals: to help all members of society live their lives and participate fully in society, and to optimize their wellbeing.

There is good evidence and NICE guidance to support mid-life interventions as being beneficial in improving health and reducing frailty in later life. These include:
- smoking cessation
- promotion of physical activity
- reduction of alcohol consumption
- improvement of diet
- maintenance of a healthy weight.

### Health and wellbeing

The Institute for Public Policy Research (2009) has identified five essential elements of wellbeing:
- resilience
- independence
- health
- income and wealth
- having a role and time.

Building resilience within an individual and their support network is increasingly seen as a buffer against the effects of frailty. This may be achieved by optimizing cognition, mood, social networks, mobility, physical reserves and so on.

We should be conscious not to equate the diseases we see with a lack of wellbeing or meaningful life. A study by Strawbridge et al. in 2002 looked at two different definitions of successful ageing in the prediction of wellbeing, comparing a self-rating scale with Rowe and Kahn’s criteria for successful ageing (absence of disease, disability and risk factors). The proportion of individuals rating themselves as ageing successfully was 50.3%, compared with only 18.8% classified as ageing successfully according to Rowe and Kahn’s criteria. Although absence of chronic conditions and maintenance of functioning were positively associated with successful ageing on both definitions, many participants with chronic conditions and functional limitations still rated themselves as ageing successfully.

### Societal and economic advantages

In high-income countries, there is an increasing and active population of older people who are making major contributions to society. An Age UK study found that in 2013, older people contributed an estimated £61 billion to the economy in England (>5% of gross domestic product). This was six times the amount spent by local authorities on social care. The main financial contributions came through continued working, informal caring, providing childcare for grandchildren to enable their children to work, and volunteering. Clearly, the benefits extend far beyond the financial aspects, with older people’s skills, knowledge and experience supporting many aspects of society.

Haematologists treat patients with disorders of the blood. This chapter focuses on general haematology, including the investigation of anaemia and non-malignant white-cell and bleeding disorders, alongside the safe management of blood transfusion. Haematological malignancies (see Ch. 17) and thrombotic disease (Ch. 29) are dealt with elsewhere.

The skills and responsibilities of haematologists extend beyond caring for the patients with specific haematological disorders attending their wards and clinics, and include ensuring that blood results reported by the analysers in the haematology laboratory are accurate, establishing that blood used for transfusions is safe and available when and where it is needed, helping other specialties interpret results of laboratory tests and guiding the use of blood products.

Key learning objectives for general haematology at undergraduate level include:

- understanding anaemia – its causes, investigation and management
- assessing whether disorders of white blood cells and platelets are due to primary haematological disease or secondary to other causes
- understanding the way that blood transfusions are carried out and the mechanisms by which safety is ensured
- understanding the mechanisms of disorders of haemostasis and thrombosis, as well as their investigation and management.

Specific opportunities for learning haematology include attending ward rounds on inpatient haematology units, attending haematology clinics to understand the problems that cause patients to be referred from general practice, seeking out patients on a haematology day unit or medical admissions ward to understand the immediate and long-term management of haematological disorders, and attending laboratory ‘morphology’ meetings, where laboratory science is correlated with individual patient care.
CLINICAL SKILLS FOR HAEMATOLOGY

History

Symptoms of haemotological disease tend to be caused by the particular abnormalities seen in individual cell lines, as described in Table 16.1. As well as taking a full general history and examining thoroughly, the features identified below should be specifically sought.

Examination

The figure opposite illustrates a number of physical signs of haematological disease. Most can be attributed to the effects of over- or under-production of different cell lineages, or are features (such as splenomegaly) of underlying haematological disease processes.

Investigations

Investigation of haematological disease generally begins with examination of the peripheral blood (Box 16.1). Bone marrow aspiration, with or without biopsy, is a crucial investigation in the diagnosis and monitoring of many haematological disorders. These procedures allow determination of cellularity (increased or decreased?) as well as morphology (do the blood cell precursor cells look as they should?). Fig. 16.1 (pp. 322–323) illustrates the procedure and the cell lineages present in bone marrow; see also page 328 and Box 16.2.

Table 16.1 Key questions from the history and clinical signs are highlighted to guide the investigation of abnormal blood counts and common haematological presentations

Fig. 16.1 Bone marrow aspiration and biopsy. (A) This is generally carried out as an outpatient procedure under local anaesthetic, using aseptic technique. Consent is obtained, and then the skin overlying the superior posterior iliac crest is cleaned and local anaesthetic injected subcutaneously and around the periosteum, which is extremely well innervated. Once the area is numb, an aspirate needle is used to obtain a liquid sample. (B) The sample is spread on a slide, stained and examined under the microscope for morphology. (C) A sample is also sent for cytogenetic analysis and a karyotype is generated, allowing identification of gross chromosomal rearrangements such as gain or loss of chromosomes or translocations. (D) A trephine needle is needed to obtain a bone biopsy. (E) The biopsy is a hard core of bone, which must be decalcified in chelating solution before being embedded in paraffin. Sections are then cut and stained, permitting the architecture of the marrow cells to be examined, and immunohistochemistry to be carried out to detect abnormal cell populations.
Fig. 16.1—cont’d (F) Haemopoiesis arises from multipotent stem cells, which give rise to all different blood types according to the presence of internal and external regulatory molecules, hormones and cytokines. As such, cell numbers are closely coordinated to respond rapidly to changes in requirements. EPO, erythropoietin; Fli3, Fms-like tyrosine kinase 3; G-CSF, granulocyte-colony-stimulating factor; GM-CSF, granulocyte-macrophage-colony-stimulating factor; IL, interleukin; MPP, multipotent progenitor; NK, natural killer; SCF, stem cell factor; TPO, thrombopoietin.
The formation of blood cells (haemopoiesis)

Blood consists of:
- red cells
- white cells
- platelets
- plasma, in which the above elements are suspended.

Plasma is the liquid component of unclotted blood, which contains soluble fibrinogen. Serum is what remains after formation of the fibrin clot.

The haemopoietic system includes the bone marrow, liver, spleen, lymph nodes and thymus. There is a huge turnover of cells, with red cells surviving for approximately 120 days, platelets approximately 7 days but granulocytes only 7 hours. The production of as many as $10^{13}$ new myeloid cells (all blood cells except for lymphocytes) per day in the normal healthy state requires tight regulation according to the needs of the body.

Blood islands are formed in the yolk sac in the third week of gestation and produce primitive blood cells, which migrate to the liver and spleen. These organs are the chief sites of haemopoiesis from 6 weeks’ to 7 months’ gestation, when the bone marrow becomes the main source of blood cells. In childhood and adult life, the bone marrow is the only source of blood cells in a normal person.

At birth, haemopoiesis takes place in the marrow of nearly every bone. As the child grows, the active red marrow is gradually replaced by fat (yellow marrow) so that haemopoiesis in the adult becomes confined to the central skeleton and the proximal ends of the long bones. Only if the demand for blood cells increases and persists do the areas of red marrow extend. Pathological processes persist do the areas of red marrow extend. Pathological processes interfering with normal haemopoiesis may result in resumption of haemopoietic activity in the liver and spleen, which is referred to as extramedullary haemopoiesis.

All blood cells are derived from pluripotent stem cells. These stem cells have two key properties: the first is self-renewal – that is, the production of more stem cells – and the second is proliferation and differentiation into progenitor cells, committed to one specific cell line. Pluripotent stem cells differentiate into mature blood cells through intermediate progenitor cells, which have lost the ability to self-renew but have high proliferative capacity. These progenitor cells can be broadly classified according to the blood cells that they are programmed to make (see Fig. 16.1). For example, the common lymphoid progenitor (CLP) gives rise to T and B lymphoid cells; the former are produced in the thymus, whereas B cell production primarily occurs in the bone marrow. The common myeloid progenitor (CMP) gives rise to all non-lymphoid cells in the bone marrow via a series of intermediate progenitor cells. These cells cannot be identified in bone marrow biopsies but are recognized by their ability to form colonies (reflecting their high proliferative capacity) when haemopoietic cells are immobilized in a soft gel matrix, the so-called colony-forming unit (CFU), which are named according to the type of cell they produce.

These haemopoietic stem and progenitor cells interact closely with a number of components contained within the specialized microenvironment of the bone marrow, including non-haemopoietic stromal cells, blood vessels and extracellular matrix, together creating a nurturing microenvironment for blood cell development. Central to this microenvironment are haemopoietic growth factors produced by stromal cells in the bone marrow and elsewhere, which are key regulators of blood cell production.

Haemopoietic growth factors

Haemopoietic growth factors are glycoproteins, which regulate the differentiation and proliferation of haemopoietic progenitor cells and the function of mature blood cells. Some growth factors are present in the circulation, whereas other growth factors are produced within the bone marrow microenvironment by stromal cells such as fibroblasts, osteoblasts or endothelial cells, or at sites of inflammation by activated T cells, monocytes and macrophages. Growth factors act on their respective cell surface receptors, expressed on haemopoietic cells at various stages of development, to maintain the haemopoietic progenitor cells and to stimulate increased production of one or more cell types in response to stresses such as blood loss and infection (see Fig. 16.1).

These haemopoietic growth factors, including erythropoietin (EPO), interleukin (IL)-3, IL-6, IL-7, IL-11, IL-12, β-catenin, stem cell factor (SCF, Steel factor or C-kit ligand) and Fls-like tyrosine kinase 3 (Flt3), act via their specific receptor on cell surfaces to stimulate downstream signalling within the cell, such as the cytoplasmic Janus kinase (JAK) pathway. This, in turn, activates signalling cascades within the cell, ultimately altering gene expression in the cell nucleus and thus influencing behaviour of the cell; for example, to promote proliferation. Colony-stimulating factors (CSFs; the prefix indicates the cell type – see Fig. 16.1), as well as interleukins and EPO, regulate the lineage-committed progenitor cells.

Thrombopoietin (TPO) is produced in the kidneys, liver and certain bone marrow stromal cells, and acts to control platelet production, along with IL-6 and IL-11.

In addition to these factors, which stimulate haemopoiesis, there are other factors that inhibit the process; these include tumour necrosis factor (TNF) and transforming growth factor beta (TGF-β).

Uses in treatment

Many growth factors have been produced by recombinant DNA techniques and are being used clinically. Examples include:
- granulocyte-colony-stimulating factor (G-CSF), used to accelerate haemopoietic recovery after chemotherapy and haemopoietic cell transplantation
- erythropoietin, used to treat anaemia in patients with chronic kidney disease and in patients with certain blood cancers
- thrombopoietin receptor agonists, used to treat immune thrombocytopenic purpura.

Peripheral blood

Automated cell counters are used to measure the haemoglobin (Hb) concentration and the number and size of red cells, white cells and platelets (see Box 16.1). Other indices can be derived from these values. A blood film examined by a haematologist or technician experienced in blood cell morphology is still an essential adjunct to the above, as definitive abnormalities of cells can be seen. This is particularly important in some haematological emergencies such as acute promyelocytic leukaemia (see p. 391) or thrombotic thrombocytopenic purpura (see p. 374), which require specific therapy within hours of diagnosis to prevent high rates of mortality.
The mean corpuscular volume (MCV) of red cells is a useful index and is used to classify anaemia (see Fig. 16.7).

The red cell distribution width (RDW) is a measure of the variability in size of red blood cells. An elevated RDW suggests increased variation in red cell size – that is, anisocytosis – and this is seen in iron deficiency.

The white cell count (WCC) (or white blood count, WBC) gives the total number of circulating leucocytes in addition to differential counts, specifically enumerating neutrophils, monocytes, lymphocytes, eosinophils and basophils.

Reticulocytes are young red cells and usually comprise less than 2.5% of red cells. The reticulocyte count gives a guide to erythroid activity in the bone marrow. An increased count is seen with increased marrow activity: for example, following haemorrhage or haemolysis, and during the response to treatment with a specific haematinic. A low count in the presence of anaemia indicates an inappropriate response by the bone marrow and may be seen in bone marrow failure (from whatever cause) or a deficiency of a haematinic.

The erythrocyte sedimentation rate (ESR) is the rate of fall of red cells in a column of blood and is a measure of the acute-phase response. The pathological process may be immunological, infective, ischaemic, malignant or traumatic. A raised ESR reflects an increase in the plasma concentration of large proteins, such as fibrinogen and immunoglobulins. These proteins cause rouleaux formation, with red cells clumping together and therefore falling more rapidly (Fig. 16.2). The ESR increases with age, and is higher in females than in males.

Plasma viscosity is a measurement that is used instead of the ESR in some laboratories. It is also dependent on the concentration of large molecules such as fibrinogen and immunoglobulins. It is not affected by the level of haemoglobin.

C-reactive protein (CRP) is a protein produced in the acute-phase response. It is synthesized exclusively in the liver and rises within 6 hours of an acute event. The CRP level rises with fever (possibly triggered by IL-1, IL-6, TNF-α, and other cytokines), in inflammatory conditions and after trauma. It follows the clinical state of the patient much more rapidly than the ESR and is unaffected by the level of haemoglobin, but it is less helpful than the ESR or plasma viscosity in monitoring chronic inflammatory diseases such as systemic lupus erythematosus (SLE).

**THE RED CELL**

**Erythropoiesis**

Red cell precursors pass through several stages in the bone marrow. The earliest morphologically recognizable cells are pro-erythroblasts. Smaller erythroblasts result from cell divisions, and precursors at each stage progressively contain less RNA and more haemoglobin in the cytoplasm. The nucleus becomes more condensed and is eventually extruded from the late normoblast in the bone marrow when the cell becomes a reticulocyte.

- Reticulocytes contain residual ribosomal RNA and are still able to synthesize haemoglobin. They remain in the marrow for about 1–2 days and are released into the circulation, where they lose their RNA and become mature red cells (erythrocytes) after another 1–2 days. Mature red cells are non-nucleated biconcave discs.
- Nucleated red cells (late erythroblasts) are not normally present in peripheral blood, but are present in extramedullary haemopoiesis and some marrow disorders (see p. 366).
- About 10% of erythroblasts die in the bone marrow, even during normal erythropoiesis. Survival of erythroblasts is dependent on erythropoietin cell signalling. The natural 10% excess production of erythroblasts (ineffective erythropoiesis) ensures a rapid drop in haemoglobin – e.g. with acute haemorrhage or haemolysis, resulting in a rise in EPO production – and causes a rapid increase in terminally differentiated red blood cells. Ineffective erythropoiesis is substantially increased in some anaemias, such as thalassaemia major and megaloblastic anaemia.
- Erythropoietin is a hormone that controls erythropoiesis. This heavily glycosylated polypeptide with a molecular weight of 30,400 Da is produced in the peritubular cells in the kidneys (90%) and in the liver (10%). Its production is regulated mainly by tissue oxygen tension, increasing production in the face of hypoxia: e.g. with anaemia or cardiac or pulmonary disease. The erythropoietin gene is one of a number of genes that is regulated by the hypoxic sensor pathway. The 3′-flanking region of these genes has a hypoxic response element, which is necessary for the induction of transcription of the gene in hypoxic cells. Hypoxia-inducible factor 1 (HIF-1) is a transcription factor, which binds to the hypoxia response element and acts as a master regulator of several genes that are responsive to hypoxia. Erythropoietin stimulates an increase in the proportion of bone marrow precursor cells committed to erythropoiesis by allowing a greater number of erythroid precursors to survive, and CFU-E are stimulated to proliferate and differentiate. Increased ‘inappropriate’ production of erythropoietin occurs in certain tumours, such as renal cell carcinoma, and from other causes, resulting in secondary erythrocytosis.

**Haemoglobin synthesis**

Haemoglobin performs the main functions of red cells, carrying oxygen to the tissues and returning carbon dioxide from the tissues to
the lungs. Each normal adult haemoglobin molecule (HbA) has a molecular weight of 68 kDa and consists of two α and two β globin polypeptide chains (α2β2). HbA comprises about 97% of the haemoglobin in adults. Two other haemoglobin types, HbA2 (α2δ2) and HbF (α2γ2), are found in adults in small amounts (1.5–3.2% and <1%, respectively) (see p. 340).

Haem synthesis occurs in the mitochondria of the developing red cell (Fig. 16.3). The major rate-limiting step is the conversion of glycine and succinic acid to δ-aminolaevulinic acid (ALA) by ALA synthase. Vitamin B6 is a coenzyme for this reaction, which is inhibited by haem and stimulated by erythropoietin. Two molecules of δ-ALA condense to form a pyrrole ring (porphobilinogen). These rings are then grouped in fours to produce protoporphyrins and, with the addition of iron, haem is formed. Haem is then inserted into the globin chains to form a haemoglobin molecule. The structure of haemoglobin is shown in Fig. 16.4.

**Haemoglobin function**

The biconcave shape of red cells provides a large surface area for the uptake and release of oxygen and carbon dioxide. Haemoglobin becomes saturated with oxygen in the pulmonary capillaries, where the partial pressure of oxygen is high and haemoglobin has a high affinity for oxygen. Oxygen is released in the tissues, where the partial pressure of oxygen is low and haemoglobin has a low affinity for oxygen.

In adult haemoglobin, a haem group is bound to each of the four globin chains; the haem group has a porphyrin ring with a ferrous atom, which can reversibly bind one oxygen molecule. The haemoglobin molecule exists in two conformations, relaxed (R) and taut (T), corresponding to oxyhaemoglobin and deoxyhaemoglobin, respectively. The binding of one oxygen molecule to deoxyhaemoglobin increases the oxygen affinity of the remaining binding sites; this property is known as ‘cooperativity’ and is the reason for the sigmoid shape of the oxygen dissociation curve (see Fig. 10.3). The binding of oxygen can also be influenced by secondary effectors, such as hydrogen ions, carbon dioxide and red cell bisphosphoglycerate (2,3-BPG). Red cell metabolism produces 2,3-BPG from glycolysis, and the binding of 2,3-BPG stabilizes the T conformation, thus reducing its affinity for oxygen and increasing release of oxygen in the tissues. The P50 is the partial pressure of oxygen at which the haemoglobin is 50% saturated with oxygen. When the primary limitation to oxygen transport is in the periphery – for example, during heavy exercise or in anaemia – the P50 is increased to enhance oxygen unloading. Furthermore, hydrogen ions and carbon dioxide added to blood cause a reduction in the oxygen-binding affinity of haemoglobin (the Bohr effect), also helping the exchange of carbon dioxide and oxygen in the tissues. When the primary limitation is in the lungs – for example, in lung disease or high-altitude exposure – the P50 is reduced to enhance oxygen loading. A summary of normal red cell production and destruction is given in Fig. 16.5.
Anaemia: an introduction

Anaemia is present when there is a decrease in haemoglobin in the blood below the reference level for the age and sex of the individual (see Box 16.1). Alterations in haemoglobin concentration may occur as a result of changes in the plasma volume, as shown in Fig. 16.6. A reduction in the plasma volume will lead to a spuriously high haemoglobin; this is seen in dehydration and in the clinical condition of apparent polycythaemia (see p. 356). A raised plasma volume produces a spurious anaemia, even when combined with a small increase in red cell volume, as occurs in pregnancy.

Anaemia can be classified in a variety of ways. For example, it can be divided into that due to decreased production or increased destruction, or alternatively into inherited or acquired causes. One common way of categorizing the various types of anaemia is by the MCV, as shown in Fig. 16.7. Anaemias are therefore commonly described as:

- hypochromic microcytic with a low MCV
- normochromic normocytic with a normal MCV
- macrocytic with a high MCV.

While there is some biological rationale for this classification, some types of anaemia can present in more than one category.

Clinical features

Patients with anaemia may be asymptomatic. A slowly falling level of haemoglobin allows for haemodynamic compensation and enhancement of the oxygen-carrying capacity of the blood. A rise in 2,3-BPG causes a shift of the oxygen dissociation curve to the right, so that oxygen is more readily given up to the tissues. Where blood loss is rapid, more severe symptoms will occur, particularly in elderly people.

Symptoms

The symptoms of anaemia are non-specific and include breathlessness, fatigue, headaches, palpitations and faintness. Anaemia exacerbates cardiorespiratory problems, especially in the elderly. For example, angina or intermittent claudication may be precipitated by anaemia. A good way to assess the effects of anaemia is to ask about breathlessness in relation to different levels of exercise (e.g. walking on the flat or climbing one flight of stairs).

Signs

- Pallor.
- Tachycardia.
- Systolic flow murmur.
- Cardiac failure.

Specific signs seen in the different types of anaemia include:

- koilonychia – spoon-shaped nails seen in longstanding iron deficiency anaemia
- jaundice – found in haemolytic anaemia
• bone deformities – found in thalassaemia major
• leg ulcers – occur in association with sickle cell disease.
Anaemia is not a final diagnosis and a cause should always be sought.

**Investigations**

**Peripheral blood**
A low haemoglobin should always be evaluated with the:
• red cell indices
• WCC
• platelet count
• reticulocyte count (as this indicates marrow activity)
• blood film, as abnormal red cell morphology (see Fig. 16.9) may indicate the diagnosis.

Where two populations of red cells are seen, the blood film is said to be dimorphic. This may, for example, be seen in patients with ‘double deficiencies’: for example, in combined iron and folate deficiency in coeliac disease or following treatment of anaemic patients with the appropriate haematinic where old red cells exhibit the changes associated with that deficiency and newly produced red cells have a normal morphology. Dimorphic populations are also seen after blood transfusion.

**Bone marrow**

Techniques for obtaining bone marrow are shown in Box 16.2 and on page 322.

Examination of the bone marrow is performed to further investigate abnormalities found in the peripheral blood:
• **Aspiration** provides a film that can be examined by microscopy for the morphology of the developing haemopoietic cells. The liquid sample obtained at aspiration can also be used for immunophenotyping (assessment of the presence or absence of antigens on the surface of cells), cytogenetic investigations, assessment for molecular markers or microbiological culture).
• **The trephine** provides a core of bone that is processed as a histological specimen and allows an overall view of the bone marrow architecture, cellularity and presence/absence of abnormal infiltrates. The specimen can be used for immunohistochemical investigations.

The following are assessed:
• cellularity of the marrow
• type of erythropoiesis (e.g. normoblastic or megaloblastic)
• morphology of all cell lineages
• cellularity of the various cell lines
• infiltration of the marrow, i.e. presence of non-haemopoietic cells such as cancer cells
• iron stores.

**Microcytic Anaemia**

Microcytic anaemia most commonly results from iron deficiency, the most common cause of anaemia globally, affecting 30% of the
world’s population. This is because of the body’s limited ability to absorb iron and the frequent loss of iron owing to bleeding. Although iron is abundant, most is in the insoluble ferric (Fe$^{3+}$) form, which has poor bioavailability. Ferrous (Fe$^{2+}$) iron is more readily absorbed.

The other causes of a microcytic hypochromic anaemia (see Fig. 16.7) include those due to a defect in globin production (thalassaemia, see p. 341) or a defect in haen synthesis, termed sideroblastic anaemia. When anaemia of chronic disease is long-standing, the iron restriction results in a fall in MCV and patients become microcytic.

Iron
Dietary intake
The average daily diet in the UK contains 15–20 mg of iron, although normally only 10% of this is absorbed. Absorption may be increased to 20–30% in iron deficiency and pregnancy.

Non-haem iron is mainly derived from cereals, which are commonly fortified with iron; it forms the main part of dietary iron. Haem iron is derived from haemoglobin and myoglobin in red or organ meats. Haem iron is better absorbed than non-haem iron, whose availability is more affected by other dietary constituents.

Absorption
Factors influencing iron and haem iron absorption are shown in Fig. 16.8 and Box 16.3.

Dietary haem iron is more rapidly absorbed than non-haem iron derived from vegetables and grain. Most haem is absorbed in the proximal intestine, with absorptive capacity decreasing distally. The intestinal haem transporter HCP1 (haem carrier protein 1) has been identified and found to be highly expressed in the duodenum. It is upregulated by hypoxia and iron deficiency. Some haem iron may be absorbed intact into the circulation via the cell by two exporter
Box 16.3 Factors influencing iron absorption

- Haem iron is absorbed better than non-haem iron
- Ferrous iron is absorbed better than ferric iron
- Gastric acidity helps to keep iron in the ferrous state and soluble in the upper gut
- Formation of insoluble complexes with phytate or phosphate decreases iron absorption
- Iron absorption is increased with low iron stores and increased erythropoietic activity, e.g. bleeding, haemolysis, high altitude
- Absorption is decreased in iron overload, except in hereditary haemochromatosis, where it is increased

proteins: BCRP (breast cancer resistant protein) and FLVCR (feline leukaemia virus subgroup C) (see Fig. 16.8).

Non-haem iron absorption occurs primarily in the duodenum. Non-haem iron is dissolved in the low pH of the stomach and reduced from the ferric to the ferrous form by a brush border ferrireductase. Cells in duodenal crypts are able to sense the body’s iron requirements and retain this information as they mature into cells capable of absorbing iron at the tips of the villi. A protein, divalent metal transporter 1 (DMT1) or natural resistance-associated macrophage protein (NRAMP2), transports iron (and other metals) across the apical (luminal) surface of the mucosal cells in the small intestine.

Once inside the mucosal cell, iron may be transferred across the cell to reach the plasma, or be stored as ferritin; the body’s iron status at the time the absorptive cell developed from the crypt cell is probably the crucial deciding factor. Iron stored as ferritin will be lost into the gut lumen when the mucosal cells are shed; this regulates iron balance. The mechanism of transport of iron across the basolateral surface of mucosal cells involves a transporter protein, ferroportin 1 (FPN 1), through its iron-responsive element (IRE). This transporter protein requires an accessory, multicopper protein, hephaestin (see Fig. 16.8).

The body iron content is closely regulated by the control of iron absorption but there is no physiological mechanism for eliminating excess iron from the body. The key molecule regulating iron absorption is hepcidin, a 25-amino acid peptide synthesized in the liver. Hepcidin acts by regulating the activity of the iron-exporting protein ferroportin by binding to ferroportin, causing its internalization and degradation, and thereby decreasing iron efflux from iron-exporting tissues into plasma. Therefore, high levels of hepcidin (occurring in inflammation states) via inflammatory cytokines, e.g. IL-6, will destroy ferroportin and limit iron absorption, and low levels of hepcidin (e.g. in anaemia, low iron stores, hypoxia) will encourage iron absorption. For example, in patients with haemochromatosis (see Fig. 34.27), mutations in the genes HFE, HJV and TFR2 interrupt hepcidin synthesis. Therefore, in the intestinal cells, a deficiency of hepcidin leads to less ferroportin being bound and thus more iron will be released into the plasma.

A longstanding mystery is why anaemias characterized by ineffective erythropoiesis, such as thalassaemia, are associated with excessive and inappropriate iron absorption. This has now been shown to be due to the downregulation of hepcidin and upregulation of ferroportin, mediated by a newly identified hormone produced by developing erythroblast-erythroferrone (Erfe).

Transport in the blood

The normal serum iron level is about 13–32 μmol/L; there is a diurnal rhythm, with higher levels in the morning. The serum iron value is of little use clinically for assessing patients’ iron status. Iron is transported in the plasma bound to transferrin, a β-globulin that is synthesized in the liver. Each transferrin molecule binds two atoms of ferric iron and is normally one-third saturated. Most of the iron bound to transferrin comes from macrophages in the reticuloendothelial system and not from iron absorbed by the intestine. These recycle the iron obtained from senescent red blood cells when haemoglobin is broken down. Transferrin-bound iron becomes attached by specific receptors to erythroblasts and reticulocytes in the marrow and the iron is removed (see Fig. 16.3).

In an average adult male, 20 mg of iron, chiefly obtained from red cell breakdown in the macrophages of the reticuloendothelial system, is incorporated into haemoglobin every day.

Iron stores

About two-thirds of the total body iron is in the circulation as haemoglobin (2.5–3 g in a normal adult man). The rest is stored in reticuloendothelial cells, hepatocytes and skeletal muscle cells (500–1500 mg). About two-thirds of this is stored as ferritin and one-third as haemosiderin in normal individuals. Small amounts of iron are also found in plasma (about 4 mg bound to transferrin), with some in myoglobin and enzymes.

Ferritin is a water-soluble complex of iron and protein. It is more easily mobilized than haemosiderin for haemoglobin formation. It is present in small amounts in plasma, proportional to the degree of iron loading, but also rises with infection and inflammation as it is an acute-phase protein.

Haemosiderin is an insoluble iron–protein complex found in macrophages in the bone marrow, liver and spleen. Unlike ferritin, it is visible by light microscopy in tissue sections and bone marrow films after staining by Perls’ reaction.

Requirements

Each day, 0.5–1.0 mg of iron is lost in the faeces, urine and sweat. Menstruating women lose 30–40 mL of blood per month, an average of about 0.5–0.7 mg of iron per day. Blood loss through menstruation in excess of 100 mL will usually result in iron deficiency, as increased iron absorption from the gut cannot compensate for such losses of iron. The demand for iron also increases during growth (about 0.6 mg/day) and pregnancy (1–2 mg/day). In the normal adult the iron content of the body remains relatively fixed. Increases in the body iron content (haemochromatosis) are classified into:

- Hereditary haemochromatosis (see p. 1300), where a mutation in the HFE gene or other iron-controlling proteins causes increased iron absorption.
- Secondary haemochromatosis (transfusion siderosis; see p. 343), due to iron overload in conditions treated by regular blood transfusion.
- Non-transfusional iron overload, where ineffective erythropoiesis drives uncontrolled iron absorption from the gut via erythrophore. This occurs in thalassaemia and other inherited anaemias (e.g. sideroblastic anaemia).

Iron deficiency

Iron deficiency anaemia develops when there is inadequate iron for haemoglobin synthesis. The causes are:

- blood loss
- increased demands, e.g. growth and pregnancy
- decreased absorption (e.g. post-gastrectomy)
- poor intake.
Most iron deficiency is due to blood loss, usually from the uterus or gastrointestinal tract. Premenopausal women are in a state of precarious iron balance owing to menstruation. A common cause of iron deficiency worldwide is blood loss from the gastrointestinal tract resulting from parasites such as hookworm infestation. The poor quality of the diet, predominantly containing vegetables, also contributes to the high prevalence of iron deficiency in low income countries. Even in developed countries, iron deficiency is not uncommon in infancy, when iron intake is insufficient for the demands of growth. It is more prevalent in infants born prematurely or where the introduction of mixed feeding is delayed.

**Clinical features**
The symptoms of anaemia are described on page 327. The following well-known clinical features of iron deficiency are generally seen only in cases of very longstanding iron deficiency:
- brittle nails
- spoon-shaped nails (koilonychia)
- atrophy of the papillae of the tongue
- angular stomatitis
- brittle hair
- a syndrome of dysphagia and glossitis (Plummer–Vinson or Paterson–Brown–Kelly syndrome, see p. 1169).

The diagnosis of iron deficiency anaemia relies on a clinical history, which should include questions about dietary intake, self-medication with non-steroidal anti-inflammatory drugs (NSAIDs; may give rise to gastrointestinal bleeding), and the presence of blood in the faeces (which may be a sign of haemorrhoids or carcinoma of the lower bowel). In women, careful enquiry should be made about the duration of periods, the occurrence of clots, and the number of sanitary towels or tampons used (3–5 per day is normal, see Box 39.1).

**Investigations**

- **Blood count and film.** A characteristic blood film is shown in Fig. 16.9. The red cells are microcytic (MCV <80 fL) and hypochromic (mean corpuscular haemoglobin (MCH) <27 pg).

There is poikilocytosis (variation in shape) and anisocytosis (variation in size).

- **Serum iron and iron-binding capacity.** Serum iron is not helpful in the assessment of clinical iron status. The transferrin saturation is a more accurate measure and iron deficiency is regularly present when this falls below 19% (Box 16.4).

- **Serum ferritin.** The level of serum ferritin reflects the amount of stored iron. The normal values for serum ferritin are 30–300 μg/L (11.6–144 nmol/L) in males and 15–200 μg/L (5.8–96 nmol/L) in females. In simple iron deficiency, a low serum ferritin confirms the diagnosis. However, ferritin is an acute-phase reactant, and levels increase in the presence of inflammatory or malignant diseases and also in the presence of liver damage. This can result in a normal or mildly raised ferritin level, even in the presence of iron deficiency. Very high levels of ferritin may be observed in hepatitis and in a rare disease, haemophagocytic lymphohistiocytosis (see p. 525).

- **Serum soluble transferrin receptors.** The number of transferrin receptors released into the serum from bone marrow erythroblasts increases in iron deficiency. The results of this immunoassay compare well with results from bone marrow aspiration in terms of estimating iron stores. This assay can help to distinguish between iron deficiency and anaemia of chronic disease (see Box 16.4), and may avoid the need for bone marrow examination; however, it is not readily available in routine clinical practice. It may sometimes be helpful in the investigation of complicated causes of anaemia.

- **Other investigations.** These will be indicated by the clinical history and examination. Investigations of the gastrointestinal tract are often required to determine the cause of the iron deficiency (see p. 1185).

**Differential diagnosis**
The presence of anaemia with microcytosis and hypochromia does not necessarily indicate iron deficiency. The most common of the other causes are thalassaemia, sideroblastic anaemia and anaemia of chronic disease, and in these disorders the iron stores are normal...
or increased. The differential diagnosis of microcytic anaemia is shown in Box 16.4.

Management
The correct management of iron deficiency is to find and treat the underlying cause, and to give iron to correct the anaemia and replace iron stores. Patients with iron deficiency who are taking iron will increase their haemoglobin level by approximately 10 g/L per week, unless, of course, other factors, such as bleeding, are present.

Oral iron is all that is required in most cases. The best preparation is ferrous sulphate. A 200 mg tablet provides 60 mg of elemental iron. Side-effects, such as nausea, diarrhoea or constipation, are extremely common and compliance is notoriously poor, particularly when the standard dose of 200 mg three times daily is prescribed. Emerging evidence supports the finding that after a dose of oral iron is taken, serum hepcidin levels rise quickly, suppressing the absorption of subsequent doses. Clinical trials will reveal whether optimal iron dosing would be daily, alternate day or even every 3 days. Optimizing absorption includes taking the tablets fasting with a glass of orange juice (vitamin C helps convert ferric to ferrous iron, aiding absorption). Tannins in tea inhibit iron absorption and should be avoided.

In developing countries, distribution of iron tablets and fortification of food are the main approaches for the alleviation of iron deficiency. However, iron supplementation programmes have been ineffective, mainly because of poor compliance. There are also concerns regarding the increased risk of infection in a population where malaria and other parasites are endemic.

Oral iron should be given for long enough to correct the haemoglobin level and to replenish the iron stores; this can take 6 months. The most common causes of failure to respond to oral iron are:

• lack of compliance
• ongoing blood loss
• incorrect diagnosis, e.g. thalassaemia trait.

These possibilities should be considered before parenteral (injected) iron is used. However, parenteral iron is indicated, for example, for those who are intolerant to oral preparations, those with severe malabsorption and those with chronic disease (e.g. inflammatory bowel disease). Iron stores are replaced much faster with parenteral iron than with oral iron but the haematological response is no quicker. Parenteral iron can be given by slow intravenous infusion of low-molecular-weight iron dextran (a test dose is required because of the risk of anaphylactoid reactions), iron sucrose, ferric carboxymaltose or iron isomaltoside 1000; oral iron should be discontinued.

Anaemia of chronic disease
One of the most common types of anaemia, particularly in hospital patients, is the anaemia of chronic disease, occurring in individuals with chronic inflammatory disease, such as Crohn’s disease, rheumatoid arthritis, SLE, polymyalgia rheumatica and malignant disease, or with chronic infections such as tuberculosis. There is a decreased release of iron from the bone marrow to developing erythroblasts, an inadequate erythropoietin response to the anaemia, and decreased red cell survival.

High levels of hepcidin expression in these contexts play a key role (see earlier). As numerous pathogens are dependent on iron for multiplication, reacting to infection and inflammation by increasing hepcidin levels and sequestering iron from the circulation became evolutionarily advantageous, and IL-6 produced during infection is a potent driver of hepcidin expression. However, chronic inflammatory conditions result in raised hepcidin levels and poor delivery of iron to the marrow, and hence anaemia. Measurement of hepcidin levels is emerging as a useful test to help distinguish anaemia of chronic disease from iron deficiency anaemia.

The serum iron and the total iron binding capacity (TIBC) are low, and the serum ferritin is normal or raised because of the inflammatory process. The serum soluble transferrin receptor level is normal (see Box 16.4). Stainable iron is present in the bone marrow but iron is not seen in the developing erythroblasts. Patients do not respond to oral iron therapy, and treatment is, in general, that of the underlying disorder, though intravenous iron may help. Recombinant erythropoietin therapy is used in the anaemia of renal disease (see p. 1394), and occasionally in inflammatory disease (rheumatoid arthritis, inflammatory bowel disease).

Sideroblastic anaemia
Sideroblastic anaemias are inherited or acquired disorders characterized by a refractory anaemia (that does not respond to simple haematinic supplementation), a variable number of hypochromic cells in the peripheral blood, and excess iron and ring sideroblasts in the bone marrow. The presence of ring sideroblasts is the diagnostic feature of sideroblastic anaemia. There is accumulation of iron in the mitochondria of erythroblasts owing to disordered haem synthesis, forming a ring of iron granules around the nucleus that can be seen with Perls’ reaction. The blood film is often dimorphic; ineffective haem synthesis is responsible for the microcytic hypochromic cells. Sideroblastic anaemias can be inherited as an X-linked disease transmitted by females or as an autosomal recessive form. A structural defect in δ-ALA synthase, the pyridoxine-dependent enzyme responsible for the first step in haem synthesis (see Fig. 16.3), is responsible for the X-linked form. Acquired causes include myeloproliferative disorders, myeloid leukaemia, drugs (e.g. isoniazid), alcohol misuse and lead toxicity (see p. 274). It can also occur in other disorders such as rheumatoid arthritis, carcinomas and megaloblastic and haemolytic anaemias. Primary acquired sideroblastic anaemia is one of the myelodysplastic syndromes (see p. 397) and is responsible for the vast majority of cases of sideroblastic anaemia in adults.

Management
Some patients respond when drugs or alcohol are withdrawn, if these are the causative agents. In occasional cases, there is a response to pyridoxine. Treatment with folic acid may be required to treat accompanying folate deficiency.

disorders (e.g. aplastic anaemia and some haemolytic anaemias) (see Fig. 16.7). In addition, this type of anaemia is seen acutely following blood loss.

MACROCYTIC ANAEMIAS

These can be divided into megaloblastic and non-megaloblastic types, depending on bone marrow findings.

Megaloblastic anaemia

Megaloblastic anaemia is characterized by the presence in the bone marrow of erythroblasts with delayed nuclear maturation because of defective DNA synthesis (megaloblasts). Megaloblasts are large and have large immature nuclei. The nuclear chromatin is more finely dispersed than normal and has an open, stippled appearance (Fig. 16.10). In addition, giant metamyelocytes are frequently seen in megaloblastic anaemia. These cells are about twice the size of normal cells and often have twisted nuclei. Megaloblastic changes occur in:

- vitamin B₁₂ deficiency or abnormal vitamin B₁₂ metabolism
- folic acid deficiency or abnormal folate metabolism
- other defects of DNA synthesis, such as congenital enzyme deficiencies in DNA synthesis (e.g. orotic aciduria), or those resulting from therapy with drugs interfering with DNA synthesis (e.g. hydroxycarbamide (hydroxyurea), azathioprine)
- myelodysplasia due to dyserythropoiesis.

Haematological findings

- The MCV is characteristically over 96 fl unless there is a coexisting cause of microcytosis, in which case there may be a dimorphic picture with a normal/low average MCV.
- The peripheral blood film shows oval macrocytes with hypersegmented polymorphs with six or more lobes in the nucleus (Fig. 16.11).
- If severe, there may be leucopenia and thrombocytopenia.
- The lactate dehydrogenase (LDH) is typically elevated (sometimes extremely so), reflecting ineffective erythropoiesis.

Biochemical basis of megaloblastic anaemia

The key biochemical problem common to both vitamin B₁₂ and folate deficiency is a block in DNA synthesis owing to an inability to methylate deoxyuridine monophosphate to deoxythymidine monophosphate, which is then used to build DNA (Fig. 16.12). The methyl group is supplied by the folate coenzyme, methylene tetrahydrofolate.

Deficiency of folate reduces the supply of this coenzyme; deficiency of vitamin B₁₂ also reduces its supply by slowing the demethylation of methyltetrahydrofolate (methyl THF) and preventing cells from receiving tetrahydrofolate for synthesis of methylene tetrahydrofolate polyglutamate.

Fig. 16.10 Megaloblasts (arrowed) in the bone marrow.

Fig. 16.11 Macrocytes and a hypersegmented neutrophil (arrowed) on a peripheral blood film.

Fig. 16.12 Biochemical basis of megaloblastic anaemia. The metabolic relationship between vitamin B₁₂ and folate, and their role in DNA synthesis. THFA, tetrahydrofolate.
Other congenital and acquired forms of megaloblastic anaemia are due to interference with purine or pyrimidine synthesis, causing an inhibition in DNA synthesis.

**Vitamin B\textsubscript{12} (cobalamin)**

Vitamin B\textsubscript{12} is synthesized by certain microorganisms, and humans are ultimately dependent on animal sources. It is found in meat, fish, eggs and milk, but not in plants. Vitamin B\textsubscript{12} is not usually destroyed by cooking. The average daily diet contains 5–30 \( \mu g \) of vitamin B\textsubscript{12}, of which 2–3 \( \mu g \) is absorbed. The average adult stores some 2–3 mg, mainly in the liver, and it may take 2 years or more after absorptive failure before vitamin B\textsubscript{12} deficiency develops, as the daily losses are small (1–2 \( \mu g \)).

Vitamin B\textsubscript{12} consists of a small group of compounds, the cobalamins, which are composed of a planar group with a central cobalt atom (corrin ring) and a nucleotide set at right angles. Vitamin B\textsubscript{12} was first crystallized as cyanocobalamin, but the main natural cobalamins have deoxyadenosyl- and methyl- and hydroxocobalamin groups attached to the cobalt atom. Deoxyadenosylcobalamin is a coenzyme for the conversion of methylmalonyl CoA to succinyl CoA. Measurement of methylmalonic acid was used as a test for vitamin B\textsubscript{12} deficiency but it is no longer carried out routinely.

**Absorption and transport**

Vitamin B\textsubscript{12} is liberated from protein complexes in food by gastric enzymes and then binds to a vitamin B\textsubscript{12}-binding protein (R’ binder), which is related to plasma transcobalamin I (TCI) and is derived from saliva. Vitamin B\textsubscript{12} is released from the R binder by pancreatic enzymes and then becomes bound to intrinsic factor.

Intrinsic factor is a glycoprotein with a molecular weight of 45 kDa. It is secreted by gastric parietal cells along with H\textsuperscript{+} ions. It combines with vitamin B\textsubscript{12} and carries it to a specific receptor on the surface of the mucosa of the ileum, cubilin. Vitamin B\textsubscript{12} enters the ileal cells and intrinsic factor remains in the lumen and is excreted. Vitamin B\textsubscript{12} is transported from the enterocytes to the bone marrow and other tissues by the glycoprotein transcobalamin II (TCII). Vitamin B\textsubscript{12} bound to TCII is known as holotranscobalamin or ‘active B\textsubscript{12}’, as this is the form of vitamin B\textsubscript{12} that is taken up by cells. Although TCII is the essential carrier protein for vitamin B\textsubscript{12}, the amount of B\textsubscript{12} on TCII is low. Vitamin B\textsubscript{12} in plasma is mainly bound to TCII (70–90%). About 1% of an oral dose of B\textsubscript{12} is absorbed ‘passively’ without the need for intrinsic factor.

**Vitamin B\textsubscript{12} deficiency**

There are a number of causes of B\textsubscript{12} deficiency and abnormal B\textsubscript{12} metabolism (Box 16.5). The most common cause of vitamin B\textsubscript{12} deficiency in adults is pernicious anaemia. Malabsorption of vitamin B\textsubscript{12} because of pancreatitis, coeliac disease or treatment with metformin is mild and does not usually result in significant vitamin B\textsubscript{12} deficiency.

**Pernicious anaemia**

Pernicious anaemia (PA) is an autoimmune disorder in which there is atrophic gastritis with loss of parietal cells in the gastric mucosa and consequent failure of intrinsic factor production and vitamin B\textsubscript{12} malabsorption.

**Pathogenesis**

This disease is common in the elderly, about 1 in 8000 of the population aged over 60 years being affected in the UK. It can be seen in all races and is more common in females than males.

There is an association with other autoimmune diseases, particularly thyroid disease, Addison’s disease and vitiligo. Approximately 50% of all patients with PA have thyroid antibodies. There is a higher incidence of gastric carcinoma with PA (1–3%) than in the general population.

Parietal cell antibodies are present in the serum in 90% of patients with PA, and also in 10% of normal individuals. Conversely, intrinsic factor antibodies, although found in only 50% of patients with PA, are specific for this diagnosis.

**Pathology**

Autoimmune gastritis (see p. 1173) affecting the fundus is present, with plasma cell and lymphoid infiltration. The parietal and chief cells are replaced by mucin-secreting cells. There is achlorhydria and absent secretion of intrinsic factor. The histological abnormality can be improved by corticosteroid therapy, which supports an autoimmune basis for the disease.

**Clinical features**

The onset of PA is insidious, with progressively increasing symptoms of anaemia. Patients are sometimes said to have a lemon-yellow colour owing to a combination of pallor and mild jaundice, caused by excess breakdown of haemoglobin. A red, sore tongue (glossitis) and angular stomatitis are sometimes present.

The neurological changes, if left untreated for a long time, can be irreversible. These neurological abnormalities occur only with very low levels of serum B\textsubscript{12} (<60 ng/L or 50 pmol/L) and occasionally are seen in patients who are not clinically anaemic. The classical neurological features are those of a polyneuropathy progressively involving the peripheral nerves and the posterior and eventually the lateral columns of the spinal cord (subacute combined degeneration; see p. 891). Patients present with symmetrical paraesthesiae in the fingers and toes, early loss of vibration sense and proprioception, and progressive weakness and ataxia. Paraplegia may result. Dementia, psychiatric problems, hallucinations, delusions and optic atrophy may occur from vitamin B\textsubscript{12} deficiency.

**Investigations**

- **Haematological findings** show the features of a megaloblastic anaemia (see p. 333).
- **Bone marrow** shows the typical features of megaloblastic erythropoiesis (see Fig. 16.10), although it is frequently not sampled in cases of straightforward macrocytic anaemia and a low serum vitamin B\textsubscript{12}.
- **Serum bilirubin** and LDH may be raised as a result of ineffective erythropoiesis. Normally, a minor fraction of serum bilirubin results from premature breakdown of newly formed red cells in
the bone marrow. In many megaloblastic anaemias, where the destruction of developing red cells is much increased, the serum bilirubin can be increased.

- **Serum vitamin B\textsubscript{12}** is usually well below 160ng/L, which is the lower end of the normal range. Serum vitamin B\textsubscript{12} can be assayed using radio-isotope dilution or immunological assays. Numerous factors can affect B\textsubscript{12} levels, such as pregnancy and the oral contraceptive pill, which lower it.
- **Holotranscobalamin** is the ‘active’ fraction of cobalamin, and its measurement may be a better marker for vitamin B\textsubscript{12} deficiency than serum vitamin B\textsubscript{12}.
- **Serum methylmalonic acid (MMA) and homocysteine (HC)** are raised in B\textsubscript{12} deficiency but testing is recommended only in complex cases, such as those where there is a strong suspicion of vitamin B\textsubscript{12} deficiency but the vitamin B\textsubscript{12} level is normal.

**Absorption tests**

Vitamin B\textsubscript{12} absorption tests are no longer performed in the UK, as radioactive B\textsubscript{12} is not available.

**Gastrointestinal investigations**

In PA, there is achlorhydria. Intubation studies can be performed to confirm this but are rarely carried out in routine practice. Endoscopy or barium meal examination of the stomach is performed only if gastrointestinal symptoms are present.

**Differential diagnosis**

Vitamin B\textsubscript{12} deficiency must be differentiated from other causes of megaloblastic anaemia, principally folate deficiency, but usually this is quite clear from the blood levels of these two vitamins.

PA should be distinguished from other causes of vitamin B\textsubscript{12} deficiency by testing for intrinsic factor antibodies (see Box 16.5). Patients negative for intrinsic factor antibodies with no other cause of vitamin B\textsubscript{12} deficiency may still have PA.

**Management**

See later.

**Folic acid**

Folic acid monoglutamate is not itself present in nature but occurs as polyglutamates. Folates are present in food as polyglutamates in the reduced dihydrofolate or tetrahydrofolate (THF) forms. Polyglutamates are broken down to monoglutamates in the upper gastrointestinal tract, and during the absorptive process these are converted to methyl THF monoglutamate, which is the main form in the serum. The methylation of homocysteine to methionine requires both methylcobalamin and methyl THF as coenzymes. This reaction is the first step in which methyl THF entering cells from the plasma is converted into folate polyglutamates. Intracellular polyglutamates are the active forms of folate and act as coenzymes in the transfer of single carbon units in amino acid metabolism and DNA synthesis (see Fig. 16.12).

**Dietary intake**

Folate is found in green vegetables, such as spinach and broccoli, and offal, such as liver and kidney. Cooking causes a loss of 60–90% of the folate. The minimal daily requirement is about 100μg.

