In the intensive care units (ICUs), glucose levels are controlled most frequently using insulin infusions. Patients receiving total parenteral nutrition can have insulin added to the bag. Standard total parenteral nutrition contains 25% dextrose so an infusion rate of 50 mL/h delivers 12.5 g of dextrose per hour.

Based on the evidence available, ICU patients with diabetes and new-onset hyperglycemia with blood glucose levels above 180 mg/dL (10 mmol/L) should be treated with insulin, aiming for target glucose levels between 140 mg/dL (7.8 mmol/L) and 180 mg/dL (10 mmol/L). In the ICU setting, aiming for blood glucose levels close to 100 mg/dL (5.6 mmol/L) is not beneficial and may even be harmful. When patients leave the ICU, target glucose values between 100 mg/dL (5.6 mmol/L) and 180 mg/dL (10 mmol/L) may be appropriate, although this view is based on clinical observations rather than conclusive evidence.

On the general surgical and medical inpatient services, most patients are treated with subcutaneous insulin regimens. Limited cross-sectional and prospective studies suggest that the best glucose control is achieved on a combination of basal and bolus regimen with 50% of daily insulin needs provided by intermediate- or long-acting insulins. Standardized order sets can reduce errors, and they often include algorithms for recognition and treatment of hypoglycemia (see http://ucsfinpatientdiabetes.pbworks.com for examples).

The morbidity and mortality in diabetic patients are twice those of nondiabetic patients. Those with new-onset hyperglycemia (ie, those without a preadmission diagnosis of diabetes) have even higher mortality—almost eightfold that of nondiabetic patients in one study. These observations have led to the question of whether tight glycemic control in the hospital improves outcomes.

B. Pregnancy and the Diabetic Patient

See Chapter 19. Tight glycemic control with normal HbA1c levels is very important during pregnancy. Early in
Patients with peripheral neuropathy, especially those with type 2 diabetes, should be referred to an endocrinologist if treatment goals are not met or if the patient requires an increasingly complex regimen to maintain glycemic control.

When to Refer

- All patients should receive self-management education when diabetes is diagnosed and at intervals thereafter. The instructional team should include a registered dietitian and registered nurse; they must be Certified Diabetes Educators (CDEs).
- Patients with type 1 diabetes should be comanaged by an endocrinologist and a primary care provider.
- Patients with type 2 diabetes should be referred to an endocrinologist if treatment goals are not met or if the patient requires an increasingly complex regimen to maintain glycemic control.
- Patients with type 2 diabetes should be referred to an ophthalmologist or optometrist for a dilated eye examination when the diabetes is diagnosed, and patients with type 1 diabetes should be referred 5 years after the diagnosis is made.
- Patients with peripheral neuropathy, especially those with loss of protective threshold (unable to detect 5.07 Semmes-Weinstein filament) or structural foot problems, should be referred to a podiatrist.
- Referrals to other specialists may be required for management of chronic complications of diabetes.

Prognosis

The DCCT showed that the previously poor prognosis for as many as 40% of patients with type 1 diabetes is markedly improved by optimal care. DCCT participants were generally young and highly motivated and were cared for in academic centers by skilled diabetes educators and endocrinologists who were able to provide more attention and services than are usually available. Improved training of primary care providers may be beneficial.

For type 2 diabetes, the UKPDS documented a reduction in microvascular disease with glycemic control, although this was not apparent in the obese subgroup. Cardiovascular outcomes were not improved by glycemic control, although antihypertensive therapy showed benefit in reducing the number of adverse cardiovascular complications as well as in reducing the occurrence of microvascular disease among hypertensive patients. In patients with visceral obesity, successful management of type 2 diabetes remains a major challenge in the attempt to achieve appropriate control of hyperglycemia, hypertension, and dyslipidemia. Once safe and effective methods are devised to prevent or manage obesity, the prognosis of type 2 diabetes with its high cardiovascular risks should improve considerably.

In addition to poorly understood genetic factors relating to differences in individual susceptibility to development of long-term complications of hyperglycemia, it is clear that in both types of diabetes, the diabetic patient's intelligence, motivation, and awareness of the potential complications of the disease contribute significantly to the ultimate outcome.

DIABETIC COMA

Coma may be due to a variety of causes not directly related to diabetes. Certain causes directly related to diabetes require differentiation: (1) Hypoglycemic coma resulting from excessive doses of insulin or oral hypoglycemic agents. (2) Hyperglycemic coma associated with either severe insulin deficiency (DKA) or mild to moderate insulin deficiency (hyperglycemic hyperosmolar state). (3) Lactic acidosis associated with diabetes, particularly in patients with diabetes stricken with severe infections or with cardiovascular collapse.
DIABETIC KETOACIDOSIS

ESSENTIALS OF DIAGNOSIS

- Hyperglycemia greater than 250 mg/dL (13.9 mmol/L).
- Metabolic acidosis with blood pH < 7.3; serum bicarbonate less than 15 mEq/L.
- Serum positive for ketones.

General Considerations

Diabetic ketoacidosis (DKA) may be the initial manifestation of type 1 diabetes or may result from increased insulin requirements in type 1 diabetes patients during the course of infection, trauma, myocardial infarction, or surgery. It is a life-threatening medical emergency with a mortality rate just under 5% in individuals under 40 years of age, but with a more serious prognosis in older adults, who have mortality rates over 20%. The National Data Group reports an annual incidence of five to eight episodes of DKA per 1000 diabetic persons. Ketoacidosis may develop in patients with type 2 diabetes when severe stress such as sepsis or trauma is present. DKA occurs in patients with type 2 diabetes when severe stress such as sepsis or trauma is present. DKA is one of the more common serious complications of insulin pump therapy, occurring in approximately 1 per 80 patient-months of treatment. Many patients who monitor capillary blood glucose regularly ignore urine ketone measurements, which signals the possibility of insulin leakage or pump failure before serious illness develops. Poor compliance, either for psychological reasons or because of inadequate education, is one of the most common causes of recurrent DKA.

Clinical Findings

A. Symptoms and Signs

The appearance of DKA is usually preceded by a day or more of polyuria and polydipsia associated with marked fatigue, nausea, and vomiting. If untreated, mental stupor ensues that can progress to coma. Drowsiness is fairly common, but frank coma only occurs in about 10% of patients. On physical examination, evidence of dehydration in a stuporous patient with rapid deep breathing and a “fruity” breath odor of acetone strongly suggests the diagnosis. Hypotension with tachycardia indicates profound fluid and electrolyte depletion, and mild hypothermia is usually present. Abdominal pain and even tenderness may be present in the absence of abdominal disease. Conversely, cholecystitis or pancreatitis may occur with minimal symptoms and signs.

B. Laboratory Findings

Typically, the patient with moderately severe DKA has a plasma glucose of 350–900 mg/dL (19.4–50 mmol/L), serum ketones at a dilution of 1:8 or greater or beta-hydroxybutyrate more than 4 nmol/L, hyperkalemia (serum potassium level of 5–8 mEq/L), slight hypotension (serum sodium of approximately 130 mEq/L), hyperphosphatemia (serum phosphate level of 6–7 mg/dL [1.9–2.3 mmol/L]), and elevated blood urea nitrogen and serum creatinine levels (Table 27–12). Acidosis may be severe (pH ranging from 6.9 to 7.2 and serum bicarbonate ranging from 5 mEq/L to 15 mEq/L); PCO₂ is low (15–20 mm Hg) related to compensatory hyperventilation. Fluid depletion is marked, typically about 100 mL/kg.

The difference between venous and arterial pH is 0.02 to 0.15 pH units and venous and arterial bicarbonate is 1.88 mEq/L. These small differences will not affect either the diagnosis or the management of DKA, and there is no need to collect arterial blood for measuring the acid-base status.