**Folate deficiency**

The causes of folate deficiency are shown in Box 16.6. The main cause is poor intake, which may occur alone or in combination with excessive utilization or malabsorption. The body’s reserves of folate are about 10mg. On a deficient diet, folate deficiency develops over the course of about 4 months, but folate deficiency may develop rapidly in patients who have both a poor intake and excess utilization of folate (e.g. patients in intensive care units).

Folic acid supplements at the time of conception and in the first 12 weeks of pregnancy reduce the incidence of neural tube defects. In the USA and Canada, mandatory fortification of grain products, such as bread, flour and rice, has substantially improved folate status and has been associated with a significant fall in neural tube defects. There is controversy about the role of folate supplementation in the reduction of cardiovascular and cerebrovascular disease by lowering homocysteine levels.

**Clinical features**

Patients with folate deficiency may be asymptomatic or may present with symptoms of anaemia or those of the underlying cause. Glossitis can occur. Unlike with B\textsubscript{12} deficiency, neuropathy does not occur.

**Investigations**

The haematological findings are those of a megaloblastic anaemia (see p. 333).

**Blood measurements**

Serum folate reflects recent folate status and intake. It is usually measured by immunological methods; a level below 3μg/L (7nmol/L) is indicative of folate deficiency. The amount of folate in the red cells is a measure of tissue folate over the lifetime of red cells; a level below 150μg/L (340nmol/L) is consistent with folate deficiency, but measurement of the serum folate is usually sufficient to diagnose folate deficiency.

**Further investigations**

In many cases of folate deficiency the cause is not obvious from the clinical picture or dietary history. Occult gastrointestinal disease should then be suspected and appropriate investigations, such as small bowel biopsy, may be performed.
Management and prevention of megaloblastic anaemia

Treatment depends on the type of deficiency. Blood transfusion is not usually indicated in chronic anaemia; indeed, it can be dangerous to transfuse elderly patients, as heart failure may be precipitated. Folic acid may produce a haematological response in vitamin B₁₂ deficiency but may aggravate the neuropathy. Large doses of folic acid alone should not be used to treat megaloblastic anaemia unless the serum vitamin B₁₂ level is known to be normal. In severely ill patients it may be necessary to treat with both folic acid and vitamin B₁₂ while awaiting serum levels.

Management of vitamin B₁₂ deficiency

Hydroxocobalamin 1000 µg can be given intramuscularly to a total of 5–6 mg over the course of 2 weeks; 1000 µg is then necessary every 3 months for the rest of the patient’s life.

Clinical improvement may occur within 48 hours and a reticulocyte can be seen some 2–3 days after starting therapy, peaking at 5–7 days. Improvement of the polyneuropathy may occur over 6–12 months but longstanding spinal cord damage is irreversible. Hypokalaemia can occur and, if severe, supplements should be given. Iron deficiency often develops in the first few weeks of therapy. Hyperuricaemia also occurs but clinical gout is uncommon. In patients who have had a total gastrectomy or an ileal resection, vitamin B₁₂ should be monitored; if levels are low, prophylactic vitamin B₁₂ should be given. Vegans may require oral B₁₂ supplements.

Oral treatment with vitamin B₁₂ can also be used in patients but good compliance with treatment is required.

Management of folate deficiency

Folate deficiency can be corrected by giving 5 mg of folic acid daily: the same haematological response occurs as is seen after treatment of vitamin B₁₂ deficiency. Treatment should be given for about 4 months to replace body stores. Any underlying cause, such as coeliac disease, should be treated.

Prophylactic folic acid (400 µg daily) is recommended for all women planning a pregnancy and in early pregnancy to reduce neural tube defects.

Women who have had a child with a neural tube defect should take 5 mg folic acid daily before and during a subsequent pregnancy.

Prophylactic folic acid, in a dose of 5 mg daily or weekly, is also given to patients with chronic haematological disorders where there is rapid cell turnover and to those undergoing renal dialysis.

Macrocytosis without megaloblastic changes

A raised MCV with macrocytosis on the peripheral blood film can occur with a normoblastic rather than a megaloblastic bone marrow.

A common physiological cause of macrocytosis is pregnancy. Macrocytosis may also occur in the newborn. Common pathological causes are:

- alcohol excess
- liver disease
- reticulocytosis (e.g. due to haemolysis)
- hypothyroidism
- some haematological disorders (e.g. aplastic anaemia, myelodysplasia, pure red cell aplasia, multiple myeloma)
- drugs (e.g. hydroxycarbamide, azathioprine)
- cold agglutinins due to autoagglutination of red cells (see p. 353) (the MCV decreases to normal with warming of the sample to 37°C).

In all these conditions, normal levels of vitamin B₁₂ and folate will be found. The exact mechanisms in each case are uncertain, but in some there is increased lipid deposition in the red cell membrane.

An increased number of reticulocytes also leads to a raised MCV because they are large cells.

High alcohol consumption is a frequent cause of a raised MCV, and in such patients the MCV can be used as a surrogate marker for monitoring excessive alcohol consumption. A full-blown megaloblastic anaemia can also occur in people who use alcohol to excess; this is due to a toxic effect of alcohol on erythropoiesis and/or to dietary folate deficiency.

ANAEMIA DUE TO MARROW FAILURE (APLASTIC ANAEMIA)

Aplastic anaemia is defined as pancytopenia with hypocellularity (aplasia) of the bone marrow; there are no leukaemic, cancerous or other abnormal cells in the peripheral blood or bone marrow. It is usually an acquired condition but may rarely be inherited.

Aplastic anaemia is due to a reduction in the number of pluripotent stem cells (see Fig. 16.1), together with a fault in those remaining or an immune reaction against them so that they are unable to repopulate the bone marrow. Failure of only one cell line may also occur, resulting in isolated deficiencies such as the absence of red cell precursors in pure red cell aplasia. Evolution to myelodysplasia, paroxysmal nocturnal haemoglobinuria (PNH) or acute myeloid leukaemia occurs in some cases, probably owing to the emergence of an abnormal clone of haemopoietic cells.

Aetiology

The causes of aplasia are shown in Box 16.7. Immune mechanisms are probably responsible for most cases of idiopathic acquired aplastic anaemia and play a part in at least the persistence of many secondary cases. Activated cytotoxic T cells in blood and bone marrow are responsible for the bone marrow failure.

Many drugs may cause marrow aplasia, including cytotoxic drugs such as busulfan and doxorubicin, which are expected to cause transient aplasia as a consequence of their therapeutic use. However, some individuals develop aplasia due to sensitivity to non-cytotoxic

Anaemia due to marrow failure (aplastic anaemia)

Inherited aplastic anaemias are rare. Multiple gene mutations have been identified. Several are tumour suppressor genes and have been seen in one-third of aplastic anaemias. Fanconi anaemia is inherited as an autosomal recessive condition and is associated with skeletal, skin, eye, renal and central nervous system abnormalities. It usually presents between the ages of 5 and 10 years and is associated with an increased risk of malignancies.

Clinical features
The clinical manifestations of marrow failure from any cause are anaemia, bleeding and infection. Bleeding is often the predominant initial presentation of aplastic anaemia with bruising and minimal trauma or blood blisters in the mouth. Physical findings include ecchymoses, bleeding gums and epistaxis. Mouth infections are common. Lymphadenopathy and hepatosplenomegaly are rare in aplastic anaemia.

Investigations
- Pancytopenia.
- The virtual absence of reticulocytes.
- A hypocellular or aplastic bone marrow with increased fat spaces (Fig. 16.13).

Differential diagnosis
Aplastic anaemia must be differentiated from other causes of pancytopenia (Box 16.8). A bone marrow trephine is essential for assessment of the bone marrow cellularity.

Management and prognosis
The treatment of aplastic anaemia depends on the underlying cause and the likelihood of spontaneous recovery of blood counts. Careful attention to supportive care is essential while awaiting bone marrow recovery and, in some cases, specific treatment can be used to accelerate marrow recovery.

The main danger is infection and stringent measures should be undertaken to avoid this (see also p. 116). Any suspicion of infection in a severely neutropenic patient (neutrophil count of $<0.5 \times 10^9/L$) should lead to the immediate institution of broad-spectrum parenteral antibiotics. Supportive care, including transfusions of red cells and platelets, should be given as necessary. The cause of the aplastic anaemia must be eliminated if possible.

The course of aplastic anaemia can be variable, ranging from a rapid spontaneous remission to a persistent, increasingly severe pancytopenia, which may lead to death through haemorrhage or infection. The most reliable determinants for the prognosis are the number of neutrophils, reticulocytes and platelets, and the cellularity of the bone marrow.

A bad prognosis (i.e. severe aplastic anaemia) is associated with the presence of two of the following three features:
- neutrophil count of $<0.5 \times 10^9/L$
- platelet count of $<20 \times 10^9/L$
- reticulocyte count of $<40 \times 10^9/L$

Haemopoietic stem cells (allogeneic bone marrow transplantation) are the treatment of choice for patients with severe aplastic anaemia under the age of 40 who have a human leucocyte antigen (HLA)-identical sibling donor, where it gives a 75–90% chance of long-term survival.

Immunosuppressive therapy is recommended for:
- patients with severe disease over the age of 40
- younger patients with severe disease who do not have an HLA-identical sibling donor
- patients who do not have severe disease but who are transfusion-dependent.

The standard immunosuppressive treatment is antithymocyte globulin (ATG) and ciclosporin, which results in response rates of 60–80% and 5-year survival rates of 75–85%.

Stem cell transplantation using matched unrelated donors is an option for patients under the age of 50 who have no matched sibling donor, and who have failed to respond to immunosuppression with ATG and ciclosporin; the results are improving (5-year survival of 65–73%). The main problems are graft rejection, graft-versus-host disease and viral infections.

Levels of haemopoietic growth factors (see Fig. 16.1) are normal or increased in most patients with aplastic anaemia, and so these factors are ineffective as primary treatment.

Steroids should not be used to treat severe aplastic anaemia, except for severe sickness due to ATG.

Adult pure red cell aplasia is associated with a thymoma in 5–15% of cases and thymectomy occasionally induces a remission. It may also be associated with autoimmune disease or be idiopathic. Steroids, cyclophosphamide, azathioprine and ciclosporin are effective treatments in some cases.

HAEMOLYTIC ANAEMIAS: AN INTRODUCTION

Haemolytic anaemias are caused by increased destruction of red cells. The red cell normally survives about 120 days, but in haemolytic anaemias the red cell survival times are considerably shortened.

Breakdown of normal red cells occurs in the macrophages of the bone marrow, liver and spleen (see Fig. 16.5).

Consequences of haemolysis

Shortening of red cell survival does not always cause anaemia, as there is a compensatory increase in red cell production by the bone marrow. If the red cell loss can be contained within the marrow’s capacity for increased output, then a haemolytic state can exist without anaemia (compensated haemolytic disease). The bone marrow can raise its output by 6–8 times by increasing the proportion of cells committed to erythropoiesis (erythroid hyperplasia) and by expanding the volume of active marrow. In addition, immature red cells (reticulocytes) are released prematurely. These cells are larger than mature cells and stain with a light blue tinge on a peripheral blood film (the description of this appearance on the blood film is polychromasia) due to the presence of residual ribosomal RNA. Reticulocytes may be counted accurately as a percentage of all red cells on a blood film using a supravalent stain for residual RNA (e.g. new methylene blue).

Sites of haemolysis

Extravascular haemolysis

In most haemolytic conditions, red cell destruction is extravascular. The red cells are removed from the circulation by macrophages in the reticuloendothelial system, particularly the spleen.

Intravascular haemolysis

When red cells are rapidly destroyed within the circulation, haemoglobin is liberated. This is initially bound to plasma haptoglobins but these soon become saturated.

Excess free plasma haemoglobin is filtered by the renal glomerulus and enters the urine, although small amounts are reabsorbed by the renal tubules. In the renal tubular cell, haemoglobin is broken down and becomes deposited in the cells as haemosiderin. This can be detected in the spun sediment of urine using Perls’ reaction. Some of the free plasma haemoglobin is oxidized to methaemoglobin, which dissociates into ferrhaem and globin. Plasma haemopexin binds ferrhaem, but if its binding capacity is exceeded, ferrhaem becomes attached to albumin, forming methaemalbumin. On spectrophotometry of the plasma, methaemalbumin forms a characteristic band; this is the basis of Schumm’s test.

The liver plays a major role in removing haemoglobin bound to haptoglobin and haemopexin, and also any remaining free haemoglobin. Free haemoglobin is toxic and scavenges nitric oxide, which is a critical signalling molecule for smooth muscle relaxation and the control of pulmonary pressures.

Evidence for haemolysis

Increased red cell breakdown is accompanied by increased red cell production. This is shown in Fig. 16.14.

Demonstration of shortened red cell lifespan

Red cell survival can be estimated from 51Cr-labelled red cells given intravenously but this test is rarely performed.

Intravascular haemolysis

This is suggested by haemosiderinuria, very low or absent haptoglobins, and the presence of methaemalbumin (positive Schumm’s test).

Various laboratory studies will be necessary to determine the exact type of haemolytic anaemia present. The causes of haemolytic anaemias are shown in Box 16.9.

INHERITED HAEMOLYTIC ANAEMIA

Red cell membrane defects

The normal red cell membrane consists of a lipid bilayer crossed by integral proteins with an underlying lattice of proteins (or cytoskeleton), including spectrin, actin, ankyrin and protein 4.1, attached to the integral proteins (Fig. 16.15).

Hereditary spherocytosis

Hereditary spherocytosis (HS) is the most common inherited haemolytic anaemia in Northern Europeans, affecting 1 in 5000. It can be inherited in an autosomal dominant or recessive manner, but in some patients occurs by spontaneous (de novo) mutation. In the absence of a family history, the most important differential diagnosis is that of autoimmune haemolytic anaemia, which can usually be excluded by a negative direct antiglobulin test. HS is caused by defects in the red cell membrane, resulting in the cells losing part of the cell membrane as they pass through the spleen, possibly because the lipid bilayer is inadequately supported by the membrane skeleton. The best-characterized defect is a deficiency in the structural protein spectrin but quantitative defects in other membrane proteins have been identified (see Fig. 16.15), with ankyrin defects being the most common. The abnormal red cell membrane in HS is associated functionally with an increased permeability to sodium, and this requires an increased rate of active transport of sodium out of the cells, which is dependent on adenosine triphosphate (ATP), produced by glycolysis. The surface-to-volume ratio decreases and the cells become spherocytic. Spherocytes are more rigid and less deformable than normal red cells. They are unable to pass through the splenic microcirculation so they have a shortened lifespan.

Clinical features

The condition may present with jaundice at birth. However, the onset of jaundice can be delayed for many years; some patients may go through life with no symptoms and are detected only during family studies. The patient may eventually develop anaemia, gallstones, splenomegaly or, rarely, ulcers on the leg. As in many haemolytic anaemias, the course of the disease may be interrupted by aplastic, haemolytic and megaloblastic crises. Aplastic anaemia usually occurs after infections, particularly with parvovirus, which infects developing erythroblasts and causes temporary abolition of red cell production. Megaloblastic anaemia is the result of folate depletion, caused by hyperactivity of the bone marrow. Chronic haemolysis leads to the formation of pigment gallstones (see p. 1315).

Investigations

- **Anaemia.** This is usually mild but occasionally can be severe.
- **Blood film.** This shows spherocytes (Fig. 16.16) and polychromasia.
- **Haemolysis.** This is evident (e.g. the serum bilirubin and urinary urobilinogen will be raised).
Inherited haemolytic anaemia

**Figure 16.14** Haemolysis: diagnostic and haematological features. DCT, direct Coombs’ test; DIC, disseminated intravascular coagulation; G6PD, glucose-6-phosphate dehydrogenase; LDH, lactate dehydrogenase; NSAIDs, non-steroidal anti-inflammatory drugs.

**Box 16.9 Causes of haemolytic anaemia**

**Inherited**
- Red cell membrane defect
  - Hereditary spherocytosis
  - Hereditary elliptocytosis
- Haemoglobin abnormalities
  - Thalassaemia
  - Sickle cell disease

**Metabolic defects**
- Glucose-6-phosphate dehydrogenase deficiency
- Pyruvate kinase deficiency
- Pyrimidine kinase deficiency

**Acquired**
- Immune
  - Autoimmune (see Box 16.16): Warm
    - Cold
  - Alloimmune:
    - Haemolytic transfusion reactions
    - Haemolytic disease of the newborn
    - After allogeneic bone marrow or organ transplantation
- Drug-induced
- Acquired membrane defects:
  - Paroxysmal nocturnal haemoglobinuria
- Mechanical:
  - Microangiopathic haemolytic anaemia
  - Valve prosthesis
  - March haemoglobinuria
- Secondary to systemic disease:
  - Renal and liver failure

**Miscellaneous**
- Infections, e.g. malaria, mycoplasma
- *Clostridium perfringens* (welchii), generalized sepsis
- Drugs and chemicals causing damage to the red cell membrane or oxidative haemolysis
- Hyperplenism
- Burns

- **Osmotic fragility.** When red cells are placed in solutions of increasing hypotonicity, they take in water, swell and eventually lyse. Spherocytes tolerate hypotonic solutions less well than do normal biconcave red cells. Osmotic fragility tests are infrequently carried out in routine practice but may be useful to confirm suspicion of spherocytosis on a blood film.

- **Direct antiglobulin (Coombs’) test.** This is negative in hereditary spherocytosis, virtually ruling out autoimmune haemolytic anaemia, in which spherocytes are also commonly present.

**Management**

Most patients require no specific treatment or need occasional transfusions during pregnancy or intercurrent infections. Rarely, patients are transfusion-dependent. For the remainder, splenectomy is indicated to relieve symptoms due to anaemia or splenomegaly, reverse growth failure and prevent recurrent gallstones. It is best to postpone splenectomy until after childhood, as sudden overwhelming fatal infections, usually due to encapsulated organisms such as pneumococci, may occur (see p. 357). Splenectomy should be preceded by appropriate immunization and followed by life-long penicillin prophylaxis. In addition to the well-known risk of bacterial infection, there is also a significant risk of adverse arterial and venous thromboembolic events after splenectomy and this needs to be taken into account when deciding whether to proceed to splenectomy.
Following splenectomy, the spherocytes persist but the haemoglobin usually returns to normal, as the red cells are no longer destroyed.

Hereditary elliptocytosis

This disorder of the red cell membrane is inherited in an autosomal dominant manner and has a prevalence of 1 in 2500 in Caucasians. The red cells are elliptical due to deficiencies of protein 4.1 or the spectrin/actin/4.1 complex, which leads to weakness of the horizontal protein interaction and to the membrane defect (see Fig. 16.15). Clinically, it is a similar condition to HS but milder. Only a minority of patients have anaemia and only occasional individuals require splenectomy.

Rarely, hereditary spherocytosis or elliptocytosis may be inherited in a homozygous fashion, giving rise to a severe haemolytic anaemia sometimes necessitating splenectomy in early childhood (hereditary pyropoikilocytosis).

Hereditary stomatocytosis

Stomatocytes are red cells in which the pale central area appears slit-like. Their presence in large numbers may occur in a hereditary haemolytic anaemia associated with a membrane defect, but excess alcohol intake is also a common cause. Although these hereditary conditions are very rare, a correct diagnosis is required; splenectomy is contraindicated, as it may result in fatal thromboembolic events.

Haemoglobin abnormalities

In early embryonic life, haemoglobins Gower 1, Gower 2 and Portland predominate. Later, fetal haemoglobin (HbF), which has two α and two γ chains, is produced (Fig. 16.17). There is increasing synthesis of β chains from 13 weeks’ gestation and at term there is 80% HbF and 20% HbA. Completion of the haemoglobin switch from HbF to HbA occurs after birth, when the genes for γ chain production are further suppressed and there is rapid increase in the synthesis of β chains. BCL IIA, a zinc finger protein, is one of a number of proteins that suppress γ gene expression and is a key genome editing target in the effort to reactivate HbF in adults with haemoglobinopathies. There is little HbF produced (normally <1%) from 6 months after birth. The δ chain is synthesized just before birth and HbA2 (α2δ2) remains at a level of about 2% throughout adult life (Box 16.10).

A normal individual has four α-globin chain genes (see Fig. 16.16), with two α-globin genes on each haploid genome (genes derived from one parent). These are situated close together on chromosome 16. The genes controlling the production of ε, γ, δ and β chains are close together on chromosome 11. The globin genes are arranged on chromosomes 16 and 11 in the order in which they are expressed and combine to give different haemoglobins. Normal haemoglobin synthesis is discussed on page 326.
Inherited haemolytic anaemia

Further reading

Haemoglobinopathies

Abnormalities can occur in:

• globin chain production – quantitative defect (e.g. thalassaemia)
• structure of the globin chain – qualitative defect (e.g. sickle cell disease)
• combined defects of globin chain production and structure (e.g. sickle cell \( \beta \)-thalassaemia).

The thalassaemias affect people throughout the world (Fig. 16.18), and at least 60 000 severely affected individuals are born every year. Normally, there is balanced (1:1) production of \( \alpha \) and \( \beta \) chains.

The defective synthesis of globin chains in thalassaemia leads to ‘imbalanced’ globin chain production, causing precipitation of the excess globin chains within the red cell precursors and resulting in ineffective erythropoiesis. Precipitation of globin chains in mature red cells leads to haemolysis. This concept of globin chain imbalance is critical in understanding the relationship between a patient’s genotype and phenotype (the greater the imbalance, the worse the phenotype), as well as understanding how novel therapies are being used to ameliorate the disease.

Beta-thalassaemia

In homozgyous (identical mutations on both alleles) or compound heterozygous (different damaging mutations on both alleles) \( \beta \)-thalassaemia, either no normal \( \beta \) chains are produced (\( \beta^0 \)) or \( \beta \)-chain production is very reduced (\( \beta^+ \)). This leaves an excess of \( \alpha \) chains, which precipitate in erythroblasts and red cells, causing ineffective erythropoiesis and haemolysis. In the carrier (heterozygous) state, the excess \( \alpha \) chains combine with \( \delta \) and result in modestly increased quantities of HbA\(_2\), which
THALASSAEMIA

is used to screen for β-thalassaemia carrier status. Heterozygous β-thalassaemia carriers exhibit asymptomatic microcytosis with or without mild anaemia. Box 16.11 shows the findings in the homozygote and heterozygote for the common types of β-thalassaemia.

Genetics

The molecular errors accounting for over 200 genetic defects leading to β-thalassaemia have been characterized. Unlike in α-thalassaemia, the defects are mainly point mutations rather than gene deletions. The mutations result in defects in transcription, RNA splicing and modification, translation via frame shifts and nonsense codons producing highly unstable β-globin, which cannot be utilized.

Clinical syndromes

Clinical syndromes in thalassaemia have changed in recent years, moving away from the ‘major’ and ‘minor’ descriptions and focusing on whether they are ‘transfusion-dependent thalassaemias’ (TDTs) or ‘non-transfusion-dependent thalassaemias’ (NTDTs; Fig. 16.19). Patients who have NTDT may require occasional blood transfusions, particularly during times of infection or pregnancy. Patients with NTDT may be transferred to the TDT category if it is decided that regular transfusions would improve their growth, development and wellbeing. Thalassaemia trait is the term still used to describe the symptomless heterozygous carrier state.

Thalassaemia trait (carrier)

This common carrier state (heterozygous β-thalassaemia) is asymptomatic. Anaemia is mild or absent. The red cells are hypochromic and microcystic with a low MCV and MCH, and the condition may be confused with iron deficiency. However, the two are easily distinguished, as in thalassaemia trait the serum ferritin and the iron stores are normal (see Box 16.4). The RDW is usually normal (see p. 324). Haemoglobin electrophoresis usually shows a raised HbA₂ and often a slightly raised HbF (see Fig. 16.23). Iron should not be given to these patients unless they also have proven coincidental iron deficiency.

Non-transfusion-dependent thalassaemia (NTDT)

This condition was previously referred to as thalassaemia intermedia. Patients are symptomatic with moderate anaemia (Hb 70–100 g/L) but do not require regular transfusions.

NTDT occurs in patients in whom the effects of the excess α-globin chains are attenuated. This can be due to a reduction in their production (co-inheritance of α-thalassaemia) or due to the α-chains being ‘mopped up’ by γ chains. While there is usually very little γ-chain production after birth, some patients may co-inherit
hereditary persistence of fetal haemoglobin', in which \(\gamma\)-chain production is increased, sometimes to substantial amounts. By reducing \(\alpha\)-chain production or increasing that of \(\gamma\) chains, there is less excess \(\alpha\)-chain precipitation, thus helping to reduce the degree of globin imbalance and causing a consequent reduction in ineffective erythropoiesis and haemolysis.

Conversely, NTDT may also arise from the inheritance of a heterozygous \(\beta^+\) mutation and an excess of \(\alpha\)-chain genes. This condition (e.g. triplicated \(\alpha\)-chain genes) arises in the same meiotic division that results in one \(\alpha\)-chain deletion (see Fig. 16.23). The more \(\alpha\)-chain genes are inherited, the greater the imbalance and the more severe the phenotype.

Patients with NTDT may have splenomegaly and bone deformities. Recurrent leg ulcers, gallstones and infections are also seen. These patients may be iron-overloaded despite a lack of regular blood transfusions. This is caused by excessive iron absorption, which results from the underlying dyserythropoiesis that drives Erfe production, suppressing hepcidin to undetectable levels (see p. 329).

Transfusion-dependent thalassaemia (TDT)
This condition was previously referred to as thalassaemia major. Most children affected by homozygous or compound heterozygous \(\beta\)-thalassaemia present during the first year of life with:
- failure to thrive and recurrent bacterial infections
- severe anaemia from 3 to 6 months, when the switch from \(\gamma\)- to \(\beta\)-chain production should normally occur
- extramedullary haemopoiesis that soon leads to hepatosplenomegaly and bone expansion, giving rise to the classical thalassaemic facies (Fig. 16.20A).

Skull X-rays in these children show the characteristic 'hair-on-end' appearance of bony trabeculation as a result of expansion of the bone marrow into cortical bone (Fig. 16.20B). The expansion of the bone marrow is also shown in an X-ray of the hand (Fig. 16.20C).

The classic features of untreated thalassaemia major are generally observed only in patients from countries that do not have good blood transfusion support.

Management of symptomatic thalassaemia
The aims of treatment are to suppress ineffective erythropoiesis, prevent bony deformities and allow normal activity, growth and development.
- **Long-term folic acid** supplements are required.
- **Regular transfusions** should be given to keep the haemoglobin above 100g/L. Blood transfusions may be required every 4–6 weeks.
- **Splenectomy** was previously used to reduce the transfusion requirements of patients with NTDT; these are associated with the development of pulmonary hypertension, however, and should be used only rarely. Splenectomy is usually delayed until after the age of 6 years because of the risk of infection; prophylaxis against infection is required (see p. 357).
- **Iron overload**, caused by repeated transfusions (transfusion haemosiderosis), may lead to damage to the endocrine glands, liver, pancreas and myocardium by adolescence. Among these complications of iron overload, cardiomyopathy and associated cardiac tachyarrhythmias are the leading causes of morbidity and mortality. Magnetic resonance imaging (MRI; myocardial T2-relaxation time) is useful for monitoring iron overload in thalassaemia; both the heart and the liver can be monitored. Iron chelation using the once-daily oral iron chelator deferasirox is now standard wherever it is available and economically accessible. Elsewhere, desferrioxamine remains the standard chelator, although it has to be administered parenterally. Desferrioxamine is given
as an overnight subcutaneous infusion on 5–7 nights each week. Ascorbic acid 200 mg daily is given, as it increases the urinary excretion of iron in response to desferrioxamine. Often, young children have a very high standard of chelation, as it is organized by their parents. However, when the children become adults and take on this role themselves, chelation may become problematic. Deferiprone, an oral iron chelator, has been available for some years and is usually used for cardiac iron overload or in combination with another chelator.

- **Intensive treatment with desferrioxamine** has been reported to reverse damage to the heart in patients with severe iron overload, but excessive doses of desferrioxamine may cause cataracts, retinal damage and sensorineural deafness. Infection with Yersinia enterocolitica occurs in iron-loaded patients treated with desferrioxamine. Iron overload should be periodically assessed by measuring the serum ferritin and by assessing hepatic iron stores by MRI.

- **Bone marrow transplantation** has been used in young patients with HLA-matched siblings. It has been successful in patients in good clinical condition with a 3-year mortality of <5%, but there is a high mortality (>50%) in patients in poor condition with iron overload and liver dysfunction. Only 25% of patients have a sibling-matched donor.

- **Prenatal diagnosis and gene therapy** are discussed on pages 15 and 22.

- **Testing of patients’ partners** should be carried out. If both partners have β-thalassaemia trait, there is a 1 in 4 chance of the pregnancy resulting in a child having β-thalassaemia major/NTDT. Therefore, couples in this situation must be offered prenatal diagnosis and counselling (see p. 17).

### Alpha-thalassaemia

#### Genetics

In contrast to β-thalassaemia, α-thalassaemia is often caused by gene deletions, although mutations of the α-globin genes may also occur. The gene for α-globin chains is duplicated on both chromosomes 16: that is, a normal person has a total of four α-globin genes. Deletion of one α-chain gene (α+) or both α-chain genes (α−) on each chromosome 16 may occur (Box 16.12 and Fig. 16.21). The former is the most common of these abnormalities.

- **Four-gene deletion** (deletion of both genes on both chromosomes). There is no α-chain synthesis and only Hb Barts (γ4) is present. Hb Barts cannot carry oxygen and is incompatible with life (see Boxes 16.10 and 16.12). Infants are either stillborn at 28–40 weeks or die very shortly after birth. They are pale and oedematous, and have enormous livers and spleens – a condition called hydrops fetalis. If this is detected in utero, intra-uterine transfusions can be given so that the fetus can grow and survive until term, at which point the baby will have NTDT.

- **Three-gene deletion**. The severe reduction in α-chain synthesis results in HbH disease, which is common in parts of Asia. HbH has four β-chains, although patients with HbH disease also have low levels of HbA and Hb Barts. HbA2 is normal or reduced. HbH does not transport oxygen and precipitates in erythroblasts and erythrocytes. There is moderate anaemia (Hb 70–100 g/L) and splenomegaly (thalassaemia intermedia). The patients usually have NTDT.

- **Two-gene deletion** (α-thalassaemia trait). There is microcytosis with or without mild anaemia. HbH bodies may be seen on staining a blood film with brilliant cresyl blue.

- **One-gene deletion**. The blood picture is usually normal but there may be microcytosis.

Globin chain synthesis studies for the detection of a reduced ratio of α to β chains may be necessary for the definitive diagnosis of α-thalassaemia trait, although standard DNA analysis using gene sequencing can detect the most common deletions that lead to α-thalassaemia trait.

#### Further reading

### Sickle syndromes

Sickle cell haemoglobin (HbS) results from a single-base mutation of adenine to thymine, which produces a substitution of valine for glutamic acid at the sixth codon of the β-globin chain (C6G→A). In the homozygous state (sickle cell anaemia), both genes are abnormal (HbSS), whereas in the heterozygous state (sickle cell trait, HbAS), only one chromosome carries the gene. As the synthesis of HbF is normal, the disease usually does not manifest itself until the HbF decreases to adult levels at about 6 months of age.

The sickle gene is most common in Africans (up to 25% gene frequency in some populations) but is also found in India, the Middle East and Southern Europe. Its distribution mirrors that of malaria infestation.

#### Pathogenesis

Deoxygenated HbS molecules are insoluble and polymerize. The flexibility of the cells is decreased, and they become rigid and take up their characteristic sickle appearance (Fig. 16.22). This process is initially reversible but, with repeated sickling, the cells eventually lose their membrane flexibility and become irreversibly sickled. This is due to dehydration, partly caused by potassium leaving the red cells via a calcium-activated potassium channel called the Gardos channel. These irreversibly sickled cells are dehydrated and dense, and will not return to normal when oxygenated. Sickling can produce:
patients have the most severe disease.

The acute chest syndrome is caused by infection, acute lung disease are the most common causes of death in adults with sickle cell disease. The acute chest syndrome is caused by infection, fever from painful vaso-occlusive crises. Overall, 25% of patients with sickle cell disease report experiencing pain on a daily basis. Fever often accompanies the pain.

Sickle cell anaemia
Clinical features
Vaso-occlusive crises
An early presentation may be acute pain in the hands and feet (dactylitis) owing to vaso-occlusion of the small vessels. Severe pain in other bones, such as the femur, humerus, vertebrae, ribs and pelvis, occurs in older children and adults. These attacks vary greatly in frequency from patient to patient, and sometimes in the same patient from year to year. Patients with sickle cell disease can be fairly asymptomatic or require multiple hospital admissions a year from painful vaso-occlusive crises. Overall, 25% of patients with sickle cell disease report experiencing pain on a daily basis. Fever often accompanies the pain.

Acute chest syndrome
This occurs in up to 30%, and pulmonary hypertension and chronic lung disease are the most common causes of death in adults with sickle cell disease. The acute chest syndrome is caused by infection, fat embolism from necrotic bone marrow in a vaso-occlusive crisis or pulmonary infarction due to sequestration of sickle cells. It is comprised of shortness of breath, chest pain, pyrexia, hypoxia and new chest X-ray changes due to consolidation. The presentation may be gradual or very rapid, carrying a risk of death in a few hours. Management is with pain relief, high-flow supplemental oxygen and antibiotics (cefotaxime and clarithromycin), which should be started immediately. Exchange transfusion will reduce the amount of HbS to less than 20% if there is no improvement. Ventilation (continuous positive airways pressure, CPAP) may be necessary. Infections can be due to chlamydia and mycoplasma, as well as Streptococcus pneumoniae. Use of an incentive spirometer to encourage deep breathing in patients admitted with vaso-occlusive crises reduces the risk of developing the acute chest syndrome.

Pulmonary hypertension
Pulmonary hypertension (defined as a mean pulmonary artery pressure of >25 mmHg by right heart catheterization) is a known consequence of sickle cell anaemia, occurring in approximately 10% of patients. Its mechanism is not understood but contributory factors probably include sickle cell vasculopathy, damage from repeated chest crises, and repeated thromboembolism and intravascular haemolysis with consequent effects on reactive oxygen species and levels of scavenging nitric oxide. Development of pulmonary hypertension raises the risk of hypoxaemia and worsening sickle cell crises, and is an independent risk factor for mortality in patients with sickle cell anaemia. Diagnosis of pulmonary hypertension in
patients with sickle cell anaemia should prompt consideration of therapies to reduce levels of HbS (see later) and also referral to a pulmonary hypertension specialist.

Anaemia
Chronic haemolysis produces a stable haemoglobin level, usually in the 60–80 g/L range, but an acute fall in haemoglobin can occur owing to:

• splenic sequestration
• bone marrow aplasia
• further haemolysis due to drugs, acute infection or associated glucose-6-phosphate dehydrogenase (G6PD) deficiency.

Splenectomy produces an acute painful enlargement of the spleen. There is splenic pooling of red cells and hypovolaemia, leading to some to circulatory collapse and death. The condition supervenes in childhood before multiple infarctions have occurred. The latter eventually lead to a fibrotic, non-functioning spleen. Liver sequestration can also occur.

Bone marrow aplasia
This most commonly follows infection with parvovirus B19, which invades proliferating erythroid progenitors. There is a rapid fall in haemoglobin with no reticulocytes in the peripheral blood because of the failure of erythropoiesis in the marrow. Patients may require transfusion until their bone marrow recovers.

Long-term problems

• Growth and development. Young children are short but regain their height by adulthood. However, they remain below the normal weight. Sexual maturation is often delayed and may require hormone therapy.

• Bones. Bones are a common site for vaso-occlusive episodes, leading to chronic infarcts. Avascular necrosis of hips and shoulders, compression of vertebrae, and shortening of bones in the hands and feet occur. These episodes are commonly the cause of the painful crisis. Osteomyelitis is more frequent in sickle cell disease and is caused by Staphylococcus aureus, Streptococcus pneumoniae and salmonella (see p. 484). Occasionally, hip joint replacement may be required.

• Infections. Infections are common in tissues susceptible to vaso-occlusion, such as bones, lungs and kidneys.

• Leg ulcers. These occur spontaneously (vaso-occlusive episodes) or follow trauma, and are usually found over the medial or lateral malleoli. They often become infected and are quite resistant to treatment; sometimes blood transfusion may facilitate ulcer healing.

• Cardiac problems. Cardiac problems occur, with cardiomegaly, arrhythmias and iron overload cardiomyopathy. Myocardial infarctions are caused by thrombotic episodes, which are not secondary to atheroma.

• Neurological complications. These occur in 25% of patients and include transient ischaemic attacks, fits, cerebral infarction, cerebral haemorrhage and coma. About 11% of patients under 20 years of age suffer strokes without a stroke prevention programme. The most common finding is obstruction of a distal intracranial internal carotid artery or a proximal middle cerebral artery. About 10% of children without neurological signs or symptoms have abnormal blood-flow velocity indicative of clinically significant arterial stenosis; such patients have a very high risk of stroke. It has been demonstrated that if children with stenotic cranial artery lesions, as demonstrated on transcranial Doppler ultrasonography, are maintained on a regular red cell transfusion exchange programme that is designed to suppress erythropoiesis, so that no more than 30% of the circulating red cells are their own, about 90% of strokes in such children are prevented. Whether they need to remain on these transfusions for life remains to be determined. Silent infarcts, seen on MRI but not manifesting clinically, have been shown to be common in children with sickle cell disease and associated with poor educational attainment.

• Cholelithiasis. Pigment stones occur as a result of chronic haemolysis.

• Liver complications. Chronic hepatomegaly and liver dysfunction are caused by trapping of sickle cells.

• Renal complications. Chronic tubulointerstitial nephritis occurs (see p. 1385).

• Priapism. An unwanted painful erection occurs because of vaso-occlusion and can be recurrent. This requires urgent treatment, as it may result in impotence. Treatment is with an α-adrenergic blocking drug, analgesia and hydration.

• Eye complications. Background retinopathy, proliferative retinopathy, vitreous haemorrhages and retinal detachments all occur. Regular yearly eye checks are required.

• Pregnancy. Impaired placental blood flow causes spontaneous abortion, intrauterine growth retardation, pre-eclampsia and fetal death. Painful episodes, infections and severe anaemia occur in the mother.

Investigations

• Blood count. The level of haemoglobin is in the 60–80 g/L range, with a high reticulocyte count (10–20%).

• Blood films. These can show features of hyposplenism (see Fig. 16.28) and sickling (see Fig. 16.22).

• Sickle solubility test. A mixture of HbS in a reducing solution such as sodium dithionite gives a turbid appearance because of precipitation of HbS, whereas normal haemoglobin gives a clear solution. A number of commercial kits, such as Sicklex, are available for rapid screening for the presence of HbS, e.g. before surgery in appropriate ethnic groups and in the emergency department.

• Haemoglobin electrophoresis (Fig. 16.23). This is always needed to confirm the diagnosis. There is no HbA, 80–95% HbS and 2–20% HbF.

• Parents. The parents of the affected child will show features of sickle cell trait.

Management
Precipitating factors (see earlier) should be avoided or treated quickly. The complications that require inpatient management are shown in Box 16.13.

Acute painful attacks require supportive therapy with intravenous fluids, along with adequate analgesia. Oxygen and antibiotics are given only if specifically indicated. Crises can be extremely painful and require strong, usually narcotic, analgesia. Morphine is the drug of choice. Milder pain can sometimes be relieved by codeine, paracetamol and NSAIDs (Box 16.14). Use of incentive spirometry is recommended for patients hospitalized for a vaso-occlusive crisis.

Infection prophylaxis is with penicillin 500 mg daily and vaccination with polyvalent pneumococcal, meningococcal and
Haemophilus influenzae type b vaccine, as all patients are without a functioning spleen (see p. 357). Folic acid is given to all patients with haemolysis.

Anaemia

Blood transfusions should be given only when there are clear indications. Patients with steady state anaemia, those having minor surgery or those having painful episodes without complications should not be transfused. Transfusions should be given acutely for acute chest syndrome and acute anaemia associated with splenic sequestration or an aplastic crisis, aiming for a haemoglobin of 100 g/L and HbS below 30%. Before elective operations, top-up transfusions given to increase the haemoglobin to 100 g/L reduce the risk of perioperative complications. During pregnancy, repeated transfusions may be used to reduce the proportion of circulating HbS to below 30% to prevent sickling and improve placental function. Regular exchange transfusions are given to children with a history of stroke (secondary prevention) or a high risk of stroke as assessed by transcranial Doppler (primary prevention). Exchange transfusions may be necessary in patients with severe or recurrent crises, or before emergency surgery. Red cells for transfusion should be matched for Rhesus (Rh) and Kell blood groups to minimize the risk of alloimmunization, which arises from the ethnic mismatch between blood donors and recipients. Ideally, patients requiring long-term transfusion, such as those with sickle cell anaemia and thalassaemia, should undergo molecular blood group typing before their first transfusion.

Hydroxycarbamide (hydroxyurea) has been widely used as therapy for sickle cell anaemia. It acts, at least in part, by increasing HbF concentrations. Hydroxycarbamide has been shown in trials to reduce the episodes of pain, the acute chest syndrome and the need for blood transfusions. Whereas, initially, only selected patients were offered hydroxycarbamide treatment, it is now offered to almost all patients with sickle cell disease from the age of 12 months. It has been shown to be safe and effective, and probably reduces long-term complications such as renal dysfunction. Blood counts must be carefully monitored to detect the development of neutropenia, which is a side-effect of the treatment.

Stem cell transplantation has been used to treat sickle cell anaemia, although in lower numbers than for thalassaemia. Children and adolescents younger than 16 years of age, who have severe complications (strokes, recurrent chest syndrome or refractory pain) and have an HLA-matched donor, are the best candidates for transplantation.

Counselling

A multidisciplinary team should be involved, with regular clinic appointments to build up relationships. Adolescents require careful counselling over psychosocial issues and drug and birth control.

Prognosis

Some patients with HbSS die in the first few years of life from either infection or episodes of sequestration. However, there is marked individual variation in severity of disease and some

Box 16.14 Management of acute painful crisis in opioid-naive adults with sickle cell disease

- Morphine/diamorphine
  - 0.1 mg/kg i.v./s.c. every 20 min until pain controlled
  - Then 0.05–0.1 mg/kg i.v./s.c. (or oral morphine) every 2–4 h

Patient-controlled analgesia (PCA)

Example for adults >50 kg

- Diamorphine/morphine
  - Continuous infusion: 0–10 mg/h
  - PCA bolus dose: 2–10 mg
  - Dose duration: 1 min
  - Lockout time: 20–30 min

Adjuvant oral analgesia

- Paracetamol 1 g 6-hourly
- ± ibuprofen4 400 mg 8-hourly
- Or diclofenac5 50 mg 8-hourly

Laxatives (all patients)

- For example:
- Lactulose 10 mL × 2 daily
- Senna 2–4 tablets daily
- Sodium docusate 100 mg × 2 daily

Caution advised with non-steroidal anti-inflammatory drugs in renal impairment. *(Adapted from Rees DC, Olujohungbe AD, Parker NE et al. Guidelines for the management of the acute painful crisis in sickle cell disease. Br J Haematol 2003; 120:744–752.)*

Fig. 16.23 Patterns of haemoglobin electrophoresis.
patients have a relatively normal lifespan with few complications. In most, length and quality of life are adversely affected and regular monitoring is important to prevent long-term complications.

**Sickle cell trait**

These individuals have no symptoms unless extreme circumstances cause anoxia, such as flying in a non-pressurized aircraft. At a population level, sickle cell trait gives some protection against *Plasmodium falciparum* malaria (see p. 564), and consequently the sickle gene has been seen as an example of a balanced polymorphism (where the advantage of the malaria protection in the heterozygote is balanced by the mortality of the homozygous condition). However, for an individual, the presence of sickle cell trait does not obviate the need for antimalarial prophylaxis. Typically, there is 60% HbA and 40% HbS. It should be emphasized that, unlike with thalassaemia trait, the blood count and film of a person with sickle cell trait are normal. The diagnosis is made by a positive sickle test or by haemoglobin electrophoresis (see Fig. 16.23).

**Other structural globin chain defects**

There are very many haemoglobin variants and most are not associated with any clinical manifestations. However, some haemoglobin variants may interact with HbS: for example, compound heterozygosity for Hbc and HbS gives rise to HbSC disease. The clinical course of HbSC disease is generally somewhat milder than that of HbSS disease, but there is an increased likelihood of retinopathy and thrombosis, which may lead to thrombosis in pregnancy.

**Combined defects of globin chain production and structure**

Abnormalities of haemoglobin structure (e.g. Hbs, C) can occur in combination with thalassaemia. The combination of $\beta$-thalassaemia trait and sickle cell trait (sickle cell $\beta$-thalassaemia) resembles sickle cell anaemia (HbSS) clinically.

HbE ($\alpha_2\beta_2\alpha^{26}_{\text{glu}}\text{lys}^\gamma\gamma$) is the most common haemoglobin variant in South-east Asia and the second most prevalent haemoglobin variant worldwide. HbE heterozygotes are asymptomatic; the haemoglobin level is normal but red cells are microcytic. Homozygous HbE causes a mild microcytic anaemia, but the combination of heterozygosity for HbE and $\beta$-thalassaemia produces a variable anaemia, which can be as severe as TDT ($\beta$-thalassaemia major).

**Prenatal screening and diagnosis of severe haemoglobin abnormalities**

Of the offspring of parents who both have either $\beta$-thalassaemia or sickle cell trait, 25% will have TDT or sickle cell anaemia, respectively. Recognition of these heterozygous states in parent and family counselling provides a basis for antenatal screening and diagnosis (see p. 17).

Pregnant women with either sickle cell trait or thalassaemia trait must be identified at antenatal booking either by selective screening of high-risk groups on the basis of ethnic origin or by universal screening of all pregnant women. Beta-thalassaemia trait can always be detected by a low MCV and MCH, and confirmed by haemoglobin electrophoresis. However, sickle cell trait is undetectable from a blood count and the laboratory needs a specific request to screen for sickle cell trait. Clearly, universal antenatal screening avoids such problems.

If a pregnant woman is found to have a haemoglobin defect, her partner should be tested. Antenatal diagnosis is offered if both are affected, as there is a risk of a severe fetal haemoglobin defect, particularly TDT. Fetal DNA analysis can be carried out using amniotic fluid, chorionic villus or fetal blood samples. Termination of pregnancy is discussed if the fetus is found to be severely affected. Chorionic villus biopsy has the advantage that it can be carried out in the first trimester, thus avoiding the need for second-trimester terminations.

**Metabolic disorders of the red cell**

**Red cell metabolism**

The mature red cell has no nucleus, mitochondria or ribosomes and is therefore unable to synthesize proteins. Red cells have only limited enzyme systems but they maintain the viability and function of the cells. In particular, energy is required in the form of ATP for maintenance of the flexibility of the membrane and the biconcave shape of the cells to allow passage through small vessels, and for regulation of the sodium and potassium pumps to ensure osmotic equilibrium. In addition, it is essential for haemoglobin to be maintained in the reduced state.

The enzyme systems responsible for producing energy and reducing power (Fig. 16.24) are:

- **the glycolytic (Embden–Meyerhof) pathway**, in which glucose is metabolized to pyruvate and lactic acid with production of ATP
- **the hexose monophosphate (pentose phosphate) pathway**, which provides reducing power for the red cell in the form of NADPH (the reduced form of nicotinamide adenine dinucleotide phosphate).

About 90% of glucose is metabolized by the former and 10% by the latter. The hexose monophosphate shunt maintains glutathione (GSH) in a reduced state. Glutathione is necessary to combat oxidative stress to the red cell, and failure of this mechanism may result in:

- **rigidity** due to cross-linking of spectrin, which decreases membrane flexibility (see Fig. 16.15) and causes ‘leakiness’ of the red cell membrane
- **oxidation of the haemoglobin molecule**, producing methaemoglobin and precipitation of globin chains as Heinz bodies localized on the inside of the membrane; these bodies are removed from circulating red cells by the spleen.

2,3-BPG is formed from a side-arm of the glycolytic pathway (see Fig. 16.24). It binds to the central part of the haemoglobin tetramer, fixing it in the low-affinity state. A decreased affinity with a shift in the oxygen dissociation curve to the right enables more oxygen to be delivered to the tissues.
In addition to the G6PD, pyruvate kinase and pyrimidine 5’ nucleotidase deficiencies described here, there are a number of rare enzyme deficiencies that need specialist investigation.

**Glucose-6-phosphate dehydrogenase deficiency**

The glucose-6-phosphate dehydrogenase (G6PD) enzyme occupies a vital position in the hexose monophosphate shunt (see Fig. 16.24), oxidizing glucose-6-phosphate to 6-phosphoglycerate with the reduction of NADP to NADPH. The reaction is necessary in red cells where it is the only source of NADPH, which is used via glutathione to protect the red cell from oxidative damage. G6PD deficiency is a common condition that presents with a haemolytic anaemia and affects millions of people throughout the world, particularly in Africa, around the Mediterranean, and in the Middle East (around 20%) and South-east Asia (up to 40% in some regions).
The gene for G6PD is localized to chromosome Xq28 near the factor VIII gene. The deficiency is therefore more common in males than in females. However, female heterozygotes can also have clinical problems due to lyonization (see p. 21), whereby, because of random X-chromosome inactivation, female heterozygotes have two populations of red cells: a normal one and a G6PD-deficient one.