The hyperkalemia occurs despite total body potassium depletion because of the shift of potassium from the intracellular to extracellular spaces that occurs in systemic acidosis. The average total body potassium deficit resulting from osmotic diuresis, acidosis, and gastrointestinal losses is about 3–5 mEq/kg. Similarly, despite the elevated serum phosphate, total body phosphate is generally depleted. Serum sodium is generally reduced due to loss of sodium.

¹Leftover urine in bladder might still contain glucose from earlier hyperglycemia.
²Alcohol can elevate plasma lactate as well as keto acids to reduce pH.
ions (7–10 mEq/kg) by polyuria and vomiting and because severe hyperglycemia shifts intracellular water into the interstitial compartment. For every 100 mg/dL of plasma glucose, serum sodium decreases by 1.6 mEq/L (5.56 mmol/L). The decrease in serum sodium may be greater when patients have more severe hyperglycemia (greater than 400 mg/dL, 22.2 mmol/L) and a correction factor of 2.4 mEq/L may be used. Hypertriglyceridemia should be considered if the corrected sodium is very low. Serum osmolality can be directly measured by standard tests of freezing point depression or can be estimated by calculating the molarity of sodium, chloride, and glucose in the serum. A convenient method of estimating effective serum osmolality is as follows (normal values in humans are 280–300 mOsm/kg):

\[\text{mOsm/kg} = 2 \times \left[\text{measured Na}^+ \right] + \frac{\text{Glucose (mg/dL)}}{18}\]

These calculated estimates are usually 10–20 mOsm/kg lower than values measured by standard cryoscopic techniques. Central nervous system depression or coma occurs when the effective serum osmolality exceeds 320–330 mOsm/L. Coma in a diabetic patient with a lower osmolality should prompt a search for cause of coma other than hyperosmolality (see Table 27–12 and Chapter 24).

Ketoadicemia represents the effect of insulin lack at multiple enzyme loci. Insulin lack associated with elevated levels of growth hormone, catecholamines, and glucagon contributes to increases in lipolysis from adipose tissue and in hepatic ketogenesis. In addition, reduced ketolysis by insulin-deficient peripheral tissues contributes to the ketoadicemia. The only true "keto" acid present is acetoacetic acid which, along with its by-product acetone, is measured by nitroprusside reagents (Acetest and Ketostix). The sensitivity for acetone, however, is poor, requiring over 10 mmol/L, which is seldom reached in the plasma of ketotic patients—although this detectable concentration is readily achieved in urine. Thus, in the plasma of ketotic patients, only acetoacetate is measured by these reagents. The more prevalent beta-hydroxybutyric acid has no ketone group and is therefore not detected by conventional nitroprusside tests. This takes on special importance in the presence of circulatory collapse during DKA, wherein an increase in lactic acid can shift the redox state to increase beta-hydroxybutyric acid at the expense of the readily detectable acetoacetic acid. Bedside diagnostic reagents are then unreliable, suggesting no ketonemia in cases where beta-hydroxybutyric acid is a major factor in producing the acidosis. Combined glucose and ketone meters (Precision Xtra, Nova Max Plus) that measure blood beta-hydroxybutyrate concentration on capillary blood are available. Many clinical laboratories also offer direct blood beta-hydroxybutyrate measurement.

Nonspecific elevations of serum amylase and lipase occur in about 16–25% of cases of DKA, and an imaging study may be necessary if the diagnosis of acute pancreatitis is being seriously considered. Leukocytosis as high as 25,000/mcL with a left shift may occur with or without associated infection. The presence of an elevated or even a normal temperature can suggest the presence of an infection, since patients with DKA are generally hypothermic if uninfected.

**Treatment**

Patients with mild DKA are alert and have pH levels between 7.25 and 7.30 and beta-hydroxybutyrate levels of 3–4 mmol/L; those with moderate ketoacidosis are either alert or little drowsy and have pH levels between 7.0 and 7.24 and beta-hydroxybutyrate levels of 4–8 mmol/L, and those with severe ketoacidosis are stuporous and have a pH < 7.0 and beta-hydroxybutyrate levels of greater than 8 mmol/L. Those with mild ketoacidosis can be treated in the emergency department, but those with moderate or severe ketoacidosis require admission to the ICU or step-down unit. Therapeutic goals are to restore plasma volume and tissue perfusion, reduce blood glucose and osmolality toward normal, correct acidosis, replenish electrolyte losses, and identify and treat precipitating factors. Gastric intubation is recommended in the comatose patient to prevent vomiting and aspiration that may occur as a result of gastric atony, a common complication of DKA. An indwelling catheter may also be necessary. In patients with preexisting heart or kidney failure or those in severe cardiovascular collapse, a central venous pressure catheter should be inserted to evaluate the degree of hypovolemia and to monitor subsequent fluid administration.

A comprehensive flow sheet that includes vital signs, serial laboratory data, and therapeutic interventions (eg, fluids, insulin) should be meticulously maintained by the clinician responsible for the patient's care. Plasma glucose should be recorded hourly and electrolytes and pH at least every 2–3 hours during the initial treatment period. Bedside glucose meters should be used to titrate the insulin therapy. The patient should not receive sedatives or opioids in order to avoid masking signs and symptoms of impeding cerebral edema.

**A. Fluid Replacement**

In most patients, the fluid deficit is 4–5 L. Initially, 0.9% saline solution is the solution of choice to help reexpand the contracted vascular volume and should be started in the emergency department as soon as the diagnosis is established. The saline should be infused rapidly to provide 1 L/h over the first 1–2 hours. After the first 2 L of fluid have been given, the intravenous infusion should be at the rate of 300–400 mL/h. Use 0.9% (“normal”) saline unless the serum sodium is greater than 150 mEq/L, when 0.45% (“half normal”) saline solution should be used. The volume status should be very carefully monitored. Failure to give enough volume replacement (at least 3–4 L in 8 hours) to restore normal perfusion is one of the most serious therapeutic shortcomings adversely influencing satisfactory recovery. Excessive fluid replacement (more than 5 L in 8 hours) may contribute to acute respiratory distress syndrome or cerebral edema. When blood glucose falls to approximately 250 mg/dL (13.9 mmol/L), the fluids should be changed to a 5% glucose-containing solution to maintain serum glucose in the range of 250–300 mg/dL (13.9–16.7 mmol/L). This will prevent the development of...
hypoglycemia and will also reduce the likelihood of cerebral edema, which could result from too rapid decline of blood glucose.

B. Insulin Replacement

Immediately after initiation of fluid replacement, regular insulin can be given intravenously in a loading dose of 0.1 unit/kg as a bolus to prime the tissue insulin receptors. Following the initial bolus, intravenous doses of insulin as low as 0.1 unit/kg/h are continuously infused or given hourly as an intramuscular injection; this is sufficient to replace the insulin deficit in most patients. A prospective randomized study showed that a bolus dose is not required if patients are given hourly insulin infusion at 0.14 unit/kg. Replacement of insulin deficiency helps correct the acidosis by reducing the flux of fatty acids to the liver, reducing ketone production by the liver, and also improving removal of ketones from the blood. Insulin treatment reduces the hyperosmolality by reducing the hyperglycemia. It accomplishes this by increasing removal of glucose through peripheral utilization as well as by decreasing production of glucose by the liver. This latter effect is accomplished by direct inhibition of gluconeogenesis and glycolysis as well as by lowered amino acid flux from muscle to liver and reduced hyperglucagonemia.

The insulin infusion should be “piggy-backed” into the fluid line so the rate of fluid replacement can be changed without altering the insulin delivery rate. If the plasma glucose level fails to fall at least 10% in the first hour, a repeat loading dose (0.1 or 0.14 unit/kg) is recommended. Rarely, a patient with immune insulin resistance is encountered, and this requires doubling the insulin dose every 2–4 hours if hyperglycemia does not improve after the first two doses of insulin. The insulin dose should be adjusted to lower the glucose concentration by about 50–70 mg/dL/h (2.8–3.9 mmol/L). If clinical circumstances prevent use of insulin infusion, then the insulin can be given intramuscularly. An initial 0.15 unit/kg of regular insulin is given intramuscularly, and at the same time, the same size dose is given intramuscularly. Subsequently, regular insulin is given intramuscularly hourly at a dose of 0.1 unit/kg until the blood glucose falls to around 250 mg/dL, when the insulin can be given subcutaneously. Patients who normally take insulin glargine or insulin detemir can be given their usual maintenance doses during initial treatment of their DKA. The continuation of their subcutaneous basal insulins means that lower doses of intravenous insulin will be needed, and there will be a smoother transition from intravenous insulin infusion to the subcutaneous regimen.