There are over 400 structural types of G6PD and mutations are mostly single amino acid substitutions (missense point mutations). The World Health Organization (WHO) has classified variants by the degree of enzyme deficiency and severity of haemolysis. The most common ones with normal activity are called type B⁺, which is present in almost all Caucasians and about 70% of black Africans, and type A⁺, which is present in about 20% of black Africans. There are many variants with reduced activity but only two are common. In the African or A⁻ type, the degree of deficiency is mild and more marked in older cells. Haemolysis is self-limiting, as the young red cells newly produced by the bone marrow have nearly normal enzyme activity. However, in the Mediterranean type, both young and old red cells have very low enzyme activity. After an oxidant shock, the haemoglobin level may fall precipitously; death may follow unless the condition is recognized and the patient is transfused urgently.

Clinical syndromes

- **Acute drug-induced haemolysis** (Box 16.15) – usually dose-related.
- **Favism** (ingestion of fava beans).
- **Chronic haemolytic anaemia.**
- **Neonatal jaundice.**
- **Infections and acute illnesses** – also precipitate haemolysis in patients with G6PD deficiency. Mothballs containing naphthalene can also cause haemolysis. The clinical features are due to rapid intravascular haemolysis with symptoms of anaemia, jaundice and haemoglobinuria.

Investigations

- **Blood count** is normal between attacks.
- **During an attack**, the blood film may show irregularly contracted cells, bite cells (cells with an indentation in the membrane), blister cells (cells in which the haemoglobin appears to have become partially detached from the cell membrane, Fig. 16.25), Heinz bodies (red cell inclusions composed of denatured haemoglobin, best seen on films stained with methyl violet) and reticulocytosis.

### Box 16.15 Drugs causing haemolysis in glucose-6-phosphate dehydrogenase deficiency

**Analgesics, e.g.**

- Aspirin
- Phenacetin (withdrawn in the UK)

**Antimalarials, e.g.**

- Primaquine
- Pyrimethamine
- Quinine
- Chloroquine
- Pamaquin

**Antibacterials e.g.**

- Most sulphonamides
- Nitrofurantoin
- Chloramphenicol
- Quinolones

**Miscellaneous drugs, e.g.**

- Dapsone
- Vitamin K
- Probenecid
- Quinidine
- Dimercaprol
- Phenylhydrazine
- Methylen blue

**Management**

- Any offending drugs should be stopped.
- Underlying infection should be treated.
- Blood transfusion may be life-saving.
- Splenectomy is not usually helpful.

**Pyruvate kinase deficiency**

This is the most common defect of red cell metabolism after G6PD deficiency; it affects thousands rather than millions of people worldwide. The site of the defect is shown in Fig. 16.24. Production of ATP is reduced, causing rigid red cells. Homozygotes have haemolytic anaemia and splenomegaly. It is inherited as an autosomal recessive condition.

**Investigations**

- **Anaemia** of variable severity is present (haemoglobin 50–100 g/L). The oxygen dissociation curve is shifted to the right as a result of the rise in intracellular 2,3-BPG, and this reduces the severity of symptoms due to anaemia.
- **Blood films** show distorted (‘prickle’) cells and a reticulocytosis.
- **Pyruvate kinase activity** is low (affected homozygotes have levels of 5–20%).

**Management**

Blood transfusions may be necessary during infections and pregnancy. Splenectomy may improve the clinical condition and is usually advised for patients requiring frequent transfusions.

**Pyrimidine 5′ nucleotidase deficiency**

This autosomal recessive disorder produces a haemolytic anaemia with basophilic stippling of the red cells. The enzyme degrades...
Acquired haemolytic anaemia

These anaemias may be divided into those that have immune, non-immune or other causes (see Box 16.9).

Aetiology

Causes of immune destruction of red cells

- Autoantibodies.
- Drug-induced antibodies.
- Alloantibodies.

Causes of non-immune destruction of red cells

- Acquired membrane defects (e.g. paroxysmal nocturnal haemoglobinuria; see p. 353).
- Mechanical factors (e.g. prosthetic heart valves or microangiopathic haemolytic anaemia; see p. 355).
- Secondary to systemic disease (e.g. renal and liver disease).

Miscellaneous causes

- Various toxic substances can disrupt the red cell membrane and cause haemolysis (e.g. arsenic, and toxins produced by *Clostridium perfringens* (welchii)).
- Malaria frequently causes anaemia owing to the combination of a reduction in red cell survival and reduced production of red cells.
- Hypersplenism (see p. 356) results in reduced red cell survival, which may also contribute to the anaemia seen in malaria.
- Extensive burns lead to denaturation of red cell membrane proteins and reduced red cell survival.
- Some drugs (e.g. dapsone, sulfasalazine) cause oxidative haemolysis with Heinz bodies.
- Some ingested chemicals (e.g. weedkillers such as sodium chloride) can cause severe oxidative haemolysis leading to acute kidney injury.

Further reading

cells at body temperature (37°C) or at lower temperatures. The major features and the causes of these two forms of AIHA are shown in Box 16.16. In warm AIHA, IgG antibodies predominate and the direct antiglobulin test is positive with IgG alone, IgG and complement, or complement only. In cold AIHA, the antibodies are usually IgM. They easily elute off red cells, leaving complement, which is detected as C3d.

Immune destruction of red cells
IgM or IgG red cell antibodies, which fully activate the complement cascade, cause lysis of red cells in the circulation (intravascular haemolysis).

IgG antibodies frequently do not activate complement and the coated red cells undergo extravascular haemolysis (Fig. 16.27). They either are completely phagocytosed in the spleen through an interaction with Fc receptors on macrophages, or lose part of the cell membrane through partial phagocytosis and circulate as spherocytes until they become sequestered in the spleen. Some IgG antibodies partially activate complement, leading to deposition of C3b on the red cell surface, and this may enhance phagocytosis, as macrophages also have receptors for C3b.

Non-complement-binding IgM antibodies are rare and have little or no effect on red cell survival. IgM antibodies, which partially rather than fully activate complement, cause adherence of red cells to C3b receptors on macrophages, particularly in the liver, although this is an ineffective mechanism of haemolysis. Most of the red cells are released from the macrophages when C3b is cleaved to C3d, and then circulate with C3d on their surface.

‘Warm’ autoimmune haemolytic anaemias
Clinical features
These anaemias may occur at all ages and in both sexes, although they are most frequent in middle-aged females. They can present as a short episode of anaemia and jaundice but they often remit and relapse, and may progress to an intermittent chronic pattern. The spleen may be palpable. Infections or folate deficiency may

---

**Fig. 16.27 Extravascular haemolysis.** This is due to interaction of antibody-coated cells with cells in the reticuloendothelial system, predominantly in the spleen. (a) Spherocytosis results from partial phagocytosis. (b) Complete phagocytosis may occur and is enhanced if there is complement as well as antibody on the cell surface. (c) Cells coated with complement only are ineffectively removed and circulate with C3d or C3b on their surface.
Investigations

- **Haemolytic anaemia** is evident (see p. 338).
- **Spherocytosis** is present as a result of red cell damage.
- **Direct antiglobulin test** is positive, with either IgG alone (35%), IgG and complement (56%), or complement alone (9%) being found on the surface of the red cells.
- **Autoantibodies** may have specificity for the Rh blood group system (e.g. for the e antigen).
- **Autoimmune thrombocytopenia** and/or neutropenia may also be present (Evans syndrome; see p. 373).
- **Abdominal CT scan** should be carried out to detect abdominal lymphoma.

Management and prognosis

Corticosteroids (e.g. prednisolone in a dose of 1 mg/kg daily) are effective in inducing a remission in about 80% of patients. Steroids reduce both production of the red cell autoantibodies and destruction of antibody-coated cells. Splenectomy is the most effective second-line therapy, but many patients prefer to avoid it because of the lack of a guaranteed successful outcome, its potential complications and the need to take antibiotic prophylaxis (see p. 357). Rituximab is effective in patients who fail to respond to steroids. Blood transfusion may be necessary if there is severe anaemia, although compatibility testing is complicated by the presence of red cell autoantibodies.

‘Cold’ autoimmune haemolytic anaemias

Low titres of IgM cold agglutinins reacting at 4°C are normally present in plasma and are harmless. At low temperatures, these antibodies can attach to red cells and cause their agglutination in the cold peripheries of the body. In addition, activation of complement may cause intravascular haemolysis when the cells return to the higher temperatures in the core of the body.

After certain infections (such as those caused by mycoplasma, cytomegalovirus or Epstein–Barr virus (EBV)), increased production of polyclonal cold agglutinins may occur, producing a mild to moderate transient haemolysis.

Chronic cold haemagglutinin disease

Chronic cold haemagglutinin disease (CHAD) usually occurs in the elderly, with a gradual onset of haemolytic anaemia owing to the production of monoclonal IgM cold agglutinins. After exposure to cold, the patient develops an acrocyanosis similar to Raynaud’s as a result of red cell autoagglutination.

Investigations

- **Red cells** agglutinate in the cold or at room temperature. Agglutination is sometimes seen in the sample tube after cooling but is more easily observed on a peripheral blood film made at room temperature. The agglutination is reversible after warming the sample. The agglutination may cause a spurious increase in the MCV (see p. 324).
- **Cold agglutinin test** demonstrates a markedly elevated titre in CHAD to more than 1:512.
- **Direct antiglobulin test** is positive with complement (C3d) alone.
- **Monoclonal IgM antibodies** have specificity for the i blood group system, usually for the I antigen but occasionally for the i antigen.

Management

Any underlying cause should be treated, if possible. Patients should avoid exposure to cold. Steroids, alkylating agents (chemotherapy) and splenectomy are usually ineffective. Treatment with anti-CD20 (rituximab) has been successful in some cases. Blood transfusion may be necessary, and if so, the patient should be in a warm environment; compatibility testing may be difficult due to the cold agglutinin.

Paroxysmal cold haemoglobinuria

Paroxysmal cold haemoglobinuria (PCH) is a rare condition associated with common childhood infections, such as measles, mumps and chickenpox. Intravascular haemolysis is associated with polyclonal IgG complement-fixing antibodies. These antibodies are biphasic, reacting with red cells in the cold in the peripheral circulation, with lysis occurring due to complement activation when the cells return to the central circulation. The antibodies have specificity for the P red cell antigen. The lytic reaction is demonstrated in vitro by incubating the patient’s red cells and serum at 4°C and then warming the mixture to 37°C (Donath–Landsteiner test). Haemolysis is self-limiting but red cell transfusions may be necessary.

Drug-induced immune haemolytic anaemia

Drug-induced immune haemolytic anaemias are rare, although over 100 drugs have been reported to cause immune haemolytic anaemia.

Testing for drug-dependent red cell antibodies is not routinely available, and rechallenge with the drug to confirm the diagnosis of drug-induced immune haemolytic anaemia is not advisable. Confirmation of the diagnosis requires:

- a temporal association between administration of a drug and haemolytic anaemia
- a positive direct antiglobulin test
- recovery after withdrawal of the drug.

Further reading

Alloimmune haemolytic anaemia

Antibodies produced in one individual react with the red cells of another. This situation occurs in haemolytic disease of the newborn, in haemolytic transfusion reactions (see p. 360), and after allotransplantation for bone marrow, renal, liver, cardiac or intestinal transplantation when donor lymphocytes transferred in the allograft (‘passenger lymphocytes’) may produce red cell antibodies against the recipient and cause haemolytic anaemia.

Haemolytic disease of the newborn

Haemolytic disease of the newborn (HDN) is caused by fetal-maternal incompatibility for red cell antigens. Maternal alloantibodies against fetal red cell antigens pass from the maternal circulation via the placenta into the fetus, where they destroy the fetal red cells. Only IgG antibodies are capable of transplacental passage from mother to fetus.

The most common type of HDN is that due to ABO incompatibility, where the mother is usually group O and the fetus group A.
Haematology

... HDN due to ABO incompatibility is usually mild and exchange transfusion is rarely needed. HDN due to RhD incompatibility has become much less common in developed countries following the introduction of anti-D prophylaxis (see later). HDN may be caused by antibodies against antigens in many blood group systems (e.g. other Rh antigens such as c and E, and Kell, Duffy and Kidd; see p. 357).

Sensitization occurs as a result of passage of fetal red cells into the maternal circulation (which most readily occurs at the time of delivery), so that first pregnancies are rarely affected. However, sensitization may occur at other times – for example, after a miscarriage, ectopic pregnancy or blood transfusion – or be due to episodes during pregnancy that cause transplacental bleeding, such as amniocentesis, chorionic villus sampling and threatened miscarriage.

Clinical features

These vary from a mild haemolytic anaemia of the newborn to intrauterine death from 18 weeks’ gestation with the characteristic appearance of hydrops fetalis (hepatosplenomegaly, oedema and cardiac failure).

Kernicterus occurs owing to severe jaundice in the neonatal period, when the unconjugated (lipid-soluble) bilirubin exceeds 250 µmol/L and bile pigment deposition occurs in the basal ganglia. This can result in permanent brain damage, choreoathetosis and spasticity. In mild cases, it may present as deafness.

Investigations

Routine antenatal serology

All mothers should have their ABO and RhD groups determined and tested for atypical antibodies after attending the antenatal booking clinic. These tests should be repeated at 28 weeks’ gestation.

If an antibody is detected, its blood group specificity should be determined and the mother should be retested at least monthly. A rising antibody titre of IgG antibodies or a history of HDN in a previous pregnancy is an indication for referral to a fetal medicine unit.

Antenatal assessment and treatment

If a clinically significant antibody capable of causing HDN, such as anti-D, anti-c or anti-K, is detected, the father’s phenotype provides useful information for predicting the likelihood of the fetus carrying the relevant red cell antigen. If the father is heterozygous, the genotype of the fetus can be determined from fetal DNA from maternal plasma.

The severity of anaemia is assessed by Doppler flow velocity of the fetal middle cerebral artery; measurement of bile pigments in the amniotic fluid is no longer routinely used. If the infant appears to have severe anaemia on non-invasive monitoring, ultrasound-guided fetal blood sampling is used to confirm this directly; if necessary, an intrauterine fetal transfusion of red cells is given.

Birth of an affected infant

A sample of cord blood is obtained at birth. This shows:
- anaemia with a high reticulocyte count
- a positive direct antiglobulin test
- a raised serum bilirubin.

Postnatal management

In mild cases, phototherapy may be used to convert bilirubin to water-soluble biliverdin, which can be excreted by the kidneys. Bilirubin levels need to be monitored and phototherapy may be needed for several days. In more severely affected cases, exchange transfusion may be necessary to replace the infant’s antibody-coated red cells with normal antigen-negative red cells and to remove bilirubin. Indications for exchange transfusion include severe anaemia or a high or rapidly rising bilirubin level.

The blood used for exchange transfusions should:
- be ABO-compatible with the mother and infant
- lack the antigen against which the maternal antibody is directed
- be fresh (no more than 5 days from the day of collection)
- be irradiated to prevent transfusion-associated graft-versus-host disease (TA-GvHD) and be cytomegalovirus (CMV)-seronegative to prevent transmission of CMV.

Avoidance of exchange transfusion is beneficial because of its risks. Antenatal administration of intravenous immunoglobulin to the mother significantly reduces the need for exchange transfusion.

Prevention of RhD immunization in the mother

Anti-D should be given after delivery when all of the following conditions are fulfilled:
- The mother is RhD-negative.
- The fetus is RhD-positive.
- There is no maternal anti-D detectable in the mother’s serum, i.e. the mother is not already immunized.

The dose is 500 IU of IgG anti-D intramuscularly within 72 hours of delivery. The Kleihauer test assesses the number of fetal cells in the maternal circulation. A blood film prepared from maternal blood is treated with acid, which elutes HbA. HbF is resistant to this treatment and can be seen when the film is stained with eosin. If large numbers of fetal red cells are present in the maternal circulation, a higher or additional dose of anti-D will be necessary.

Prophylaxis may be required by RhD-negative women at other times when sensitization may occur, such as after an ectopic pregnancy, threatened miscarriage or termination of pregnancy. The dose of anti-D is 250 IU before 20 weeks’ gestation and 500 IU after 20 weeks. A Kleihauer test should be carried out after 20 weeks to determine whether more anti-D is required.

Of previously non-immunized RhD-negative women carrying RhD-positive fetuses, 1–2% became immunized by the time of delivery. Antenatal prophylaxis with anti-D has been shown to reduce the incidence of immunization during pregnancy, and its routine use has been implemented in the UK. It can be given as two doses of anti-D immunoglobulin of either 500 IU or 1500 IU (one at 28 weeks’ gestation and one at 34 weeks), or as a single dose of 1500 IU either at 28 weeks’ gestation or between 28 and 30 weeks. In the UK in 2016, the National Institute for Care and Health Excellence (NICE) recommended fetal D typing using maternal plasma to avoid the administration of anti-D to RhD-negative women carrying RhD-negative fetuses.

Non-immune haemolytic anaemia

Paroxysmal nocturnal haemoglobinuria

Paroxysmal nocturnal haemoglobinuria (PNH) is a rare form of haemolytic anaemia that results from the clonal expression of
haemopoietic stem cells that have mutations in the X-linked gene PIG-A. These mutations cause impaired synthesis of glycosylphosphatidylinositol (GPI), which anchors many proteins, such as decay accelerating factor (DAF; CD55), to the cell surface, and membrane inhibitor of reactive lysis (MIRL; CD59) to cell membranes. CD55, CD59 and other proteins are involved in complement degradation (at the C3 and C5 levels), and in their absence, the haemolytic action of complement continues.

Clinical features

The major clinical signs are intravascular haemolysis, venous thrombosis and haemoglobinuria. Haemolysis may be precipitated by infection, iron therapy or surgery. Characteristically, only the urine voided at night and in the morning on waking is dark in colour, although the reason for this phenomenon is not clear. In severe cases, all urine samples are dark. Urinary iron loss may be sufficient to cause iron deficiency. Some patients present insidiously with signs of anaemia and recurrent abdominal pains.

Venous thrombotic episodes may occur at atypical sites and severe thromboses may be a feature: for example, in hepatic (Budd–Chiari syndrome), mesenteric or cerebral veins. The cause of the increased predisposition to thrombosis is not known, but may be complement-mediated activation of platelets deficient in CD55 and CD59. Another suggestion is that intravascular haemolysis, which releases haemoglobin in the plasma, lowers plasma nitric oxide, causing the symptoms and venous thrombosis.

Investigations

- **Intravascular haemolysis** is evident (see p. 338).
- **Flow cytometric analysis** of red cells with anti-CD55 and anti-CD59 is undertaken.
- **Bone marrow** is sometimes hypoplastic (or even aplastic), despite haemolysis.

Management and prognosis

PNH is a chronic disorder requiring supportive measures such as blood transfusions, which are necessary for patients with severe anaemia. However, treatment with eculizumab has revolutionized therapy. The drug is administered intravenously every 7 days for the first 5 weeks, and then every 2 weeks thereafter. It is a recombinant humanized monoclonal antibody that prevents the cleavage of C5 (and therefore formation of the membrane attack complex). It reduces intravascular haemolysis, haemoglobinuria and the need for transfusion, and improves quality of life. Eculizumab also lowers the risk of thrombosis, the leading cause of mortality in PNH. It is now also being used in pregnancy. The most serious risk of terminal complement blockade is infection with Neisseria meningitidis; thus, vaccination against *N. meningitidis* is recommended 2 weeks before commencing treatment.

Long-term anticoagulation may be necessary acutely for patients with recurrent thrombotic episodes. Its long-term value is unclear with the use of eculizumab. In patients with bone marrow failure, treatment options include immunosuppression with antilymphocyte globulin, ciclosporin or bone marrow transplantation. Eculizumab does not alleviate bone marrow failure. Bone marrow transplantation has been successfully carried out using either HLA-matched sibling donors in patients under the age of 50 or matched unrelated donors in patients under the age of 25.

The course of PNH is variable. PNH may transform into aplastic anaemia or acute leukaemia, but may remain stable for many years and the PNH clone may even disappear, which must be taken into account if considering potentially dangerous treatments such as bone marrow transplantation. The median survival is 10–15 years.

### Mechanical haemolytic anaemia

Red cells may be injured by physical trauma in the circulation. Direct injury may cause immediate cell lysis or be followed by resealing of the cell membrane with the formation of distorted red cells or ‘fragments’. These cells may circulate for a short period before being destroyed prematurely in the reticuloendothelial system.

The causes of mechanical haemolytic anaemia include:

- damaged artificial heart valves
- march haemoglobinuria, in which there is damage to red cells in the feet, associated with prolonged marching or running
- microangiopathic haemolytic anaemia (MAHA), in which fragmentation of red cells occurs in an abnormal microcirculation because of malignant hypertension, eclampsia, haemolytic uraemic syndrome, thrombotic thrombocytopenic purpura, vasculitis or disseminated intravascular coagulation.

### Polycythaemia

Polycythaemia (or erythrocytosis) is defined as an increase in haemoglobin or haematocrit (HCT). Haematocrit is a more reliable indicator of polycythaemia than haemoglobin, which may be disproportionately low in iron deficiency. Relative erythrocytosis is where the red cell volume is normal but there is a decrease in the plasma volume.

Polycythaemia can be classified as primary or secondary. Primary polycythaemia (polycythaemia vera) is a neoplastic process (see p. 394). Secondary polycythaemia can be congenital or acquired. The latter is due to either an appropriate increase in erythropoietin in response to hypoxia, or an inappropriate increase in erythropoietin associated with ectopic production by tumours, such as a renal carcinoma. The causes of polycythaemia are given in **Box 16.17**.

**Box 16.17 Causes of polycythaemia**

**Primary**

- Polycythaemia vera

**Congenital**

- Mutations in erythropoietin receptor
- High-oxygen-affinity haemoglobins
- Mutations in hypoxia-sensing pathways, e.g. Chuvash polycythaemia mutation in von Hippel–Lindau gene

**Secondary**

**Due to an inappropriate (hypoxic) increase in erythropoietin**

- High altitude
- Chronic lung disease
- Cardiovascular disease (right-to-left shunt)
- Sleep apnoea

**Due to an inappropriate increase in erythropoietin**

- Renal disease: renal cell carcinoma, Wilms’ tumour
- Hepatocellular carcinoma
- Adrenal tumours
- Cerebellar haemangioblastoma
- Massive uterine leiomyoma
- Over-administration of erythropoietin
- Treatment with androgen preparations

**Relative**

- Stress or spurious polycythaemia
- Dehydration
- Burns

Further reading

Secondary polycythaemias
Many high-oxygen affinity haemoglobin mutants (HOAHMs) have been described that lead to increased oxygen affinity but decreased oxygen delivery to the tissues, resulting in compensatory polycythaemia. A congenital autosomal recessive disorder (Chuvash polycythaemia) is due to a defect in the oxygen-sensing erythropoietin production pathway caused by a mutation of the von Hippel–Lindau (VHL) gene, resulting in an increased production of erythropoietin.

Serum erythropoietin (EPO) levels are normal or raised in secondary polycythaemia. Rarely, the discovery of a high EPO level may be a clue to the presence of an EPO-secreting tumour.

Management
Treatment is that of the precipitating factor; for example, renal or posterior fossa tumours need to be resected if possible. The most common cause is heavy smoking, which can produce as much as 10% carboxyhaemoglobin, and this can lead to polycythaemia because of a reduction in the oxygen-carrying capacity of the blood. Heavy smokers also often have respiratory disease.

Complications of secondary polycythaemia are distinct to those seen in polycythaemia vera, and although hyperviscosity symptoms and thromboembolic episodes can occur, management depends on the underlying cause. Complications due to myeloproliferative disease, such as progression to myelofibrosis or acute leukaemia, do not develop. Venesection may be symptomatically helpful in certain patients with secondary polycythaemia, particularly if the HCT is above 0.54.

‘Relative’ or ‘apparent’ polycythaemia (Gaisböck’s syndrome)
This condition was originally thought to be stress-induced. The red cell volume is normal there is a relative polycythaemia, as a result of a decreased plasma volume. ‘Relative’ polycythaemia is more common than polycythaemia vera and occurs in middle-aged men, particularly in association with smoking, high alcohol intake, obesity and high blood pressure. The condition may present with cardiovascular problems, such as myocardial or cerebral ischaemia. For this reason, it may be justifiable to venesection selected patients. Management also requires modification of lifestyle factors, such as smoking and alcohol.

THE SPLEEN

The spleen is the largest lymphoid organ in the body and is situated in the left hypochondrium. There are two anatomical components:
• the red pulp, consisting of sinuses lined by endothelial macrophages and cords (spaces)
• the white pulp, which has a structure similar to that of lymphoid follicles.

Blood enters via the splenic artery and is delivered to the red and white pulp. During the flow the blood is ‘skimmed’, with leucocytes and plasma preferentially passing to white pulp. Some red cells pass rapidly through into the venous system while others are held up in the red pulp.

Function
Sequestration and phagocytosis
Normal red cells, which are flexible, pass through the red pulp into the venous system without difficulty. Old or abnormal cells are damaged by the hypoxia, low glucose and low pH found in the sinuses of the red pulp and are therefore removed by phagocytosis along with other circulating foreign matter. Howell–Jolly and Heinz bodies and sideroblastic granules have their particles removed by ‘pitting’ and are then returned to the circulation. IgG-coated red cells are removed through their Fc receptors by macrophages.

Extramedullary haemopoiesis
Pluripotent stem cells are present in the spleen and proliferate during severe erythroid stress, such as in haemolytic anaemia, thalassaemia major and myelofibrosis. This occurs due to the presence of anaemia, despite every available marrow cavity already being fully engaged in haemopoiesis. It is usually a feature of ineffective erythropoiesis.

Immunological function
About 25% of the body’s T lymphocytes and 15% of B lymphocytes are present in the spleen. The spleen shares the function of production of antibodies with other lymphoid tissues.

Blood pooling
Up to one-third of the platelets are sequestrated in the spleen and can be rapidly mobilized. Enlarged spleens pool a significant percentage (up to 40%) of the red cell mass.

Splenomegaly
The spleen enlarges from under the left costal margin inferiorly and medially. It is dull to percussion and it may be possible to palpate a notch along its leading edge, which further differentiates the mass from an enlarged left kidney. The spleen typically measures 11 cm in its longest dimension. An enlarged spleen is only palpable if it is 1.5–2 times the size of a normal spleen. Ultrasound or CT scanning may be used to confirm splenomegaly and may also provide other useful information, such as the presence of abdominal lymphadenopathy.

Aetiology
A clinically palpable spleen can have many causes:
• infection:
  – acute, e.g. septic shock, infective endocarditis, typhoid, infectious mononucleosis
  – chronic, e.g. tuberculosis, brucellosis
  – parasitic, e.g. malaria, kala-azar and schistosomiasis
• inflammation: rheumatoid arthritis, sarcoidosis, SLE
• haematological factors: haemolytic anaemia, haemoglobinopathies, and the leukaemias, lymphomas and myeloproliferative disorders
• portal hypertension: liver disease
• miscellaneous: storage diseases (e.g. Gaucher’s disease), amyloidosis, primary and secondary neoplasias, tropical splenomegaly. Massive splenomegaly is seen in myelofibrosis, chronic myeloid leukaemia, chronic malaria, kala-azar or, rarely, Gaucher’s disease.

Hypersplenism
This can result from splenomegaly of any cause. It is commonly seen with splenomegaly due to haematological disorders, portal hypertension, rheumatoid arthritis (Felty’s syndrome) and lymphoma. Hypersplenism produces:
• pancytopenia
• haemolysis due to sequestration and destruction of red cells in the spleen
• increased plasma volume.

Management
This is often dependent on the underlying cause; splenectomy is sometimes required for severe anaemia or thrombocytopenia.
Problems after splenectomy
Splenectomy is performed mainly for:
- trauma
- immune thrombocytopenic purpura (see p.373)
- haemolytic anaemias (see p. 338)
- hypersplenism.

One immediate problem is an increased platelet count (usually 600–1000 × 10^9/L) for 2–3 weeks. Thromboembolic phenomena may occur. In the longer term, there is an increased risk of overwhelming infections, particularly pneumococcal ones.

Prophylaxis against infection after splenectomy or splenic dysfunction
See Box 16.18 for prophylactic measures. All patients should be educated about the risk of infection and the importance of its early recognition and treatment. They should be given an information leaflet and should carry a card or bracelet to alert health professionals to their risk of overwhelming infection.

Post-splenectomy haematological features
- **Thrombocytosis** persists in about 30% of cases.
- **WCC** is usually normal but there may be a mild lymphocytosis and monocytosis.
- **Abnormalities in red cell morphology** are the most prominent changes and include Howell–Jolly bodies (contain basophilic nuclear remnants), Pappenheimer bodies (contain sideroblastic granules), target cells and irregular contracted red cells (Fig. 16.28). Pitted red cells can be counted.

Splenic atrophy
This is seen in sickle cell disease due to infarction. Hyposplenism is also seen in a wide range of non-haematological diseases, including coeliac disease, dermatitis herpetiformis and, occasionally, ulcerative colitis. Post-splenectomy haematological features are seen.

BLOOD TRANSFUSION

The cells and proteins in the blood express antigens that are controlled by polymorphic genes: that is, a specific antigen may be present in some individuals but not in others. A blood transfusion may immunize the recipient against donor antigens that the recipient lacks (alloimmunization), and repeated transfusions increase the risk. Similarly, the transplacental passage of fetal blood cells during pregnancy may alloimmunize the mother against fetal antigens inherited from the father. Antibodies stimulated by blood transfusion or pregnancy, such as Rh antibodies, are termed **immune antibodies** and are usually IgG, in contrast to **naturally occurring antibodies**, such as ABO antibodies, which are made in response to environmental antigens present in food and bacteria, and are usually IgM.

BLOOD GROUPS

The blood group antigens are proteins, glycoproteins or carbohydrates attached to glycoproteins on the surface of red cells; more than 300 blood groups are recognized. The ABO and Rh systems are the two major blood groups, but incompatibilities involving many other blood groups (e.g. Kell, Duffy, Kidd) may also cause haemolytic transfusion reactions and/or HDN.

ABO system
This is the most important blood group system in transfusion practice because naturally occurring IgM anti-A and anti-B antibodies are capable of producing rapid and severe intravascular haemolysis of incompatible red cells.

The ABO system is under the control of three allelic genes, A, B and O, producing the genotypes and phenotypes shown in Box 16.19.

The precursor for A and B antigens is the H antigen, which codes for an enzyme that attaches fucose to galactose on an oligosaccharide structure on the red cell membrane (Fig. 16.29). The A and B genes control specific enzymes responsible for the addition to H of N-acetylgalactosamine for group A, and α-galactose for group B. The O gene is amorphic and does not transform H; therefore O is
The A, B and H antigens are present on most body cells. They are also found in soluble form in tissue fluids, such as saliva and gastric juice, in the 80% of the population who possess secretor genes.

**Rh system**

There is a high frequency of development of IgG RhD antibodies in RhD-negative individuals after exposure to RhD-positive red cells. The antibodies formed cause HDN and haemolytic transfusion reactions.

This system is coded by allelic genes: C and c, E and e, and D and no D, signified as d. They are inherited as triplets on each chromosome 1, one from each pair of genes (i.e. CDE/cde). RhD-negative individuals have no D protein in the red cell membrane, which explains why it is so immunogenic when RhD-negative individuals are exposed to RhD antigen through transfusion or pregnancy. In Caucasians, the RhD-negative phenotype almost always results from a complete deletion of the RhD gene; in black Africans, it can also result from an inactive gene containing stop codons in the reading frame.

**PROCEDURE FOR BLOOD TRANSFUSION IN HOSPITALS**

The safety of blood transfusion in hospitals depends on meticulous attention to detail at each stage leading to and during the transfusion. Avoidance of simple errors involving patient and blood sample identification at the time of collection of the sample for compatibility testing and at the time of transfusion would avoid most serious haemolytic transfusion reactions, almost all of which involve the ABO system.

**Pre-transfusion compatibility testing**

**Blood grouping**

The ABO and RhD groups of the patient are determined.

**Antibody screening**

The patient’s serum or plasma is screened for atypical antibodies that may cause a significant reduction in the survival of the transfused red cells. The patient’s serum or plasma is tested against red cells from at least two group O donors, expressing a wide range of red cell antigens, for detection of IgM red cell alloantibodies (using a direct agglutination test of cells suspended in saline) and IgG antibodies (using an indirect antiglobulin test, see Fig. 16.26). About 10% of patients have a positive antibody screening result; in this case, further testing is carried out using a comprehensive panel of typed red cells to determine the blood group specificity of the antibody (clinically significant red cell antibodies are detected in about 20% of patients with positive antibody screens).

**Selection of donor blood and compatibility testing**

**Selection procedures**

Donor blood of the same ABO and RhD group as the patient is selected. Matching for additional blood groups is carried out for patients with clinically significant red cell antibodies (see later), and for patients who are likely to be multi-transfused and are at high risk of developing antibodies: for example, in sickle cell disease. Many hospitals routinely provide Kell-negative blood for women of childbearing age to minimize the risk of alloimmunization due to anti-K and subsequent HDN.

**Compatibility testing procedures**

**Timing of sample collection**

The timing of sample collection for compatibility testing must take account of pregnancy or recent transfusion, as both may stimulate antibodies that could cause a haemolytic transfusion reaction. Blood samples should be collected no more than 3 days in advance of the transfusion if the patient has been transfused or pregnant within the preceding 3 months.

**Patients without atypical red cell antibodies**

The full crossmatch involves testing the patient’s serum or plasma against the donor red cells suspended in saline in a direct agglutination test, and also using an indirect antiglobulin test. In many hospitals this serological crossmatch is now omitted, as a negative antibody screen makes it highly unlikely that there will be any incompatibility with the donor units. Error in the collection or labeling of the patient sample or a mix-up of samples in the laboratory are much greater risks. Where the antibody screen is negative, laboratories can use their information system to check the patient records and authorize the release of ABO-compatible donor units (computer or electronic crossmatching).
**Box 16.20 Complications of blood transfusion**

**Immunological**

*Alloimmunization and incompatibility*

- Red cells:
  - Immediate haemolytic transfusion reactions
  - Delayed haemolytic transfusion reactions
- Leucocytes and platelets:
  - Non-haemolytic (febrile) transfusion reactions
  - Transfusion-related acute lung injury (TRALI)
  - Poor survival of transfused platelets and granulocytes
  - Post-transfusion purpura
- Transfusion-associated graft-versus-host disease (TA-GvHD)

- Plasma proteins:
  - Uncarial and anaphylactic reactions

**Non-immunological**

*Transmission of infection*

- Viruses:
  - CMV, cytomegalovirus; HAV/HBV/HCV/HEV, hepatitis A/B/C/E virus; HIV, human immunodeficiency virus; HTLV-1, human T-cell leukaemia (or lymphotropic) virus 1; WNV, West Nile virus.

Electronic issue can be extended to previously unallocated blood at fridges remote from the main laboratory (‘remote blood issue’). This is only possible using blood fridges that are electronically linked to the blood transfusion laboratory information system. The printing of compatibility labels for the blood and its collection are under electronic control, applying the same rules as electronic issue from the main laboratory. Issue of blood using this process reduces the time it takes to provide blood for patients needing it urgently, particularly at hospitals without a blood transfusion laboratory, because transport of blood from the central laboratory is not required. There are good examples of centralized transfusion services in cities such as Oxford in the UK, and Pittsburgh and Seattle in the USA, and this model is likely to be increasingly employed in the future.

**Patients with atypical red cell antibodies**

Donor blood should be selected that lacks the relevant red cell antigen(s), as well as being of the same ABO and RhD group as the patient. A full crossmatch should always be carried out in case new antibodies have developed.

Several other systems for blood grouping, antibody screening and crossmatching are available to hospital transfusion laboratories. They do not depend on agglutination of red cells in suspension, but rather on the differential passage of agglutinated and unagglutinated red cells through a column of dextran gel matrix (e.g. DiaMed and Ortho Biovue systems), or on the capture of antibodies by red cells immobilized on the surface of a microplate well (e.g. Capture-R solid phase system).

Blood ordering

Hospitals are increasingly relying on electronic systems for blood ordering; some include algorithms for the appropriate use of blood, with ‘alerts’ if there is non-compliance with agreed blood count triggers for transfusion. Electronic systems also provide the tools for feedback of comparative data on blood use to clinical teams and for the improved documentation of consent to transfusion.

Elective surgery

Many hospitals have guidelines for the ordering of blood for elective surgery (maximum surgical blood ordering schedules). These are aimed at reducing unnecessary crossmatching, which increases the risk of blood eventually becoming outdated and wasted. Many operations in which blood is required only occasionally for unexpectedly high blood loss can be classified as ‘group and save’; this means that, where the antibody screen is negative, blood is not reserved in advance but can be made available quickly if necessary – that is, in a few minutes – using the electronic crossmatch procedure described. If a patient has atypical antibodies, and is undergoing any procedure or surgery that may result in the need for transfusion, compatible blood should always be reserved in advance; this may take several days if the patient has multiple or unusual antibodies.

**Emergencies**

There may be insufficient time for full pre-transfusion testing. The options include:

- Blood required immediately – 2 units of O RhD-negative blood (‘emergency stock’) are used, to allow additional time for the laboratory to group the patient.
- Blood required in 10–15 min – blood of the same ABO and RhD groups as the patient is used (‘group compatible blood’).
- Blood required in 45 min – most laboratories will be able to provide fully crossmatched blood within this time.

**Complications of blood transfusion**

Reporting schemes under the term ‘haemovigilance’ have been established in many countries, including the Serious Hazards of Transfusion (SHOT) scheme in the UK, which produced its first report in 1997. SHOT reported 136 deaths due to blood transfusion between 2010 and 2017, of which 54% were due to pulmonary complications: predominantly transfusion-associated circulatory overload (TACO; **Box 16.20**). Delays in transfusion were thought to be responsible for 23% of deaths, and other complications of transfusion for the remainder. **Fig. 16.30** shows data from the SHOT reports indicating that ‘incorrect blood component transfused’ is the most frequent type of serious incident; it may result in mortality or serious morbidity, although it is not the most frequent cause of morbidity and mortality. Errors in clinical areas, in either the collection of the blood sample for compatibility testing, the collection of blood from the fridge and/or the administration of blood, are more frequent than laboratory errors.
Prevention of wrong blood transfusions

The potentially serious consequences of errors in transfusion emphasize the need for meticulous procedures. Good training of staff is essential, and regular reviews of practice to ensure compliance with standard procedures are also required. New approaches include the use of barcode patient identification and new technology at the bedside. Handheld devices can prompt staff through the key steps and check that the barcode on the patient’s wristband matches the barcode on the unit of blood (Box 16.21).

Immunological complications

Alloimmunization

Blood transfusion carries a risk of alloimmunization to the many ‘foreign’ antigens present on red cells, leucocytes, platelets and plasma proteins. Alloimmunization also occurs during pregnancy – to fetal antigens inherited from the father and not shared by the mother (see p. 353).

Alloimmunization does not usually cause clinical problems, such as a haemolytic transfusion reaction, with the first transfusion but these may occur with subsequent transfusions. There may also be delayed consequences of alloimmunization, such as HDN and rejection of tissue or organ transplants.

Incompatibility

Transfusion of blood cells, such as red cells and platelets, into a recipient who has antibodies against antigens on the cells may result in poor survival of the transfused cells, and also in harmful effects of the antigen–antibody reaction.

Red cell complications: haemolytic transfusion reaction (immediate)

This is the most serious and life-threatening complication of blood transfusion and is usually due to ABO incompatibility. There is complement activation by the antigen–antibody reaction, usually caused by IgM anti-A and/or anti-B antibodies. The initial symptoms and signs, such as rigors, lumbar pain, dyspnoea, hypotension and haemoglobinuria, may begin a few minutes after starting the transfusion. Renal failure may develop. Activation of coagulation also occurs, and bleeding due to disseminated intravascular coagulation (DIC) is a bad prognostic sign. Emergency treatment for shock (see p. 220) is needed to maintain blood pressure and renal function.

Diagnosis

This is confirmed by finding evidence of haemolysis (e.g. haemoglobinuria), and incompatibility between donor and recipient. All documentation should be checked to detect errors such as:
• failure to check the identity of the patient when taking the sample for compatibility testing (i.e. sample from the wrong patient)
• mislabelling of the blood sample with the wrong patient’s name
• simple labelling or handling errors in the laboratory
• errors in the collection of blood, leading to delivery of the wrong blood to the ward/theatre
• failure to perform proper identity checks before the blood is transfused (i.e. blood transfused to the wrong patient).

Investigations
To confirm where the error occurred, blood grouping should be carried out on:
• the patient’s original sample (used for the compatibility testing)
• a new sample taken from the patient after the reaction
• the donor units.

At the first suspicion of any serious transfusion reaction, the transfusion should always be stopped, and the donor units returned to the blood transfusion laboratory with a new blood sample from the patient to exclude a haemolytic transfusion reaction.

Red cell complications: haemolytic transfusion reaction (delayed)
This occurs in patients alloimmunized by previous transfusions or pregnancies. The antibody level is too low to be detected by pre-transfusion compatibility testing but a secondary immune response is seen after the transfusion, resulting in destruction of the transfused cells, usually by IgG antibodies.

Haemolysis is usually extravascular, as the antibodies are IgG, and the patient may develop anaemia and jaundice about a week after the transfusion, although most episodes are clinically silent. The blood film shows spherocytosis and reticulocytosis. The direct antiglobulin test is positive and detection of the antibody is usually straightforward.

Leucocyte complications: non-haemolytic (febrile) transfusion reactions
The typical cause of febrile reactions after red cell transfusions is the presence of leucocyte antibodies in patients who have previously been transfused or pregnant. Antibodies against donor leucocytes lead to the release of pyrogens. The mechanism of febrile reactions is different after platelet transfusions, where the release of cytokines from donor leucocytes is the most likely cause. Typical signs are flushing and tachycardia, fever (>38°C), chills and rigors, which are uncomfortable for the patient but not life-threatening. Aspirin may be used to reduce the fever, although it should not be given to patients with thrombocytopenia. The routine introduction of leucocyte-reduced blood in the UK to minimize the risk of transmission of variant Creutzfeldt–Jakob disease (vCJD) by blood transfusion (see later) has reduced the incidence of febrile reactions. Universal leucocyte reduction of all blood components is common in European countries, but the proportion of blood components that are leucocyte-reduced is variable across the USA.

Transfusion-related acute lung injury
Potent leucocyte antibodies in the plasma of donors, who are usually multiparous women, may cause transfusion-related acute lung injury (TRALI), characterized by dyspnoea, fever, cough, and shadowing in the perihilar and lower lung fields on the chest X-ray. Prompt respiratory support is essential and mechanical ventilation is frequently necessary. TRALI usually resolves within 48–96 hours but the mortality was 13% in the 305 cases of TRALI reported to SHOT up to 2013. The avoidance of female plasma in the preparation of fresh frozen plasma (FFP) and pooled platelets, and the testing of female platelepheresis donors for leucocyte antibodies have been implemented in many developed countries to reduce the risk of TRALI, and the number of reported cases has reduced considerably.

Transfusion-associated graft-versus-host disease
Transfused donor lymphocytes that share an HLA haplotype with the patient are able to circulate, as they are not rejected; they may recognize the patient as ‘foreign’ and cause an acute GvHD reaction, including pancytopenia. It is usually fatal but no cases have occurred in the UK for many years, probably because of routine leucocyte reduction of blood components. However, certain groups of immunosuppressed patients at particular risk of TA-GvHD should receive irradiated blood to minimize the danger. Such patients include those with congenital or acquired immunodeficiencies: for example, individuals who have had treatment with purine analogue drugs, patients with Hodgkin lymphoma, those who have undergone haemopoietic stem cell transplantation, and fetuses and neonates who have received an intrauterine transfusion.

Platelet complications: post-transfusion purpura
See page 372.

Plasma protein complications: urticaria and anaphylaxis
Urticarial reactions are often attributed to plasma protein incompatibility but, in most cases, they are unexplained. They are common but rarely severe; stopping or slowing the transfusion and administering chlorphenamine 10 mg i.v. are usually sufficient treatment.

Anaphylactic reactions (see p. 64) occasionally occur; severe reactions are seen in patients lacking IgA, who produce anti-IgA that reacts with IgA in the transfused blood. The transfusion should be stopped and adrenaline (epinephrine) 0.5 mg i.m. and chlorphenamine 10 mg i.v. should be given immediately; endotracheal intubation may be required. Patients who have had severe urticarial or anaphylactic reactions should receive washed red cells, or blood from IgA-deficient donors for patients with IgA deficiency.

Immunosuppression
Transfusions are known to have a negative effect on the survival of subsequent renal allografts, due to transfusion-induced immunomodulation. The precise mechanism is unclear but may be associated with the transfusion of allogeneic leucocytes. Other possible clinical effects caused by transfusion-induced immunosuppression, such as an increase in postoperative infection and tumour recurrence, have been proposed but remain unproven.

Non-immunological complications

Transmission of infection
While stringent measures are being taken to minimize the risk of transfusion-transmitted infection, it may never be possible to guarantee that donor blood is absolutely ‘safe’. The current approach to the safety of blood components and plasma in the UK and other developed countries is cautious but it is not an absolute guarantee of safety. Clinicians should always consider the patient’s requirement for transfusion carefully, and only transfuse if clinically appropriate (see later).

Viral transmission
Donor blood in the UK is currently tested for hepatitis B virus (HBV), hepatitis C virus (HCV), hepatitis E virus (HEV), human
immunodeficiency virus (HIV)-1 and human T-cell leukaemia (or lymphotropic) virus 1 (HTLV-1). CMV-seronegative blood is given to fetuses, neonates and pregnant women. Blood services continue a vigilant search for new infectious agents (‘emerging’ infections) that may be transmitted by blood transfusion and for methods to prevent their transmission, including donor screening, testing and pathogen inactivation. Donor questionnaires record recent travel to exclude possible risk of West Nile virus (WNV), the causal agent of meningoencephalitis, which has been transmitted by transfusion and transplantation in the USA, or Zika virus in light of the 2015-16 epidemic.

The risk of transmission of viral infections by blood transfusion varies from country to country, depending on factors such as the underlying prevalence of transfusion-transmitted infections in the population and the measures taken to minimize the risk of transmission. Viral transmission via blood transfusion is still a major issue in lower income countries. In the UK, the risk of transmission of HIV by blood transfusion is extremely low: less than 1 in 19 million units transfused. Prevention is based on self-exclusion of donors in ‘high-risk’ groups and testing of each donation for anti-HIV. The risk of transmission of HBV is less than 1 in 2 million units transfused. There have been no cases of transmission of HCV in the UK since 2010. Various measures, including treatment with solvents and detergents, are used for inactivating viruses in plasma products, such as coagulation factor concentrates or intravenous immunoglobulin.

**Bacterial transmission**

Bacterial contamination of blood components is rare but it is one of the most frequent causes of death associated with transfusion. Some organisms, such as *Yersinia enterocolitica*, can proliferate in red cell concentrates stored at 4°C, but platelet concentrates stored at 22°C are a more frequent cause of contamination. Measures to avoid bacterial contamination include strict donor arm cleansing, diversion of the initial blood collection to samples for testing rather than into the collection bag, and bacterial detection systems for platelet concentrates, which have been implemented in most developed countries. Such systems were implemented in the UK in 2011, and there have been no cases of bacterial transfusion-transmitted infections since 2017.

**Transfusion-transmitted syphilis** is very rare. Spirochaetes do not survive for more than 72 hours in blood stored at 4°C, and each donation is tested using the *Treponema pallidum haemagglutination assay* (TPHA).

**Variant Creutzfeldt–Jakob disease**

In the UK, four transmissions of vCJD occurred following a blood transfusion; the last one was reported in 2004. A number of measures were taken to minimize the risk, including universal leucocyte reduction of blood components in 1999 because the prion protein was thought to be primarily associated with lymphocytes. Blood donors are excluded if they have had a blood transfusion since 1980. UK donor plasma is not used for the manufacture of blood products; imported plasma from the USA is employed instead. For children under the age of 16 years, FFP is sourced from plasma (from unremunerated donors) imported from the USA, on the basis that exposure to bovine spongiform encephalitis (BSE) from food was eliminated by 1 January 1996. FFP for this group is treated with methylthioninium chloride (methylene blue) to inactivate viruses.

**Transfusion-associated circulatory overload**

See page 1077.

---

**Iron overload**

See page 343.

**STRATEGIES FOR THE AVOIDANCE OF UNNECESSARY TRANSFUSION**

These include:

- strict evidence-based criteria for the use of blood components and blood products, both the threshold (‘trigger’) for decision-making about the need for transfusion, e.g. haemoglobin concentration or platelet count, and the dose; single-unit transfusions are often sufficient to raise the patient’s blood count above the threshold for transfusion (‘Don’t use 2 when 1 will do’)
- discontinuing drug therapy such as anticoagulants and anti-platelet drugs wherever possible, as these may potentiate bleeding in surgical patients
- identification and treatment of anaemia prior to surgery and in pregnancy
- use of antifibrinolytic drugs, e.g. tranexamic acid in major surgery
- use of intraoperative cell salvage of blood in major surgery.

Artificial haemoglobin solutions and other blood substitutes suitable for routine clinical use have not yet been developed. They generally have a short intravascular half-life, and a recent meta-analysis found a significant risk of mortality and myocardial infarction.

**Autologous transfusion**

An alternative to using blood from volunteer donors is to use the patient’s own blood. There are three types of autologous transfusion:

- **Predeposit.** The patient donates 2–5 units of blood at approximately weekly intervals before elective surgery.
- **Preoperative haemodilution.** Immediately before surgery, 1 or 2 units of blood are removed from the patient and then retransfused to replace operative losses.
- **Blood salvage.** Blood lost during or after surgery may be collected and retransfused. Several techniques of varying levels of sophistication are available. The operative site must be free of bacteria and bowel contents. Salvage was thought to be contraindicated in cancer surgery because of the risk of facilitating metastases but many centres are using it with apparent safety in this setting.

The use of predeposit autologous transfusion was largely driven by concerns about transfusion-transmitted infection, particularly in the USA. It has been abandoned in the UK and in most developed countries, except for rare cases when it is not possible to identify compatible blood because of multiple antibodies. There is little evidence that predeposit autologous transfusion reduces blood requirements, and blood is perceived as being ‘safe’. Blood salvage is increasingly being employed as a way of avoiding the use of donor blood. In developing countries, autologous blood and blood from relatives are commonly chosen because of a lack of donor blood.

**BLOOD, BLOOD COMPONENTS AND BLOOD PRODUCTS**

Most blood collected from donors is processed as follows:

- **Blood components,** such as red cell and platelet concentrates, FFP and cryoprecipitate, are prepared from a single donation of blood by simple separation methods such as centrifugation and...
are transfused without further processing. Platelet concentrates are also prepared by plateletpheresis (see later).

- **Blood products**, such as coagulation factor concentrates, albumin and immunoglobulin solutions, are prepared by complex processes using the plasma from many donors as the starting material (UK donor plasma is not used; see earlier).

In most circumstances, it is preferable to transfuse only the blood component or product required by the patient (‘component therapy’) rather than using whole blood. This is the most effective way of using donor blood, which is a scarce resource, and reduces the risk of complications from transfusion of unnecessary components of the blood.

Patients should be provided with information about blood transfusion wherever possible, and given the opportunity to ask questions: for example, about alternatives to transfusion. This discussion should be documented. Some patients, such as Jehovah’s Witnesses, may refuse transfusion and need specialized management when they undergo surgery or receive medical treatments that usually require blood transfusion.

**Whole blood**

A unit of whole blood consists of 450 mL±10% of blood from a suitable donor plus 63 mL of anticoagulant, which is then leukocyte-depleted. Blood stored at 4°C is given a ‘shelf-life’ of 5 weeks in the UK (6 weeks in other some countries), when at least 70% of the transfused red cells should survive normally. Whole blood is rarely used for transfusion, as donated blood is processed into red cell concentrates and other blood components. However, there is renewed interest in considering its use in major haemorrhage.

**Red cell concentrates**

Virtually all the plasma is removed and is replaced by about 100 mL of an optimal additive solution, such as SAG-M, which contains sodium chloride, adenine, glucose and mannitol. The mean volume is about 330 mL. The PCV is about 0.57 L/L but the viscosity is low, as there are no plasma proteins in the additive solution; this allows fast administration, if necessary.

Red cell concentrates are used to increase the oxygen-carrying capacity of patients with major haemorrhage, and to treat non-bleeding patients with severe anaemia by maintaining the haemoglobin above 70 g/L; a higher threshold – haemoglobin of 90 g/L, say – is used in severe cardiovascular disease. Algorithms for the management of major haemorrhage highlight the need for the early transfusion of FFP and platelets to support haemostasis (Fig. 16.31).

**Washed red cell concentrates**

These are preparations of red cells suspended in saline, produced by cell separators that remove all but traces of plasma proteins. They are used in patients who have had severe recurrent urticarial or anaphylactic reactions.

**Platelet concentrates**

These are prepared either by centrifugation of whole blood or by plateletpheresis of blood from single donors using cell separators. They may be stored for up to 7 days at 22°C with agitation and bacterial culture to minimize the risk of bacterial transmission. They are used to treat bleeding in patients with severe thrombocytopenia, and prophylactically to prevent bleeding in patients with bone marrow failure when the platelet count is <10 x 10^9/L.

**Granulocyte concentrates**

These are prepared from whole blood as ‘buffy coats’ or from blood from single donors using cell separators, and are used for patients with severe neutropenia when there is evidence of bacterial infection. The numbers of granulocytes collected may be increased by treating donors with G-CSF and steroids. The half-life of granulocytes is of the order of a few hours only and thus granulocytes need to be collected and transfused on a daily basis, making the practicalities of this treatment challenging.

**Fresh frozen plasma**

FFP is prepared by freezing the plasma from 1 unit of blood to −30°C to maintain the concentration of coagulation factors. The volume is approximately 200 mL. FFP contains all the coagulation factors present in fresh plasma and is used mostly for replacement of coagulation factors in acquired coagulation factor deficiencies, such as massive haemorrhage and DIC. It may be further treated by a pathogen-inactivation process – for example, methylene blue or solvent detergent – to minimize the risk of disease transmission. For children, see page 362.

**Prothrombin complex concentrates**

These contain factors II, VII, IX and X, and have replaced FFP as the recommended treatment for rapid reversal of warfarin overdose in patients with an elevated international normalized ratio (INR) and bleeding because of their superior efficacy and lower risk of allergic reactions and volume overload.

**Cryoprecipitate**

This is obtained by allowing the frozen plasma from a single donation to thaw at 4–8°C and removing the supernatant. The typical adult dose is 2 pools each containing 5 donor units. Cryoprecipitate contains factor VIII:C, von Willebrand factor (VWF) and fibrinogen, and may be useful in DIC and other conditions where the fibrinogen level is very low. Fibrinogen concentrates are now available, and are increasingly being used for the treatment of patients with acquired disorders of haemostasis.

**Specific coagulation factor concentrates**

Specific factor concentrates are available for factors VII, VIII, IX, X, XI, XIII and VWF. These are freeze-dried preparations of the specific factor prepared from large pools of plasma. All products come from plasma sources at low risk of vCJD and are virus-inactivated during manufacture with either heat or chemicals. They are used for treating patients with inherited coagulation factor deficiencies, where recombinant coagulation factor concentrates are unavailable (see p. 375).

**Albumin**

There are two preparations:

- **Human albumin solution 4.5%** contains 45 g/L albumin and 160 mmol/L sodium. It is available in 50, 100, 250 and 500 mL bottles.
- **Human albumin solution 20%** contains approximately 200 g/L albumin and 130 mmol/L sodium. It is available in 50 and 100 mL bottles.

Human albumin solutions are considered to be inappropriate fluids for acute volume replacement or the treatment of shock. However, they are indicated for treatment of acute severe hypalbuminaemia and as the replacement fluid for plasma exchange. The 20% albumin solution is particularly useful for patients with nephrotic syndrome or liver disease who are fluid-overloaded and resistant to diuretics.

**Normal immunoglobulin**

This is prepared from normal plasma. It is used to treat hypogammaglobulinaemia, prevent infections, and in high doses to treat
patients with autoimmune disorders: for example, immune thrombocytopenic purpura (see p. 374).

**Specific immunoglobulins**

These are obtained from donors with high titres of antibodies. Many preparations are available, such as anti-D, anti-hepatitis B and anti-varicella zoster.

**Therapeutic use of haemopoietic stem cell transplantation**

The use of haemopoietic stem cells to regenerate the bone marrow of patients whose own, usually diseased, marrow has been ablated by radiation and/or chemotherapy is the first and, to date, the only routine ‘stem cell therapy’ in clinical practice. Haemopoietic stem cell transplantation (HSCT) is used in a range of haematological malignancies, and occasionally in other cancers and non-malignant disorders, such as sickle cell disease. It relies on the regenerative potential of transfused haemopoietic stem cells to repopulate the marrow niche that has been rendered temporarily or permanently hypoplastic by chemotherapy with or without additional radiotherapy. Such procedures vary in the source of the stem cells (Box 16.22) and in the type and intensity of the preparatory conditioning regimen.

**Autologous stem cell transplantation**

Most anticancer drugs have a sigmoid dose–response relationship, which suggests that, up to a point, a higher dose of a cytotoxic drug will induce a greater response. However, increasing a cytotoxic drug dose is often not possible owing to toxicity. For those chemotherapeutic agents with a dose-limiting toxicity of bone marrow failure, infusion of previously harvested...
haemopoietic stem cells is able to ‘rescue’ the haemopoietic system and permits the use of higher doses to overcome tumour drug resistance. Haemopoietic stem cells are collected either from the patient’s bone marrow or, more commonly, from the peripheral blood by leucopheresis, following stem cell mobilization from the marrow niche by the administration of the growth factor G-CSF (see p. 324), with or without chemotherapy. These stem cells are stored by cryopreservation and then re-infused intravenously after an intensive chemotherapy regimen. This approach has been particularly effective in relapsed lymphomas, myeloma, and germ cell tumours, and the large majority of HSCT procedures are carried out to treat these conditions. However, tumour contamination of the re-infused stem cells remains a reality. The infused stem cells take a period of 2–4 weeks to regenerate normal blood cell production, and therefore patients undergoing autologous HSCT experience a prolonged period of severe cytopenias and immunosuppression, with a consequent treatment-related mortality in the region of 1–5%.

**Allogeneic HSCT**

**Conventional myeloablative allogeneic HSCT**

Conventional myeloablative allogeneic HSCT combines the cytotoxic effect of high-dose chemotherapy and/or radiotherapy with a potent immunotherapy effect. Historically, the transplantation of donor haemopoietic cells has been combined with myeloablative chemotherapy with or without radiotherapy, with the dual effects of treating the malignancy and causing temporary immunosuppression that allows the graft to ‘take’. Donors are usually fully matched at the major HLA antigens. Thus siblings are more likely to be found to be potential donors (25% chance for each sibling) than unrelated volunteers, who have to be carefully selected by HLA matching using large sample registries of potential donors. Allogeneic transplantation has been successfully used in a number of haemopoietic malignancies: most commonly, acute leukaemias. Engraftment of the donor immune system, with anti-tumour activity (graft-versus-tumour), is primarily responsible for the increased effectiveness of this approach. Complications include GvHD, an alloimmune reaction of the donor cells against normal host organs, which can affect 30–50% of transplant recipients and is potentially fatal. Immunosuppression, both from conditioning therapy and from the immunosuppressive drugs (ciclosporin or tacrolimus) given to prevent GvHD, results in a high incidence of opportunistic infection and viral reactivation, such as CMV. All patients receive prophylactic antibacterial, antifungal and antiviral drugs. Mortality from conventional allogeneic stem cell transplantation is therefore a major problem, with 15–40% at risk of dying from the procedure, depending on the age and status of the recipient and the degree of HLA compatibility of the donor. The use of donor lymphocyte infusions following allogeneic HSCT, while losing some of the specificity, has produced the strongest evidence for the efficacy of immunotherapy via graft-versus-tumour activity with clinical remissions observed, albeit with a risk of triggering GvHD.

**Non-myeloablative allogeneic HSCT**

The considerable toxicity associated with conventional myeloablative allogeneic HSCT limits use of the procedure to younger patients. This is problematic, as many haematological malignancies for which allogeneic HSCT is indicated primarily affect older patients. To address this, allogeneic HSCT approaches using ‘reduced-intensity conditioning’ have been developed since the turn of the century and are based on drugs such as fludarabine, which are primarily immunosuppressive rather than myeloablative. This maintains the anticancer ‘graft-versus-leukaemia’ effect of the transplant without the toxicity of conventional allogeneic stem cell transplantation. Treatment-related mortality is lower and the technique can be used successfully, particularly in the elderly and those with co-morbidities. GvHD remains an obstacle to success, however. Non-myeloablative allogeneic transplants are now more common than conventional myeloablative HSCT procedures.

**Further reading**

**THE WHITE CELL**

The five types of leucocyte found in peripheral blood are: neutrophils, eosinophils and basophils (all called granulocytes), and lymphocytes and monocytes (see also Ch. 3). The development of these cells is shown in Fig. 16.1.

**Neutrophils**

The earliest morphologically identifiable precursors of neutrophils in the bone marrow are myeloblasts, large cells constituting up to 3% of the nucleated cells in the marrow. The nucleus is large and contains 2–5 nuclei. The cytoplasm is scanty and contains no granules. Promyelocytes are similar to myeloblasts but have some primary cytoplasmic granules, containing enzymes such as myeloperoxidase. Myelocytes are smaller cells without nuclei but with more abundant cytoplasm and both primary and secondary granules. Indentation of the nucleus marks the change from myelocyte to metamyelocyte. The mature neutrophil is a smaller cell with a nucleus that has 2–5 lobes, with predominantly secondary granules in the cytoplasm, which contain lysozyme, collagenase and lactoferrin.

Peripheral blood neutrophils are equally distributed into a circulating pool and a margaining pool lying along the endothelium.
of blood vessels. In contrast to the prolonged maturation time of about 10 days for neutrophils in the bone marrow, their half-life in the peripheral blood is extremely short: only 6–8 hours. In response to stimuli (e.g. infection, corticosteroid therapy), neutrophils are released into the circulating pool from both the maturing pool and the marrow. Immature white cells are released from the marrow when a rapid response (within hours) occurs in acute infection (described as a ‘shift to the left’ on a blood film).

**Function**
The prime function of neutrophils is to ingest and kill bacteria, fungi and damaged cells. Neutrophils are attracted to sites of infection or inflammation by chemotaxis. Recognition of foreign or dead material is aided by the coating of particles with immunoglobulin and complement (opsonization), as neutrophils have Fc and C3b receptors (see p. 44). The material is ingested into vacuoles, where it is subjected to enzymic destruction; this is either oxygen-dependent, with the generation of hydrogen peroxide (myeloperoxidase), or oxygen-independent (lysosomal enzymes and lactoferrin). Leucocyte alkaline phosphatase (LAP) is an enzyme found in leucocytes. It is raised when there is a neutrophilia due to an acute illness. It is also raised in polycythaemia and myelofibrosis, and reduced in chronic myeloid leukaemia.

**Neutrophil leucocytosis**
A rise in the number of circulating neutrophils to more than $10 \times 10^9/L$ occurs in bacterial infections or is a result of tissue damage. It may also be seen in pregnancy, during exercise, secondary to smoking and after corticosteroid administration (Box 16.23). With any tissue necrosis, there is a release of various soluble factors, causing a leucocytosis. Interleukin 1 is also released in tissue necrosis and causes a pyrexia. The pyrexia and leucocytosis that accompany a myocardial infarction are a good example of this and may be wrongly attributed to infection.

A **leucocytoblastic blood film** (an overproduction of white cells, with many immature cells and nucleated red cells) may occur in severe infection, tuberculosis, malignant infiltration of the bone marrow, and occasionally after haemorrhage, haemolysis and severe haemolytic or megaloblastic anaemia.

**Neutropenia and agranulocytosis**
Neutropenia is defined as a circulatory neutrophil count of less than $1.5 \times 10^9/L$. The causes are given in Box 16.24. A virtual absence of neutrophils is called agranulocytosis. Note that patients from African and Caribbean backgrounds may have somewhat lower neutrophil counts, termed ‘ethnic neutropenia’. This is due to a greater proportion of the neutrophils residing close to the vessel walls and not an absolute reduction in total neutrophil production or function.

Neutropenia caused by viruses is probably the most common type. Chemotherapy and radiotherapy predictably produce neutropenia; many other drugs (e.g. anti-thyroid drugs such as carbimazole, and some antibiotics) have been known to produce an idiosyncratic cytopenia and a drug cause should always be considered.

**Clinical features**
Infections may be frequent, are often serious, and become more likely as the neutrophil count falls. An absolute neutrophil count of less than $0.5 \times 10^9/L$ is regarded as ‘severe’ neutropenia and may be associated with life-threatening infections, such as pneumonia and septicaemia. A characteristic glazed mucositis occurs in the mouth, and ulceration is common.

**Box 16.23 Causes of a neutrophil leucocytosis**
- Bacterial infections
- Tissue necrosis, e.g. myocardial infarction, trauma
- Inflammation, e.g. gout, rheumatoid arthritis
- Drugs, e.g. corticosteroids, lithium
- Acute haemorrhage or haemolysis
- Administration of granulocyte colony-stimulating factor (G-CSF)
- Haematological:
  - Myeloproliferative disease
  - Leucocytoblastic leukaemia (see text)
- Physiological, e.g. pregnancy, exercise
- Malignant disease, e.g. bronchial, breast, gastric
- Metabolic, e.g. renal failure, acidosis
- Congenital, e.g. leucocyte adhesion deficiency, hereditary neutrophilia
- Smoking

**Investigations**
The blood film shows marked neutropenia. The appearance of the bone marrow will indicate whether the neutropenia is due to depressed production or increased destruction of neutrophils. Neutrophil antibody studies are performed if an immune mechanism is suspected. Viral serology, in particular for HIV, should be undertaken.

**Management**
Antibiotics should be given as necessary to patients with acute severe neutropenia (see p. 116). Exposure to infections should be minimized.

If the neutropenia seems likely to have been caused by a drug, all current drug therapy should be stopped. Recovery of the neutrophil count usually occurs after about 10 days. G-CSF (see p. 324) is used to decrease the period of neutropenia after chemotherapy and haemopoietic transplantation. It is also employed successfully in the treatment of chronic neutropenia.

Steroids and high-dose intravenous immunoglobulin are used to treat patients with severe autoimmune neutropenia and recurrent infections, and G-CSF has produced responses in some cases.

**Eosinophils**
Eosinophils are slightly larger than neutrophils and are characterized by a nucleus, usually with two lobes, and large cytoplasmic granules that stain deep red. The eosinophil plays a part in allergic responses (see p. 45) and in the defence against infections with helminths and protozoa.
Lymphocytes (lymphocyte count $>$ 5 × 10⁹/L) occur in response to viral infections, particularly EBV, CMV and HIV, and chronic infections such as tuberculosis and toxoplasmosis. It is also found in chronic lymphocytic leukaemia and in some lymphomas.

**Basophils**

The nucleus of basophils is similar to that of neutrophils but the cytoplasm is filled with large, black granules. The granules contain histamine, heparin and enzymes such as myeloperoxidase. The physiological role of the basophil is not known. Binding of IgE causes the cells to degranulate and release histamine and other contents involved in acute hypersensitivity reactions (see p. 62).

Basophils are usually few in number ($<$ 1 × 10⁹/L) but are significantly increased in some myeloproliferative disorders, such as chronic myeloid leukaemia. Basophilia should prompt further investigations.

**Monocytes**

Monocytes are slightly larger than neutrophils. The nucleus has a variable shape and may be round, indented or lobulated. The cytoplasm contains fewer granules than neutrophils. Monocytes are precursors of tissue macrophages and dendritic cells; they spend only a few hours in the blood but can continue to proliferate in the tissues for many years.

A monocytosis ($>$ 0.8 × 10⁹/L) may be seen in chronic bacterial infections, such as tuberculosis or infective endocarditis, chronic neutropenia and myelodysplasia, particularly chronic myelomonocytic leukaemia.

**Lymphocytes**

Lymphocytes form nearly half of circulating white cells. They descend from pluripotent stem cells (see Fig. 16.1). Circulating lymphocytes are small cells, a little larger than red cells, with a dark-staining central nucleus. There are two main types: T and B lymphocytes (see p. 43).

Lymphocytosis (lymphocyte count $>$ 5 × 10⁹/L) occurs in response to viral infections, particularly EBV, CMV and HIV, and chronic infections such as tuberculosis and toxoplasmosis. It is also found in chronic lymphocytic leukaemia and in some lymphomas.

**HAEMOSTASIS**

The integrity of the circulation is maintained by blood flowing through intact vessels lined by endothelial cells. Haemostasis is the host defence mechanism that protects this integrity after injury to the vessel wall and tissue injury. It is a complex process that depends on interactions between the vessel wall, leucocytes, platelets, and coagulation and fibrinolytic mechanisms. Haemostatic systems are normally quiescent but, following tissue injury, become rapidly activated. The formation of the haemostatic plug is shown in Fig. 16.32.

**Vessel wall**

The vessel wall is lined by endothelium, which, in normal conditions, prevents platelet adhesion and thrombus formation. This property is partly due to its negative charge but also to:

- thrombomodulin and heparan sulphate expression
- synthesis of prostacyclin (prostaglandin I₂, PGI₂) and nitric oxide (NO), which cause vasodilation and inhibit platelet aggregation
- production of plasminogen activator.

Injury to vessels causes reflex vasoconstriction, while endothelial damage results in loss of antithrombotic properties, activation of platelets and coagulation, and inhibition of fibrinolysis (see Fig. 16.32).

**Platelets**

**Platelet adhesion**

When the vessel wall is damaged, the escaping platelets come into contact with and adhere to collagen and subendothelial bound VWF. This adherence is mediated through glycoprotein Ib (GPIb). Glycoprotein Ib/IIa is then exposed, forming a second binding site for VWF. Within seconds of adhesion to the vessel wall, platelets begin to undergo a shape change from a disc to a sphere, spread along the subendothelium, and release the contents of their cytoplasmic granules. These are the dense bodies (containing adenosine diphosphate (ADP) and serotonin) and the α-granules (containing platelet-derived growth factor, platelet factor 4, β-thromboglobulin, fibrinogen, VWF, fibronectin, thrombospondin and other factors).

**Platelet activation**

The release of ADP leads to a conformational change in the fibrinogen receptor, the glycoprotein Ib/IIa complex (GPIIb/IIIa), on the surfaces of adherent platelets, allowing it to bind to fibrinogen (Fig. 16.33).

**Platelet aggregation**

As fibrinogen is a dimer, it can form a direct bridge between platelets and so binds platelets into activated aggregates (platelet aggregation; see Fig. 16.32B), and further platelet release of ADP occurs. A self-perpetuating cycle of events is set up, leading to formation of a platelet plug at the site of the injury.
Coagulation

After platelet aggregation and release of ADP, the exposed platelet membrane phospholipids are available for the assembly of coagulation factor enzyme complexes (tenase and prothrombinase). The presence of thrombin encourages fusion of platelets, and fibrin formation reinforces the stability of the platelet plug. Central to normal platelet function is prostaglandin synthesis, which is induced by platelet activation and leads to the formation of thromboxane A\(_2\) (TXA\(_2\)) in platelets (Fig. 16.34). TXA\(_2\) is a powerful vasoconstrictor and also lowers cyclic adenosine monophosphate (AMP) levels and initiates the platelet release reaction. Prostacyclin (PGI\(_2\)) is synthesized in vascular endothelial cells and opposes the actions of TXA\(_2\). It produces vasodilation and increases the level of cyclic AMP, preventing platelet aggregation on the normal vessel wall, as well as limiting the extent of the initial platelet plug after injury.

Coagulation and fibrinolysis

Coagulation involves a series of enzymatic reactions that lead to the conversion of soluble plasma fibrinogen to fibrin-based clot (Fig. 16.35). Roman numerals are used for most of the factors, but I and II are referred to as fibrinogen and prothrombin, respectively; III, IV and VI are redundant. The active forms are denoted by ‘a’. The coagulation factors are primarily synthesized in the liver and are either serine protease enzyme precursors (factors IX, X and XI, and thrombin) or co-factors (V and VIII), except for fibrinogen, which is polymerized to form fibrin.

Coagulation pathway

This enzymatic amplification system was traditionally divided into ‘extrinsic’ and ‘intrinsic’ pathways. This concept is useful for the interpretation of clinical laboratory tests, such as the prothrombin time (PT) and activated partial thromboplastin time (APTT) (see Fig. 16.39), but is unrepresentative and oversimplifies in vivo coagulation. Coagulation is initiated by tissue damage (see Fig. 16.35):

- Tissue damage exposes tissue factor (TF), which binds to factor VII.
- The TF–factor VII complex directly converts factor X to active factor Xa, and some factor IX to factor IXa.
- In the presence of factor Xa, tissue factor pathway inhibitor (TFPI) inhibits further generation of factor Xa and factor IXa.
- Following inhibition by TFPI, the amount of factor Xa produced is insufficient to maintain coagulation. Further factor Xa, to allow haemostasis to progress to completion, can be generated only by the alternative factor IX/factor VIII pathway. However, enough thrombin exists at this point to activate factor VIII, which dramatically increases the activity of factor IXa (generated by TF–factor VIIa), so further activation of factor X can proceed. Without the amplification and consolidating action of factor VIII/factor IX, bleeding will ensue, as generation of factor Xa is insufficient to sustain haemostasis.
- Similarly, thrombin activates factor V, dramatically enhancing the conversion of prothrombin to thrombin by factor Xa.
- Thrombin hydrolyses the peptide bonds of fibrinogen, releasing fibrinopeptides A and B, and allowing polymerization between fibrinogen molecules to form fibrin. At the same time, thrombin, in the presence of calcium ions, activates factor XIII, which stabilizes the fibrin clot by cross-linking adjacent fibrin molecules.

---

**Fig. 16.32** Formation of the haemostatic plug: sequential interactions between the vessel wall, platelets and coagulation factors. (A) Contact of platelets with collagen via the platelet receptor glycoprotein IIb (GPIb) and von Willebrand factor (VWF) in plasma activates platelet prostaglandin synthesis, which stimulates release of adenosine diphosphate (ADP) from the dense bodies. Vasoconstriction of the vessel occurs as a reflex and by release of serotonin and thromboxane A\(_2\) (TXA\(_2\)) from platelets. (B) Release of ADP from platelets induces platelet aggregation and formation of the platelet plug. The coagulation pathway is stimulated, leading to the formation of fibrin. (C) Fibrin strands are cross-linked by factor XIII and stabilize the haemostatic plug by binding platelets and red cells.
Factor VIII
Factor VIII is a key co-factor in the coagulation pathway. It is associated with its carrier protein VWF. When activated, factor VIII increases the conversion of factor X to Xa by factor IXa by approximately 200,000-fold. VWF functions to protect factor VIII from premature proteolytic breakdown and locates it to areas of vascular injury. Factor VIII:C has a molecular weight of about 350 kDa.

Von Willebrand factor
VWF is a glycoprotein with a monomeric molecular weight of about 250 kDa, which readily forms multimers in the circulation with molecular weights of up to 20,000 kDa. It is synthesized by endothelial cells and megakaryocytes, and stored in platelet granules as well as endothelial cells. The high-molecular-weight multimeric forms of VWF are the most biologically active (see p. 376 and Fig. 16.40). It has a primary role as an adhesive protein binding to platelets, surface glycoproteins and constituents of connective tissue. It also acts as a carrier protein for factor VIII.

Factor V
Factor V is similar to factor VIII in that it is a non-enzymatic co-factor. In its thrombin-activated form, factor Va, it significantly enhances the conversion of prothrombin to thrombin.

Physiological limitation of coagulation
Without a physiological system to limit blood coagulation, excessive thrombosis could ensue. The natural anticoagulant mechanism regulates and localizes thrombosis to the site of injury.

Antithrombin
Antithrombin (AT), a member of the serine protease inhibitor (serpin) superfamily, is a potent inhibitor of coagulation. It inactivates the serine proteases by forming stable complexes with them, and its action is greatly potentiated by heparin.

Activated protein C
This is generated from its vitamin K-dependent precursor, protein C, by thrombin; thrombin activation of protein C is greatly enhanced when thrombin is bound to thrombomodulin on endothelial cells (Fig. 16.36). Activated protein C inactivates factor Va and factor VIIIa, reducing further thrombin generation.
Protein S
This is a co-factor for protein C, which acts by enhancing binding of activated protein C to the phospholipid surface. It circulates bound to C4b binding protein but some 30–40% remains unbound and active (free protein S).

Other inhibitors
Other natural inhibitors of coagulation include \( \alpha_2 \)-macroglobulin, \( \alpha_1 \)-antitrypsin and \( \alpha_2 \)-antiplasmin.

Fibrinolysis
Fibrinolysis is a normal haemostatic response that helps to restore vessel patency after vascular damage. The principal component is the enzyme plasmin, which is generated from its inactive precursor plasminogen (Fig. 16.37). This is achieved principally via tissue plasminogen activator (t-PA) released from endothelial cells. Some plasminogen activation may also be promoted by urokinase, produced in the kidneys. Other plasminogen activators (factor XII and prekallikrein) are of minor physiological importance.

Plasmin
Plasmin is a serine protease, which breaks down fibrinogen and fibrin into fragments X, Y, D and E, collectively known as fibrin (and fibrinogen) degradation products (FDPs), D-dimer is produced when cross-linked fibrin is degraded. Its presence in the plasma indicates that the coagulation mechanism has been activated.

Fibrinolytic system
This is activated by the presence of fibrin. Plasminogen is specifically adsorbed to fibrin and fibrinogen by lysine-binding sites. However, little plasminogen activation occurs in the absence of polymerized fibrin, as fibrin also has a specific binding site for plasminogen activators, whereas fibrinogen does not (Fig. 16.38).

Tissue plasminogen activator
This is inactivated by plasminogen activator inhibitor-1 (PAI-1). Activated protein C inactivates PAI-1 and therefore induces fibrinolysis (see Fig. 16.36). Inactivators of plasmin, such as \( \alpha_2 \)-antiplasmin (see Fig. 16.38) and thrombin-activatable fibrinolysis inhibitor (TAFI), also contribute to the regulation of fibrinolysis.

Is there a generalized haemostatic defect?
Supportive evidence for a generalized haemostatic defect includes bleeding from multiple sites, spontaneous bleeding, and excessive bleeding after injury.

Is the defect inherited or acquired?
A family history of a bleeding disorder should be sought. Severe inherited defects usually become apparent in infancy, sometimes at the time of birth with prolonged bleeding from the umbilical cord,
while mild inherited defects may only come to attention later in life; for example, with excessive bleeding after surgery, childbirth, dental extractions or trauma. Some milder defects are revealed by routine coagulation screens that are performed before surgical procedures.

**Is the bleeding suggestive of a vascular/platelet defect or a coagulation defect?**

**Vascular/platelet bleeding**

This is characterized by easy bruising and spontaneous bleeding from small vessels. There is often bleeding into the skin. Purpura includes both petechiae, small skin haemorrhages varying from pinpoint size to a few millimetres in diameter that do not blanch on pressure, and ecchymoses, larger areas of bleeding into the skin. Bleeding also occurs from mucous membranes, especially the nose and mouth.

**Coagulation disorders**

These are typically associated with bleeding after injury or surgery and, in more severe forms, haemarthroses and muscle haematomas. There is often a short delay between the precipitating event and overt haemorrhage or haematoma formation.

**Laboratory investigations**

**Blood count and film**

These show the number and morphology of platelets and any blood disorder, such as leukaemia or lymphoma. The normal range for the platelet count is 150–400 × 10⁹/L.

**Coagulation tests**

These are performed on blood collected into citrate, which neutralizes calcium ions and prevents clotting.

- **The prothrombin time (PT)** (also see p. 1016) is measured by adding tissue factor (thromboplastin) and calcium to the patient’s plasma and establishing the length of time taken for the blood to clot. The normal PT is 11.5–13.5 sec. When used to measure warfarin-based oral anticoagulation, the PT is expressed as the international normalized ratio, or INR (see p. 1016). The PT measures factors VII, X, V, prothrombin and fibrinogen (the classic ‘extrinsic’ pathway, Fig. 16.39), and is prolonged if any of these factors is low. It may also be abnormal in liver disease, or if the patient is on oral anticoagulants, including warfarin and some direct oral anticoagulants that target factor Xa.
- **The activated partial thromboplastin time (APTT)** is also sometimes known as the PTT with kaolin (PTTK). It is measured by adding a surface activator (such as kaolin, micronized silica or ellagic acid), phospholipid (to mimic platelet membrane) and calcium to the patient’s plasma. The normal APTT is 26–37 sec and depends on the exact methodology. The APTT measures factors XII, XI, IX, VIII, X, V, prothrombin and fibrinogen (the classic ‘intrinsic’ pathway), and is prolonged in deficiencies of one or more of these factors. It is not dependent on factor VII.
- **The thrombin time (TT)** is measured by adding thrombin to the patient’s plasma. The normal TT is 12–14 sec; it is prolonged in fibrinogen deficiency, in qualitative defects of fibrinogen (dysfibrinogenaemia) or in the presence of inhibitors such as heparin or FDPs.
- **Correction tests** can be used to differentiate prolonged times in the PT, APTT and TT due to various coagulation factor deficiencies and inhibitors of coagulation. Prolonged PT, APTT or TT due to coagulation factor deficiencies can be corrected by addition of normal plasma to the patient’s plasma. Failure to correct after addition of normal plasma is suggestive of the presence of an inhibitor of coagulation.
- **Factor assays** are used to confirm coagulation defects, especially where a single inherited disorder is suspected.
- **Special tests of coagulation** will often be required to confirm the precise haemostatic defect. Such tests include estimation of fibrinogen and FDPs, platelet function tests such as platelet aggregation, and platelet granule contents.
- **Bleeding time** measures platelet plug formation in vivo. Classically, a sphygmomanometer cuff is inflated to 40 mmHg and, using a template, standardized incisions are made in the forearm. The time taken for bleeding to stop is recorded. Prolonged times are seen in platelet function defects, and when the platelet count is <100 × 10⁹/L. Nowadays, this test is very rarely done, as it can scar and is painful.
VASCULAR DISORDERS

Vascular disorders (Box 16.26) are characterized by easy bruising and bleeding into the skin. Bleeding from mucous membranes sometimes occurs but the bleeding is rarely severe. Laboratory investigations, including the bleeding time, are normal.

Hereditary haemorrhagic telangiectasia

This is a rare disorder with autosomal dominant inheritance. In most cases, mutations occur in one of three genes – ENG, ALK1 or SMAD4 – that encode components of the TGF-β signalling pathway that is involved in blood vessel development. Dilation of capillaries and small arterioles produces characteristic small, red spots that blanch on pressure in the skin and mucous membranes, particularly the nose and gastrointestinal tract. Recurrent epistaxis and chronic gastrointestinal bleeding are the major problems that cause chronic iron deficiency anaemia. Vascular malformations also occur in pulmonary, hepatic cerebral and spinal vasculature.

Easy bruising syndrome

This is a common benign disorder often seen in otherwise healthy women. It is characterized by bruises on the arms, legs and trunk with minor trauma, possibly because of skin vessel fragility. It may give rise to the suspicion of a serious bleeding disorder.

Senile purpura and purpura due to steroids

These are both caused by atrophy of the vascular supporting tissue.

Purpura due to infections

This is mainly caused by damage to the vascular endothelium. The rash of meningococcal septicaemia is particularly characteristic (see Fig. 20.21).

Henoch–Schönlein purpura

This is a mainly a disease of children (see p. 1368). It is a type III hypersensitivity (immune complex) reaction that is often preceded by an acute upper respiratory tract infection. Purpura is seen mainly on the legs and buttocks. Abdominal pain, arthritis, haematuria and rash of meningococcal septicaemia is particularly characteristic.

PLATELET DISORDERS

Bleeding due to thrombocytopenia or abnormal platelet function is characterized by purpura and bleeding from mucous membranes. Bleeding is uncommon with platelet counts of more than 50 × 10⁹/L, and severe spontaneous bleeding is unusual with platelet counts over 20 × 10⁹/L (Box 16.27).

Thrombocytopenia

This is caused by reduced platelet production in the bone marrow, excessive peripheral destruction of platelets or sequestration in an enlarged spleen (Box 16.28). The underlying cause may be revealed

Episodes of inexplicable bleeding or bruising

These may represent abuse, either self-inflicted or caused by others. The various forms of artificial or factitious purpura may be expressions of emotional or psychiatric disturbance.

Impaired production

- Selective megakaryocyte depression:
  - Rare congenital defects
  - Drugs, chemicals and viruses
- As part of a general bone marrow failure:
  - Cytotoxic drugs and chemicals
  - Radiation
  - Megaklastic anaemia
  - Leukaemia
  - Myelodysplastic syndromes
  - Myeloma
  - Myelofibrosis
  - Solid tumour infiltration
  - Aplastic anaemia
  - HIV infection

Excessive destruction or increased consumption

- Autoimmune – immune thrombocytopenic purpura
- Drug-induced, e.g. glycoprotein IIb/IIIa inhibitors, penicillins, thiazides
- Secondary immune (systemic lupus erythematosus, chronic lymphocytic leukaemia, viruses, drugs, e.g. heparin, bivalirudin)
- Alloimmune neonatal thrombocytopenia
- Post-transfusion purpura
- Disseminated intravascular coagulation
- Thrombotic thrombocytopenic purpura

Sequestration

- Splenomegaly
- Hyperplenism

Dilutional

- Massive transfusion

(From Colvin BT. Disorders of haemostasis. Medicine 2004; 32:27–33, with permission from Elsevier)
by history and examination but a bone marrow examination will show whether the numbers of megakaryocytes are reduced, normal or increased, and will provide essential information on morphology. Specific laboratory tests may be useful to confirm the presence of conditions such as PNH or SLE.

**Immune thrombocytopenic purpura**

In immune thrombocytopenic purpura (ITP), thrombocytopenia is due to immune destruction of platelets. The antibody-coated platelets are removed following binding to Fc receptors on macrophages.

**ITP in children**

This occurs most commonly in the 2–6-year age group. ITP has an acute onset with mucocutaneous bleeding and there may be a history of a recent viral infection, including varicella zoster or measles. Although bleeding may be severe, life-threatening haemorrhage is rare (approximately 1%). Bone marrow examination is not usually performed unless there are atypical clinical or laboratory features.

**ITP in adults**

The presentation is usually less acute than in children. ITP is characteristically seen in women and may be associated with other autoimmune disorders such as SLE, thyroid disease and autoimmune haemolytic anaemia (Evans syndrome). It is also seen in patients with chronic lymphocytic leukaemia and solid tumours, and after infections with viruses such as HIV. Platelet autoantibodies are detected in about 60–70% of patients and are presumed to be present, although not detectable, in the remaining patients; the antibodies often have specificity for platelet membrane glycoproteins Iib/IIIa and/or lb.

**Clinical features**

Major haemorrhage is rare and is seen only in patients with severe thrombocytopenia. Easy bruising, purpura, epistaxis and menorrhagia are common. Physical examination is normal except for evidence of bleeding. Splenomegaly is rare.

**Investigations**

The only blood count abnormality is thrombocytopenia. The diagnosis is based on exclusion of other causes of thrombocytopenia using the history, clinical examination, blood count and blood film. Normal or increased numbers of megakaryocytes are found in the bone marrow, but bone marrow examination is unnecessary unless there are unusual findings clinically or on the blood film. The detection of platelet autoantibodies is not essential for confirmation of the diagnosis.

**Management**

**Children**

Children do not usually require treatment, as the thrombocytopenia is short-lived. Treatment should be reserved for serious bleeding or urgent surgery. Where treatment is necessary, corticosteroids and intravenous immunoglobulin are effective in more than 80% of children and raise the count more rapidly than steroids alone. Chronic ITP is unusual in children and requires specialist management.

**Adults**

Patients with platelet counts of more than $30 \times 10^9/L$ generally require no treatment unless they are about to undergo a surgical procedure. Those with even lower platelet counts may not require treatment unless they have spontaneous bruising or bleeding.

**First-line therapy**

This consists of oral corticosteroids (1 mg/kg body weight). Approximately 66% will respond to prednisolone but relapse is common when the dose is reduced. Only 33% of patients can expect a long-term response, and long-term remission is seen in just 10–20% of patients after stopping prednisolone. Patients who fail to respond to corticosteroids or require high doses to maintain a safe platelet count should be considered for splenectomy.

Intravenous immunoglobulin is effective. It raises the platelet count in 75%, and in 50% the platelet count will normalize. Responses are only transient (3–4 weeks), with little evidence of any lasting effect. However, intravenous immunoglobulin is very useful where a rapid rise in platelet count is desired: for example, before surgery.

**Second-line therapy**

Therapies include:

- **Splenectomy**, to which the majority of patients respond; two-thirds will achieve a normal platelet count. About 50% of patients who do not have a complete response can still expect some improvement in the platelet count.
- **Rituximab (anti-CD20)**, to which about 60% of patients respond, although only 15–20% have long-lasting responses.
- **Thrombopoietin receptor agonists**, such as romiplostim and eltrombopag, which drive increased platelet production. They have been shown to increase platelet counts significantly in ITP on a long-term basis and are approved drugs for refractory ITP.
- **Platelet transfusions**, reserved for intracranial or other extreme haemorrhage, where emergency splenectomy may be justified.

**Other immune thrombocytopenias**

**Drugs**

Many drugs have been reported to cause immune thrombocytopenia. The same drugs can be responsible for immune haemolytic anaemia, thrombocytopenia or neutropenia in different patients.

**Heparin-induced thrombocytopenia**

See page 1014.

**Neonatal alloimmune thrombocytopenia**

This condition is due to fetomaternal incompatibility for platelet-specific antigens, usually for human platelet alloantigen 1a (HPA-1a), and is the platelet equivalent of HDN. The mother is HPA-1a-negative and produces antibodies that destroy the HPA-1a-positive fetal platelets. Thrombocytopenia is self-limiting after delivery, but platelet transfusions may be required initially to prevent or treat bleeding associated with severe thrombocytopenia; platelets are prepared from HPA-1a-negative volunteers or the mother herself. Severe bleeding, such as intracranial haemorrhage, may also occur in utero.

Antenatal treatment of the mother – usually with intravenous immunoglobulin and/or steroids – has been effective in preventing haemorrhage in severely affected cases.

**Post-transfusion purpura**

Post-transfusion purpura (PTP) is rare, occurring 7–10 days after a transfusion of platelet-containing blood components, usually red cells. PTP is associated with a platelet-specific alloantibody, usually anti-HPA-1a in an HPA-1a-negative individual. PTP always occurs in patients who have previously been immunized, either by blood transfusion or by pregnancy; hence it is more common in women. The cause of the destruction of the patient’s own platelets is not well understood but they may be destroyed as ‘bystanders’ during
the acute immune response to HPA-1a. PTP is self-limiting; intra-venous immunoglobulin is the treatment of choice if there is severe thrombocytopenia and/or bleeding.

**Thrombotic thrombocytopenic purpura**

Thrombotic thrombocytopenic purpura (TTP) is a rare but very serious condition, in which platelet consumption leads to profound thrombocytopenia. There is a characteristic symptom complex of florid purpura, fever, fluctuating cerebral dysfunction and microangiopathic haemolytic anaemia with red cell fragmentation, often accompanied by acute kidney injury. The coagulation screen is usually normal but LDH levels are markedly raised as a result of haemolysis. TTP stems from endothelial damage and microvascular thrombosis. This occurs due to a reduction in ADAMTS-13 (a disintegrin-like and metalloproteinase domain with thrombospondin-type motifs), a protease that is normally responsible for regulating the size of VWF. ADAMTS-13 is needed to break down ultra-large von Willebrand factor multimers (UL VWFMs) into smaller, haemostatically active fragments that interact with platelets. Reduction in ADAMTS-13 results in the adhesion and aggregation of platelets to UL VWFMs and multilaminar microthrombi. In most sporadic cases, there is a true deficiency of the ADAMTS-13, associated with antibodies to ADAMTS-13. In some congenital cases, the deficiency is due to mutations in the ADAMTS-13 gene. Secondary causes of acute TTP include pregnancy, oral contraceptives, SLE, infection and drug treatment, including the use of ticlopidine and clopido-grel. Such cases may have a variable ADAMTS-13 activity at presentation, and may or may not have associated antibodies to ADAMTS-13.

**Management**

Plasma exchange is the mainstay of treatment. It provides a source of ADAMTS-13 and removes associated autoantibody in acute TTP. Cryoprecipitate and solvent-detergent FFP both contain ADAMTS-13. Pulsed intravenous methylprednisolone is given acutely; increasingly, rituximab is also a primary treatment of choice. Disease activity is monitored by measuring the platelet count and serum LDH. Platelet concentrates are contraindicated. The untreated condition has a mortality of up to 90% but modern management has reduced this figure to about 10%. Recurrent and relapsing TTP occurs, often associated with a persistent lack of ADAMTS-13. In secondary TTP cases, identifiable precipitants of drugs should be stopped. Caplacizumab is a single-variable-domain immunoglobulin directed to the A1 region of the VWF. It inhibits the VWF interaction with glycoprotein Ib and has recently been shown to lead to faster normalization of the platelet count and a lower rate of recurrent TTP.

**Platelet function disorders**

Platelet function disorders (Box 16.29) are usually associated with excessive bruising and bleeding and, in some of the acquired forms, with thrombosis. The platelet count is often normal and the bleeding time is prolonged. The rare inherited defects of platelet function require more detailed investigations, such as platelet aggregation studies and factor VIII and VWF assays, as there is often a clinical overlap in symptoms with von Willebrand disease.

If there is serious bleeding or if the patient is about to undergo surgery, drugs with antiplatelet activity should be withdrawn and any underlying condition should be corrected if possible.

### Box 16.29 Inherited and acquired types of platelet dysfunction

**Inherited**

- **Glanzmann’s thrombasthenia** – lack of platelet membrane glycoprotein Ib/IIa complex, resulting in defective fibrinogen binding and failure of platelet aggregation
- **Bernard-Soulier syndrome** – lack of platelet membrane glycoprotein Ib/IX/V complex (the binding site for von Willebrand factor), causing failure of platelet adhesion and moderate thrombocytopenia
- **Storage pool disease** – lack of the storage pool of platelet dense bodies, causing poor platelet function

**Acquired**

- Myeloproliferative disorders
- Renal and liver disease
- Paraproteinaemias
- Drug-induced, such as with non-steroidal anti-inflammatory drugs (aspirin) or other platelet inhibitory drugs

Platelet dysfunction can be a major component of bleeding in renal disease, although other components are often also seen. The degree of the platelet-related defect is broadly proportional to the plasma urea concentration: platelet function is impaired by urea, guanidinosuccinic acid and other phenolic metabolites that accumulate in chronic kidney disease. Dialysis partially corrects platelet function. The haematocrit should be increased to over 0.30 and non-specific use of desmopressin may be helpful. Platelet transfusions may be required if these measures are unsuccessful or if the risk of bleeding is high.

**Thrombocytosis**

The platelet count may rise above 400 × 10⁹/L as a result of:

- splenectomy
- malignant disease
- inflammatory disorders, such as rheumatoid arthritis and inflammatory bowel disease
- major surgery and haemorrhage
- myeloproliferative disorders
- iron deficiency.

Thus, thrombocytosis is part of the acute-phase reaction, although platelet numbers are also elevated following splenectomy because of the loss of a major site of platelet destruction. **Essential thrombocytocaemia**, a myeloproliferative neoplasm (see p. 394), and other myeloproliferative conditions such as polycythaemia vera, myelofibrosis and chronic myeloid leukaemia, may also be associated with a high platelet count.

A persistently elevated platelet count can lead to arterial or venous thrombosis. It is usual to treat the underlying cause of the thrombocytosis but sometimes a small dose of aspirin (75 mg) is also given. In myeloproliferative diseases, the primary risk is thrombosis and specific action is often taken to reduce the platelet count, usually with hydroxy-carbamide (hydroxyurea). Paradoxically, there is also a risk of abnormal bleeding if the platelet count is very high.

**Further reading**

Inherited coagulation disorders are uncommon and usually involve deficiency of one factor only. Acquired coagulation disorders occur more frequently and almost always involve several coagulation factors (see p. 377).

In inherited coagulation disorders, deficiencies of all factors have been described. Those leading to abnormal bleeding are rare, apart from haemophilia A (factor VIII deficiency), haemophilia B (factor IX deficiency) and von Willebrand's disease.

Haemophilia A

This is due to a lack of factor VIII. VWF is normal in haemophilia (Fig. 16.40). The prevalence of haemophilia A is about 1 in 5000 of the male population. It is inherited as an X-linked disorder. If a female carrier has a son, he has a 50% chance of having haemophilia; a daughter has a 50% chance of being a carrier. All daughters of men with haemophilia are carriers and the sons are normal.

Although a large number of different genetic defects have been found in the factor VIII gene, a common gene inversion in intron 22 is causative in approximately 50% of families with severe disease. There is a high mutation rate, one-third of cases being apparently sporadic with no family history of haemophilia.

Clinical features and investigations

The clinical features depend on the level of factor VIII. The normal level of factor VIII is 50–150 IU/dL.

- Levels of <1 IU/dL (severe haemophilia) are associated with frequent spontaneous bleeding from early life, typically into joints and muscles. Without adequate treatment, such recurrent bleeding into joints leads to crippling joint deformity.
- Levels of 1–5 IU/dL (moderate haemophilia) are associated with severe bleeding following injury and occasional spontaneous bleeds.

Management

Bleeding is treated by administration of factor VIII concentrate by intravenous infusion to achieve normalization of levels. Factor VIII concentrate is available as a plasma-derived or recombinant product. Recombinant products are the treatment of choice but economic constraints often limit availability, particularly in developing countries.

Many patients with severe haemophilia treat themselves at home with regular factor VIII infusions three or more times per week.
to prevent recurrent bleeding into joints and subsequent joint damage. Such ‘prophylaxis’ is usually started in early childhood (around 2 years of age). Otherwise, patients at home may treat as and when they have a bleed: ‘on-demand’ treatment.

For surgery, levels should be kept to normal until healing has occurred; as factor VIII has a half-life of 12 hours, it is often administered twice daily to maintain the required level.

New bioengineered factor VIII products are increasingly being used. They have a half-life approximately 1.5 times that of base factor VIII and can be used either to reduce the frequency of infusion or to improve the level of haemostatic protection.

Gene therapy trials, using adeno-associated virus AAV to transfer a copy of a functional VIII gene, have recently shown considerable promise in the potential management of severe haemophilia A (see p. 34).

For those with milder haemophilia, synthetic vasopressin (desmopressin, an analogue of vasopressin) – intravenous, subcutaneous or intranasal – produces a 3–5-fold rise in factor VIII and VWF levels. It is very useful in patients with a baseline level of factor VIII of over 10 IU/dL. It avoids the complications associated with blood products and is useful for treating and preventing bleeding in mild haemophilia.

People with haemophilia should be registered at a comprehensive care centre (CCC), which takes responsibility for their full medical care, including social and psychological support.

Complications

Up to 30% of people with severe haemophilia will, during their lifetime, develop antibodies to factor VIII that inhibit its action. Such inhibitors usually develop after the first few treatment doses of factor VIII. Inhibitors are relatively rare in moderate and mild haemophilia, and are often associated with specific molecular defects.

Management of inhibitor patients is very difficult, as infused factor VIII is rapidly inactivated. Acute bleeding events require treatment with agents that can bypass factor VIII, such as recombinant factor VIIIa or activated prothrombin complex concentrates. Alternative non-factor VIII replacement therapies using bispecific antibodies that can bind both factor IX and factor X, so partially mimicking factor VIII, have been shown to be highly effective alternative therapies to prevent bleeding in haemophilia A with inhibitors and are increasingly being used. Such treatments can also be effective in patients without inhibitors.

In those recently identified as having developed an inhibitor, the long-term aim is to eradicate the inhibitory antibody. This is done using immune tolerance induction strategies, sometimes with additional immunosuppression, and is successful in around 80% of cases.

Although a historical legacy of plasma-derived concentrates, the risk of viral transmission has been virtually eliminated (see p. 361). Many died as a consequence of HIV and HCV infection, however a considerable number of patients remain that have HIV and/or HCV infection.

Carrier detection and antenatal diagnosis

Owing to lyonization early in embryonic life (i.e. random inactivation of one chromosome; see p. 21), some female carriers may have low levels of factor VIII while others will have normal levels. Carrier detection is, therefore, definitively carried out using molecular genetic testing/mutation analysis. Antenatal diagnosis may be carried out by molecular analysis of chorionic villus biopsy at 11–12 weeks’ gestation if selective termination is being considered, or by third-trimester amniocentesis if not.

Haemophilia B (Christmas disease)

Haemophilia B is caused by a deficiency of factor IX. The inheritance and clinical features are identical to those of haemophilia A, but the incidence is only about 1 in 30000 males. It has been identified as the type of haemophilia that affected the Russian royal family. The half-life of factor IX is longer than that of factor VIII, at 18 hours. Haemophilia B is treated with factor IX concentrates, recombinant factor IX being generally available, and prophylactic doses are given twice a week. New bioengineered factor IX concentrates have a half-life 3–5 times that of regular factor IX. Desmopressin is ineffective. Although gene therapy for severe haemophilia B has offered hope for some time, recent data have demonstrated achievement of near-normal factor IX levels using a variant factor IX gene with increased activity (see p. 34).

Von Willebrand’s disease

von Willebrand’s disease (VWD) is caused by a deficiency or abnormality of VWF (see Fig. 16.40). As VWF has a critical role as an adhesive protein in the platelet vessel wall interaction, the absence of VWF leads to impaired platelet adhesion to the subendothelium. Reduced VWF levels also lead to factor VIII deficiency, as factor VIII is not protected from premature degradation. VWF reduction in VWD therefore leads to a dual haemostatic defect.

The VWF gene is located on chromosome 12 and numerous mutations have been identified. VWD has been classified into three types:

- **Type 1** is partial quantitative deficiency of VWF; significant type 1 VWD is usually inherited as an autosomal dominant.
- **Type 2** is due to a qualitative abnormality of VWF; it too is usually inherited as an autosomal dominant.
- **Type 3** is recessively inherited and patients have virtually complete deficiency of VWF. Their parents are often phenotypically normal.

Many subtypes of VWD are described, particularly type 2 variants, which reflect the specific qualitative changes in the VWF protein.

Clinical features

These are very variable. **Type 1** and **type 2** patients usually have relatively mild clinical features. Bleeding follows minor trauma or surgery, and epistaxis and menorrhagia often occur. Haemarthroses are rare. **Type 3** patients have more severe bleeding but rarely experience the joint and muscle bleeds seen in haemophilia A.

Characteristic laboratory findings are shown in Box 16.30. Classically VWF activity is measured as its platelet dependent function in the presence of ristocetin.

Management

Management depends on the severity of the condition and may be similar to that of mild haemophilia, including the use of desmopressin where possible. Although recombinant VWF is becoming available, plasma-derived factor VIII concentrates that contain intact VWF are the mainstay of replacement therapy. These specific products are used to treat bleeding or to cover surgery in patients who require replacement therapy, such as those with type 3 (severe) VWD and those who do not respond adequately to desmopressin. Cryoprecipitate could be used as a source of VWF but is avoided if possible, since it is not virus-inactivated.

Further reading

Vitamin K deficiency
Vitamin K is necessary for the γ-carboxylation of glutamic acid residues on coagulation factors II, VII, IX and X, and on proteins C and S. Without it, these factors cannot bind calcium. Deficiency of vitamin K (see also p. 1239) may be due to:
- **Inadequate stores**, as in HDN and severe malnutrition, especially when combined with antibiotic treatment
- **Malabsorption of vitamin K**, a fat-soluble vitamin, which occurs in cholestatic jaundice owing to the lack of intraluminal bile salts
- **Oral anticoagulant drugs**, many of which are vitamin K antagonists.

The PT and APTT are prolonged (see Box 16.30) and there may be bruising, haematuria and gastrointestinal or cerebral bleeding. Minor bleeding is treated with phytonadione (vitamin K₃) 10 mg intravenously. Some correction of the PT is usual within 6 hours but it may not return to normal for 2 days.

Newborn babies have low levels of vitamin K and this may cause minor bleeding in the first week of life (*classical haemorrhagic disease of the newborn*). Vitamin K deficiency also causes *late haemorrhagic disease of the newborn*, which occurs 2–26 weeks after birth and results in severe bleeding such as intracranial haemorrhage. Most infants with these syndromes have been exclusively breast-fed, and both conditions are prevented by administering 1 mg i.m. vitamin K to all neonates (see p. 1239). Concerns about the safety of this strategy are unfounded.

Liver disease
Liver disease may result in a number of defects in haemostasis:
- **Vitamin K deficiency**. This occurs owing to intrahepatic or extrahepatic cholestasis.
- **Reduced synthesis**. Reduced synthesis of coagulation factors (including natural anticoagulant proteins) may be the result of severe hepatocellular damage. The use of vitamin K does not improve the results of abnormal coagulation tests, but it is generally given to ensure that a treatable cause of failure of haemostasis has not been missed.
- **Thrombocytopenia**. This results from hypersplenism due to splenomegaly associated with portal hypertension, or from folic acid deficiency.
- **Functional abnormalities**. Functional abnormalities of platelets and fibrinogen are found in many patients with liver failure.

**Disseminated intravascular coagulation**. DIC occurs in acute hepatic failure.

**Disseminated intravascular coagulation**
Disseminated intravascular coagulation (DIC) never occurs in isolation. Recognition that the patient has a clinical disorder that may result in DIC (Box 16.31) is the key to investigation and management. DIC arises because of systemic activation of coagulation either by release of procoagulant material, such as tissue factor, or via cytokine pathways as part of the inflammatory response. Such systemic activation leads to widespread generation of fibrin and deposition in blood vessels, leading to thrombosis and multiorgan failure. Due to the widespread coagulation activation there is consumption of platelets and coagulation factors, and secondary activation of fibrinolysis leading to production of FDPs and D-dimer. These further contribute to the coagulation defect by inhibiting fibrin polymerization (Fig. 16.41). The consequences of these changes are a mixture of initial thrombosis, followed by a bleeding tendency due to consumption of coagulation factors and dysregulated fibrinolytic activation.

**Clinical features**
The underlying disorder is usually obvious. The patient is often acutely ill and shocked. The clinical presentation of DIC varies from no bleeding at all to profound haemostatic failure with widespread haemorrhage. Bleeding may occur from the mouth, nose and venepuncture sites, and there may be widespread ecchymoses.

Thrombotic events occur as a result of vessel occlusion by fibrin and platelets. Any organ may be involved but the skin, brain and kidneys are most often affected.

**Investigations**
The diagnosis needs to encompass both clinical and laboratory aspects. It is often suggested by the underlying condition of the patient. If the patient has an underlying disorder known to be compatible with overt DIC, the International Society on Thrombosis and Haemostasis (ISTH) scoring system is a useful diagnostic tool and provides an objective assessment (Box 16.32).

In severe cases with haemorrhage:
- The PT, APTT and TT are usually very prolonged and the fibrinogen level is markedly reduced.
- High levels of FDPs, including D-dimer, are found, owing to the intense fibrinolytic activity stimulated by the presence of fibrin in the circulation.
- There is severe thrombocytopenia.
- The blood film may show fragmented red blood cells.

**Management**
The cornerstone of management is treatment of the underlying condition and intensive support to manage hypoxia, acidosis and organ failure. In those that are not bleeding, this is often all that is necessary. Transfusions of platelet concentrates, FFP, cryoprecipitate and red cell concentrates is indicated in patients who are bleeding or to cover interventions. Transfusion of blood components on the basis of coagulation tests alone is not required. Inhibitors of fibrinolysis, such as tranexamic acid, should not be used in DIC, as dangerous fibrin deposition may result. In those cases with a dominant thrombotic component, the cautious use of unfractionated heparin should be considered. In critically ill, non-bleeding patients with DIC, thromboprophylactic doses of heparin are recommended.

**Excessive fibrinolysis**
Excessive fibrinolysis occurs in certain malignancies, such as acute promyelocytic leukaemia, and during surgery involving tumours of the prostate, breast, pancreas and uterus owing to release of tissue plasminogen activators.
Primary hyperfibrinolysis is very rare but activation of fibrinolysis occurs in DIC as a secondary event in response to intravascular deposition of fibrin.

The clinical picture is similar to that of DIC, with widespread bleeding. Laboratory investigations are also similar, with a prolonged PT, APTT and TT, a low fibrinogen level and increased FDPs, although fragmented red cells and thrombocytopenia are not seen because disseminated coagulation with widespread fibrin deposition is not present.

If the diagnosis is certain, fibrinolytic inhibitors, such as tranexamic acid, can be given but evidence for their efficacy is lacking.

Massive transfusion
Few platelets and reduced levels of clotting factors are found in stored blood, although there are adequate amounts of the other coagulation factors. During massive transfusion (defined as transfusion of a volume of blood equal to the patient’s own blood volume within 24 hours, e.g. >10 units in an adult), the platelet count and PT and APTT should be checked at intervals.

Transfusion of platelet concentrates, FFP and cryoprecipitate should be given if thrombocytopenia or defective coagulation is thought to be contributing to continued blood loss. Other problems of massive transfusion are described on page 221.

Inhibitors of coagulation

**Factor VIII autoantibodies** arise occasionally in patients without haemophilia but with autoimmune disorders such as SLE, in elderly patients, with malignant disease and sometimes after childbirth. There can be severe bleeding. Immediate bleeding problems are managed with concentrates that bypass factor VIII activity (e.g. recombinant factor VIIIa or activated prothrombin complex concentrates, see p. 363). Longer-term therapy aims to eliminate the autoantibody using immunosuppression, such as steroids, cyclophosphamide or rituximab.

**Lupus anticoagulant antibodies** (see p. 460) are autoantibodies directed against phospholipids (antiphospholipid antibodies); they cause prolongation of phospholipid-dependent coagulation tests, particularly the APTT, but do not inhibit coagulation factor activity.

CORE SKILLS AND KNOWLEDGE

The haematological malignancies include leukaemias, myeloproliferative neoplasms, lymphomas and myeloma. They are uncommon but not rare, lymphoma being the fifth most common cancer in the UK.

Haemato-oncologists divide their time between inpatient care, outpatient clinics, chemotherapy day units and the diagnostic laboratory. In smaller centres, malignant haematology may comprise only one aspect of the work of a haematologist. In larger centres, haematologists will focus purely on the treatment of malignant disease. Here, they will often be engaged with clinical trials, medical education and research.

Inpatient wards accommodate those requiring investigation and those receiving intensive chemotherapy, in addition to patients requiring management of the acute complications caused by their disease or its treatment. More specialist units will accommodate patients undergoing autologous or allogeneic stem cell transplantation (SCT).

Key to learning objectives for haemato-oncology at undergraduate level include:
- understanding acute leukaemia and the role of SCT
- learning about the lymphomas and myeloma, and their different management strategies
- having an appreciation of the key approaches to treatment with use of cytotoxics, immunotherapy, small molecules and radiotherapy

Specific opportunities for learning haematology-oncology include attending ward rounds on inpatient haematology-oncology wards and transplant units, spending time at the haematology-oncology day unit and becoming familiar with how chemotherapy is delivered, meeting patients presenting with haematological malignancy and following their diagnostic work-up, and attending the haematology-oncology multidisciplinary team meeting to review diagnostic material, and to discuss management options.
### CLINICAL SKILLS FOR HAEMATOLOGICAL ONCOLOGY

#### History

Ask about relevant symptoms (which may each arise acutely or have a chronic and insidious onset) and risk factors for malignancy, and elicit the information needed for guiding treatment (Box 17.1).

#### Assessing suitability for treatment

A patient’s *performance status* is a key determinant of how well they are likely to cope with intensive anti-cancer treatment, such as chemotherapy or stem cell transplantation (SCT) (see Box 6.13). Asking questions about various activities of daily living (personal care, e.g. washing and dressing, and domestic tasks, e.g. shopping or preparing food) allows performance status to be assessed, and also monitored over time.

#### Examination

### Box 17.1 Taking a history in haematology oncology

#### Symptoms of bone marrow failure
- Symptoms of anaemia – fatigue, shortness of breath, reduced exercise capacity
- Thrombocytopenia – easy bruising/bleeding
- Leucopenia – recurrent infection

#### Symptoms caused by mass effect of malignant tissue
- Abdominal discomfort from splenic enlargement
- Neck, jaw, axillary or groin swelling from enlarged lymph nodes

#### Systemic symptoms
- Malaise
- FEVERS (>38°C)
- Sweats (particularly at night, drenching)
- Weight loss (should always be quantified; >10% unintentional weight loss over 6 months is considered significant)

#### Family history
- Haematological problems and malignancy
- Potential donors where allogeneic transplantation may be considered: ages and health of siblings

#### Risk factors
- Previous exposure to cytotoxins
- Previous exposure to ionizing radiation
- Viral infection

#### Fitness for treatment
- Medical co-morbidity that may influence treatment approach
- Social circumstances, including an assessment of performance status (see later)
Clinical skills for haematological oncology

**Box 17.2 Treatments in haematological malignancy**

**Cytotoxics**
- Target rapidly growing cells and have historically formed the basis of conventional anti-cancer chemotherapy, remaining the backbone of most treatment regimens
- Classes include alkylating agents (e.g. cyclophosphamide), anthracyclines (e.g. doxorubicin), vinca alkaloids (e.g. vincristine) and purine analogues (e.g. mercaptopurine, 6-MP)

**Immunotherapy**
- Monoclonal antibodies target a protein on the surface of the malignant cell (rituximab, one of the most commonly used monoclonal antibodies in the treatment of haematological malignancies, targets the CD20 molecule on B lymphocytes and triggers cell death)
- Antibodies either target the tumour cell directly or can act as a vector for toxins

**Corticosteroids**
- Synthetic high-dose corticosteroids, e.g. dexamethasone, induce cell death in malignant lymphoid cells
- Have a prominent role alongside other forms of anti-cancer treatment in all B-cell malignancies, including myeloma

**Molecular therapy**
- An increased understanding of the pathophysiology of disease has allowed the development of treatments targeting specific pathways, e.g. FLT3 inhibitors such as midostaurin, which block abnormal cell signalling in acute myeloid leukaemia, or venetoclax, which blocks the mutated anti-apoptotic protein Bcl-2 in chronic lymphocytic leukaemia

**Stem cell transplantation**
- Involves transfer of pluripotent stem cells from either a donor (allogeneic) or the patient (autologous), following myeloablative chemo- or radiotherapy
- Generally attempted once remission has been achieved using other forms of therapy, to destroy any malignant cells
- Transplanted cells permit bone marrow recovery, and in allogeneic SCT replace the patient’s own abnormal bone marrow with an alternative, normally functioning, haemopoietic system

**Novel therapies**
- e.g. Chimeric antigen receptor (CAR) T-cell therapy, an experimental treatment that involves collecting a patient’s own T cells and modifying them to express a receptor that will bind a particular protein expressed by the tumour; the cells are expanded and re-infused, and when they meet their target malignant cell, they attack and destroy it
- Dramatic responses may be observed, even in chemotherapy-resistant cancer

**Radiotherapy**
- Targets solid tumour masses, e.g. groups of enlarged lymph nodes in early-stage lymphomas, plasmacytomas (see p. 410) and residual disease post treatment

**Surgery**
- Although of limited use in treatment of these conditions, surgery has a role in obtaining diagnostic tissue through biopsy
- Neurosurgery may relieve spinal cord compression, though steroids and radiotherapy are more frequently indicated
- Orthopaedic fixation of pathological fractures may be required in patients with myeloma

**Aims of treatment**

Not all treatment intent will be curative. In indolent disease, treatments are focused on slowing progression or managing symptoms and complications. Factors affecting treatment include:

- **Patient factors.** Performance status or frailty scores are helpful in estimating how well patients may tolerate a particular treatment. Open discussion with the patient is vital. Potential side-effects and complications of treatment must be balanced against the likelihood of a favourable outcome.
- **Disease factors.** Better understanding of pathophysiology has given us prognostic markers (e.g. FLT3 in acute myeloid leukaemia), and data gathered from large-cohort analyses inform increasingly accurate scoring systems.
- **Treatment factors.** The expense of newer therapies results in restricted prescribing in most healthcare systems. Enrolment in clinical trials gives some access to these drugs before their cost-effectiveness can be fully evaluated.

**INTRODUCTION**

Haematological malignancies cover a wide range of blood-based and solid cancers, and their diversity and nomenclature can be confusing. The updated 2016 World Health Organization (WHO) classification contains over 150 distinct entities, many of which have been added since the previous version from 2008. There is an increasing emphasis on underlying genetic abnormalities, as well as histology and immunophenotype. It is beyond the needs of generalists (and most haematologists) to be aware of all these conditions, but a few principles can hopefully provide an overview of this group of cancers and their pathogenesis, clinical behaviour and treatment.

**Aetiology**

(See Box 6.4.)

Like all cancers, haematological malignancies are caused by the acquisition of genetic changes within a normal cell, leading to development of a clonal population. These may be large-scale chromosomal abnormalities (translocations, deletions or duplications), which can be detected by cytogenetic analysis, or point mutations within a specific gene, which require DNA sequencing technology for analysis (Fig. 17.1).

Most of these events are random, although their incidence generally increases with age. However, not all mutations will necessarily lead to a malignancy and there is an increasing awareness of the accumulation of mutations as part of the normal ageing process. For example, mutations in genes such as DNMT3A and ASXL1 are commonly found in older people’s myeloid cells with no evidence of myelodysplasia (MDS) or acute myeloid leukaemia (AML); this is referred to as CHIP – clonal haemopoiesis of indeterminate potential. Similarly, the t(14;18) translocation associated with follicular lymphoma is found in around 50% of healthy individuals circulating lymphocytes.

Previous radiation exposure (usually as part of radiotherapy treatment for a previous cancer) and cytotoxic chemotherapy can cause genetic abnormalities and subsequent malignancy. This is most commonly seen in myeloid malignancy with the development of therapy-related MDS or AML.

**Viral infections** are implicated as a cause of a number of haematological cancers: for example, human T-cell leukaemia (or lymphotropic) virus type 1 (HTLV-1) in adult T-cell leukaemia/lymphoma (ATLL), in which integration of viral DNA into regulatory T cells leads to malignant transformation. Epstein–Barr virus (EBV) can have a similar effect in other lymphomas, including Hodgkin lymphoma. Human immunodeficiency virus (HIV) infection predisposes to certain non-Hodgkin lymphomas, but the mechanisms appear to be primarily immunosuppression and co-infection with other viruses such as EBV and human herpesvirus 8 (HHV8), rather than direct HIV viral integration.

**Treatments**

Treatment plans (Box 17.2) are guided by a large volume of clinical trial evidence that exists for all haematological malignancies, and often patients can be offered enrolment into clinical trials of novel agents.

**Previous**
**Immunosuppression** due to long-term use of systemic therapies can increase the risk of lymphoma. This is seen most commonly in post-transplant lymphoproliferative disorder (PTLD), which can occur in patients receiving immunosuppressive therapy after renal or other transplants. Again, the majority of cases are due to EBV infection.

**Congenital conditions** that predispose to haematological malignancy are rare, but a small number of conditions do exist in which a germline genetic disorder increases the risk of leukaemias developing. These include Down’s syndrome (trisomy 21), which can be associated with a transient myeloproliferative disorder in the neonatal period as well as an increased risk of both AML and acute lymphoblastic leukaemia (ALL), and bone marrow failure syndromes, such as Fanconi anaemia (see p. 337).

**Pathogenesis**

Haematological malignancies can mainly be characterized based on the *normal counterpart cell within the haemopoietic system*. For example, AML is derived from a haemopoietic stem cell that has acquired mutations, leading to rapid proliferation of an abnormal population. These cells share some morphological and immunophenotypic appearances with normal myeloid precursor cells in the bone marrow, but their unchecked proliferation and inability to undergo differentiation lead to a neoplastic population. Myeloma, in contrast, is a cancer of plasma cells derived from a post-germinal centre B cell, whose function in producing antibodies is reflected in the abnormal monoclonal paraprotein that their malignant counterpart secretes.

Haematological cancers can be broadly divided between *myeloid* and *lymphoid* lineages (see Fig. 16.1). Myeloid disorders arise from those lineages within the marrow that produce granulocytes, red cells or platelets. Lymphoid disorders can arise from either B- or T-cell lineages. This classification is summarized in Box 17.3 and the specific subdivision of the lymphoid malignancies is illustrated in Fig. 17.2. This division may not, however, accurately represent the cell of origin: for example, chronic myeloid leukaemia (CML) can undergo a lymphoid blast transformation into an ALL-like disease, reflecting the fact that the CML clone is derived from a haemopoietic stem cell (HSC) with both myeloid and lymphoid differentiation potential.

**Fig. 17.2** Differentiation of T and B lymphocytes and their relationship to neoplasms. Top (above dotted line): **T-cell differentiation.** Progenitor T cells from the bone marrow enter the thymus and develop into different naive T cells. αβ T cells leave the thymus, are exposed to antigen (AG) and undergo blast transformation. They then develop into CD4+ and CD8+ effector and memory T cells. T regulatory cells are the major type of CD4+ effector cell. The other specific effector T cells are the follicular helper T cell (TFH) in the germinal centres (GC). On antigenic stimulation, T-cell responses to antigenic stimulation pathways of natural killer cells (NK) and γδ T cells are unknown. **Bottom: B-cell differentiation.** Precursor B cells mature in the bone marrow and undergo apoptosis or mature to naive B cells. Following exposure to antigen and blast transformation, they develop into short-lived plasma cells or enter the GC. Somatic hypermutation and heavy chain class switching occur here (not shown). The transformed cells of the GC (centroblasts) undergo apoptosis or develop into centrocytes. Post-GC cells include long-lived plasma cells and memory/marginal cells. DLBCL, diffuse large B-cell lymphoma; CLL/SLL, chronic lymphocytic leukaemia/small lymphocytic lymphoma; Ig, immunoglobulin; MALT, mucosa-associated lymphoid tissue. (Redrawn from information in Swerdlow SH, Campo E, Harris NL et al. (eds). WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues, 4th edn. Geneva: WHO; 2008.)
Early genetic changes

The number, type and sequence of acquired genetic mutations determine the phenotype of the condition. CML, for example, has a clear initiating event (the Philadelphia chromosome translocation) that defines the condition and has led to effective targeted therapy. Other malignancies have a wider variety of driver mutations, producing a more heterogeneous group of conditions with variable responses to different treatments.

Cellular phenotypes

The pattern of mutations can lead to a more dysplastic (abnormal appearance and function) or more proliferative phenotype. The stem cell defect in MDS, for example, leads to dysplastic cells with a consequent reduction in normal haemopoiesis. De novo AML, in contrast, is characterized by the rapid proliferation of large numbers of immature cells, which can move out of the bone marrow into the peripheral blood, causing a leucocytosis as well as failure of normal haemopoiesis.

Haematological malignancies can also be divided, based on the speed of disease evolution, into acute or chronic conditions. Acute disorders (e.g. AML, Burkitt lymphoma) are rapidly progressive and fatal within days to weeks if not treated, whereas chronic disorders (e.g. CLL, follicular lymphoma) are typically indolent and slowly progressive, and patients can live with them for long periods. In contrast to acute conditions, however, chronic malignancies are less amenable to curative treatment.

New mutational events

Additional mutational events can occur within the malignant populations, causing changes to the disease's behaviour (clonal evolution), with a subset of cells becoming dominant and leading to disease progression (Fig. 17.3). This can occur under the selection pressure of drug treatment, with resistant clones emerging over time, and this explains, for example, the loss of response to a drug after a period of remission. A sudden change in behaviour from a chronic to acute condition is often called a high-grade transformation, with examples including Richter's transformation of CLL to a high-grade lymphoma, or blast crisis of CML.

Leukaemic and lymphomatous presentations

A final division can be made between blood-based or solid presentations, depending on whether there is primarily a marrow-based leukaemic presentation (with or without obvious circulating disease in the peripheral blood), or a nodal or extranodal lymphomatous presentation (in which soft tissue masses predominate). Again, this distinction is not hard and fast; CLL and small lymphocytic lymphoma (SLL) are considered to be essentially the same disease, despite CLL being predominantly blood-based and SLL primarily solid. It does, however, affect treatment strategies, and the need for imaging in staging and response assessment.

Investigations

Full blood count

The full blood count (FBC) is the most fundamental test used to pick up the majority of haematological cancers. Although the basic parameters and cell differential can be performed manually, this is now generally performed as an automated test.

The basic results produced by an automated FBC are:
- haemoglobin (Hb) concentration
- white cell count (WCC) and proportions of cells in the different white cell populations (‘differential’)
- platelet count (see Box 16.1).

Abnormal counts and cell populations should automatically raise a flag, alerting laboratory staff to an unexpected result that requires further investigation. As with all laboratory tests, the FBC is subject to both internal and external quality assurance testing to ensure that all laboratories report results accurately and precisely.

![Fig. 17.3 Clonal evolution in a population of leukaemic cells from a patient with acute myeloid leukaemia (AML).](attachment:image.png)
Morphology
Blood films
Blood cells can be easily viewed by spreading a droplet of blood into a film on to a microscope slide and staining it to reveal the appearance and number of the cells (Fig. 17.4). Certain conditions have morphological features that are characteristic (e.g. Auer rods in AML cells), and although definitive diagnosis usually requires additional tests (see later), expertise at blood film examination remains a key skill for all haematologists involved in diagnosis.

Bone marrow aspirate morphology
While many leukaemias are visible in the peripheral blood, others blood cancers require examination of the cells within the bone marrow to make a formal diagnosis. Slide preparation and staining techniques are similar, and the normal marrow aspirate shows a wide range of precursor cells at various stages of development (see Fig. 16.1).

Histology
Histological examination can be performed on a bone marrow biopsy (trephine), which can provide better assessment of cellularity and fibrosis, as well as an overall assessment of the tissue structure and the presence and character of any malignant population (Fig. 17.5). Immunohistochemical staining can provide a specific diagnosis. The same staining techniques are also used on lymph node and other biopsies, in particular for lymphomas.

Biochemistry
Routine biochemical testing is used to assess organ damage and tumour lysis. Specific tests (e.g. lactate dehydrogenase (LDH), beta-2-microglobulin (B2M)) are used as part of a number of staging systems in myeloma and lymphoma.

Immunological assessment of paraproteins is an essential part of the diagnosis and response assessment of myeloma and some other blood cancers (see later).

Immunophenotyping
Cell surface proteins act as markers that can be used to characterize and quantify malignant cell populations. Analysis of solid samples (bone marrow trephines, lymph node biopsies etc.) is performed by immunohistochemistry.

On liquid samples (peripheral blood, bone marrow aspirate and so on), it is performed by flow cytometry. In this process, cells are stained with fluorescently labelled antibodies and analysed with specially designed analysers. The combination of cell size and appearance, together with the pattern of surface markers, identifies a profile or immunophenotype that is characteristic of a particular diagnosis (Fig. 17.6).

Immunophenotypic identification of malignant cell populations is an essential part of the diagnosis of almost all haematological malignancies. As an example, acute leukaemia cells may appear identical by morphology but have very different immunophenotype profiles:
- AML (CD13+, CD33+, CD117+)
- B-lineage ALL (CD10+, CD19+)

This information has a direct impact on treatment, different chemotherapy combinations being used for the different conditions (Fig. 17.7).

Cytogenetics
Cancer is characterized by genetic abnormalities within the malignant cell populations, and these abnormalities can increasingly be detected in many haematological cancers, either to confirm a diagnosis, or to act as biomarkers that can provide information on the likely timescale and behaviour of the disease (prognostic), and/or the likely response to a specific drug or treatment (predictive).

Chromosomal abnormalities (translocations, insertions, deletions, inversions) may be detected by two major cytogenetic techniques:
- G-band karyotyping detects large structural abnormalities in chromosomes when they are condensed during metaphase. This technique will detect the t(9;22) Philadelphia chromosome translocation in CML (see Fig. 2.23), and many of the major structural abnormalities associated with AML prognosis (e.g. inv16, monosomy 7).
**Fluorescence in situ hybridization (FISH)** assesses cells during interphase and so is useful for slower-growing cancers; however, it will only detect specific abnormalities using pre-designed fluorescently labelled probes. This technique is commonly used for detecting prognostically significant abnormalities in myeloma (e.g. t(4;14), 17p deletion) (see Fig. 17.11).

**Molecular genetics**

Abnormalities in specific genes can be detected by DNA sequencing technologies, again providing important prognostic and predictive information. Gene mutations that are known to be of relevance may be specifically screened for. In AML, for example, mutations in the FLT3 gene denote a poor prognosis, and detection of this abnormality may lead to a decision to proceed to an allogeneic transplant. In CML, the T315I mutation in the BCR-ABL fusion gene is associated with poor response to standard therapy, and may prompt a change to the alternative drug ponatinib.

Use of high-throughput ‘next-generation sequencing’ (see p. 31) technologies allows for the investigation of a number of genes of interest in a single assay. These are increasingly being used as the number of known relevant mutations grows and advances in technology and bio-informatic analysis make this approach more cost-effective.

As an example, TET2, SF3B1 and ASXL1 are commonly mutated in MDS, and their detection can be helpful in making this diagnosis in unclear cases, as well as informing prognosis. With the development of novel drugs that have activity against specific mutations, the use of gene panels is likely to increase.

**Minimal residual disease testing**

Traditionally, assessment of disease response in leukaemia relied on morphological examination of the blood or bone marrow. Flow cytometry and molecular technologies are increasingly being used to detect very low levels of malignant cells in so-called minimal residual disease (MRD) assays. An MRD-positive result can predict relapse before it is visible by morphology, and may prompt an early change in treatment. Conversely, an MRD-negative result can provide confidence for de-escalating treatment, or for not pursuing further intensive treatments such as allogeneic transplant.

Two major methods are used for MRD testing:

- **Flow cytometry.** This utilizes the same methodology as immunophenotyping to detect low levels of malignant cells in the peripheral blood. Ideally, a sample at diagnosis is used to identify the distinctive immunophenotypic profile of the malignant cell population. This can then be employed to look for persistence or early relapse of the same cell population.

- **Quantitative polymerase chain reaction (qPCR).** This powerful technique allows the amplification of a specific sequence of DNA or RNA, and can be used to detect low levels of disease in a number of conditions:
  - gene fusions, e.g. BCR-ABL in CML
  - immunoglobulin gene rearrangements in B-cell ALL
  - T-cell receptor gene rearrangements in T-cell ALL.
Tissue typing
For patients who may go on to allogeneic stem cell transplantation (SCT), it is important to collect a blood sample for tissue typing at diagnosis, so that potential donors may be identified. Testing identifies donors who match the patient’s human leucocyte antigen (HLA) type and is done by genetic testing, ideally at the HLA-A, B, C, DP, DQ and DR loci. Testing packs can be sent out to siblings, to be returned for testing at the regional laboratory. If no related donors are identified, a search can be performed on national and international donor registries.

Radiological imaging
Although, as with all cancers, a tissue sample is required to make a diagnosis and commence treatment, radiological imaging plays a key role in the staging, response assessment and investigation of haematological cancers.

Plain films
These are rarely used for formal staging but may still be helpful in initial investigation and assessment of complications (e.g. long bone fractures as a presenting symptom of myeloma).

Ultrasound scans
These are useful for assessment of soft tissue masses: for example, in the characterization of enlarged lymph nodes. Ultrasound-guided biopsies are a common method of making an initial lymphoma diagnosis.

Computed tomography scans
These are frequently employed to gain accurate imaging to stage tumours at diagnosis and to assess response. In myeloma, where the main site of organ damage is the bones, low-dose, non-contrast computed tomography (CT) scans are sufficient, whereas assessment of soft tissue masses – for example, in lymphoma – requires a contrast scan. CT-guided biopsies are an effective method of obtaining tissue from deeper-lying areas.

Nuclear medicine scans
Nuclear medicine scans, especially fluorodeoxyglucose positron emission tomography (FDG-PET), are increasingly used in combination with CT (CT-PET) to visualize metabolically active areas of disease. This technique is helpful for assessing response after therapy, and in particular to distinguish between active residual tumour and fibrotic tissue after treatment.

Magnetic resonance imaging
Magnetic resonance imaging (MRI) can provide detailed views of particular organs and has benefits in a number of specific situations (e.g. bone marrow, brain, spinal cord). Diffusion-weighted MRI can provide functional information similar to that obtained by PET scanning and is increasingly being used in myeloma assessment.

Multidisciplinary team and specialist integrated haematological malignancy diagnostic service
As already outlined, a number of different techniques are used in making a diagnosis of a haematological cancer, as well as in providing the relevant staging and prognostic information to guide treatment. Diagnostic reports can be integrated into a single document, incorporating all relevant pathological information. This is often carried out as part of a specialist integrated haematological malignancy diagnostic service (SIHMDS), which may be run on a regional basis.

Review of pathology and radiology results at diagnosis, response assessment and disease progression should ideally be done in a multidisciplinary team (MDT) meeting, where clinical, pathological and radiological data can be discussed by an extended expert team, who can then formulate a specific management plan for the patient.

LEUKAEMIAS

There are four main subtypes, as discussed earlier:
- acute myeloid leukaemia (AML)
- acute lymphoblastic leukaemia (ALL)
- chronic myeloid leukaemia (CML)
- chronic lymphocytic leukaemia (CLL).

These are relatively uncommon diseases with an incidence of about 10/100 000 per year. They can occur at any age and the type of leukaemia varies with age: ALL is mainly seen in childhood and CLL is a disease of the elderly.

Leukaemia can be diagnosed by examination of a stained smear; these forms may be seen in increased incidences in survivors of Hiroshima, Nagasaki and, more recently, Chernobyl, and in patients treated with ionizing radiation.

Aetiology
In the majority of patients the cause is unknown but several factors have been associated:
- Radiation. This can induce genetic damage to haemopoietic precursors; ALL, AML and CML have been seen in increased incidences in survivors of Hiroshima, Nagasaki and, more recently, Chernobyl, and in patients treated with ionizing radiation.
- Chemicals and drugs. Exposure to benzene, used in industry, may lead to marrow damage. AML occurs after treatment with chemotherapy drugs such as alkylating agents (e.g. melphalan) and topoisomerase-II inhibitors (e.g. etoposide).
- Genetic factors. Leukaemia risk is highly elevated in a number of germline conditions that result in genetic instability or bone marrow failure. These include Fanconi anaemia, ataxia telangiectasia and Li–Fraumeni syndrome. The risk is elevated some 30 times in Down’s syndrome (trisomy 21). There is a high degree of concordance among monozygotic twins. Several genes have also been associated with familial AML, such as CEBPA and RUNX1.
- Viruses. ATLL is a rare type of leukaemia that is associated with HTLV-1, found particularly in Japan and the Caribbean.

Acute leukaemias
The acute leukaemias increase in incidence with advancing age. Acute myeloid (myeloblastic, myelogenous) leukaemia has a
median age at presentation of 65 years and may arise de novo or against a background of myelodysplasia or prior cytotoxic chemotherapy (‘therapy-related’). *Acute lymphoid (lymphoblastic) leukaemia* has a substantially lower median age at presentation and, in addition, is the most common malignancy in childhood. The simplified WHO classification shown in Box 17.4 also shows that a small number of acute leukaemias have an indeterminate immunophenotype between myeloid and lymphoblastic.

**Clinical features**
The majority of patients with acute leukaemia, regardless of subtype, present with symptoms (Box 17.5) reflecting inadequate haemopoiesis secondary to infiltration of the bone marrow by leukaemic cells, symptoms due to tissue infiltration by leukaemic cells, the consequences of a high white blood cell count, or substance release from the tumour cells.

**Investigations**
**For confirming diagnosis**
- **Blood count.** Haemoglobin and platelets are low. White blood cell count is usually raised, reflecting the proliferating population, but may be low if the leukaemic cells are confined to the bone marrow.
- **Blood film.** Blast cells are almost invariably seen (Fig. 17.8A). Lineage may be identified morphologically, e.g. the presence of Auer rods is pathognomonic for a diagnosis of AML.
- **Bone marrow aspirate.** Increased cellularity (Fig. 17.8B), reduced erythropoiesis and reduced megakaryocytes may be seen. Replacement by blast cells is over 20% (often approaching 100%). Lineage is confirmed by immunophenotyping, e.g. AML – CD33 or CD13; B lineage ALL – CD10 and CD19; and T lineage ALL – CD3 (see Fig. 17.7). Cytogenetic and FISH analysis, as well as molecular genetics, may be used for prognostication.
- **Chest X-ray.** Mediastinal widening is often present in T-lymphoblastic leukaemia.
- **Cerebrospinal fluid examination.** This is performed in all patients with ALL, as the risk of central nervous system involvement is high. It is less critical in AML.
- **Coagulation profile.** This is performed to exclude the presence of disseminated intravascular coagulation (DIC), particularly associated with acute promyelocytic leukaemia (APML): raised prothrombin time and activated partial thromboplastin time, reduced fibrinogen, and increased fibrinogen degradation products, e.g. D-dimers.

**For planning therapy**
- **Biochemistry:** serum urate, renal and liver function tests.
- **Cardiac function:** electrocardiography and echocardiogram to assess cardiac function before considering intensive chemotherapy, which may include cardiotoxic anthracycline drugs.
- **HLA type:** performed for identification of potential stem cell donors for allogeneic transplantation.
- **HIV, hepatitis B virus (HBV) and hepatitis C virus (HCV) status.**

Management

Untreated acute leukaemia is invariably fatal, most often within weeks to months, though with judicious palliative care it may be extended, perhaps to a year. Treatment with curative intent may be successful, or may fail, either because the leukaemia does not respond (refractory), because the disease returns after an initial favourable response (relapse), or because the patient succumbs to complications of the therapy (treatment-related mortality).

At initial presentation, acute leukaemias range from being probably curable (e.g. childhood ‘good-risk’ ALL) through to probably incurable (e.g. AML with adverse cytogenetic features in the elderly). Since curative treatment carries considerable morbidity and potential mortality, it is essential for the risk/benefit ratio to be clearly understood by physician and patient alike.

Palliative therapy

Every attempt should be made to ensure that patients are able to stay at home as much as possible, while making available the full range of supportive care. Palliation may well include low-dose chemotherapy in addition to blood product support and antimicrobials.

Curative therapy

The decision to treat with curative intent, particularly if successful, implies severe disruption of normality for the patient and family for at least 6 months and often up to a year. In the short term, it may demand transfer to another hospital, as acute leukaemia should be treated only in units seeing a sufficient number of patients. It is highly likely to involve admission to hospital for up to a month in the first instance, with further, partly predictable, subsequent admissions of several days’ to weeks’ duration, requiring discussions and decisions about work or education.

The decision to treat with curative intent implies that the chance of cure justifies the risks of the therapy. It does not imply that cure is guaranteed or even expected.

Active therapy

Supportive care

This forms the basis of treatment, whether for cure or palliation:

- **Avoidance of symptoms of anaemia** (keeping haemoglobin >80–100 g/L). Repeated transfusion of packed red cells is needed (irradiation of cells may be required, e.g. in patients who have received purine analogue drugs such as fludarabine).
- **Prevention or control of bleeding** (keeping platelet count >10 × 10⁹/L in the stable patient, >20 × 10⁹/L in the septic patient, or >50 × 10⁹/L if a procedure is planned, e.g. lumbar puncture). The role of prophylactic platelet transfusion has been evaluated and remains superior to any alternative, certainly for patients with AML.
- **Correction of coagulation abnormalities**. This is achieved with fresh frozen plasma (FFP) to keep the activated partial thromboplastin time ratio and international normalized ratio (INR) <1.5 times normal, and with cryoprecipitate to keep the fibrinogen level >1.5 g/dL. This is a particular risk in APML, which is associated with activation of the coagulation system (DIC). Norethisterone is given to women of menstrual age to avoid menorrhagia during their thrombocytopenic phase.
- **Treatment of infection** (see Box 6.25):
  - **Prophylactic**. Education of patients, relatives and staff about diet, hand-washing and isolation facilities is necessary. Selected antibiotics, antifungals, antivirals and *Pneumocystis jirovecii* prophylaxis may be required.
  - **Therapeutic**. Fever is managed using a local protocol/algorithm for antibiotic and antifungal combinations.
- **Control of hyperuricaemia (tumour lysis)**. This should be achieved with hydration, prophylactic allopurinol and occasionally rasburicase (see p. 118). Indwelling venous devices, such as a peripherally inserted central catheter (PICC) or Hickman line, are required to allow easy access to the blood for tests and administration of therapy. Sperm banking is offered to postpubertal men and oocyte collection to women, if there is time before treatment.

Specific treatment

The initial requirement of therapy is to return the peripheral blood and bone marrow to normal (complete remission, CR). This ‘induction chemotherapy’ is tailored to the particular leukaemia and the individual patient’s risk factors. Since this treatment is not leukaemia-specific but also impairs normal bone marrow function, it leads to a major risk of life-threatening infection, which increases the risk of early death in the short term.

Successful remission induction is always followed by further treatment (consolidation), which consists either of further cycles of chemotherapy or of allogeneic haemopoietic stem cell ‘bone marrow’ transplantation. The specific treatment details are determined by the type of leukaemia and by the patient’s risk factors and tolerance of treatment. Without consolidation, recurrence is almost inevitable, reflecting the lack of sensitivity of a morphological ‘complete remission’. Cytogenetics and molecular genetic techniques can identify residual leukaemic cells not detected morphologically (minimal residual disease, MRD), which are highly predictive of recurrence.

---

**Fig. 17.8 Acute leukaemia.** (A) Peripheral blood film showing characteristic blast cells. The arrow points to the abnormal blast cell. (B) Bone marrow aspirate showing particle with increased cellularity. (Courtesy of Dr Manzoor Mangi.)
Refractory disease

Failure to achieve morphological CR with two cycles of therapy (‘refractory’) carries almost as bad a prognosis as the untreated leukaemia. If CR can be achieved – by new experimental approaches, for instance – cure may still be possible with SCT (see p. 364). A small proportion of patients with refractory disease may also be cured by myeloablative SCT.

Stem cell transplant

The decision on whether to proceed to allogeneic transplant is based on two factors:

- **Relapse risk.** This depends on cytogenetic and other risk factors at diagnosis, and response to induction therapy (morphology and MRD).
- **Transplant-related mortality (TRM).** This varies, depending on the age and fitness of the patient and the quality of the donor match.

Patients should proceed to transplantation only if the reduction in relapse risk outweighs likely TRM, leading to an improved overall survival. For example, transplantation would be appropriate for a younger, fitter patient with poor-risk disease, but not for someone with inv(16) (lower relapse risk) or an older patient with multiple co-morbidities (high predicted TRM).

Acute myeloid leukaemia

Prognosis

In AML, the prognosis is dependent on a range of key variables, the main ones being age, cytogenetics and specific gene mutations (Fig. 17.9 and Box 17.6), and, increasingly, the presence of MRD after initial therapy.

Management

**Young patients: intensive therapy unless unfit**

Treatment with curative intent is undertaken in the majority of adults below the age of 60 years, provided there is no significant co-morbidity. Treatment success reflects the cytogenetic pattern. CR will be achieved in about 80% of patients under the age of 60. Failure is due to either resistant leukaemia (10%) or treatment-related mortality (10%) – usually caused by infection or haemorrhage. Approximately 50% of those entering CR will be cured (i.e. approximately 40% overall), although this varies from 60–70% in the favourable cytogenetic group to 10–20% in the adverse cytogenetic group.

Those with ‘favourable risk’ disease (e.g. inv(16)) are treated with moderately intensive combination chemotherapy. This always includes an anthracycline such as daunorubicin and cytarabine, and consolidation with a minimum of a further three cycles of treatment given at 3–4-week intervals. Patients with favourable-risk disease do not benefit from allogeneic SCT during their first complete remission, as the risks outweigh the benefits.

Those with ‘intermediate-risk’ disease (e.g. normal karyotype, +8, +21) are a heterogeneous and increasingly complex group. Where possible, they should be given consolidation chemotherapy after an initial remission has been achieved, followed by allogeneic transplantation in most cases. The confirmation of deep remission by MRD negativity (e.g. of NPM1 transcripts) may be sufficient to move some patients into a good risk group and remove the need for transplant.

Patients with adverse cytogenetics (e.g. 7−, 5−, complex karyotype) should proceed to SCT in first complete remission (CR1) because they respond poorly to conventional chemotherapy and have a high risk of relapse, which can be reduced to some extent by transplant.

**Older patients: intensive versus non-intensive strategies**

The initial treatment of the older patient (>60 years) is much more contentious. A decision needs to be taken initially as to whether the patient is ‘fit’ enough to tolerate intensive chemotherapy. This will require a full assessment of their co-morbidities and organ function. Older patients tolerate cytotoxic therapy less well than younger patients due to additional co-morbidities, and their disease is often more aggressive in its biology; for example, adverse cytogenetics are more common with increasing age. As a result,

treatment-related morbidity and mortality are both higher and outcome is less successful.

Reduced-intensity allogeneic transplantation is increasingly being used for this group but is still limited by its toxicity. For those who are not fit for intensive chemotherapy, treatment will have a palliative aim to improve marrow function and to maximize quality of life. Choice of therapy will include low-dose cytarabine, azacitidine, oral cytotoxics (such as hydroxycarbamide) or enrolment into any one of a range of clinical trials of novel agents.

**Relapsed AML**

The management of recurrence is undertaken on an individual basis, since the overall prognosis is very poor, despite the fact that second remissions may be achieved. Long survival following recurrence is rarely achieved without allogeneic transplantation. Novel or trial therapies should be considered. The use of MRD monitoring may identify patients in CR who are in the early stages of relapse and need pre-emptive therapy before frank marrow relapse occurs.

Newer agents that target the FLT3 mutation present in a significant proportion of cases of AML (e.g. midostaurin) may be given in conjunction with conventional chemotherapy. Other novel therapies include chemotherapy-labelled monoclonal antibodies (gemtuzumab ozogamicin) and hypomethylating agents (e.g. azacitidine).

**Acute promyelocytic leukaemia**

Acute promyelocytic leukaemia (APML) is a variant of AML, occurring in 10–15% of cases. It is characterized by the translocation t(15; 17), which produces a PML-RARA fusion gene and has particular morphological features. There is an almost invariable coagulopathy, which remains a major cause of early death. The empirical discovery that all-trans-retinoic acid (ATRA) causes differentiation of promyelocytes and rapid reversal of the bleeding tendency was a major breakthrough.

APML is treated with ATRA combined with several courses of chemotherapy, or in combination with arsenic trioxide, which induces apoptosis via activation of the caspase cascade (see Fig. 3.9). CR and molecular remission (MR) occur in at least 90% of younger adults with APML, and at least 70% will expect to be cured. Transplantation is necessary only if the leukaemia is not eliminated at the molecular level, or following recurrence and re-induction therapy.

**Acute lymphoblastic leukaemia**

This condition may present in leukaemic phase with significant marrow involvement (acute lymphoblastic leukaemia, ALL) or as localized bulky disease, typically a mediastinal mass (lymphoblastic lymphoma). The tumour cells in each condition are indistinguishable and similar therapies are therefore used.

**Prognosis**

A number of clinical and laboratory features are determinants of treatment response and survival in ALL (Box 17.7). Increasingly, therapeutic strategies based on prognostic risk are being used in management. MRD stratification is increasingly employed to select patients who are at high risk (for treatment intensification) or low risk (for treatment de-escalation).

The prognosis of ALL in childhood is now excellent: CR is achieved in almost all, with up to 80% being alive without recurrence at 5 years. Failure occurs most frequently in those with high presentation blast counts or an 11q23 MLL translocation. Current treatment strategies lessen therapy for ‘good-risk’ children in order to avoid some of the long-term consequences of therapy, such as avascular necrosis of bone, infertility, neurotoxicity and cardiotoxicity.

The situation is far less satisfactory for adults, the prognosis getting worse with advancing years. Co-morbidity and t(9; 22) translocation increase in frequency with age. Between 30% and 40% of patients continue in durable first remissions, resulting in approximately 25–30% overall patient cure. Disease that is refractory to first-line therapy carries a very poor prognosis.

As with AML, most recurrences occur within the first 3 years and the outcome is extremely poor. Second remissions, though usually achieved, are rarely durable, except following allogeneic transplantation. Isolated extramedullary recurrences, however, may be cured.

**Management**

As with AML, the overall strategy is to achieve an initial remission with induction chemotherapy, and then consolidate the response with either further cycles of chemotherapy, or an allogeneic transplant in selected patients, depending on relapse risk and estimated TRM. The drug combinations used differ, however, with initial induction typically consisting of vincristine, a glucocorticoid, an anthracycline and asparaginase, and different agents used for consolidation cycles. Similar to AML, older and less fit patients may receive a non-intensive treatment strategy, which is not curative in intent but aims to prolong life and reduce complications.

A major difference between treatment for ALL and that for AML is the need for central nervous system-directed therapy, due to the higher risk of infiltration. Prophylaxis should be given with intrathecal chemotherapy (under platelet cover if necessary) as soon as blasts are cleared from the blood. Depending on risk, this may be continued for up to 2 years and complemented by high doses of systemic cytarabine or methotrexate. Cranial irradiation was previously given to all patients to reduce the risk of relapse within the central nervous system; risk-adapted strategies now reserve this for those patients at very high risk.

The presence of the t(9;22) Philadelphia translocation (see Fig. 2.23) has traditionally been associated with increased risk, but the use of imatinib and other tyrosine kinase inhibitors (TKIs) originally developed for CML have improved outcomes considerably. These agents can be used in combination with intensive or non-intensive chemotherapy.

| Box 17.7 Risk factors in acute lymphoblastic leukaemia (ALL) |
|---|---|---|
| Risk factor | Good | Poor |
| Age | Younger | Older |
| WCC | <30 x 10^9/L for B lineage | >30 x 10^9/L for B lineage |
| | <100 x 10^9/L for T lineage | >100 x 10^9/L for T lineage |
| Immunophenotype | CD10+ common ALL | Pro-B ALL |
| Cytogenetic aberrations | t(12; 21) hyperdiploidy | t(9; 22) or t(4; 11) hypodiploidy |
| Time to response | Early clearance of blasts | Failure to achieve CR within 3–4 weeks |
| Minimal residual disease | MRD negative | MRD positive |
| Extramedullary disease | CSF clear | CSF positive |

CR, complete remission; CSF, cerebrospinal fluid; MRD, minimal residual disease; WCC, white cell count.
After intensive induction and consolidation, maintenance therapy is used to reduce the risk of disease recurrence in those patients who did not receive a transplant. This is typically comprised of 2 years of treatment with methotrexate and mercaptopurine, although more intensive regimens are used by many groups.

Novel cytotoxic drugs, including clofarabine and nelarabine, are increasingly used for relapsed/refractory cases, as are a range of monoclonal antibodies in B-ALL, including rituximab (anti-CD20), inotuzumab (calicheamicin-labelled anti-CD22) and blinatumomab (CD19/CD3 bi-specific T-cell engager antibody). Chimeric antigen receptor T-cell (CAR-T) immunotherapy has shown significant promise in ALL and is likely to see increased use in coming years.

Further reading

Chronic leukaemias

Chronic myeloid leukaemia

Chronic myeloid leukaemia, which accounts for about 14% of all leukaemias, is a member of the family of myeloproliferative neoplasms (MPNs); it is almost exclusively a disease of adults, the peak of presentation being between 40 and 60 years. It is defined by the presence of the Philadelphia chromosome (see Fig. 2.23), which is demonstrated either cytogenetically (95%) or molecularly (5%). Unlike the acute leukaemias, which are either rapidly reversed or rapidly fatal, CML has a more slowly progressive course through three distinct phases: chronic phase, accelerated phase and blast crisis. If left untreated, the disease will evolve through these phases and ultimately transform to acute leukaemia (blast crisis – 75% myeloid, 25% lymphoid) or myelofibrosis, with death in a median of 3–4 years. Fortunately, targeted therapy to arrest disease progression is highly effective in the majority of patients.

Clinical features

CML usually presents in the chronic phase and some patients have no symptoms.

Symptoms

When present, symptoms include:
- symptomatic anaemia (e.g. shortness of breath)
- abdominal discomfort due to splenomegaly
- weight loss
- fever and sweats in the absence of infection
- headache (occasionally) or priapism due to hyperleucocytosis
- bruising and bleeding (uncommon).

Signs

These include:
- pallor
- splenomegaly, often massive
- lymphadenopathy (uncommon; suggests blast crisis)
- extramedullary soft tissue leukaemic deposit – ‘chloroma’ (indicates blast crisis)
- retinal haemorrhage due to leucostasis.

Investigations

- Blood count. Haemoglobin is low (normochromic and normocytic) or normal; the white blood cell count is raised (usually >100 x 10^9/L); and platelets are low, normal or raised.
- Blood film. There is neutrophilia with the whole spectrum of mature myeloid precursor cells. Basophils and eosinophils are elevated. Increased numbers of blasts are suggestive of an accelerated phase or blast crisis (Fig. 17.10).
- Bone marrow aspirate. Increased cellularity is seen, with greater numbers of myeloid precursors. Cytogenetics reveals a t(9; 22) translocation (the Philadelphia chromosome; see Fig. 2.23B).
- FISH or RT-PCR. These demonstrate the cytogenetic/molecular abnormality. They are also used to monitor response to therapy quantitatively.

Management

Treatment has been transformed by the advent of imatinib, a TKI that specifically blocks the enzymatic action of the BCR-ABL fusion protein and is still usually first-line treatment for the chronic phase, although second-generation TKIs may be used. Imatinib produces a complete cytogenetic remission (no detectable Ph+ cells in the marrow) in 70% of patients. A significant proportion will lose molecularly detectable BCR-ABL transcripts from the blood, achieving a molecular response (MR) of varying depths: MR3 (a 3 log reduction; <0.1%), MR4 (<0.01%) or MR5 (<0.001%). Side-effects of imatinib include nausea, headache, rashes and cytopenias. Imatinib can be continued indefinitely, although discontinuation can be considered in those who respond optimally and achieve a sustained deep molecular response (MR4). Patients need to be closely monitored, with around two-thirds able to remain off treatment without disease recurrence.

Resistance to imatinib as a single agent may develop as a result of secondary BCR-ABL kinase mutations beyond t(9; 22). If patients do not tolerate imatinib or respond suboptimally, mutation analysis should be performed and a second-generation TKI, such as dasatinib, nilotinib or bosutinib, should be commenced. Those who have developed a T315I mutation should be offered ponatinib.

In accelerated and blast phases the approach is to combine a second-line TKI with intensive chemotherapy, as for acute leukaemia. SCT should then be considered with the aim of achieving a durable remission.

Chronic lymphocytic leukaemia

Chronic lymphocytic leukaemia (CLL) is the most common leukaemia, occurring predominantly in later life and increasing in frequency with advancing years (the median age of presentation is around 70 years). It results from the clonal expansion of small B lymphocytes with characteristic immunophenotype. The majority of patients are asymptomatic and are identified as a chance finding on investigations.

Fig. 17.10 Blood film showing blast cells (arrow) in chronic myeloid leukaemia.
a blood count performed for another indication. Others, however, present with the features of marrow failure or immunosuppression. The median survival is about 10 years and prognosis correlates with clinical stage at presentation (Box 17.8). A number of cytogenetic and molecular abnormalities are now recognized as being of prognostic significance (see later). This condition may present in leukaemic phase with significant marrow/blood involvement (CLL) or may present as localized disease (small lymphocytic lymphoma, SLL). The tumour cells in each condition are indistinguishable and a similar therapeutic approach is therefore used. Nearly all cases of CLL will be preceded by a monoclonal B-cell lymphocytosis (MBL) where there are fewer than $5 \times 10^9/L$ circulating clonal B cells. However, this condition is also present in approximately 12% of the healthy population, and the relationship between MBL and CLL is analogous to that between monoclonal gammapathy of uncertain significance (MGUS) and myeloma (see p. 407). High-count MBL (over $0.5 \times 10^9/L$) should be distinguished from low-count MBL populations, as these patients will need review at least annually for disease evolution and infection risk.

**Clinical features**

The majority of patients are asymptomatic at presentation. When they are present, common symptoms are:
- recurrent infection because of (functional) leucopenia and immune failure (reduced immunoglobulins)
- anaemia due to haemolysis or marrow infiltration
- painless lymphadenopathy
- left upper quadrant discomfort (from splenomegaly).

The most common findings on examination are:
- anaemia
- lymphadenopathy (may involve a single area or be generalized)
- hepatosplenomegaly, sometimes massive.

**Investigations**

- **Blood count** reveals a normal or low haemoglobin; a raised white blood cell count, which may be very high; lymphocytosis (criteria for diagnosis $>5 \times 10^9/L$); and normal or low platelets.
- **Blood film** demonstrates small or medium-sized mature and normal-appearing lymphocytes. Smudge cells may be seen in vitro. No immature blasts are evident.
- **Bone marrow** reflects peripheral blood, often very heavily infiltrated with lymphocytes.
- **Immunophenotyping** typically shows CD19+, CD5+ or CD23+ B cells with weak expression of CD22, CD79b and surface immunoglobulin (kappa and lambda light chains).
- **Cytogenetics/FISH analyses** identifying 17p deletion or p53 mutation is essential prior to treatment, as this will influence choice of therapy (Fig. 17.11).
- **Direct Coombs’ test** may be positive if there is haemolysis.
- **Immunoglobulins** are low or normal.

**Prognosis**

The clinical course of CLL is variable. Prognosis is influenced by age and clinical stage, as well as pace of disease, measured by doubling time. Cytogenetic abnormalities are detected in more than 90% of cases. Patients with an isolated deletion of 13q have a better prognosis, in contrast to those with either 11q deletion or 17p deletion (sites of the tumour suppressor genes ATM and TP53, respectively), who tend to follow a rapidly evolving clinical course. Mutation within the immunoglobulin heavy chain variable region (IGHV) predicts an indolent course, and expression of ZAP70, a 70-kDa tyrosine kinase protein, correlates reasonably well with mutational status. Patients with mutated IGHV have median survival of more than 20 years in contrast to 8 years in patients with unmutated IGHV. High expression of CD38 on leukaemic cells may also indicate an adverse prognosis. Next-generation sequencing (see p. 31) has identified certain genes (**NOTCH1, SF3B1**) whose mutation influences prognosis.

**Management**

In CLL, the major consideration is when to treat; indeed, 30% of patients will never require intervention. Treatment depends on disease ‘stage’ (see Box 17.8). Early-stage disease is usually managed expectantly, advanced-stage disease is always treated immediately,

---

4Lymphocytosis is present in all stages of the disease. 5Progression is defined by weight loss, fatigue, fever, massive organomegaly and a rapidly increasing lymphocyte count. 6Lymphoid areas include the cervical, axillary and inguinal lymph nodes, the spleen and the liver.

---

**Fig. 17.11 Fluorescence in situ hybridization (FISH) photomicrograph of a patient with chronic lymphocytic leukaemia.** (A) 17p (green probe) and 11q (red probe) shows two green signals (TP53 deletion) with normal diploid complement of 11q. (B) 12 centromere (green probe) and 13q14 (red probe) shows three green signals (trisomy 12) with normal diploid complement of 13q. **(Courtesy of Debra Lillington, Barts and the London NHS Trust.)**
and the approach to the intermediate stage is variable. Indications for treatment are:

- marrow failure, manifest by worsening anaemia and/or thrombocytopenia that is not autoimmune
- massive or progressive splenomegaly or lymphadenopathy
- progressive disease demonstrated by doubling of the lymphocyte count in less than 6 months
- systemic symptoms (fever, night sweats or weight loss)
- presence of haemolysis or other immune-mediated cytopenias that are poorly responsive to steroids.

### General/supportive treatment

Anaemia due to haemolysis is treated with steroids. Anaemia and thrombocytopenia caused by marrow infiltration are treated with chemotherapy and, when necessary, transfusion. Erythropoietin (EPO, see p. 325) may avoid the need for transfusions, particularly in patients receiving chemotherapy. Infection is treated as indicated, with prophylactic antibiotic, antiviral, anti-Pneumocystis and antifungal therapy potentially being given during periods of chemotherapy. Immunoglobulin replacement may be helpful, as well as pneumococcal, Haemophilus influenzae type B (Hib) and influenza vaccination. Live vaccines should be avoided. Allopurinol is given to prevent hyperuricaemia.

### Specific treatment

Choice of therapy will depend on patient-related factors, such as age and co-morbidity, adverse prognostic features, and anticipated response to and toxicities of therapy. A range of therapies are available and these must be tailored to the patient’s age, fitness, prior therapy exposure and concurrent co-morbidities.

- **Ibrutinib**, a Bruton’s tyrosine kinase (BTK) inhibitor, should be offered to those individuals with TP53 disruption, as they are poorly responsive to conventional chemo-immunotherapy. This is taken orally and is generally well tolerated, although an increased risk of atrial fibrillation is observed. Venetoclax (a BCL-2 inhibitor) is a second-line option.
- **Fludarabine**, a purine analogue, in combination with cyclophosphamide and rituximab, is still first-line treatment for younger, fitter patients.
- **Obinutuzumab** or **ofatumumab**, both novel anti-CD20 monoclonal antibodies, are preferred in the elderly or less fit to rituximab in combination with chlorambucil. Bendamustine is an alternative alkylator that may be appropriate for first-line therapy in older and less fit patients who cannot tolerate FCR (fludarabine, cyclophosphamide, rituximab).
- **Allogeneic SCT** with non-myeloablative conditioning regimens is occasionally considered in fit patients with high-risk disease.

### Lymphomatous transformation

CLL may undergo lymphomatous (Richter’s) transformation in 5–10% of cases, most typically to diffuse large B-cell lymphoma, although Hodgkin-like transformation is also recognized. In around half of cases, the high-grade lymphoma is clonally unrelated to the CLL clone and these cases respond to treatment in a similar way to de novo diffuse large B-cell lymphoma (DLBCL). Where lymphoma is clonally related, outcomes are poorer.

### Hairy cell leukaemia

Hairy cell leukaemia (HCL) is a clonal proliferation of abnormal B (or, very rarely, T) cells, which, as in CLL, accumulate in the bone marrow and spleen. It is a rare disease; median age at presentation is 52 years and the male to female ratio is 4:1. The bizarre name relates to the appearance of the cells on a blood film and in the bone marrow: they have an irregular outline owing to the presence of filament-like cytoplasmic projections. **BRAF** mutations (see p. 691) are seen in almost all cases.

### Clinical features

Clinical features include anaemia, fever and weight loss. Splenomegaly occurs in 80% but lymphadenopathy is uncommon. Anaemia, neutropenia, thrombocytopenia and low monocyte counts are found.

### Management

The purine analogues cladribine and pentostatin have specific activity in this condition; complete remission is achieved in 90% with just one cycle of treatment. The remissions can last for many years and patients can be successfully retreated. Splenectomy or rituximab is sometimes used in cases that do not respond to these drugs.

### Further reading

### MYELOPROLIFERATIVE NEOPLASMS

Myeloproliferative neoplasms are clonal stem cell disorders characterized by uncontrolled proliferation of one or more of the cell lines in the bone marrow, usually erythroid, myeloid and/or megakaryocyte lines. Myeloproliferative disorders include:

- polycythaemia vera (PV)
- essential thrombocythaemia (ET)
- myelofibrosis
- chronic myeloid leukaemia (CML).

The first three disorders are grouped together, as there can be transition from one disease to another: for example, PV can lead to myelofibrosis. They may also transform to AML. They are often characterized by a genetic lesion in JAK2, MPL or CALR. The non-leukaemic myeloproliferative neoplasms (PV, ET and myelofibrosis) will be discussed in this section, CML having been described earlier.

### Polycythaemia vera

The investigation of polycythaemia is covered on page 395. While it is important to exclude secondary causes of polycythaemia, the presence of a mutation of the JAK2 gene is strongly suggestive of primary polycythaemia (polycythaemia vera). This is a clonal stem cell disorder in which there is an excessive proliferation of erythroid, myeloid and/or megakaryocytic progenitor cells. Over 95% of patients with PV have acquired mutations of the JAK2 gene, in the vast majority of cases a point mutation that causes the substitution of phenylalanine for valine at position 617 (JAK2V617F). JAK2 is a cytoplasmic tyrosine kinase that transduces signals, especially those triggered by haemopoietic growth factors such as EPO, in normal and neoplastic cells. The significance of the discovery of the JAK2 mutation in myeloproliferative neoplasms is two-fold: first, and of immediate significance, is the clinical utility of the detection of JAK2 mutations for the diagnosis of PV, and second is the prospect of the development of new treatments for the myeloproliferative disorders based on targeting JAK2 activity.
Clinical features

The onset is insidious. PV is more common in patients aged over 60 and may present with fatigue, itching, vertigo, headache and visual disturbance. These symptoms are common in the older population and consequently PV is easily missed. Patients may also present with complications of the disease relating to thrombosis or haemorrhage. Increasingly, PV is detected on routine blood tests conducted for other reasons. Severe itching may occur after a hot bath or when the patient is warm. Gout due to increased cell turnover may be a feature, and peptic ulceration occurs in a minority of patients. Thrombosis and haemorrhage are the major complications of PV.

The patient may be plethoric, and have a dusky cyanosis and injection of the conjunctivae. The spleen is palpable in 70% and is useful in distinguishing PV from secondary polycythaemia. The liver is enlarged in 50% of patients.

Diagnosis

JAK2 mutation screening is routine in the investigation of polycythaemia and is fully incorporated into diagnostic criteria. Although World Health Organization (WHO) criteria require a bone marrow biopsy for diagnosis in adults, current British guidelines do not mandate this in the presence of a confirmed JAK2 mutation (Box 17.9). Red cell mass studies are now rarely required.

The measurement of red cell and plasma volume is not routinely required. Measurement of serum ferritin can be useful to detect cases of iron-deficient PV. There may be a raised serum uric acid, leucocyte alkaline phosphatase and raised serum vitamin B₁₂ and vitamin B₁₂ binding protein (transcobalamin 1).

Management

Course and treatment

Treatment is designed to maintain a normal blood count and to prevent the complications of the disease, particularly thromboses and haemorrhage. The aim is to keep the haematocrit below 0.45.

There are three types of specific treatment:

• Venesection. During initial phases of treatment, the removal of 400–500 mL of blood weekly will successfully relieve many of the symptoms of PV. Iron deficiency eventually limits erythropoiesis and only infrequent venesection is required. Venesection is often used as the sole treatment, with the aim of maintaining a haematocrit of <0.45.

• Chemotherapy. Continuous or intermittent treatment with hydroxyurea (hydroxyurea) is used in patients who do not tolerate venesection or who have other poorly controlled features of the disease, such as thrombocytosis, symptomatic splenomegaly or thrombosis. Interferon-alfa is also effective; it is administered by subcutaneous injection but can cause unacceptable toxicity. Low-dose intermittent busulfan may be more convenient for elderly people but use must be weighed against potential long-term complications, such as the increased risk of leukaemia development.

• Ruxolitinib. This JAK2 inhibitor is more widely used in myelofibrosis but may have a role in patients who have severe symptoms such as pruritus or splenomegaly.

• Low-dose aspirin. Aspirin 75 mg daily with the above treatments is routinely used for patients with PV in the absence of contraindications.

• Anagrelide. This inhibits megakaryocyte differentiation and is useful for thrombocytosis.

Iron replacement should be avoided in patients with iron-deficient PV, as this can result in a dangerous rebound polycythaemia.

General measures

• Allopurinol. This can be given to block uric acid production. The pruritus is lessened by avoiding very hot baths.

• Surgery. Polycythaemia should be controlled before surgery. Patients with uncontrolled PV have a high operative risk. In an emergency, the haematocrit must be reduced by venesection and appropriate fluid replacement.

Prognosis

PV develops into myelofibrosis in 12–21% of cases and into AML in 5% as part of the natural history of the disease.

Essential thrombocythaemia

ET is a myeloproliferative neoplasm, closely related to PV, which is characterized by a persistently raised platelet count. Patients usually have normal haemoglobin levels, although mild anaemia may occur. The WCC is elevated in some patients. At diagnosis, the platelet count will usually be above 600 × 10⁹/L and may be as high as 2000 × 10⁹/L, or rarely even higher.

Clinical features

ET presents either symptomatically with thromboembolic or, less commonly, bleeding problems, or incidentally (e.g. at a routine medical check). Erythromelalgia, severe burning pain, erythema and warmth of the extremities (primarily the feet and, to a lesser extent, the hands) may occur.

Investigations

The diagnosis of ET is based on a sustained platelet count of 450 × 10⁹/L or more, in the absence of a possible reactive cause of thrombocytosis (Box 17.10) and of other haematological malignancy associated with thrombocytosis (e.g. PV, myelofibrosis). In selected cases a bone marrow biopsy is necessary; however, the requirement for this has largely been replaced by molecular tests. The JAK2 mutation test (see PV) is useful in that the gene is mutated in about half of all cases of ET, confirming a myeloproliferative neoplasm. For the remaining 50% of patients with a normal JAK2 gene, testing for mutations in caiaretinculin (CALR) or the thrombopoietin

---

(i) Box 17.9 Recommended diagnostic criteria for polycythaemia vera (PV)

JAK2-positive PV (requires both criteria)

- A1: Haematocrit >0.52 in men, >0.48 in women or raised red cell mass (>25% above predicted)
- A2: Mutation in JAK2

JAK2-negative PV (requires A1–A4 plus another A or two B criteria)

- A1: Haematocrit ≥0.60 in men, ≥0.56 in women or raised red cell mass (>25% above predicted)
- A2: Absence of mutation in JAK2
- A3: No cause of secondary erythrocytosis
- A4: Bone marrow histology consistent with PV
- A5: Palpable splenomegaly
- A6: Presence of an acquired genetic abnormality (excluding BCR-ABL) in the haemopoietic cells

B1: Thrombocythaemia (platelet count >450 × 10⁹/L)

B2: Neutrophil count >10 × 10⁹/L in non-smokers, ≥12.5 × 10⁹/L in smokers

B3: Radiological evidence of splenomegaly

B4: Low serum erythropoietin

Haematological oncology

17

396

receptor (MPL) will be informative in most cases, abrogating the need for a bone marrow biopsy. As a generalization, a person with a very high platelet count (>1000 × 10^9/L), who is clinically normal with good health, will most likely prove to have ET. In a patient who has a lower platelet count (e.g. 600 × 10^9/L) and is in poor health, the diagnosis can be more difficult.

Management

Due to the thrombotic risk, aspirin should be given to all ET patients, unless contraindicated. Treatment to reduce the platelet count (‘cytoreduction’) is recommended for patients with any high-risk feature:

- age >60 years
- platelet count >1500 × 10^9/L
- disease-related thrombosis or haemorrhage.

Treatment is usually with hydroxyurea (hydroxyurea), to control the platelet count to below 400 × 10^9/L. Alternative cytoreductive agents include anagrelide or busulfan. Interferon-alfa is also effective; it is administered by subcutaneous injection but can be difficult to tolerate due to side-effects. ET may eventually transform into PV, myelofibrosis or acute leukaemia, but the disease may not progress for many years.

Secondary thrombocytosis

Other disorders that may give rise to reactive high platelet counts include autoimmune rheumatic disorders and malignancy. Individuals who have been splenectomized (for any reason, including trauma) sometimes have high platelet counts.

Myelofibrosis

Myelofibrosis is a debilitating myeloproliferative neoplasm characterized by clonal proliferation of stem cells and abnormal myeloid cells in the bone marrow, liver, spleen and other organs. It may be primary or develop late in the course of ET or PV. Increased fibrosis in the bone marrow is caused by hyperplasia of abnormal megakaryocytes, which release fibroblast-stimulating factors such as platelet-derived growth factor.

Clinical features

The disease presents insidiously with lethargy, weakness and weight loss. Patients often complain of a ‘fullness’ in the upper abdomen due to splenomegaly, which may be massive. Severe pain related to respiration may indicate perisplenitis secondary to splenic infarction, and bone pain and attacks of gout can complicate the illness. Extramedullary haemoipoiesis can develop, typically in the spleen but also affecting other organs. Bruising and bleeding occur because of thrombocytopenia or abnormal platelet function.

Investigations

- Full blood count shows anaemia with leucoerythroblastic features. Poikilocytes and red cells with characteristic teardrop forms are seen (Fig. 17.12). The WCC may be >1000 × 10^9/L, and the differential WCC may be very similar to that seen in CML; leucopenia may also develop later. The platelet count may be very high but in later stages thrombocytopenia occurs.
- Bone marrow aspiration is often unsuccessful owing to the fibrotic state of the bone marrow, which may give a clue to the presence of the condition. A bone marrow trephine is necessary to show the markedly increased fibrosis. Increased numbers of megakaryocytes may be seen.
- Cytogenetic and molecular analysis shows the absence of the Philadelphia chromosome (BCR-ABL fusion gene); this helps to distinguish myelofibrosis from CML. A JAK2 mutation is present in approximately 60% of cases and a CALR mutation in 25%.

Management

This consists of general supportive measures, such as blood transfusion, analgesics, antihistamines and allopurinol. Treatment for myelofibrosis is often difficult but an estimation of prognosis
from a prognostic scoring system is a good basis on which to start planning a strategy for the individual patient. This may range from observation alone in those with the best prognosis to drug treatment or allogeneic SCT, offering a hope of cure for younger patients.

Historically, symptomatic splenomegaly was managed using hydroxycarbamide, radiotherapy and, in some cases, splenectomy. However, the latter is associated with very significant morbidity and mortality in patients with myelofibrosis and the former two are of limited benefit. A new and very promising development in the treatment of myelofibrosis is targeted therapy with JAK inhibitors. Ruxolitinib is the first such JAK inhibitor treatment in routine clinical use. Ruxolitinib results in substantial spleen reduction and improvement in symptoms in many patients with higher-risk myelofibrosis. Although ruxolitinib may improve life expectancy in patients with myelofibrosis, it does not eradicate the disease and underlying fibrosis remains in the vast majority of patients.

Prognosis

Patients may survive for 10 years or more, though median survival is 4–5 years with risk factors for poor prognosis, including cytopenias, presence of circulating blast cells, constitutional symptoms and the presence of poor-risk cytogenetics (e.g. monosomy 7) or molecular genetic mutations (e.g. ASXL1 or EZH2). Death occurs in 10–20% of cases by transformation to AML. The other most common causes of death are progressive bone marrow failure and infection.

Other myeloproliferative neoplasms

Rare myeloproliferative neoplasms include chronic eosinophilic leukaemia, a disorder that is associated with gene fusions that activate tyrosine kinase activity and may be treated with imatinib, as for CML; chronic neutrophilic leukaemia; and a heterogeneous group described as ‘myeloproliferative neoplasm, unclassifiable’.

MYELODYSPLASIA

Myelodysplasia (MDS) describes a group of acquired bone marrow disorders caused by a defect in haemopoietic stem cells. They are characterized by progressive bone marrow failure with quantitative and qualitative abnormalities in at least one of the three myeloid cell lines (red cells, granulocyte/monocytes and platelets). MDS covers a heterogeneous group of conditions with varying presentations and prognosis, for which there is a wide spectrum of treatment approaches ranging from observation to allogeneic SCT. Although the natural history of MDS is variable, there is a high morbidity and mortality owing to bone marrow failure and transformation to AML, which occurs in about 30% of cases. The current WHO classification of MDS is shown in Box 17.11.

Clinical features

MDS occurs mainly in the elderly and presents with symptoms of anaemia, infection or bleeding due to pancytopenia. MDS should be suspected in patients with otherwise unexplained cytopenias or macrocytosis.

Investigations

Serial blood counts show evidence of increasing bone marrow failure with anaemia, neutropenia and thrombocytopenia, either alone or in combination.

The bone marrow cellularity can be increased, normal or reduced, irrespective of the pancytopenia. Dysplasia in one or more of the erythroid, granulocytic and megakaryocytic lineages is usually present (Fig. 17.13). The percentage of bone marrow blast cells is important for classification and prognostic risk stratification in MDS. If this percentage rises above 20%, the diagnosis changes from MDS to AML. Ring sideroblasts seen with a specific iron stain are present in some subtypes.

Cytogenetic abnormalities (e.g. 7–, 5–) are common and are important for prognostic stratification. Certain specific abnormalities will also change the diagnosis to AML irrespective of blast count: for example, t(8;21) and inv(16). Somatic point mutations are commonly present. A poor survival rate is seen in those carrying mutations in TP53, EZH2, ETV6, RUNX1 and ASXL1.

Management

MDS is a heterogeneous disease and management is dependent on clinical features and predicted prognosis; the latter can be estimated using international prognostic scoring systems that incorporate blood counts, bone marrow blast percentage and cytogenetics. Treatment strategy is based on the behaviour and clinical burden of the disease and the likely prognosis, as well as the age and fitness of the patient. For example, an older patient may be managed with transfusion support alone, while a younger, fitter patient with high-risk disease may be considered for the higher-risk but potentially curative strategy of allogeneic SCT.

| Box 17.11 World Health Organization classification of myelodysplasia (MDS) |
|-----------------|---------------|--------------|-----------------|
| **Name**        | **Dysplastic lineages** | **Cytopenias** | **BM and PB blasts** |
| MDS with single lineage dysplasia (MDS-SLD) | 1 | 1 or 2 | BM <5%, PB <1%, no Auer rods |
| MDS with multi-lineage dysplasia (MDS-MLD) | 2 or 3 | 1–3 | BM <5%, PB <1%, no Auer rods |
| MDS with ring sideroblasts (MDS-RS) | 1–3 | 1–2 | BM <5%, PB <1%, no Auer rods |
| MDS with isolated del(5q) | 1–3 | 1–3 | BM 5–9% or PB 2–4%, no Auer rods |
| MDS with excess blasts (MDS-EB) | 0–3 | 0–3 | BM 10–19% or PB 5–19%, or Auer rods |

*A Cytopenias defined as: Haemoglobin <100 g/L; platelet count <100 x 109/L; neutrophil count <1.8 x 109/L. BM, bone marrow; PB, peripheral blood.
17

Haematological oncology

Treatment options include the following:

- **Supportive care** is the mainstay for all patients with MDS and symptomatic low blood counts. It includes red cell and platelet transfusion, and the prevention and treatment of MDS-associated bleeding and infection.

- **Erythropoietin** can be used in selected patients with low-risk MDS, symptomatic anaemia and inappropriately low endogenous EPO levels.

- **Iron chelation** should be considered for patients with good prognostic MDS who develop secondary iron overload (transfused with more than 20 units of red cells or serum ferritin >1000 μg/L).

- **Hypomethylating agents** (e.g. azacitidine, decitabine) are useful in selected patients.

- **Immunosuppressive agents**, such as ciclosporin and anti-thymocyte globulin, may be used in selected patients with a hypocellular bone marrow.

- **Intensive chemotherapy** schedules used for AML (see p. 390) may be used in selected patients with high-risk MDS and higher numbers of bone marrow blasts, but the remission rate is less than for AML, and prolonged pancytopenia may occur owing to poor haemopoietic regeneration caused by the defect in stem cells.

- **Lenalidomide** (a thalidomide analogue) has been proven to be remarkably successful in the treatment of early-stage MDS with a chromosome 5q deletion (the 5q− syndrome).

- **Allogeneic SCT** offers the hope of cure for carefully selected MDS patients who have a matched donor. Due to the potential morbidity and mortality associated with allogeneic SCT, this procedure is usually restricted to patients without major comorbidities who have higher-risk MDS and in whom the risk:benefit balance is clear.

**MDS/MPN overlap syndromes**

- MDS/MPN with ring sideroblasts and thrombocytosis
- MDS/MPN, unclassifiable.

Due to the rarity of these conditions, protocols are less well established but treatment principles are similar to those for MDS (e.g. supportive care for cytopenias) and MPNs (e.g. cy toreduction for elevated blood counts). Similarly, more intensive approaches, including transplantation, may be considered for selected younger patients.

**Further reading**

**LYMPHOMAS**

The lymphomas are malignancies of the lymphoid system and disease may arise at any site where lymphoid tissue is present. Certain subtypes have increased in frequency over the past 50 years for reasons that are not clear, the overall incidence being 15–20 per 100 000 population, which makes them the fifth most common malignancy in the Western world. Most often, patients have peripheral lymphadenopathy or symptoms due to occult lymph nodes, although approximately 20% arise at primary extranodal sites. A relatively small proportion present with lymphoma-associated ‘B’ symptoms of weight loss, fever and sweats. The natural history and clinical course vary widely with the subtype.

A significant proportion of patients are cured, and many others are helped, in terms of both quality and length of life.

The increasingly complex WHO classification of tumours of haemopoietic and lymphoid tissues primarily distinguishes Hodgkin lymphoma from non-Hodgkin lymphoma, an umbrella term covering a multiply subclassified spectrum of B- and T-cell malignancies.
Overall management strategy common to all lymphomas

A suspected diagnosis of lymphoma should always be confirmed by an excision biopsy of the relevant tissue that is large enough to allow histological, immunological and molecular analysis. Core biopsy is an acceptable substitute for biopsy of impalpable, ‘occult’ disease but fine needle aspiration is inadequate. The opinion of an expert haematopathologist is essential.

Investigations

Once the diagnosis is established, treatment strategy will depend on the outcome of investigations that are common to all the lymphomas (Box 17.12). These allow prognosis to be estimated and inform treatment decisions; a ‘stage’ is notionally assigned to the modification of the Ann Arbor classification for all nodal lymphomas (see later), despite the fact that this was planned only for Hodgkin lymphoma.

The tests listed in Box 17.12 are essential for planning specific therapy. Serum uric acid measurement is helpful, particularly in those lymphomas that carry a risk of tumour lysis syndrome (see p. 118); tests of cardiac function are valuable when potentially cardiotoxic chemotherapy is to be recommended, as is assessment of HIV and hepatitis B and C status.

Once treatment has begun, benefit is assessed at intervals, and re-evaluation (‘restaging’) performed at the end of a course of therapy. Depending on the outcome, future plans will be made. In the event of a decision to stop treatment, surveillance will initially be close, the interval between attendances being extended with the passage of time. Beyond 5 years, the focus of attention is on the possible long-term consequences of therapy rather than the disease itself. When initial therapy has been less successful than wished, management is dictated by individual circumstances. As conventional treatment options are exhausted, experimental therapy may be broached.

Hodgkin lymphoma

Hodgkin lymphoma (HL) has a stable incidence of approximately 3 per 100,000 in the Western world, and there is a male predominance of approximately 1.3:1. The majority of cases occur between the ages of 16 and 65, with a peak in the third decade.

Aetiology

There is epidemiological evidence linking previous infectious mononucleosis with HL; up to 40% of patients with HL have increased Epstein–Barr virus (EBV) antibody titres at the time of diagnosis, and EBV DNA has been demonstrated in tissue from patients with HL. These data suggest a role for EBV in pathogenesis. Other viruses have not been detected but other environmental and occupational exposures to pathogens have been postulated.

Diagnosis

HL is subclassified, according to the WHO classification (Box 17.13), into:

• **Classical Hodgkin lymphoma (CHL)**, the hallmark of which is the Reed–Sternberg cell (Fig. 17.14). CHL accounts for 90–95% of cases and is further subdivided into four distinct categories.

• **Nodular lymphocyte-predominant HL (NLPHL)**, characterized by the lymphocyte-predominant or ‘popcorn cell’.

Clinical features

The most common presentation of HL is painless cervical lymphadenopathy, commonly described in examination as ‘rubbery’. A smaller proportion of patients (often young women) present with disease localized to the mediastinum, with cough due to mediastinal lymphadenopathy (Fig. 17.15); others present with ‘generalized disease’, including hepatosplenomegaly and constitutional ‘B’ symptoms. Other less common symptoms, undoubtedly associated with HL but not recognized in the staging classification, are pruritus and alcohol-related pain at the site of lymphadenopathy.

For diagnosis

- Clinical history and examination
- Performance status
- Comprehensive geriatric assessment (see p. 302)
- Chest X-ray for mediastinal widening (see Fig. 17.15)
- CT scan of chest, abdomen, pelvis ± neck
- CT-PET scan (see Fig. 17.16)
- Bone marrow biopsy (only required if PET is not being used to assess bone marrow involvement for staging)
- Blood count, differential, film

For planning specific therapy

- Electrolytes and renal function, liver function tests and biochemistry
- Serum uric acid
- Virology: HIV, hepatitis B and C
- Cardiac function (e.g. echocardiogram)
- Respiratory function (e.g. spirometry testing)
- Referral for fertility preservation

4 Depending on circumstances.

CT, computed tomography; HIV, human immunodeficiency virus; PET, positron emission tomography.

Fig. 17.14 Histological appearance of Hodgkin lymphoma. Scattered mononuclear Hodgkin cells and a classical malignant binucleate Reed–Sternberg cell (arrowed) are seen to right of centre on a background of benign small lymphocytes and histiocytes. (Courtesy of Dr AJ Norton.)
Investigations
These are summarized in Box 17.12. Baseline PET-CT is standard practice to establish extent and distribution of metabolically active sites of disease (Fig. 17.16). This enables ‘stage’ to be assigned according to the Cotswolds modification of the Ann Arbor classification (Box 17.14). Patients with early-stage disease should be categorized as having favourable or unfavourable disease (Box 17.15). The Hasenclever International Prognostic Score (IPS) is applied to patients with advanced-stage disease (Box 17.16). On the basis of ‘stage’ and other prognostic factors, patients with HL are divided into three groups (see Box 17.15). Criteria for unfavourable disease are defined by either Germinal Hodgkin Study Group (GHSG) or European Organization for Research and Treatment of Cancer (EORTC) parameters.

Management
Principles of management

Management is aimed towards a curative intent with expectation of success. Older patients, with or without co-morbidity, require considerable modification of therapy. Patients with HIV infection should be managed, in conjunction with their HIV clinicians, in the same way as those who are seronegative. NLPHEL is a separate entity that, being strongly CD20-positive, is often treated with rituximab chemo-immunotherapy. Early-stage disease can be treated with radiotherapy alone.

Designations applicable to any disease state
A No symptoms
B Fever (temperature >38°C), drenching night sweats, unexplained loss of >10% of body weight within the previous 6 months
X Bulky disease (a widening of the mediastinum by more than one-third or the presence of a nodal mass with a maximal dimension >10 cm)
E Involvement of a single extranodal site that is contiguous or proximal to the known nodal site

Treatment of early-stage disease
Chemotherapy, comprising 2–4 cycles of doxorubicin, bleomycin, vinblastine and dacarbazine (ABVD), which is non-sterilizing and of a low second cancer risk, followed by involved field radiotherapy (20–30 Gy), results in more than 90% experiencing sustained remission. Current trials suggest that radiotherapy should not be omitted, as doing so leads to small increases in relapse rates.

Treatment of advanced-stage disease
This is also curable for a significant proportion of patients (see Box 17.16). Cyclical chemotherapy starts with two cycles of ABVD before interim PET scanning determines future cycles (response-adjusted therapy). Involved field irradiation to sites that were initially bulky is considered on completion of chemotherapy. The major short-term toxicity relates to myelosuppression and mucositis, the mortality being no more than 1% and the long-term risks being to the heart and lungs. Infertility and second malignancy are uncommon.

After two cycles of treatment, patients undergo interim scanning and response-adjusted therapy. When interim PET shows complete metabolic remission, bleomycin can be dropped from future cycles to minimize pulmonary toxicity for those with a good prognosis. If interim PET shows residual disease, therapy is escalated to BEACOPP with the addition of etoposide (E), procarbazine (P) and prednisolone (P). This regimen has a greater toxicity profile, with an impact on late effects.

Management of resistant and relapsed disease
Patients with primary refractory disease or relapsed disease are offered salvage chemotherapy with the aim of achieving a complete metabolic remission. This is followed by high-dose therapy with a BEAM autograft (carmustine, etoposide, cytarabine and melphalan).

Experimental approaches
With such excellent results with first- and second-line conventional therapy, the number of patients who experience treatment failure is small. However, this subset has poor outcomes and requires new treatment strategies. The antigen-targeted immunoconjugate, anti-CD-30-austatin (SGN-35, brentuximab), can be used in patients relapsing following autologous SCT if they have had at least two previous therapies. The immune checkpoint blockers pembrolizumab and nivolumab show promising response rates. Identifying these high-risk patients at diagnosis, with the aim of incorporating these drugs upfront in more intensive regimens, is the focus of current clinical trials. Allogeneic haemopoietic stem cell transplantation (HSCT) has a role, though its timing, in the context of newer drugs, is under discussion.

Long-term follow-up
The risks of late effects of therapy, particularly second malignancy and cardiac and endocrine problems, require appropriate surveillance.

Non-Hodgkin lymphomas
As defined by the WHO classification (Box 17.17), approximately 80% of non-Hodgkin lymphoma (NHL) is of B-cell origin and 20% of T-cell origin, there being considerable geographical variation. The incidence has increased, not necessarily for all subtypes, from 5 to 15 per 100 000 per year in the last half-century.

Aetiology
A family history is associated with a minor increase in risk of lymphoma, and common genetic polymorphisms with only a small risk for an individual may be significant in population terms. Certain inherited immunodeficiency syndromes, such as ataxia–telangiectasia and Wiskott–Aldrich syndrome, are associated with an increased risk of lymphoma. Patients with HIV-related immunosuppression or those on immunosuppressive drugs also have an increased risk. Infective viral precipitants are known, such as HTLV-1, which is causally related to adult T-cell lymphoma/leukaemia. There is a very strong epidemiological relationship between EBV and endemic Burkitt lymphoma, and a lesser one with both sporadic Burkitt lymphoma and Hodgkin lymphoma. Bacterial infection may also cause disease: for example, Helicobacter pylori in gastric mucosa-associated lymphoid tissue (MALT) lymphoma, and Chlamydia psittaci in ocular MALT lymphoma.

Pathogenesis
Malignant clonal expansion of lymphocytes occurs at different stages of lymphocyte development, leading to the different subtypes of lymphoma (see Fig. 17.2). In general, neoplasms of non-dividing mature lymphocytes are ‘indolent’, whereas those of proliferating cells (e.g. lymphoblasts) are much more ‘aggressive’. Malignant transformation is usually due to errors in gene rearrangements, which occur during the class switch, or gene recombinations for immunoglobulin and T-cell receptors. Thus, many of the errors occur within immunoglobulin loci or T-cell receptor loci.

The NHLs are subclassified according to the cell of origin (T or B lineage) and the stage of lymphocytic maturation at which they develop (precursor or mature).
Box 17.17 Modified World Health Organization classification of lymphoid neoplasms (2017)

**B-cell lymphomas**

**Mature B-cell lymphoma**
- Chronic lymphocytic leukaemia/small lymphocytic lymphoma
- B-cell prolymphocytic leukaemia
- Splenic marginal zone lymphoma
- Hairy cell leukaemia
- Lymphoplasmacytoid lymphoma
- Extramedullary marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue (MALT-lymphoma)
- Follicular lymphoma
- Mantle cell lymphoma
- Diffuse large B-cell lymphoma
- Primary diffuse large B-cell lymphoma of the central nervous system
- Primary mediastinal (thymic) large B-cell lymphoma
- Intravascular large B-cell lymphoma
- Primary effusion lymphoma
- Burkitt lymphoma/leukaemia

**T/NK cell lymphomas**

**Mature T/NK-cell lymphoma**
- T-cell prolymphocytic leukaemia
- T-cell large granular lymphocytic leukaemia
- Chronic lymphoproliferative disorder of NK cells
- Aggressive NK-cell leukaemia
- Adult T-cell leukaemia/lymphoma
- Extramedullary NK/T-cell lymphoma, nasal type
- Enteropathy-type T-cell lymphoma
- Hepatosplenic T-cell lymphoma
- Subcutaneous panniculitis-like T-cell lymphoma
- Mycosis fungoides
- Sézary’s syndrome
- Primary cutaneous CD30+ peripheral T-cell lymphoproliferative disorders
- Peripheral T-cell lymphoma, unspecified
- Angio-immunoblastic T-cell lymphoma
- Anaplastic large-cell lymphoma ALK-positive
- Anaplastic large-cell lymphoma ALK-negative

**Genetic features**

Burkitt lymphoma was the first tumour in which a cytogenetic change was shown to involve the translocation of a specific gene (Box 17.18). The most frequent change is where the MYC oncogene is translocated from chromosome 8 to a position near the constant region of the immunoglobulin heavy chain gene (IGH) on chromosome 14, resulting in upregulation of MYC. Other cytogenetic abnormalities associated with human lymphoma are the t(11; 18) in follicular lymphoma, involving upregulation of BCL2, or the t(11; 14) in mantle cell lymphoma, involving upregulation of the cell cycle regulator cyclin D1. Gene expression profiling and next-generation sequencing (see p. 31) have identified new molecular subclasses of lymphoma with prognostic significance.

**Clinical features**

The most common presentation overall is with painless lymphadenopathy or with local symptoms caused by a lymph node mass. Primary extranodal lymphomas present with soft tissue masses and related symptoms at the relevant site. The more common subtypes of NHL are described here.

B-cell lymphomas

See Fig. 17.17.

**Follicular lymphoma**

This is the second most common NHL (comprising approximately 20% of lymphomas worldwide).

**Clinical features and course**

Follicular lymphoma occurs in middle to late life, being rare in childhood. The majority of patients present with painless lymphadenopathy at more than one site, although a small proportion will be ill, some with ‘B’ symptoms. Percutaneous core biopsy or excisional biopsy establish the grade and tumour and may reveal transformation to DLBCL.

Treatment, where indicated, is with chemo-immunotherapy, targeting the CD20 antigen expressed on almost all B-cell lymphomas. The illness has been shown to regress spontaneously in some cases, which has led to an expectant policy of treatment for many patients. The clinical course following initiation of treatment is remitting–recurring. Transformation to DLBCL occurs in up to 25% of patients over 15 years. Death is due to resistant disease, transformed or not, the complications of therapy, or unrelated causes. The median survival now exceeds 10 years. Prognostic factors comprising the Follicular Lymphoma International Prognostic Index (FLIPI) are shown in Box 17.19.

**Management**

**General management**

The ‘well’ patient – asymptomatic, without organ impairment, ‘bulky disease’ or evidence of rapid progression or transformation – should be managed expectantly, after a careful explanation of the rationale. Around 50% of patients will progress and require therapy over the following 2.5 years, 20% will undergo spontaneous regression and 15% will require no treatment more than 10 years from diagnosis. Indications for treatment of low-grade NHL are shown in Box 17.20.

**Initial treatment: early disease**

Stage IA or 2A non-bulky disease is treated with involved field radiotherapy, which almost always induces complete remission, 50% of patients being disease-free after 10–15 years. In terms of overall survival, there are no randomized trials to show that this is better than expectant management (i.e. observing and treating if progression occurs).
Occasionally, in fitter patients, allogeneic HSCT is considered. Treatment and autologous SCT are used to consolidate the response. When second remission is achieved, in appropriate patients, high-dose chemotherapy regimens can be used in conjunction with monoclonal antibody therapy. Maintenance can again be given. When disease recurs and is confirmed, in younger patients without co-morbidity there is a high expectation of cure. Treatment is assigned on the basis of the revised International Prognostic Index (R-IPI; Box 17.21 and Fig. 17.19).

Prognosis

There has been a dramatic improvement in the overall survival pattern of follicular lymphoma since anti-CD20 therapy introduction. Median survival has been extended well beyond 10 years. Improvements in disease-free survival, after both initial and second-line therapy, are encouraging.

Diffuse large B-cell lymphoma

This is the most common adult lymphoma worldwide (increasing in incidence with age) and the second most common lymphoma in childhood, accounting for approximately 30% of all cases. There is a slight male preponderance. Our understanding of DLBCL’s molecular and genetic features is growing, which has led to the description of subgroups. Gene expression profiling has recognized germininal centre B-cell-like (GCB) and activated B-cell like (ABC) subgroups, with the latter having an inferior clinical outcome (Fig. 17.18). Patients with MYC, BCL2 and/or BCL6 rearrangements represent a subtype of DLBCL that does considerably less well with conventional therapy. This increased understanding of variability within the disease may help us define groups of patients who are likely to do badly with conventional therapy, and towards whom future targeted therapies may be directed.

Clinical features

The majority of patients present with painless lymphadenopathy clinically, at one or several sites. Intra-abdominal disease presents with bowel symptoms due to compression or infiltration of the gastrointestinal tract. In a small proportion, there is a primary mediastinal presentation, with symptoms and signs akin to those of HL. There may be ‘B’ symptoms, which should not be confused with symptoms related to the site of involvement. Investigation will lead to the demonstration of either locally or systemically advanced disease in the majority of cases. The illness is itself rapidly progressive without intervention, death occurring within months rather than years.

Management

Initial treatment

Treatment should be initiated immediately after the diagnosis is confirmed. In younger patients without co-morbidity there is a high expectation of cure. Treatment is assigned on the basis of the revised International Prognostic Index (R-IPI; Box 17.21 and Fig. 17.19).

Initial treatment: advanced disease (stages II–IV)

Chemo-immunotherapy incorporating an anti-CD20 monoclonal antibody (either rituximab or obinutuzumab) is the treatment of choice. ‘R-CHOP’ (rituximab with cyclophosphamide, doxorubicin, vincristine and prednisolone) and R-bendamustine are used in patients with FLIPI scores of 0–1; O-CHOP (obinutuzumab substituted for rituximab) and O-bendamustine is used in those with FLIPI scores of 2 or more. The two antibody treatments show no overall survival difference, but progression-free survival at 3 years appears improved with the use of obinutuzumab. It has been shown that continuing rituximab or obinutuzumab ‘maintenance’ every 2 months for 2 years also lengthens progression-free survival, although any benefits for overall survival remain unproven.

Second therapy and beyond

Patients are managed expectantly in the first instance, provided full re-evaluation, including repeat biopsy, reveals no evidence of transformation. A number of options are available, which will be determined by the individual patient and the first-line therapy. Options include the range of chemo-immunotherapy chosen as first-line treatment and also use of purine analogues. Maintenance can again be given. When second remission is achieved, in appropriate patients, high-dose treatment and autologous SCT are used to consolidate the response. Occasionally, in fitter patients, allogeneic HSCT is considered.

Haematological oncology

Box 17.21 Adverse prognostic factors in diffuse large B-cell lymphoma (R-IPI)

- Age >60 years
- Stage III or IV, i.e., advanced disease
- High serum lactate dehydrogenase level
- More than one extranodal site involved
- ECOG performance status 2 or more (see Box 6.13)

ECOG, Eastern Cooperative Oncology Group; R-IPI, revised International Prognostic Index. 1 point is given for each prognostic marker. These classify the prognosis as very good (0 points), good (1–2 points) or poor (>2 points). See Fig. 17.19 for the impact of these categories on survival.

Box 17.22 Types of Burkitt lymphoma

Endemic
- Are always EBV-associated
- Occurs in equatorial Africa
- Corresponds to the distribution of malaria

Sporadic
- Affects mainly children and young adults; the median age is 30
- Are EBV-related in 30%

Immunodeficiency-related
- Seen mainly in association with HIV infection
- May produce a similar picture post transplant

The curative approach involves re-evaluation, followed by second-line (salvage) chemotherapy; the response rate is approximately 50%. If at least a further partial remission is achieved, patients proceed to high-dose chemotherapy followed by an autograft. Overwhelmingly, the best results are achieved in those entering a second CR. When disease does not respond to salvage chemotherapy, clinical trials, including novel agents, may be considered.

Fig. 17.19 Survival curves for the revised International Prognostic Index (R-IPI) in diffuse large B-cell lymphoma. (Adapted from Sehn LH, Berry B, Chhanabhai M et al. The revised IPI is a better predictor of outcome than the standard IPI for patients with DLBCL treated with RCHOP. Blood 109; 1857–1861.)

Prognosis

The outlook for patients with DLBCL improved after the incorporation of rituximab into the initial therapy, overall survival now being between 32% and 83%, depending on risk group. The challenge of progressive disease following initial treatment is considerable, with less than 20% of patients overall staying alive in the long term.

Burkitt lymphoma

This is the most rapidly proliferating lymphoma, with a doubling time approaching 100% and a very rapid evolution. The most common childhood malignancy worldwide, it has a male to female preponderance of approximately 3:1 and occurs at all ages. There are three types (Box 17.22).

The most common presenting feature in the endemic type is a rapidly growing jaw tumour in a young child (Fig. 17.20). The next most common is an abdominal mass that is often associated with bone marrow involvement. Other common sites are the central nervous system, kidney and testis.

Investigation is along conventional lines for lymphoma and must be conducted as a matter of urgency. A different staging classification is applied to children.

Management

Burkitt lymphoma should be treated with curative intent whenever feasible, regardless of HIV status. Once investigation is completed, the patient must be haemodynamically and metabolically stable prior to initiation of specific therapy. Particular attention must be paid to the risk of the tumour lysis syndrome and so rasburicase prophylaxis should be given if available (see p. 118). Very frequent monitoring of electrolyte balance, especially potassium and phosphate levels, is essential for at least 72 hours after treatment is commenced.

Standard treatment is comprised of intensive, cyclical combination chemotherapy, if possible, to include cyclophosphamide, methotrexate and cytarabine in high doses. The details of this, and the number of cycles administered, will be determined by the number of low-risk features. Prophylactic central nervous system therapy is essential: intrathecal methotrexate or cytarabine is often given, in addition to high-dose systemic administration.

The palliative approach involves both chemotherapy and irradiation.
Prognosis
In the Western world, the prognosis of Burkitt lymphoma has improved markedly in recent years. The chances of cure are 90% for ‘low-risk’ patients and exceed 60% for ‘poor-risk’ patients, as well as HIV-positive cases, provided all treatment can be administered. Patients are considered cured if they reach 2 years in remission. For those who relapse or do not achieve remission, prognosis is poor. Although there may be further chemoresponsiveness, it is rare for second-line therapy to be more than transiently beneficial, regardless of whether it is followed by consolidation with either myeloablative chemotherapy or allogeneic HSCT.

Mantle cell lymphoma
This is one of the less common B-cell lymphomas, usually presenting in later life, with a male to female preponderance of 3:1. The most frequent presentation is with painless lymphadenopathy, often generalized. There may be non-specific symptoms of tiredness, or features related to the gastrointestinal tract. 'B' symptoms occur in fewer than 50%. Examination and standard investigation usually confirm generalized lymphadenopathy with or without hepatosplenomegaly. In patients with bowel symptoms, multiple lesions are frequently found on endoscopy. The bone marrow is usually involved and there may well be lymphoma cells in the peripheral blood (Fig. 17.21). The t(11; 14) translocation with dysregulation of cyclin D1 is a classical feature of this lymphoma. IGHV mutation status and expression of SOX11 can identify a subtype of indolent disease that can be monitored without the need for immediate treatment.

Management
In the majority of patients, therapy is started after investigation has been completed. It is usual for disease to regress with chemotherapy, although it is not often that CR is achieved. A prognostic index (MIPI) is used to help determine the best treatment option. Younger, fitter patients are treated with relatively intensive chemotheraphy, incorporating cycles of high-dose cytarabine and cyclophosphamide with rituximab, followed by high-dose therapy and autologous SCT (e.g. BEAM or LEAM autograft (lomustine, etoposide, cytarabine and melphalan)). Allogeneic transplantation is considered in appropriate patients with high-risk disease. Older, less fit patients are treated with less intensive therapy, such as R-CHOP followed by rituximab maintenance, or bortezomb-containing regimens. Progression is inevitable and there are a range of second-line approaches, including ibrutinib (a BTK inhibitor), bortezomib and bendamustine.

Prognosis
Untreated mantle cell lymphoma has a natural history that lies between that of DLBCL and follicular lymphoma with features of high- and low-grade lymphoma. The prognosis is around 8–12 years in patients well enough to tolerate intensive therapy.

Lymphoplasmacytic lymphoma
This is an uncommon B-cell malignancy, which is known as Waldenström’s macroglobulinaemia when associated with an immunoglobulin M (IgM) paraprotein and bone marrow infiltration. It usually occurs in later life, the incidence being approximately the same in men and women. It may be preceded by IgM monoclonal gammapathy of uncertain significance (MGUS), in which there is an IgM paraprotein but no bone marrow infiltration of symptoms relating to the paraprotein. The presentation is with lymphadenopathy or, alternatively, symptoms of anaemia or hyperviscosity caused by the paraprotein (e.g. headaches, visual disturbance). Examination and investigation usually reveal little beyond minimal adenopathy and, commonly, splenomegaly.

Management
Following completion of investigation, the critical decision is whether to initiate specific therapy or not. In an emergency, with severe symptoms of hyperviscosity, it is most appropriate to lower the paraprotein by plasmapheresis. Other symptomatic patients should receive a rituximab-containing regimen. Responses are seen in the majority of cases but with variable depth and durability. Treatment is appropriate only when symptomatic progression is clearly documented, most often by a fall in the haemoglobin or a significant rise in the IgM paraprotein. In this setting, ibrutinib can be used, and is effective particularly in patients with MYD88 mutations (present in 90%) and wild-type CXCR4 (mutated in 30%). In the very small proportion of younger patients in whom CR is achieved, consolidation
with autologous SCT is considered. Similarly, in the same group of patients who have recurrent disease, which is again responsive, allogeneic HSCT is also used.

**Prognosis**

Lymphoplasmacytic lymphoma is a relatively rare chemotherapy- and immunotherapy-sensitive disease, which may follow an indolent course for some years without therapy. The 5-year survival rate is around 78%; 10–20% of patients die of unrelated causes, as it presents in later life.

**Primary central nervous system lymphoma**

This diffuse, large B-cell lymphoma occurs in both the immunocompetent (predominantly age 55–70) and the immunosuppressed, in the context of HIV infection or following solid organ transplantation. It presents with symptoms relating to single or multiple parenchymal mass lesions. The diagnosis needs to be made on the basis of a biopsy, particularly in the immunocompromised, in whom an infectious aetiology of the symptoms, such as toxoplasmosis, is possible. A contrast-enhanced MRI scan is the first choice of investigation; cerebrospinal fluid is usually normal. Further investigation is necessary to exclude the possibility that the cerebral lesion is a manifestation of generalized disease.

**Management**

Intensive chemotherapy, with high-dose methotrexate, cytarabine, thiotepa and rituximab, is used. Less fit patients are offered less intense chemotherapy and/or radiotherapy. If there is a good response to treatment, consolidation is with autologous SCT in those fit enough. The overall results have improved with new regimens but prognosis remains poor.

**Marginal zone lymphoma**

This is an uncommon B-cell lymphoma associated with chronic inflammation or infection. Mucosa-associated lymphoid tissue (MALT) is the commonest form of marginal zone lymphoma. MALT of the salivary glands is linked with Sjögren’s syndrome. Gastric MALT lymphoma is closely associated with *Helicobacter pylori* infection and presents with symptoms of gastric ulceration or a mass, indigestion or bleeding; the diagnosis is made by endoscopic biopsy to include confirmation of both lymphoma and *H. pylori* status. Careful assessment of extranodal sites is required.

**Management**

Management is dependent on whether or not disease is localized and symptomatic. If only ‘low-grade’ gastric MALT lymphoma is present, *Helicobacter eradication therapy is the treatment of choice (see p. 1175). This almost invariably alleviates the symptoms. Re-evaluation is carried out after 6, 12 and 24 months with endoscopy, repeat biopsy and photography. In general, a conservative approach is followed, as responses may take many months to achieve and rapid progression is very unlikely. Failure is uncommon, but if it does occur, biopsy should be repeated. If the histology is unchanged after further *Helicobacter eradication therapy (if necessary), either rituximab chemotherapy, single-agent rituximab or low-dose involved-field radiotherapy is likely to be effective or possibly curative. Overall, the prognosis is very good, a very large proportion of patients being alive 10 years after diagnosis.

Any evidence of transformation to DLBCL should be treated as high-grade lymphoma. *Helicobacter eradication therapy should also be given but should not be considered definitive treatment. The potential risk of gastric perforation or haemorrhage because of therapy is not a contraindication to treatment. Surgery is rarely needed but irradiation is used for persistent disease. The prognosis is approximately the same as for nodal DLBCL of equivalent extent.

**Peripheral T-cell lymphomas**

T-cell lymphomas can present in nodal, extranodal, cutaneous and predominantly leukaemic forms. They describe a large group of rare diseases, less common than their B-cell counterparts and varying in their behaviour from indolent to aggressive. Many subtypes carry poor prognoses due to disappointing responses to treatment (Fig. 17.22).

The two most common subtypes of nodal T-cell lymphoma are ‘peripheral T-cell lymphoma, not otherwise specified (NOS)’ and ‘angio-immunoblastic T-cell lymphoma’, which together account for about 50% of T-cell lymphomas. Both occur in the middle-aged to elderly population, the primary presentation being lymphadenopathy. In contrast to the B-cell lymphomas, ‘B’ symptoms are common. Patients with angio-immunoblastic T-cell lymphoma also present with inflammatory symptoms of fever, rash and arthritis. Anaplastic T-cell lymphoma (ALCL), particularly when anaplastic lymphoma kinase (ALK)-positive, has a better prognosis than other subtypes.

**Management**

Following standard investigation, which usually reveals widespread disease, patients are treated with cyclical combination chemotherapy as for DLBCL. CD20 is not expressed on T cells and so rituximab is not used; as yet, there is no equivalent drug for T-cell lymphoma. Symptoms almost invariably resolve, although

---

*Fig. 17.22 Relative frequencies of T-cell lymphoma subtypes in adults. ALK, anaplastic lymphoma kinase; NOS, not otherwise specified. (Reproduced with permission from WHO. Swerdlow SH, Campo E, Harris NL et al (eds). WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues, 4th edn. Geneva: WHO; 2008; Fig 8.07.)*
they may recur between cycles. Overall, the outcome of treatment is worse than for DLBCL, in terms of quality of response, duration of response and overall survival. Other than in ALC, autologous SCT or allograft should be considered in first remission. Second-line therapy is rarely satisfactory, although a small proportion of patients may benefit from allogeneic SCT to consolidate a second response.

Mycosis fungoides and Sézary’s syndrome

Mycosis fungoides is the most common cutaneous lymphoma. It predominantly arises in, and is confined to, the skin, spreading to other organs only latterly in the disease. The rare leukaemic variant is known as Sézary’s syndrome. It has a long natural history, presenting with multiple erythematous lesions, plaques and tumours, and multiple skin biopsies are required to establish a diagnosis. The presentation and management of skin disease are discussed on page 692. A wide range of agents can be used in advanced-stage disease, it is rare to achieve a durable response and the prognosis is poor. Early-stage disease carries a relatively good prognosis. Median survival for Sézary’s syndrome is 3.1 years.

Further reading

MYELOMA AND OTHER PLASMA CELL DISORDERS

The classification of this group of related conditions is presented in Box 17.23; the most significant is myeloma.

Myeloma

Myeloma (or multiple myeloma) is a cancer of plasma cells. As with their normal counterpart, these cells usually produce immunoglobulin, but the neoplastic nature of the population means this is a non-functional monoclonal paraprotein (or ‘M band’). The paraprotein is usually an intact immunoglobulin, most commonly IgG (55%) or IgA (20%), and more rarely IgM or IgD. There is normally also an imbalance in the free light chains (kappa or lambda), which can be detected in the urine (Bence Jones protein) and blood (serum free light chains, SFLC) (Fig. 17.23). Around 15% of cases will have no intact immunoglobulin but are light chain only, while 5% of cases are completely non-secretory.

Not all paraproteins are produced by plasma cell disorders. B-cell lymphoproliferative disorders, such as low-grade B-cell NHL and CLL can produce a paraprotein, and Waldenström’s macroglobulinaemia is caused by an IgM-producing lymphoplasmacytic lymphoma. Non-malignant disorders producing a paraprotein include poorly controlled HIV infection and autoimmune conditions, although these are more likely to be transient and should resolve with treatment of the underlying condition.

The abnormal plasma cell population can be identified on bone marrow aspirate or biopsy (trephine), with the imbalance of kappa:lambda restricted plasma cells demonstrated by flow cytometry (aspirate) or immunohistochemistry (biopsy) (Fig. 17.24).

Myeloma is predominantly a disease of the elderly, median age at presentation being over 60 years. It is rare under 40 years of age. The annual incidence is 4 per 100 000 and disease is more common in males and in black Africans, but less common in Asians.

Clinical features

These include

• bone pain: most commonly backache, owing to vertebral involvement (60%)
• symptoms of anaemia
• recurrent infections
• symptoms of renal failure (20–30%)
• symptoms of hypercalcaemia

rarely, symptoms of hyperviscosity and bleeding due to thrombocytopenia.

Patients can be asymptomatic, the diagnosis being suspected by abnormal ‘routine’ blood tests. Life-threatening complications are shown in Box 17.24.

The clinical features of myeloma are related to the underlying pathology:

• Bone marrow infiltration with plasma cells. This results in anaemia, neutropenia and thrombocytopenia.
• Paraprotein secretion. This may (rarely) result in symptoms of hyperviscosity. In addition, there is a reduction in the levels of normal immunoglobulin (immune paresis), contributing to the tendency to contract recurrent infections (Fig. 17.25).
• Free light chain secretion. This leads to deposition in the renal tubules, causing renal impairment by cast nephropathy. Other factors such as hypercalcaemia, use of non-steroidal anti-inflammatory drugs (NSAIDs) and, rarely, the deposition of AL amyloid can also contribute to renal injury (see p. 1357).
• Bone disease. Dysregulation of bone remodelling leads to the typical lytic lesions, usually seen in the spine, skull, long bones and ribs (Fig. 17.26). There is increased osteoclastic activity without increased osteoblast formation of bone, causing fractures of long bones, vertebral collapse and hypercalcaemia. Soft tissue plasmacytomas also occur and they are the usual cause of spinal cord compression.

Box 17.23 World Health Organization classification of plasma cell neoplasms (2017)

• Monoclonal gammopathy of undetermined significance
• Plasma cell myeloma
• Plasma cell myeloma variants:
  • Smouldering (asymptomatic) plasma cell myeloma
  • Non-secretory myeloma
  • Plasma cell leukaemia
• Plasmacytoma:
  • Solitary plasmacytoma of bone
  • Extra-osseous plasmacytoma
• Monoclonal immunoglobulin deposition diseases
  • Primary amyloidosis (see p. 1357)
  • Light chain and heavy chain deposition diseases
• Heavy chain diseases:
  • Gamma (γ) heavy chain disease
  • Mu (μ) heavy chain disease
  • Alpha (α) heavy chain disease
The spectrum of plasma cell disorders is classified based on the degree of plasma cell infiltration and the presence of end-organ damage (Box 17.25). Previously, a diagnosis of myeloma required more than 10% plasma cell infiltrate, together with at least one of the four ‘CRAB’ features:

- hypercalcaemia: Ca >2.75 mmol/L
- renal impairment: creatinine clearance <40 mL/min or serum creatinine >177 μmol/L
- anaemia: haemoglobin <100 g/L or >20 g/L below normal
- bone involvement: one or more osteolytic lesions of ≥5 mm on X-ray, CT scan or PET scan.

The diagnostic criteria were updated in 2014 to include three additional ‘biomarker’ features, which are associated with a high risk of transformation to symptomatic disease:

- involved/uninvolved SFLC ratio (e.g. kappa:lambda) of ≥100
- bone marrow plasma cell infiltration of ≥60%
- ≥2 focal lesions on MRI scan.

Although they may be related, other non-CRAB manifestations of end-organ damage (e.g. hyperviscosity, recurrent bacterial infections, AL amyloidosis, peripheral neuropathy) are non-specific and not diagnostic of myeloma. The presence of a paraprotein does not in itself make a diagnosis of myeloma.

Investigations
General
- Full blood count. Haemoglobin, white cell count and platelet count are normal or low.
- Erythrocyte sedimentation rate. This is often high.
- Blood film. There may be rouleaux formation as a consequence of the paraprotein. Circulating plasma cells are present in the aggressive plasma cell leukaemia variant of myeloma.
• MRI spine. This is useful if there is back pain; it may show imminent compression or collapse. It can also pick up occult lesions not seen on CT (as per the updated diagnostic criteria).

Histology
Bone marrow aspirate or trephine shows characteristic infiltration by clonal plasma cells (see Fig. 17.24).

Staging and prognosis
Patients can be risk-stratified using the International Staging System (ISS), based on the levels of albumin and B2M:

- **ISS Stage I**: B2M <3.5 mg/L and serum albumin ≥35 g/L.
- **ISS Stage II**: neither stage I nor stage III.
- **ISS Stage III**: B2M ≥5.5 mg/L.

Via FISH and microarray techniques, cytogenetic abnormalities can be detected in most cases of myeloma, and have a bearing on prognosis. Hyperdiploidy is associated with a good prognosis, while some translocations affecting the IgH locus on chromosome 14 are associated with poor prognosis – for example, t(4;14), t(14;16) and t(14;20) – as are other findings such as 17p−, 1q+ and 1p−. The most important of these, together with LDH levels, have been incorporated into a revised ISS staging system (R-ISS):

- **R-ISS I**: ISS stage I and normal LDH and no del(17p), t(4;14) or t(14;16) by FISH.
- **R-ISS II**: neither stage I nor stage III.
- **R-ISS III**: ISS stage III and elevated LDH and/or del(17p), t(4;14) or t(14;16) by FISH.

This system is based on clinical trial data, and clearly divides patients into distinct groups for overall survival (10 years, 6 years and 1.3 years) for R-ISS groups I, II and III.

Management

Supportive therapy

- **Anaemia** should be corrected; blood transfusion may be required. Erythropoietin often helps. Transfusion should be undertaken slowly in patients with hyperviscosity.
- **Hypercalcaemia and kidney injury** should be treated urgently with hydration, bisphosphonates and high-dose steroids. Hyperviscosity can be managed with plasmapheresis.
- **Infection** should be treated promptly with antibiotics.
- **Bone pain** can be alleviated most rapidly by radiotherapy and systemic chemotherapy or high-dose dexamethasone. NSAIDs should be avoided because of the risk of acute kidney injury. Bisphosphonates such as zoledronate, which inhibit osteoclast activity, help ensure rapid normocalcaemia and, given long-term, reduce skeletal events such as pathological fracture, cord compression and bone pain.
- **Pathological fractures** may also be prevented by prompt orthopaedic surgery with pinning of lytic bone lesions at critical sites seen on the skeletal survey, such as the femoral shaft. Kyphoplasty and vertebroplasty may be useful in treating vertebral fractures.

Specific therapy

Although myeloma remains incurable for the vast majority of patients, there is now a large number of drugs that can be used in combination and in sequence to prolong survival and reduce complications.

- **Steroids**. Dexamethasone and prednisolone both commonly form part of combination therapies, and of initial management of acute complications.
• **Cytotoxic chemotherapy drugs**, e.g. melphalan and cyclophosphamide. Melphalan is used as high-dose therapy in autologous SCT.

• **Proteasome inhibitors**. Bortezomib was the first of these agents and is commonly given subcutaneously. Carfilzomib, an irreversible proteasome inhibitor, may have greater efficacy but can have cardiotoxic side-effects. ixazomib is a newer oral agent.

• **‘Immunomodulatory drugs’**. Thalidomide, and subsequent agents such as lenalidomide and pomalidomide, act in conjunction with the cereblon protein to alter the transcriptional profile of myeloma cells, leading to cell death. They can be given over an extended period of time.

• **Monoclonal antibodies**. Daratumumab and isatuximab (anti-CD38), as well as elotuzumab (anti-SLAMF7), have anti-myeloma activity, particularly when given in combination with other agents.

• **Others**. These include bendamustine, panobinostat and venetoclax. Anti-myeloma agents typically work most effectively when given in combination: for example, bortezomib, thalidomide and dexamethasone are highly efficacious when used together. Combinations are selected based on efficacy, side-effect profile and previous treatment history, as well as funding availability: many are high-cost drugs.

Younger patients who are fit enough for intensive chemotherapy will typically have an autologous SCT in their first and sometimes second remission, to consolidate a good response to therapy. This typically increases the duration of remission and overall survival time. Myeloma will inevitably relapse after each initial response, and although subsequent remissions are achievable, they tend to be less sustained with each treatment course as the cancer becomes more resistant to treatment. Despite this, current treatments have transformed the prognosis of myeloma with ongoing improvement; in this fast-moving field, further improvements are expected.

Immunological therapies have the potential to cure a small subset of patients, with the use of allogeneic transplant sometimes considered for young patients with high-risk disease. CAR-T cell immunotherapy has great potential but is currently an investigational treatment.

**Smouldering (asymptomatic) myeloma**

In this condition there is a significant paraprotein (IgG or IgA >30 g/L, or urinary light chain excretion >0.5 g/day) and/or a marrow plasma cell infiltration of more than 10% but no end-organ damage or biomarkers of symptomatic myeloma. Most, but not all, patients will eventually progress to symptomatic myeloma, with a median time to progression of about 5 years. The risk is highest for those with an elevated SFLC ratio, high bone marrow plasma cell infiltration and paraprotein over 30 g/L. These patients can be managed with close monitoring in clinic.

**Monoclonal gammopathy of undetermined significance**

Monoclonal gammopathy of undetermined significance (MGUS) describes an isolated finding of a monoclonal paraprotein in the serum or urine that does not fulfil the diagnostic criteria for smouldering or symptomatic myeloma. The risk of progression to myeloma is approximately 1% per year, with risk factors including elevated SFLC ratio, paraprotein of more than 15 g/L and non-IgG subtype.

**Solitary plasmacytoma**

This is an isolated tumour of neoplastic plasma cells. It may be a solitary plasmacytoma of bone within the skeleton or a soft tissue extramedullary plasmacytoma outside the marrow cavity. These can be treated curatively with radiotherapy, although a high proportion (especially bone plasmacytomas) will eventually progress to systemic myeloma.

**Heavy chain diseases**

These rare conditions are characterized – as the name suggests – by the production of a heavy-chain-only paraprotein. They are usually caused by a B-cell lymphoproliferative condition.

**Monoclonal gammopathies of clinical significance**

Apart from the entities outlined above, in which the plasma cell disorder is acting in a malignant or pre-malignant manner, there are a number of other conditions in which the clonal population is relatively small but secondary clinical effects occur. These are discussed in more detail in the relevant organ-based chapters.

• **AL amyloidosis** involves organized fibrillary deposits in the kidneys, heart, gastrointestinal tract, skin and nerves. It is usually caused by a lambda-light chain isotype. Other subtypes of amyloid (e.g. hereditary ATTR amyloid and reactive AA amyloid) are not caused by a plasma cell disorder (see p. 1358).

• **Monoclonal gammopathies of renal significance** constitutes a group of renal pathologies caused by immunoglobulin deposits (see p. 1365). Like AL amyloid, all of these may be treated with myeloma-directed therapies, e.g. bortezomib, cyclophosphamide and dexamethasone.

• **POEMS syndrome** is a rare disease characterized by polyneuropathy, organomegaly, endocrinopathy, monoclonal plasma cell disorder and skin changes (see p. 890). High levels of vascular endothelial growth factor (VEGF) are common and may be the mediating mechanism.

Rheumatology
Anisur Rahman and Ian Giles

CORE SKILLS AND KNOWLEDGE

Musculoskeletal complaints are very common, comprising 25–30% of consultations in primary care. The majority of patients have soft tissue complaints or osteoarthritis, with inflammatory arthritis and autoimmune rheumatic diseases having a much lower prevalence, of between 0.01% and 1% of the population.

Rheumatology is mainly an outpatient specialty, with care being delivered by multidisciplinary teams including nurse specialists, physiotherapists and other allied health professionals. Apart from general rheumatology clinics, specialist clinics often exist (sometimes in tertiary referral centres) for patients with inflammatory conditions such as rheumatoid arthritis or systemic lupus erythematosus. Few patients require admission to hospital but many receive day case infusions of biological disease-modifying drugs.

Key learning outcomes in musculoskeletal disease include:
- learning to distinguish mechanical from inflammatory problems, and then identifying the number and pattern of joint involvement as well any extra-articular features in patients with inflammatory multisystem disease
- becoming familiar with the main drug categories, of analgesics and medication that alters the immune response
- learning how to examine joints, and when to order autoantibody tests.

Opportunities for learning include sitting in general and specialist rheumatology clinics, observing musculoskeletal and joint injection lists, talking with and examining patients attending day units for infusions of medication, and attending imaging meetings.
**CLINICAL SKILLS FOR RHEUMATOLOGY**

**Taking a musculoskeletal history**

In most rheumatological disorders (Box 18.1), the diagnosis is **clinical**: that is, made on the history and examination, and then supported by investigations. Taking a thorough history is therefore crucial, and the main points to consider are:

1. **Who is the patient?**
   - **Age**: osteoarthritis, polymyalgia rheumatica and giant cell arteritis present mainly in patients over the age of 50. Autoimmune rheumatic diseases and inflammatory arthritis frequently present in people under 50.
   - **Gender**: rheumatoid arthritis (RA), Sjögren’s syndrome, systemic lupus erythematosus (SLE) and systemic sclerosis are more common in women, whereas gout and ankylosing spondylitis are more common in men.
   - **Ethnicity**: SLE is more common in African–Caribbean people than in other ethnicities.
   - **Occupation**: jobs that involve heavy use of one part of the body can lead to soft tissue pain and/or OA; for example, in the low back, hips and knees of people who do a lot of heavy lifting. Musculoskeletal pain may also affect people’s ability to do their job, or care for children or dependents. The effects of these on quality of life should be assessed.

2. **Has something happened to the patient?**
   - **Physical trauma**: trauma to a particular region of the body may cause pain there and/or in related regions.
   - **Psychosocial stress and depression**: physical, psychological and social factors interact to contribute to symptoms. In musculoskeletal disorders, pain may cause distress and poor sleep, which in turn build up muscle tension and worsen the pain (see p. 429). Acute stressful events, such as bereavement, bullying, abuse and redundancy, may exacerbate these symptoms.

3. **What are the symptoms?**
   - **Pain**:
     - **Where is it?** The pattern of joint involvement is a useful clue to the diagnosis (Box 18.2).
     - **Is it arising from joints, spine, muscles or bone, with local tenderness?**
     - **Could it be referred from another site?** Joint pain is localized but may radiate distally – shoulder to upper arm; hip to thigh and knee.
     - **Is it constant, intermittent or episodic?**
     - **Are there aggravating or precipitating factors?** Is it made worse by activity and eased by rest (mechanical), or worse after rest (inflammatory)?

   - **Joint pain is local**. Look for symmetry or asymmetry; shoulder and pelvic girdle stiffness and pain are more common in men.

   - **Swelling**
     - **Does it affect one joint or several?** Look for symmetry or asymmetry, and/or a peripheral or proximal pattern. An acute monoarthritis may be due to trauma, gout, pseudogout or sepsis (fever or immunosuppression). A polyarthritis is more likely to be due to OA or RA.

   - **Is it constant or does it come in short-lived or longer episodes?**

   - **Is there associated inflammation** (redness and warmth)?

   - **Extra-articular symptoms**:
     - Osteoarthritis and soft tissue problems are not usually associated with symptoms outside the joints.
     - Features such as rash, breathlessness, neurological symptoms or blood disorders suggests that the locomotor problem may be one facet of a more systemic disorder, such as RA, psoriatic arthritis or SLE.

4. **What medication is the patient taking?**
   - **Could a drug be a cause?** Diuretics may precipitate gout in men and older women. Steroids can cause avascular necrosis.

   - **Have the symptoms responded to medication?** A good response to a trial of oral or intramuscular corticosteroid suggests an inflammatory or autoimmune problem.

5. **What is the family history?**

**Examination of the joints**

See page 415 for more detail on how to structure both a screening examination for limb and spinal disease and a detailed examination of individual joints. The technique for joint aspiration is presented later in Fig. 18.2 and Box 18.7.

**Approach to the patient**

A full description of how to take a musculoskeletal history is found on page 412.

Always observe patients, looking for disabilities, as they walk into the room and sit down. General and neurological examinations are often necessary, and may reveal some of the signs described in the figure on page 413. Guidelines for rapid examinations of the limbs and spine are shown in Box 18.3.

Examining an individual joint involves three stages: looking, feeling and moving (Box 18.4). A screening examination of the locomotor system, known by the acronym GALS (global assessment of the locomotor system), has been devised. Video demonstrations are available (see “Further reading”). GALS has been modified for examination of children.

**Further reading**

**Anatomy and physiology of the normal joint**

A joint can be defined as a place where two or more bones meet. There are three types of joints: fibrous, fibrocartilaginous and synovial.

**Fibrous and fibrocartilaginous joints**

These include the intervertebral discs, the sacroiliac joints, the pubic synphysis and the costochondral joints. Skull sutures are fibrous joints. Little movement occurs at such joints.

---

**Box 18.3 Rapid examinations of the limbs and spine**

**Upper limbs**
- **Raise the arms sideways to the ears (abduction). Reach behind the neck and back.** Difficulties with these movements indicate a shoulder or rotator cuff problem.
- **Hold the arms forwards, with elbows straight and fingers apart, palm up and palm down.** Fixed flexion at the elbow indicates an elbow problem. Examine the hands for swelling, wasting and deformity.
- **Place the hands in the ‘prayer’ position with the elbows apart.** Flexion deformities of the fingers may be due to arthritis, flexor tenosynovitis or skin disease. Painful restriction of the wrist limits the person’s ability to move the elbows out with the hands held together.
- **Make a tight fist.** Difficulty with this indicates a loss of flexion or grip. Grip strength can be measured.

**Lower limbs**
- **Ask the patient to walk** a short distance away from and towards you, and to stand still. Look for abnormal posture or stance.
- **Ask the patient to stand on each leg.** Severe hip disease causes the pelvis on the non-weight-bearing side to sag (positive Trendelenburg test).
- **Watch the patient stand and sit,** looking for hip and/or knee problems.
- **Ask the patient to straighten and flex each knee.**

- **Ask the patient to place each foot in turn on the opposite knee with the hip externally rotated.** This tests for painful restriction of the hip or knee. Abnormal hips or knees must be examined with the patient lying down.
- **Move each ankle up and down.** Examine the ankle joint and tendons, medial arch and toes while the patient is standing.

**Spine**
- **Stand behind the patient.**
- **Ask the patient to (a) bend forwards to touch the toes with straight knees, (b) extend backwards, (c) flex sideways and (d) look over each shoulder, flexing and extending and side-flexing the neck.** Observe abnormal spinal curves – scoliosis (lateral curve), kyphosis (forward bending) or lordosis (backward bending). A cervical and lumbar lordosis and a thoracic kyphosis are normal. Muscle spasm is worse while standing and bending. Leg length inequality leads to a scoliosis that decreases on sitting or lying (the lengths are measured with the patient lying down).
- **Ask the patient to lie supine.** Examine any restriction of straight-leg raising (see disc prolapse, below).
- **Ask the patient to lie prone.** Examine for anterior thigh pain during a femoral stretch test (flexing knee while prone), which indicates a high lumbar disc problem.
- **Palpate the spine and buttocks for tender areas.**

**Box 18.4 Examination of the joint**

**Look at the appearance of the joint**
- **Swelling** – could be bony, fluid or synovial
- **Deformity:**
  - **Valgus,** where the distal bone is deviated laterally (e.g. knock-knees or genu valgum)
  - **Varus,** where the distal bone is deviated medially (bow-legs or genu varum)
  - **Fixed flexion or hyperextension**
  - **Rash** – especially psoriasis
  - **Muscle wasting** – easier to see in large muscles like the quadriceps
  - **Scars** – from surgery or trauma
  - **Signs of inflammation**
  - **Symmetry:**
    - Are the right and left joints (e.g. hips, knees, any other paired joint) the same?
    - If not, which do you think is abnormal?

**Feel**
- **Swelling:**
  - **Fluid swelling** (effusion) usually represents increased synovial fluid in inflammatory arthritis, but can be due to blood or pus
  - **Synovial swelling** is rubbery or boggy and usually occurs in inflammatory arthritis
  - **Bony swelling,** such as Heberden’s nodes in the fingers, is usually seen in osteoarthritis
  - **Warmth** – a warm joint may be inflamed or infected
  - **Tenderness** – may represent joint inflammation, but many people have chronic tenderness all over the body (e.g. in fibromyalgia)

**Move**
- **Active movement:**
  - Is the range full and pain-free?
  - Is the movement fluid?
  - In the hands, can the patient perform fine movements?
  - In the legs, can the patient walk properly?
  - Compare movements on the right and left sides – are they symmetrical?
  - Is there crepitus when the joint is moved?
  - If active movement is limited, try passive movement:
    - In a joint problem both will usually be affected.
    - In a muscle or nerve problem, passive movement may remain full.
Investigation of rheumatic disease

Synovial joints
Synovial joints (Fig. 18.1) include the ball-and-socket joints (e.g. hip) and the hinge joints (e.g. interphalangeal). They are designed to allow movement, which is restricted to a required range, and stability is maintained during use. The load is distributed across the surface, thus preventing damage by overloading or disuse. Each structural component of a synovial joint plays a key functional role, and different components are affected in different disease processes.

Juxta-articular bone
Bone structure and physiology are discussed on page 473. The bone that abuts a joint (juxta-articular bone) is highly vascular and comprises a light framework of mineralized collagen enclosed in a thin coating of tougher, cortical bone. It withstands pressure poorly if the normal intra-articular covering of hyaline cartilage is worn away, as in osteoarthritis (OA; see p. 433). This process can lead to abnormalities of bone growth and remodelling (see p. 433).

Articular cartilage
The hyaline cartilage lining the bones within a joint is called articular cartilage. It is avascular and derives nourishment from synovial fluid. It is predominantly composed of type II collagen, encoded by the COL2A1 gene, which forms a mesh-like network. Chondrocytes secrete collagen and proteoglycans, and are embedded in the cartilage. Defects in articular cartilage and underlying bone are features of osteoarthritis.

Synovium and synovial fluid
The joint capsule, which is connected to the periosteum, is lined with synovium, which is a few cells thick and vascular. Its surface is smooth, non-adherent, and is permeable to proteins and crystals. Synovial fluid is a highly viscous fluid secreted by the synovial cells and has a similar consistency to plasma. Glycoproteins ensure a low coefficient of friction between the cartilaginous surfaces. Tendon sheaths and bursae are also lined by synovium. Inflammation of the synovium is a feature of inflammatory arthritis.

Ligaments and tendons
These structures stabilize joints. Ligaments are variably elastic and this contributes to the stiffness or laxity of joints (see p. 432). Tendons are inelastic and transmit muscle power to bones. The joint capsule is formed by intermeshing tendons and ligaments. The point where a tendon or ligament joins a bone is called an enthesis and may be the site of inflammation. Whereas most ligaments and tendons run outside the joints, some, like the supraspinatus tendon in the shoulder and the cruciate ligaments in the knee, run through the joint. Inflammation or trauma to these joints can cause severe joint symptoms.

Blood vessels and nerves
The ligaments, periosteum, synovial tissue and capsule of the joint are richly supplied by blood vessels and nerves. Pain usually derives from inflammation of these sites because the synovial membrane is relatively insensitive.

Skeletal muscle
This tissue consists of bundles of myocytes containing actin and myosin molecules. These molecules interdigitate and form myofibrils, which cause muscle contraction in a similar way to myocardial muscle (see p. 1024). Bundles of myofibrils (fasciculi) are covered by connective tissue, the perimysium, which merges with the epimysium (covering the muscle) and forms the tendon, which attaches to the bone surface (enthesis).

Though not strictly a component of the joint itself, muscles are so closely related to joints that strain and tension in muscles are commonly interpreted by patients as joint pain. Pain in muscles and ligaments (myofascial pain) is a very common cause of locomotor symptoms. Primary inflammatory disease of muscle (myositis) is far less common.

INVESTIGATION OF RHEUMATIC DISEASE
Investigations are unnecessary in many of the common musculoskeletal problems; the diagnosis is clear from the history and examination findings. Tests help to exclude another condition and to reassure the patient or their primary care physician.

Useful blood screening tests
- Full blood count:
  - White cell count. Neutrophilia is seen in bacterial infection (e.g. septic arthritis). It also occurs with corticosteroid treatment. Lymphopenia is found in viral illnesses or SLE. Neutropenia may reflect drug-induced bone marrow suppression. Eosinophilia is seen in eosinophilic granulomatosis with polyangiitis (EGPA) (see p. 991).
  - Platelets. Raised platelets occur with any chronic inflammation. Thrombocytopenia is seen in drug-induced bone marrow suppression and may be a feature of SLE.
  - Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP). An increase in these reflects inflammation. Plasma viscosity is also raised in inflammatory disease.
  - Bone and liver biochemistry. A raised serum alkaline phosphatase may indicate liver or bone disease. A rise in liver enzymes is often seen with drug-induced toxicity. For other investigations of bone, see pages 474.

Other blood and urine tests
- Protein electrophoresis (and/or immunofixation), serum free light chain testing and urinary Bence Jones protein – to exclude myeloma as a cause of a raised ESR.

• Serum uric acid – for gout.
• Antistreptolysin O titre – in rheumatic fever.

Serum autoantibody studies

- **Rheumatoid factors (RFs)** (see also p. 439). RFs are detected by enzyme-linked immunosorbent assay (ELISA). RFs are antibodies (usually immunoglobulin (Ig) M, but also IgG or IgA) against the Fc portion of IgG. They are detected in 70% of people with RA, but are not diagnostic. RFs are detected in many autoimmune rheumatic disorders (e.g. SLE), in chronic infections, and in asymptomatic older people (Box 18.5).

- **Anti-citrullinated peptide antibodies (ACPA).** These antibodies are directed against citrullinated antigens, vimentin, fibrinogen, alpha enolase and type II collagen. They are measured by an ELISA technique and are present in up to 80% of people with RA. They have a high specificity for RA (90%, with a sensitivity of 60%). They are helpful in early disease when the RF is negative, to distinguish it from acute transient synovitis (see Box 18.28). Positivity for RF and/or ACPA is associated with a worse prognosis and an increase in the likelihood of bony erosions in people with RA.

- **Antinuclear antibodies (ANAs).** These are detected by indirect immunofluorescent staining of fresh frozen sections of rat liver or kidney or Hep-2 cell lines. Different patterns reflect a variety of antigenic specificities that occur with different clinical pictures. ANA is used as a screening test for SLE and systemic sclerosis – a negative ANA makes either condition highly unlikely – but low titres occur in RA and chronic infections and in normal individuals, especially the elderly (Box 18.6).

- **Anti-double-stranded DNA (dsDNA) antibodies.** These are usually detected by a precipitation test (Farr assay). ELISA or an immunofluorescent test using *Crithidia luciliae* (which contains dsDNA). Raised anti-dsDNA is highly specific for SLE; the levels usually rise and fall in parallel with disease activity so can be used to monitor the level of treatment required.

- **Anti-extractable nuclear antigen (ENA) antibodies** (see Box 18.38). These produce a speckled ANA fluorescent pattern, and can be identified by ELISA. The most commonly measured ENAs are:
  - **anti-Ro and anti-La,** which occur in Sjögren’s syndrome and SLE
  - **anti-Sm,** which is highly specific for SLE
  - **anti-Jo-1,** which is the most common of the anti-tRNA synthetase enzymes that occur in some people with dermatomyositis or polymyositis
  - **anti-topoisomerase I (anti-Scl 70),** which is specific for systemic sclerosis
  - **anti-RNA polymerase I and III,** which occur in systemic sclerosis and are associated with pulmonary fibrosis.

- **Anti-neutrophil cytoplasmic antibodies (ANCAs)** (see p. 466). These are predominantly IgG autoantibodies directed against the primary granules of neutrophil and macrophage lysosomes. They are strongly associated with small-vessel vasculitis. Two major clinically relevant ANCA patterns are recognized on immunofluorescence:
  - **proteinase 3 (PR3-ANCA),** also called cytoplasmic or cANCA, producing a granular immunofluorescence and seen in granulomatosis with polyangiitis (GPA)
  - **myeloperoxidase (MPO-ANCA),** also called perinuclear or pANCA, producing a perinuclear stain and seen in microscopic polyangiitis and EGPA.

- **Antiphospholipid antibodies** These are detected in the antiphospholipid syndrome (see p. 456).

- **Complement.** Low complement levels indicate consumption and suggest an active disease process in SLE.

Joint aspiration and examination of synovial fluid

Examination of joint (or bursa) fluid is used mainly to diagnose septic, reactive or crystal arthritis. The appearance of the fluid is an indicator of the level of inflammation. The procedure is often undertaken in combination with injection of a corticosteroid. Aspiration alone is therapeutic in crystal arthritis (Fig. 8.2 and Box 18.7).

Aspiration and analysis of synovial fluid are always indicated when septic or crystal-induced arthritis is suspected, particularly a monoarthritis. Normal fluid is clear and straw-coloured, and contains fewer than 3000 white blood cells (WCC)/mm³. Inflammatory
Box 18.7 Joint aspiration

This is a sterile procedure that should be carried out in a clean environment. Explain the procedure to the patient; obtain consent.

1. Decide on the site to insert the needle and mark it.
2. Clean the skin and your hands scrupulously.
3. Draw up local anaesthetic (and corticosteroid if it is being used).
4. Insert the needle, injecting local anaesthetic as it advances; if a joint effusion is suspected, attempt to aspirate as you advance it.
5. If fluid is obtained, change syringes and aspirate fully.
6. Examine the fluid in the syringe and decide whether or not to proceed with a corticosteroid injection (if fluid is clear or slightly cloudy) or send for microbiological tests.
7. Cover the injection site and advise the patient to rest the affected area for a few days. Warn the patient that the pain may increase initially but to report urgently if this persists beyond a few days, if the swelling worsens or if they become febrile, because this might indicate an infected joint.

Aspirated fluid is sent for microscopy, Gram-stain and culture. Different types of crystals can be identified using polarized light microscopy. Fluid from septic arthritis is often excessively turbid.

Box 18.7 Joint aspiration

Fluid is cloudy and contains more than 3000 WCC/mm$^3$. Septic fluid is opaque and less viscous, and contains up to 75000 WCC/mm$^3$. There is much overlap.

Polarized light microscopy is performed for crystals:

- **gout**: negatively bi-refrangent, needle-shaped crystals of sodium urate
- **calcium pyrophosphate deposition arthropathy**: rhomboidal, weakly positively bi-refrangent crystals of calcium pyrophosphate.

**Gram-staining** is essential if septic arthritis is suspected and may identify the organism immediately. Joint fluid should be cultured and antibiotic sensitivities requested.

Diagnostic imaging and visualization

- **X-rays** can be diagnostic in certain conditions (e.g. established RA) and are the first investigation in many cases of trauma. X-rays can detect joint space narrowing, erosions in RA, calcification in soft tissue, new bone formation, e.g. osteophytes, and decreased bone density (osteopenia) or increased bone density (osteosclerosis):
  - In acute low back pain (see p. 421), X-rays are indicated only if the pain is persistent, recurrent, associated with neurological symptoms or signs, worse at night or associated with symptoms such as fever or weight loss.
  - Radiological changes are common in older people and may not indicate symptomatic OA or spondylosis, a term that implies OA within the spine.
  - X-rays are of little diagnostic value in early inflammatory arthritis but are useful as a baseline from which to judge later change.
  - **Ultrasound** is particularly useful for periarticular structures, soft tissue swellings and tendons, and for detecting active synovitis in inflammatory arthritis. It is increasingly used to examine the shoulder and other structures during movement, e.g. shoulder impingement syndrome (see p. 419). Doppler ultrasound measures blood flow and hence inflammation. Ultrasound may be used to guide local corticosteroid injections.
  - **Magnetic resonance imaging (MRI)** shows bone changes and intra-articular structures in striking detail. Visualization of particular structures can be enhanced with different resonance sequences. $T_1$-weighted MRI is used for anatomical detail, $T_2$-weighted for fluid detection and short tau inversion recovery (STIR) for the presence of bone marrow oedema. MRI is more sensitive than X-rays in the early detection of articular and periarticular disease. Gadolinium injection enhances inflamed tissue. MRI is especially useful for detection of damage to non-bony tissues in or near joints, e.g. meniscal tears in the knee and torn rotator cuff muscles in the shoulder; detection of nerve root compression in the spine; detection of inflamed muscle in myositis; and early detection of synovitis in inflammatory arthritis.
  - **Computerized axial tomography (CT)** is useful for detecting changes in calcified structures but the dose of radiation is high.
  - **Bone scintigraphy** utilizes radionuclides, usually $^{99m}$Tc, and detects abnormal bone turnover and blood circulation; although non-specific, it helps in detecting areas of inflammation, infection or malignancy. It is best used in combination with other anatomical imaging techniques.
  - **Dual-energy X-ray absorptiometry (DXA) scanning** uses very low doses of X-irradiation to measure bone density and is used in the screening and monitoring of osteoporosis.
  - **Positron emission tomography (PET) scanning** uses radionuclides, which decay by emission of positrons. $^{18}$F$^*$ Fluorodeoxyglucose uptake indicates areas of increased glucose metabolism. PET is used to locate tumours and demonstrate large-vessel vasculitis, e.g. Takayasu's arteritis (see p. 1132). PET scans are combined with CT to improve anatomical details.

Other tests to investigate rheumatological disease

- **Arthroscopy** is a direct means of visualizing a joint, particularly the knee or shoulder. Biopsies can be taken, surgery performed in certain conditions (e.g. repair or trimming of meniscal tears), and loose bodies removed.
- **Nerve conduction studies and electromyography** are used to diagnose nerve entrapment syndromes (such as carpal or tarsal tunnel) and to distinguish myositis from neuropathies.

<th>CLINICAL CONDITIONS IN RHEUMATOLOGY</th>
</tr>
</thead>
<tbody>
<tr>
<td>These can be divided into three types:</td>
</tr>
<tr>
<td><strong>Pain arising from soft tissues around joints</strong>, such as muscles and tendons. The joints themselves are normal. These are the most common locomotor problems, and are generally self-limiting or respond to simple analgesia, physiotherapy or exercise.</td>
</tr>
</tbody>
</table>
18 Rheumatology

Diseases of the joints themselves. Osteoarthritis is more common than inflammatory arthritis, especially in the elderly.

Autoimmune rheumatic diseases. These include disorders such as systemic lupus erythematosus (SLE), where the locomotor symptoms are just one manifestation of a systemic disorder.

COMMON REGIONAL MUSCULOSKELETAL PROBLEMS

See Fig. 18.3.

Pain in the neck and shoulder

See Box 18.8.

Mechanical or muscular neck pain (shoulder girdle pain)

Unilateral or bilateral muscular-pattern neck pain is common and usually self-limiting. Chronic burning neck pain occurs because of muscle tension from anxiety and stress.

Spondylosis seen on X-ray increases after the age of 40 years but it is not always related to pain. Spondylosis can, however, cause stiffness and increases the risk of mechanical or muscular neck pain. Muscle spasm is palpable and tender, and may lead to abnormal neck posture (e.g. acute torticollis). Muscular-pattern neck pain is not localized but affects the trapezius muscle, the C7 spinous process and the paracervical musculature (shoulder girdle pain). Pain often radiates upwards to the occiput and is commonly associated with tension headaches. These features are also seen in chronic widespread pain (see p. 429).

Management

Patients are given short courses of analgesic therapy, along with reassurance and explanation. Physiotherapists can help to relieve spasm and pain, teach exercises and relaxation techniques, and improve posture. An occupational therapist can advise about the ergonomics of the workplace if the problem is work-related (see p. 430).

Nerve root entrapment

This is caused by an acute cervical disc prolapse or pressure on the root from spondylotic osteophytes narrowing the root canal.

Acute cervical disc prolapse presents with unilateral pain in the neck, radiating to the interscapular and shoulder regions. This diffuse, aching, dural pain is followed by sharp, electric shock-like pain down the arm, in a nerve root distribution, often with pins and needles, numbness, weakness and loss of reflexes (Box 18.9).

Cervical spondylosis occurs in the older patient with posterolateral osteophytes compressing the nerve root and causing root pain (see Fig. 26.64), commonly at C5/C6 or C6/C7; it is seen on oblique radiographs of the neck. An MRI scan clearly distinguishes facet joint OA, root canal narrowing and disc prolapse.

Management

A support collar, rest, analgesia and sedation are used initially as necessary. Patients should be advised not to carry heavy items.
Pain may take a few weeks or months to settle and the patient anxious), analgesia, a short-term support collar and physiotherapy. Management is with reassurance (the patient is often distressed and nature of these symptoms has led to controversy about their cause.

Shoulder pain: Shear forces

The shoulder is a shallow joint with a large range of movement. The humeral head is held in place by the rotator cuff, which is part of the joint capsule. It comprises the tendons of infraspinatus and teres minor posteriorly, supraspinatus superiorly, and teres major and subscapularis anteriorly. The rotator cuff (particularly supraspinatus) prevents the humeral head from blocking against the acromion during abduction; the deltoid pulls up and the supraspinatus pulls in to produce a turning movement, and the greater tuberosity glides under the acromion without impingement. Shoulder pathology restricts or is made worse by shoulder movement. Specific diagnoses are difficult to make clinically but may be clearer on imaging.

Pain in the shoulder

The shoulder is a shallow joint with a large range of movement. The humeral head is held in place by the rotator cuff, which is part of the joint capsule. It comprises the tendons of infraspinatus and teres minor posteriorly, supraspinatus superiorly, and teres major and subscapularis anteriorly. The rotator cuff (particularly supraspinatus) prevents the humeral head from blocking against the acromion during abduction; the deltoid pulls up and the supraspinatus pulls in to produce a turning movement, and the greater tuberosity glides under the acromion without impingement. Shoulder pathology restricts or is made worse by shoulder movement. Specific diagnoses are difficult to make clinically but may be clearer on imaging.

Management

Management is with reassurance (the patient is often distressed and anxious), analgesia, a short-term support collar and physiotherapy. Pain may take a few weeks or months to settle and the patient anxious), analgesia, a short-term support collar and physiotherapy. Management is with reassurance (the patient is often distressed and nature of these symptoms has led to controversy about their cause.

Whiplash injury

Whiplash injury results from acceleration–deceleration forces applied to the neck, usually in a road traffic accident when the car of a person wearing a seat belt is struck from behind. A simple decision plan based on clinical criteria helps to distinguish those most at risk and who warrant radiography. There is a low probability of serious bony injury if there is:

- no midline cervical tenderness
- no focal neurological deficit
- normal alertness
- no intoxication
- no other painful distracting injury.

CT scans are reserved for those with bony injury. MRI scans occasionally show severe soft tissue injury. Whiplash injuries may lead to litigation or insurance claims.

Whiplash injury is a common cause of chronic neck pain, although most people recover within a few weeks or months. Delayed recovery depends, in part, on the severity of the initial injury. The pattern of chronic neck pain is often complex, involving pain in the neck, shoulder and arm. It may be accompanied by subjective symptoms, such as headache, dizziness and poor concentration. The subjective nature of these symptoms has led to controversy about their cause.

Management

Management is with reassurance (the patient is often distressed and anxious), analgesia, a short-term support collar and physiotherapy. Pain may take a few weeks or months to settle and the patient anxious), analgesia, a short-term support collar and physiotherapy. Management is with reassurance (the patient is often distressed and nature of these symptoms has led to controversy about their cause.

**Box 18.10 Differential diagnosis of ‘shoulder’ pain**

- Rotator cuff tendonitis pain is worse at night and radiates to the upper arm.
- Painful shoulders produce secondary muscular neck pain.
- Muscular neck pain (also known as shoulder girdle pain) does not radiate to the upper arm.
- Cervical nerve root pain is usually associated with pins and needles or neurological signs in the arm.

should be warned of this. Clinical trial evidence shows no benefit with prolonged physiotherapy.

**Pain in the shoulder**

The shoulder is a shallow joint with a large range of movement. The humeral head is held in place by the rotator cuff, which is part of the joint capsule. It comprises the tendons of infraspinatus and teres minor posteriorly, supraspinatus superiorly, and teres major and subscapularis anteriorly. The rotator cuff (particularly supraspinatus) prevents the humeral head from blocking against the acromion during abduction; the deltoid pulls up and the supraspinatus pulls in to produce a turning movement, and the greater tuberosity glides under the acromion without impingement. Shoulder pathology restricts or is made worse by shoulder movement. Specific diagnoses are difficult to make clinically but may be clearer on imaging.

Pain in the shoulder can sometimes be due to problems in the neck; the differential diagnosis is shown in **Box 18.10**. Early inflammatory arthritis and polymyalgia rheumatica in the elderly may present with shoulder pain.

**Rotator cuff (supraspinatus) tendonosis**

This condition is a common cause of shoulder pain at all ages. It follows trauma in 30% of cases and is bilateral in under 5%. The pain radiates to the upper arm and is made worse by arm abduction and elevation, which are often limited. The pain is often worse during the middle of the range of abduction, reducing as the arm is raised fully; a so-called ‘painful arc syndrome’. When examined from behind, the scapula rotates earlier than usual during elevation. Passive elevation reduces impingement and is less painful. Severe pain virtually immobilizes the joint, although some rotation is retained (compare adhesive capsulitis; see below). There is also painful spasm of the trapezius. There may be an associated subacromial bursitis. Isolated subacromial bursitis occurs after direct trauma, falling on to the outstretched arm or elbow. Acromioclavicular osteophytes increase the risk of impingement and may need to be removed surgically.

X-ray is often normal but ultrasound is very useful to distinguish bursitis, tendonitis and partial or complete tendon tears. Corticosteroid injections can be guided by ultrasound.

**Management**

Analgesics, NSAIDs and/or physiotherapy may suffice, but severe pain responds to an injection of corticosteroid into the subacromial bursa (see **Fig. 18.5**). Patients should be warned that 10% will develop worse pain for 24–48 hours after injection. Some 70% improve over 5–20 days and mobilize the joint themselves. Physiotherapy helps persistent stiffness. If injection in the clinic is unsuccessful ultrasound-guided corticosteroid injections may be more effective.

**Torn rotator cuff**

This condition is caused by trauma but also occurs spontaneously in the elderly and in RA. It prevents active abduction of the arm.

---

**Fig. 18.4** Magnetic resonance image of the cervical spine. A large central disc prolapse (arrowed) is shown at the C6/7 level, and smaller disc bulges at C3/4 and C4/5.

**Fig. 18.5** Patients should be warned that 10% will develop worse pain for 24–48 hours after injection. Some 70% improve over 5–20 days and mobilize the joint themselves. Physiotherapy helps persistent stiffness. If injection in the clinic is unsuccessful ultrasound-guided corticosteroid injections may be more effective.
but patients learn to initiate elevation using the unaffected arm. Once elevated, the arm can be held in place by the deltoid muscle.

In younger people, the tear is repaired surgically but this is rarely possible in the elderly or in RA. Some patients require arthroscopic surgery.

**Calcific tendonosis and bursitis**

Calcium pyrophosphate deposits in the tendon are visible on X-ray but they are not always symptomatic. The pathogenesis is unclear, although ischaemia may play a part. The deposit is usually just proximal to the greater tuberosity. It may lead to acute or chronic recurrent shoulder pain and restriction of movement. A local corticosteroid injection may relieve the pain. The calcification may persist or resolve. Aspiration or breaking up of the deposit under ultrasound control may be required for persistent pain. Rarely, arthroscopic removal is necessary.

Shedding of crystals into the subacromial bursa causes a bursitis with severe pain and shoulder restriction. The shoulder feels hot and is swollen, and an X-ray shows a diffuse opacity in the bursa. The differential diagnosis of calcific bursitis is gout, pseudogout or septic arthritis. Aspiration and injection with corticosteroid can help.

**Adhesive capsulitis (true ‘frozen’ shoulder)**

This condition can develop with rotator cuff lesions, or following hemiplegia, chest or breast surgery, or myocardial infarction and in diabetics. Initially, it causes severe shoulder pain and a gradually reducing range of movement, leading to a ‘frozen’ phase where there is loss of all shoulder movements but little pain. NSAIDs and intra-articular injections of local anaesthetic and corticosteroids are helpful in the painful phase. Subsequently, there is usually a gradual improvement in function over weeks to months. Therapeutic exercises and physiotherapy help in later phases. Once the pain settles, arthroscopic release speeds functional recovery.

**Pain in the elbow**

Pain in the elbow can be due to epicondylitis, inflammatory arthritis or, occasionally, OA.

**Epicondylitis**

Two common sites where the insertions of tendons into bone become inflamed (enthesitis) are the common wrist extensor origin at the lateral humeral epicondyle (‘tennis elbow’) and the common wrist flexor origin at the medial epicondyle (‘golfer’s elbow’). Despite the names, both conditions are usually unrelated to either sport!

There is local tenderness. Pain radiates into the forearm on using the affected muscles – typically, gripping or holding a heavy bag in tennis elbow or carrying a tray in golfer’s elbow. Pain at rest also occurs.

**Management**

Advise rest and arrange review by a physiotherapist. A local injection of corticosteroid at the point of maximum tenderness is helpful when the pain is severe (Fig. 18.6) but needs physiotherapy follow-up to prevent recurrences. Avoid the ulnar nerve when injecting golfer’s elbow. Both conditions settle spontaneously eventually, but occasionally persist and require surgical release.

**Pain in the hand and wrist**

See Box 18.11. Hand pain is commonly caused by injury or repetitive, work-related activities. When associated with pins and needles or numbness, it suggests a neurological cause arising at the wrist, elbow or neck. Pain and stiffness that are worse in the morning are due to tenosynovitis or inflammatory arthritis. The distribution of hand pain often indicates the diagnosis.

**Tenosynovitis**

The finger flexor tendons run through synovial sheaths and under loops that hold them in place. Inflammation occurs with repeated or unaccustomed use, or in inflammatory arthritis. The thickened sheaths are often palpable.

*Flexor tenosynovitis* causes finger pain when gripping and stiffness of the fingers in the morning. Occasionally, a tendon causes a trigger finger, when the finger remains flexed in the morning or after gripping, and has to be pulled straight. A tender tendon nodule is palpable, usually in the distal palm. Trigger finger or thumb is more common in diabetic patients.
Dorsal tenosynovitis is less common, except in RA. The hourglass swelling extends from the back of the hand and under the extensor retinaculum.

De Quervain’s tenosynovitis causes pain and swelling around the radial styloid, where the abductor pollicis longus tendon is held in place by a retaining band. There is local tenderness, and the pain at the styloid is worsened by flexing the thumb into the palm.

Management
Resting, splinting and NSAIDs may help. Local corticosteroids injected alongside the tendon under low pressure (not into the tendon itself) are helpful. Occasionally, surgery is needed if symptoms persist.

Carpal tunnel syndrome
This condition arises due to median nerve compression in the limited space of the carpal tunnel. Thickened ligaments, tendon sheaths or bone enlargement can cause it, but it is usually idiopathic. (Causes are discussed on p. 888.) The history is usually typical and diagnostic, the patient waking with numbness, tingling and pain in a median nerve distribution. The pain may radiate to the forearm. Wasting of the thenar eminence muscles develops with sensory loss in the radial three and a half fingers. The pain may be produced by tapping the nerve in the carpal tunnel (Tinel’s sign) or by holding the wrist in flexion (Phalen’s test).

Management
Management is with a splint to hold the wrist in dorsiflexion overnight, which relieves the symptoms and is diagnostic; used nightly for several weeks, it may produce full recovery. If it does not, a corticosteroid injection into the carpal tunnel (avoid the site) are helpful. Occasionally, surgery is needed if symptoms persist. Persistent symptoms or nerve damage produce prolonged latency across the carpal tunnel on nerve conduction studies and require surgical decompression.

Other conditions causing pain
Inflammatory arthritis
This may present with pain, swelling and stiffness of the hands. In RA, the wrists, proximal interphalangeal (PIP) joints and metacarpophalangeal (MCP) joints are affected symmetrically. In psoriatic arthritis and reactive arthritis, a finger may be swollen (dactylosis), or the distal interphalangeal (DIP) joints and nails are affected asymmetrically.

Nodal osteoarthritis
This affects the DIP and, less commonly, PIP joints, which are initially swollen and red. The inflammation and pain settle but bony swellings remain (see p. 435).

First carpometacarpal osteoarthritis
This causes pain at the base of the thumb when gripping, or painless stiffness at the base of the thumb, often in people with nodal OA.

Scaphoid fractures
These cause pain in the anatomical snuffbox. They are not seen immediately on X-ray; if there is clinical suspicion, a cast is necessary. Untreated scaphoid fractures can eventually cause pain because of failed union.

Ganglion
A ganglion is a jelly-filled, often painless swelling caused by a partial tear of the joint capsule or tendon sheath. The wrist is a common site. Treatment is not essential, as many resolve or cause little trouble; otherwise, surgical excision is the best option.

Dupuytren’s contracture
This condition is a painless, palpable fibrosis of the palmar aponeurosis, with fibroblasts invading the dermis. It causes puckering of the skin and gradual fixed flexion, usually of the ring and little fingers. It is more common in males, Caucasians, individuals with diabetes mellitus, and those who overuse alcohol. A similar fibrosis occurs in the feet and is often more aggressive. Intraligamental steroid injections may help in early disease and some advocate transcutaneous needle aponeurotomy. Percutaneous collagenase injection into the lesion has been shown to be effective in several studies and is now first-line treatment used before surgery. Surgical release of the contracture is restricted to those with severe deformity of the fingers.

Pain in the lower back
Low back pain is a common symptom. It is often traumatic and work-related, although lifting apparatus, other mechanical devices and improved office seating help to avoid it. Episodes are generally short-lived and self-limiting, and patients attend a physiotherapist or osteopath more often than a doctor. Chronic back pain is the cause of 14% of long-term disability in the UK. The causes are listed in Box 18.12.

The majority of cases of low back pain are uncomplicated and arise from mechanical causes. Management of this type of back pain is summarized in Box 18.13.

One should be alert to clues in the history and examination that could suggest more serious causes of low back pain. These ‘red flag’ clues (summarized in Fig. 18.7) include the following:

- starts before the age of 20 years or after 50
- pain has persisted for more than 6 weeks
- is worse at night or in the morning, when an inflammatory arthritis (e.g. ankylosing spondylitis), infection or a spinal tumour may be the cause
- is associated with a systemic illness, fever or weight loss
- is associated with neurological symptoms or signs, especially new onset incontinence, which may suggest cauda equina compression.

**Investigations**

- **Spinal X-rays** are required only if the pain is associated with ‘red flag’ symptoms or signs.
- **MRI** (Figs. 18.8 and 18.9) is preferable to CT scanning when neurological signs and symptoms are present. CT scans demonstrate bony pathology better. Interpretation of the relevance of the findings may require a specialist opinion.
- **Bone scans** are useful in infective and malignant lesions but are also positive in degenerative lesions.
- **Full blood count, ESR and biochemical tests** are required only when the pain is likely to be due to malignancy, infection or a metabolic cause. Normal ESR and CRP distinguish mechanical back pain from polymyalgia rheumatica, a likely differential in the elderly.
Mechanical low back pain

Mechanical low back pain starts suddenly, may be recurrent and is helped by rest. It is often precipitated by an injury and may be unilateral or bilateral. It is usually short-lived.

Examination

The back is stiff and a scoliosis may be present when the patient is standing. Muscular spasm is visible and palpable, and causes local pain and tenderness. It lessens when sitting or lying. Excessive rest should be avoided. Once a patient develops low back pain, although the episode itself is usually self-limiting, there is a significantly increased risk of further back pain episodes. Risk factors for recurrent back pain include:

- female sex
- increasing age
- pre-existing chronic widespread pain (fibromyalgia)
- psychosocial factors, such as high levels of psychological distress, poor self-rated health and dissatisfaction with employment.

Chronic low back pain is a major cause of disability and time off work and is reduced by appropriate early management.

Spinal movement occurs at the disc and the posterior facet joints, and stability is normally achieved by a complex mechanism of spinal ligaments and muscles. Any of these structures may be a source of pain. An exact anatomical diagnosis is difficult but some typical syndromes are recognized (see below). They are often associated with, but not necessarily caused by, radiological spondylosis (see p. 893).

Postural back pain develops in individuals who sit in poorly designed, unsupportive chairs.

Lumbar spondylosis

The fundamental lesion in spondylosis occurs in an intervertebral disc, a fibrous structure whose tough capsule inserts into the rim of the adjacent vertebrae. This capsule encloses a fibrous outer zone and a gel-like inner zone. The disc allows rotation and bending.

Changes in the discs occasionally start in teenage years or early twenties and often increase with age. The gel changes chemically, breaks up, shrinks and loses its compliance. The surrounding fibrous zones develop circumferential or radial fissures. In the majority, this is initially asymptomatic but visible on MRI as decreased hydration. Later, the discs become thinner and less compliant. These changes cause circumferential bulging of the intervertebral ligaments.

Reactive changes develop in adjacent vertebrae; the bone becomes sclerotic and osteophytes form around the rim of the vertebra (see Fig. 18.9). The most common sites of lumbar spondylosis are L5/S1 and L4/L5.

In young people, disc prolapse through an adjacent vertebral end-plate produces a Schmorl's node on X-ray. This process is painless but may accelerate disc degeneration.

Spondylosis may be symptomless but can cause:

- episodic mechanical spinal pain
- progressive spinal stiffening
- facet joint pain
- acute disc prolapse, with or without nerve root irritation
- spinal stenosis
- spondylolisthesis.

Facet joint syndrome

Lumbar spondylosis also causes secondary OA of the misaligned facet joints. Pain is typically worse on bending backwards and when straightening from flexion. It is lumbar in site, unilateral or bilateral, and radiates to the buttock. The facet joints are well seen on MRI and may show OA, an effusion or a ganglion cyst. Direct corticosteroid injections into the joints under imaging may help but their long-term value is unclear. Physiotherapy to reduce hyperlordosis and weight reduction are helpful.

Management of mechanical back pain

Adequate analgesia to allow normal mobility and avoidance of bed rest is best, combined with physical treatments such as physiotherapy, back muscle training regimens and manipulation. Manipulation produces more rapid pain relief in some patients. Acupuncture may help. Re-education in lifting and exercises help to prevent recurrent attacks of pain. Most episodes recover, irrespective of the treatment given. A positive approach probably reduces the development of chronic pain. A comfortable sleeping position should be adopted using a mattress of medium (not hard) firmness.

Acute lumbar disc prolapse

The central disc gel may extrude into a fissure in the surrounding fibrous zone and cause acute pain and muscle spasms. These events are often self-limiting. A disc prolapse occurs when the extrusion extends beyond the limits of the fibrous zone (see Fig. 18.9). The weakest point is posterolateral, where the disc may impinge on emerging spinal nerve roots in the root canal.

The episode often starts dramatically during lifting, twisting or bending, and produces a typical combination of low back pain and muscle spasm, and severe, lancinating pains, paraesthesia, numbness and neurological signs in one leg (rarely both). The back pain is diffuse and usually unilateral, and radiates into the buttock. The muscle spasm leads to a scoliosis that reduces when lying down. The nerve root pain develops with, or soon after, the onset. The site of the pain and other symptoms are determined by the root affected (Box 18.14). A central high lumbar disc prolapse may cause spinal cord compression and long tract signs (i.e. upper motor neurone).

Below L2/L3, it produces lower motor neurone lesions.

Examination

On examination, the back often shows a marked scoliosis and muscle spasm. The straight-leg-raising test, while the patient is lying, is positive in a lower lumbar disc prolapse – raising the straight leg beyond 30° produces pain radiating down the leg further than the knee. Slight limitation or pain in the back limiting this movement is seen with mechanical back pain. Pain in the affected leg produced by a straight raise of the other leg suggests a large or central disc prolapse.

prolapse. Look for perianal sensory loss and urinary retention or incontinence, which indicate a cauda equina lesion – a neurosurgical emergency (see p. 893). An upper lumbar disc prolapse produces a positive femoral stretch test: pain in the anterior thigh when the knee is flexed in the prone position.

**Management**
Advise a short period (2–3 days) of bed rest, lying flat for a lower disc but semi-reclining for a high lumbar disc, and prescribe analgesia and muscle relaxants. Once the pain is tolerable, encourage the patient to mobilize and refer them to a physiotherapist for exercises and preventative advice. The investigation of choice is MRI, which identifies the abnormal disc and any compressed nerves. An imaging-guided epidural or nerve root canal injection reduces pain rapidly, although the evidence that it speeds resolution or prevents surgery is unclear. Caudal epidural injections are less effective than lumbar ones. Resuscitation equipment must be available for these procedures. Referral to a surgeon for possible microdiscectomy or hemi-laminectomy is necessary if the neurological signs are severe, if the pain persists and is severe for more than 6–10 weeks, or if the disc is central. If bladder or anal sphincter tone is affected, it becomes a neurosurgical emergency.

**Spinal and root canal stenosis**
Progressive loss of disc height, OA of the facet joints, posterolateral osteophytes and buckling of the ligamentum flavum all contribute to root canal stenosis. These changes cause nerve root pain or spinal root claudication – pain and paraesthesiae in a root distribution brought on by walking and relieved slowly by rest. The associated sensory symptoms, slower recovery when the patient rests, and presence of normal foot pulses distinguish this from peripheral arterial claudication. Severe cervical spondylosis may also produce spinal claudication, often with arm symptoms and signs.

The investigation of choice to identify the location and extent of stenosis is MRI. Spinal canal stenosis at more than one level is often associated with severe spondylosis and/or a congenitally narrow spinal canal. It causes buttock and bilateral leg pain, ‘heaviness’, paraesthesiae and numbness when walking. Rest helps, as does bending forwards, a manoeuvre that opens the spinal canal. Specialist surgical advice is necessary.

**Spondylolisthesis**
This condition occurs in adolescents and young adults when bilateral congenital pars interarticularis defects cause instability and permit a vertebra to slip, with or without preceding injury. Rarely, a cauda equina syndrome develops, with loss of bladder and anal sphincter control, and saddle-distribution anaesthesia. It is diagnosed radiologically and can be seen on plain radiographs, though MRI may be necessary if entrapment of nerve roots or cauda equina syndrome is suspected. Low back pain in adolescents warrants investigation, and spondylolisthesis requires orthopaedic assessment. It needs monitoring during the growth spurt.

A degenerative spondylolisthesis may also develop in older people with lumbar spondylosis and OA of the facet joints.

**Diffuse idiopathic skeletal hyperostosis**
Diffuse idiopathic skeletal hyperostosis (DISH, or Forestier’s disease) affects the spine and extraspinal locations. It causes bony overgrowths and ligamentous ossification, and is characterized by flowing calcification over the anterolateral aspects of the vertebrae. The spine is stiff but not always painful, despite the dramatic changes seen on plain radiographs, which are the imaging investigation of choice. Ossification at muscle insertions around the pelvis produces radiological ‘whiskering’. Similar changes occur at the patella and in the feet. It is more common in people with metabolic syndrome (high body mass index (BMI), diabetes mellitus, hypertension and dyslipidaemia; see p. 1250).

**Management** is with analgesics or NSAIDs for pain, and exercise to retain movement and muscle strength.

**Osteoporotic crush fracture of the spine**
Osteoporosis is asymptomatic but leads to an increased risk of fracture of peripheral bones, particularly neck of femur and wrist, and thoracic or lumbar vertebral crush fractures. Such vertebral fractures may develop with no or minimal trauma. They may develop painlessly or cause agonizing localized pain that radiates around the ribs and abdomen. Multiple fractures lead to an increased thoracic kyphosis. They cause disability and reduced quality of life. The diagnosis is confirmed by X-rays, showing loss of anterior vertebral body height and wedging, with sparing of the vertebral end-plates and pedicles. Bone oedema on MRI indicates that a fracture is recent. An underlying tumour and pathological fracture need to be excluded.

**Management**
Advise bed rest and analgesia until the severe pain subsides over a few weeks, then gradual mobilization. It may warrant hospitalization, and the prescription of intravenous bisphosphonates or subcutaneous or nasal calcitonin to relieve pain. There may be some residual pain and deformity.

The role of percutaneous vertebroplasty and balloon kyphoplasty remains unclear; there are no randomized controlled trials (RCTs) showing any benefit. Both involve inserting a needle through a pedicle into the affected vertebral body under CT guidance with the aim of stabilizing the fracture. Kyphoplasty involves inflating a balloon filled with methyl methacrylate cement in order to restore vertebral shape. Vertebroplasty is the injection of cement alone, without restoring vertebral shape. Pain relief is usual with both but the risks are higher with vertebroplasty.

Bone density measurement and preventative treatment of osteoporosis are essential (see p. 477).

**Septic discitis**
Septic discitis may cause severe pain and rapid adjacent vertebral destruction. It is seen on MRI and requires urgent neurosurgical referral.

**Ankylosing spondylitis**
Buttock pain and low back stiffness in a young adult suggest axial spondyloarthritis (e.g. ankylosing spondylitis) (see p. 448), especially if they are worse at night and in the morning.

**Pain in the hip**
‘Hip’ refers to a wide area between the upper buttock, trochanter and groin. It is useful to ask the patient to point to the site of pain and its field of radiation (Box 18.15).

**Osteoarthritis of the hip**
OA (see p. 433) is the most common cause of hip joint pain in a person over the age of 50 years. It gives rise to pain in the buttock and groin on standing and walking. Stiff hip movements cause difficulty in putting on a sock and may produce a limp. Sudden-onset pain
may be associated with an effusion on MRI and can be treated by an ultrasound-guided steroid injection. Severe hip OA is characterized by pain and limitation even at rest and abnormal gait. In severe cases, total hip replacement is the only successful therapy.

**Lateral hip pain syndrome: trochanteric bursitis and gluteus medius tendinopathy**

This syndrome may be due to trochanteric bursitis and caused by trauma or unaccustomed exercise. It also occurs in inflammatory arthritis. The pain over the trochanter is worse on going up stairs, lying on that side in bed and crossing the legs. The best management is unclear but exercises help, as may a local corticosteroid injection, although the evidence base for treatment is poor. Surgery is rarely necessary. Lateral hip pain may be referred from the upper lumbar spine. A tear of the gluteus medius tendon at its insertion into the trochanter causes a similar syndrome but does not respond to injection.

**Meralgia paraesthetica**

This condition causes numbness and burning dysesthesia (increased sensitivity to light touch) over the anterolateral thigh, and may be precipitated by a sudden increase in weight, an injury or pelvic surgery. It is usually self-limiting but can be helped by amitriptyline or gabapentin at night.

**Fracture of the femoral neck**

This fracture usually occurs after a fall, occasionally spontaneously. There is pain in the groin and thigh, weight-bearing is painful or impossible, and the leg is shortened and externally rotated. Occasionally, a fracture is not displaced and remains undetected. X-rays are diagnostic. Anyone with a hip fracture, especially after minimal trauma, should be reviewed for osteoporosis (see p. 477).

**Avascular necrosis (osteonecrosis) of the femoral head**

This condition is uncommon but occurs at any age. (Risk factors are discussed on p. 482.) There is severe hip pain. X-rays are diagnostic after a few weeks, when a well-demarcated area of increased bone density is visible at the upper pole of the femoral head. The affected bone may collapse. Early, the X-ray is normal but bone scintigraphy or MRI demonstrates the lesion and shows bone marrow oedema.

### Pain in the knee

The knee depends on ligaments and quadriceps muscle strength for stability. It is frequently injured, particularly during sports. Trauma or overuse of the knee leads to a variety of peri- and intra-articular problems. Some are self-limiting; others require physiotherapy, local corticosteroid injections or surgery.

Painful knee problems can be divided into those that arise within the joint and those that arise in the soft tissues around the joint (Box 18.16). Only problems arising within the joint are likely to cause accumulation of fluid (effusion). Identification and aspiration of fluid from effusions are relevant diagnostic procedures.

**Knee joint effusions**

An effusion of the knee causes swelling, stiffness and pain. The pain is often more severe with an acute onset and with increasing inflammation because the capsule that contains the pain receptors is stretched. A full clinical history must include a past medical, family and drug history.

**Examination**

A large and tense effusion is easily seen and felt on each side of the patella and in the suprapatellar pouch, and is fluctuant. The effusion delays the patella tapping against the femur when it is pressed firmly and quickly with the knee held straight and relaxed (the ‘patellar tap’ sign). Small effusions also demonstrate the ‘bulge’ sign when the patient is lying with the quadriceps relaxed. For this test, apply a gentle sweeping pressure, first to the medial side of the joint and then, watching the medial dimple, to the lateral side. Slightly delayed bulging of the medial dimple indicates fluid in the joint.

#### Box 18.16 Pain in the knee: causes

**Problems arising within the joint**

- Osteoarthritis
- Inflammatory arthritis
- Meniscal tear
- Cruciate ligament tear
- Chondromalacia
- Osteochondritis dissecans
- Spontaneous osteonecrosis of the knee

**Problems arising in tissues around the joint**

**Medial**

- Medial ligament strain
- Anserine bursitis

**Anterior**

- Pre-patellar bursitis
- infrapatellar bursitis
- Quadriceps tendon enthesitis
- Osgood–Schlatter disease

**Posterior**

- Popliteal (Baker’s) cyst

**Other**

- Hypermobility syndrome
- Referred from hip joint

**Trauma and overuse**
Investigations

These are:
- blood tests (urate, blood cultures)
- aspiration (see Fig. 18.2) and examination of the knee effusion.

The basic technique of aspiration is described in Box 18.7. If the fluid obtained is very cloudy, septic arthritis (or occasionally gout) is the likeliest diagnosis. Slightly cloudy or blood-stained fluid that does not clot is likely to indicate pseudogout. Frank blood that clots suggests a haemarthrosis. Fluid should be sent for Gram-stain and culture if sepsis is suspected. It should be sent for polarized light microscopy if looking for crystals (see p. 436).

Pain arising from within the knee

Osteoarthritis of the knee

Minor radiographic changes of OA (see Fig. 18.16) are very common in those aged over 50 years and do not usually cause pain, which is more likely to arise from surrounding soft tissues. X-ray appearances and the degree of pain felt in OA of the knee are not closely correlated. Marked valgus, varus or fixed flexion deformities suggest severe OA. For severe cases, surgery, usually total knee replacement, is the treatment of choice. In milder cases, pain relief, physiotherapy and, sometimes, intra-articular corticosteroid injections may help.

Inflammatory arthritis of the knee

Monoarthritis of the knee, associated with severe pain and marked redness, may be due to septic arthritis, gout or pseudogout. A cool, clear, viscous effusion is seen in elderly people with moderate or severe symptomatic OA (see p. 434). RA rarely presents with knee involvement alone, though seronegative spondyloarthritis may do so.

Haemarthrosis of the knee

This condition is caused by:
- trauma: meniscal, cruciate or synovial lining tear
- clotting or bleeding disorders, e.g. haemophilia, sickle cell disease or von Willebrand’s disease.

Torn meniscus

The menisci are partially attached fibrocartilages that stabilize the rounded femoral condyles on the flat tibial plateaux. In the young, they are resilient, but this decreases with age. They can be torn by an injury, commonly in sports that involve twisting and bending. The history is usually diagnostic. There is immediate medial or lateral knee pain and swelling within a few hours. The affected side is tender. If the tear is large, the knee may lock flexed. The immediate treatment is to apply ice. MRI demonstrates the tear (Fig. 18.10). In most circumstances, especially in active sportspeople, early arthroscopic repair or trimming of the torn meniscus is essential. Surgical intervention reduces recurrent pain, swelling and locking but not the risk of secondary OA. In older patients with OA plus meniscal tear, surgery is no more effective than physiotherapy alone. The long-term benefit of early repair of tears is not yet known. Post-surgical quadriceps exercises aid a return to sport and other activities.

Torn cruciate ligaments

Torn cruciate ligaments account for around 70% of knee haemarthroses in young people. They often coexist with a meniscal tear. Partial cruciate tears are difficult to diagnose clinically. On flexing the knee to 90°, a torn anterior cruciate allows the tibia to be pulled forwards on the femur. MRI is the investigation of choice. Such injuries need urgent orthopaedic referral, reconstructive surgery usually being necessary in young active adults. There is a significant incidence of secondary OA.

Chondromalacia patellae

This diagnosis is made arthroscopically. The retropatellar cartilage is fibrillated. In most cases, the pain settles eventually. When there is patellar misalignment, it may need surgery, as does recurrent patellar dislocation in adolescent girls.

Osteochondritis dissecans

This condition occasionally causes knee pain and swelling in adolescents and young adults, more commonly males. It is probably traumatic, possibly with hereditary predisposing factors. A fragment of bone and its attached cartilage detach by shearing, most commonly from the lateral aspect of the medial femoral condyle.

There is aching pain after activity and, if the fragment becomes loose, locking or ‘giving way’ occurs. The lesion is seen on a tunnel-view X-ray but MRI is more sensitive, especially if the fragment is undisplaced. Undisplaced lesions are treated with rest, then isometric quadriceps exercises. Loose fragments can be fixed arthroscopically or removed. A similar lesion affecting the lateral femoral condyle occurs in older people.

Spontaneous osteonecrosis of the knee

Osteonecrosis may occur spontaneously or after injury. There is local pain and there are marked bone marrow changes on MRI (Fig. 18.11A) or single-photon emission computed tomography (SPECT; Fig. 18.11B). In particular, weight-bearing must be avoided. Pamidronate by infusion is sometimes used. Spontaneous osteonecrosis of the knee (SONK) may progress to bone infarction and require replacement surgery.

Pain from structures around the knee

Medial knee pain

There may be medial or lateral ligament strain but the medial ligament is more commonly affected. There is pain at the ligament’s insertion into the upper medial tibia, which is worsened by standing or stressing the affected ligament.

Anserine bursitis causes pain and localized tenderness 2–3 cm below the posteromedial joint line in the upper part of the tibia at
Common regional musculoskeletal problems

18

the site of the bursa. It occurs in obese women, often with valgus deformities, and in breast-stroke swimmers. 

Management is with physiotherapy and a local corticosteroid injection.

Anterior knee pain
Anterior knee pain is common in adolescence. In many cases, no specific cause is found, despite investigation. This is called ‘anterior knee pain syndrome’ and settles with time. Isometric quadriceps exercises and avoidance of high heels both help the condition. Patients and parents often need firm reassurance. Abnormal patellar tracking may be a cause and may need surgical treatment. Hypermobility of joints causes joint pain, maltracking and, rarely, recurrent patellar dislocation (see also p. 432).

Pre- and infrapatellar bursitis
This can occur in patients whose jobs involve frequent kneeling (‘housemaid’s knee’, ‘clergyman’s knee’, ‘carpet-layer’s knee’). There is local pain, tenderness and sometimes swelling. Avoidance of kneeling and a local corticosteroid injection are helpful. Septic bursitis can occur.

Osgood–Schlatter disease
Osgood–Schlatter disease causes pain and swelling over the tibial tubercle. It is a traction apophysitis of the patellar tendon and occurs particularly in teenage sports players.

Enthesitis
This may occur at the patellar end of the quadriceps tendon (jumper’s knee).

Posterior knee pain
Popliteal cyst (Baker’s cyst)
In approximately 5% of people with a knee effusion, a swollen, painful popliteal cyst develops. The semi-membranosus bursa in some individuals has a valve-like connection to the knee, allowing the effusion to flow into the bursa but not back. The cyst is best seen and felt in the popliteal fossa with the patient standing. 

Ruptured popliteal cyst
Fluid escapes into the soft tissue of the popliteal fossa and upper calf, causing sudden and severe pain, swelling and tenderness of the upper calf.

A history of previous knee problems and the sudden onset of pain and tenderness high in the calf suggest a ruptured cyst rather than a deep vein thrombosis (DVT). A diagnostic ultrasound examination distinguishes a ruptured cyst from a DVT (see p. 1003), which can avoid inappropriate treatment with anticoagulants. Analgesics or NSAIDs, rest with the leg elevated, and aspiration and injection with corticosteroids into the knee joint are required.

Pain in the shin, calf and ankle

Sever’s disease
This is a traction apophysitis of the Achilles tendon in young people (compare Osgood–Schlatter disease, p. 427).

Pain at the insertion of the Achilles tendon into the calcaneum is an enthesitis. This is traumatic or it can complicate spondyloarthritis. Raising the shoe heel reduces pain. Occasionally, a low-pressure corticosteroid injection near the enthesis is necessary.

Achilles tendonosis
This causes a painful, tender swelling a few centimetres above the tendon’s insertion. Advise against walking barefoot and jumping. Tendon damage or rupture can occur with quinolone, e.g. ciprofloxacin therapy. Therapeutic ultrasound is helpful. (Caution: a local injection may cause the tendon to rupture.) Autologous platelet concentrates are used but evidence of efficacy is poor. Procedures to remove or sclerose new blood vessels in the inflamed areas may help.

Achilles bursitis
This lies clearly anterior to the tendon and can be safely injected with corticosteroid.

Compartment syndromes
The muscles of the lower leg are enclosed in fascial compartments, with little room for expansion to occur. Compartment syndromes can be acute and severe, such as following exercise. 

In anterior tibial syndrome there is severe pain in the front of the shin, occasionally with foot drop. Immediate surgical decompression to prevent muscle necrosis is sometimes required.
Chronic compartment syndrome produces pain in the lower leg that is aggravated by exercise and may therefore be mistaken for a vascular or neurological disorder.

Pain in the foot

See Box 18.17. The feet are subjected to extreme pressures by weight-bearing and inappropriate shoes. They are commonly painful. Broad, deep, thick-soled shoes are essential for sporting activities, prolonged walking or standing, and in people with congenitally flat or arthritic feet.

There are two common types of foot deformity:
- **Flat feet.** These stress the ankle and throw the hindfoot into a valgus (everted) position. A flat foot is rigid and inflexible.
- **High-arched feet.** These place pressure on the lateral border and ball of the foot.

The foot is affected by a variety of inflammatory arthritic conditions. After the hand, the foot joints are the most commonly affected by RA. The diagnosis depends on assessment of the distribution of the joints affected, the pattern of other joint problems or the finding of an associated condition (e.g. psoriasis; see p. 664).

**Hallux valgus**
The big toe migrates laterally. In the congenital form, the first metatarsal bone is displaced medially (metatarsus primus varus). The shape of modern shoes causes later onset of hallux valgus. It is a common complication of RA.

**Hallux rigidus**
OA of the first metatarsophalangeal (MTP) joint in a normally aligned or valgus joint causes hallux rigidus: a stiff, dorsiflexed and painful big toe. Careful choice of footwear and the help of a podiatrist suffice for most cases but some require surgery.

**Metatarsalgia**
This is common, especially in women who wear high heels, after trauma and in those with hammer toes. The ball of the foot is painful to walk and stand on. Callusities and pressure-induced bursae develop under the metatarsal heads. RA causes misalignment of the metatarsal bones and severe metatarsalgia.

**Management** is with podiatry and the wearing of appropriate shoes. Surgery is occasionally needed, particularly in the rheumatoid foot.

**Morton’s neuroma**
This usually occurs between the third and fourth metatarsal heads. It causes pain, burning and numbness in the adjacent surfaces of the affected toes when walking. It is helped by wearing wider, cushion-soled shoes. Occasionally, a steroid injection or excision is necessary.

**Stress fractures of the metatarsals**
These cause sudden, severe, weight-bearing pain in the distal shaft of the fractured metatarsal bone. They occur after unaccustomed walking or with new shoes. There is local tenderness and swelling, but initially X-rays are normal and diagnosis delayed (Fig. 18.12). A radioisotope bone scan or MRI reveals the fracture earlier than X-rays. Reduced weight-bearing for a few weeks usually suffices. Underlying osteoporosis may be a cause.

**Tarsal tunnel syndrome**
This is an entrapment neuropathy of the posterior tibial nerve at the medial malleolus. It produces burning, tingling and numbness of the toes, sole and medial arch. The nerve is tender below the malleolus and, when tapped, produces a shock-like pain (Tinel’s sign). A local steroid injection under the retinaculum, between the medial malleolus and calcaneum, is helpful.

**Plantar fasciitis**
This is an enthesitis at the insertion of the plantar fascia into the calcaneum. It produces localized pain under the heel when standing and walking, and local tenderness. It occurs alone or in spondyloarthritis. Obesity, particularly in flat-footed people who walk a lot, can predispose to plantar fasciitis.

**Plantar spurs**
These are traction lesions at the insertion of the plantar fascia in older people and are usually asymptomatic. They become painful after trauma.
Calcaneal bursitis

This is a pressure-induced (adventitious) bursa that produces diffuse pain and tenderness under the heel. Compression of the heel pad from the sides is painful, which distinguishes it from plantar fascia pain.

Clinical features and management of heel pain

Whatever the cause, heel pain is always worse in the morning as soon as weight is placed on the foot.

All these lesions are treated with heel pads, and reduced walking; they are often self-limiting. A dorsiflexion splint at night to stretch the plantar fascia is worth trying. When an injection is necessary, a medial approach is used, rather than advancing through the heel pad, often under ultrasound guidance.

Pain in the chest

Musculoskeletal conditions are sometimes a cause of chest pain. An example is Tietze’s disease. In this condition, pain arises from the costosternal junctions. It is usually unilateral and affects one, two or three ribs. There is local tenderness, which helps to make the diagnosis. The condition is benign and self-limiting. It often responds well to anti-inflammatory drugs. Other causes of chest wall pain include rib fractures due to trauma, osteoporosis or a malignant deposit. Costochondral pain occurs in ankylosing spondylitis (see p. 448). In people with heart disease, costochondral pain may cause severe anxiety but it is not like angina and the patient should be reassured.

Pain associated with sport and the performing arts

Pain in muscles and soft tissues is common after sport or associated with performing arts, such as dancing or playing musical instruments. General advice, such as warming up properly and using appropriate supportive footwear for running, can help. However, in cases of prolonged pain or where the person suffering pain is a professional sportsperson or performer, referral to a sports medicine specialist is advisable.

Further reading

CHRONIC PAIN SYNDROMES

Chronic pain is defined as pain lasting more than 3 months (the natural tissue-healing time). Many rheumatological illnesses (e.g. RA and OA) cause pain of such duration but are not considered as chronic pain syndromes. In chronic pain syndromes, the pain generally has no clear structural cause or curative treatment and is often combined with psychological distress, poor sleep and altered use of the muscles due to the pain (called fear-avoidance behaviour or abnormal pain behaviour). This altered behaviour can lead to more stress and tension in the muscles, exacerbating the pain (Fig. 18.13). The pain suffered by these patients is neither imaginary nor artefactual, even though there may be no structural abnormality in the painful area. There is a problem with the pain processing system in the nervous system, leading to amplification of pain signals. Psychological factors often contribute to this amplification, and the pain can make psychological distress worse, in a vicious circle. The combination of physical pain and psychological distress makes these syndromes difficult to manage.

Living with chronic pain is difficult. Patients may become anxious, depressed or socially isolated, and their quality of life is reduced. There are often adverse effects on employment, personal relationships and dependence on others. Consultations need to address these issues, as well as the pain itself, to be effective. In chronic pain syndromes, patients need help to lead a more normal life despite their pain, and are best referred to a specialist, multidisciplinary pain service. Medications alone are not the answer.

These syndromes can be conveniently subdivided into chronic widespread pain (above and below the waist and on both sides of the body) and chronic regional pain (any other distribution). Both are very common. Epidemiological studies show that the prevalence of chronic widespread pain is 10–11% and that of chronic regional pain 20–30%.

Chronic widespread pain

Pain that starts in a single area can spread to other areas of the body, as more muscles become tense and tender. Conversely, patients with chronic widespread pain can develop new, localized causes of pain (e.g. appendicitis, OA) that can be treated successfully. It should not be assumed that every pain in these patients is always due to the same chronic problem.

Two of the main causes of chronic widespread pain are fibromyalgia and hypermobility spectrum disorders (see p. 432).
Fibromyalgia

Fibromyalgia is not a diagnosis of exclusion. It can occur in patients who have other illnesses like RA and SLE. Individuals suffer chronic widespread pain with disrupted and unrefreshing sleep, constant tiredness and tender points detectable on pressing their muscles (Fig. 18.14). Multiple other symptoms, such as irritable bowel syndrome (IBS), tension headaches, dysmenorrhoea, atypical facial or chest pain and forgetfulness, often coexist. It occurs in about 1 in 50 people, can develop at any age and affects women more than men (2:1). The diagnosis is clinical, and blood tests and imaging are normal. These tests may be requested to exclude other causes of pain.

Management

See p. 771. A clear explanation of the diagnosis is vital. While being honest about the fact that there is no cure for fibromyalgia, it is also necessary to reassure the patient that it is not arthritis and that the pain is not causing damage to joints or muscles. Many patients have never had an explanation of the cause of their symptoms, which leads to fear and doubt. Treatment options that can be offered (not cure) are described below. Management guidelines stress use of non-drug measures instead of or alongside drugs.

Drugs

There is evidence from clinical trials for use of analgesics, anticonvulsants and antidepressants. Commonly used drugs include amitriptyline (which may also improve sleep), pregabalin, paracetamol, tramadol and gabapentin. Benefits, however, are often short-term and adverse effects common.

Non-drug therapies

A sympathetic, psychosocial, multidisciplinary approach is appropriate. A graded, supervised aerobic exercise regimen over 3 months is safe and effective. When depression is present, it should be treated. Cognitive behavioural therapy can help the person to pace their life more effectively and to cope better. Pain management programmes, combining psychology with physiotherapy, are designed to improve physical function and quality of life but do not reduce pain intensity. Acupuncture can lessen pain in some cases but the effect is usually transient.

Chronic regional pain

Chronic (work-related) upper-limb pain syndrome

This term is preferred to ‘repetitive strain injury’ (RSI). The predominant symptoms are pain in all or part of one or both arms. A specific lesion, such as tennis elbow or carpal tunnel syndrome, or muscular-pattern neck pain often develops first, and early recognition and treatment may prevent chronicity. After a variable period, the pain becomes more diffuse and no longer simply work-related, and there is often severe distress. It is seen in keyboard workers and in musicians. When it arises at work, it is often at a time of stress, such as changing work practices, shortage of staff or disharmony.

Management

If possible, there should be a brief period off work and a gradual return to activity as the pain settles. Use of analgesia and NSAIDs, with physiotherapy, is helpful during the initial phase to prevent a vicious circle developing. Amitriptyline or pregabalin is helpful for some patients.

A review of working practices and the positioning of screen, keyboard and chair are essential, as is support of the patient by their manager. Musicians are helped by expert advice on playing technique and should reduce playing times temporarily, but not stop completely.

Temporomandibular pain dysfunction syndrome

This pain syndrome is a disorder of the temporomandibular joint that is associated with nocturnal tooth grinding or abnormalities of bite. It occurs in anxious people. It gives rise to pain in one or both temporomandibular joints.

Dental correction of the bite helps a few, but when no dental cause is found, low-dose tricyclic antidepressant therapy is used. Many patients are made worse by unnecessary dental treatment.

Complex regional pain syndrome

Complex regional pain syndrome (CRPS) is a rare condition (prevalence 20:100 000), in which regional neuropathic pain is associated with abnormal sensory, autonomic, motor and/or trophic changes. There are two types. In CRPS type I, there is no identifiable overt nerve lesion, whereas such a lesion is identifiable in CRPS type II. CRPS usually occurs after trauma but the pain is disproportionate in time or intensity to that usually caused by such an injury. It may also develop after central nervous system lesions (e.g. strokes) or without cause.

Its features are pain and other sensory abnormalities, including hyperaesthesia; and autonomic vasomotor dysfunction, leading to abnormal blood flow and sweating; and motor system abnormalities, leading to structural changes of superficial and deep tissues (trophic changes). Not all components need be present. The sensory, motor and sympathetic nerve changes are not restricted to the distribution of a single nerve and may be remote from the site of origin 20:100 000, in which regional neuropathic pain is associated with abnormal sensory, autonomic, motor and/or trophic changes.