C. Potassium

Total body potassium loss from polyuria and vomiting may be as high as 200 mEq. However, because of shifts of potassium from cells into the extracellular space as a consequence of acidosis, serum potassium is usually normal to slightly elevated prior to institution of treatment. As the acidosis is corrected, potassium flows back into the cells, and hypokalemia can develop if potassium replacement is not instituted. If the patient is not uremic and has an adequate urinary output, potassium chloride in doses of 10–30 mEq/h should be infused during the second and third hours after beginning therapy as soon as the acidosis starts to resolve. Replacement should be started sooner if the initial serum potassium is inappropriately normal or low and should be delayed if serum potassium fails to respond to initial therapy and remains above 5 mEq/L, as in cases of chronic kidney disease. Occasionally, a patient may present with a serum potassium level less than 3.5 mEq/L, in which case insulin therapy should be delayed until the potassium level is corrected to greater than 3.5 mEq/L. An ECG can be of help in monitoring the patient’s potassium status: High peaked T waves are a sign of hyperkalemia, and flattened T waves with U waves are a sign of hypokalemia. Foods high in potassium content should be prescribed when the patient has recovered sufficiently to take food orally. Tomato juice has 14 mEq of potassium per 240 mL, and a medium-sized banana provides about 10 mEq.

D. Sodium Bicarbonate

The use of sodium bicarbonate in management of DKA has been questioned since clinical benefit was not demonstrated in one prospective randomized trial and because of the following potentially harmful consequences: (1) development of hypokalemia from rapid shift of potassium into cells if the acidosis is overcorrected; (2) tissue anoxia from reduced dissociation of oxygen from hemoglobin when acidosis is rapidly reversed (leftward shift of the oxygen dissociation curve); and (3) cerebral acidosis resulting from lowering of cerebrospinal fluid pH. It must be emphasized, however, that these considerations are less important when very severe acidosis exists. Therefore, it is recommended that bicarbonate be administered in DKA if the arterial blood pH is 7.0 or less, with careful monitoring to prevent overcorrection. One or two ampules of sodium bicarbonate (one ampule contains 44 mEq/50 mL) should be added to 1 L of 0.45% saline with 20 mEq KCl or to 400 mL of sterile water with 20 mEq KCl and infused over 1 to 2 hours. (Note: Addition of sodium bicarbonate to 0.9% saline would produce a markedly hypertonic solution that could aggravate the hyperosmolar state already present.) It can be repeated until the arterial pH reaches 7.1, but it should not be given if the pH is 7.1 or greater since additional bicarbonate would increase the risk of rebound metabolic alkalosis as ketones are metabolized. Alkalosis shifts potassium from serum into cells, which could precipitate a fatal cardiac arrhythmia.

E. Phosphate

Phosphate replacement is seldom required in treating DKA. However, if severe hypophosphatemia of less than 1 mg/dL (0.32 mmol/L) develops during insulin therapy, a small amount of phosphate can be replaced per hour as the potassium salt. Three randomized studies, though, in which phosphate was replaced in patients with DKA did not show any apparent clinical benefit from phosphate administration. Moreover, attempts to use potassium phosphate as the sole means of replacing potassium have led to
a number of reported cases of severe hypocalcemia with
tetany. To minimize the risk of inducing tetany from too-
rapid replacement of phosphate, the average deficit of
40–50 mmol of phosphate should be replaced intrave-
nously at a rate no greater than 3–4 mmol/h in a 60- to
70-kg person. A stock solution (Abbott) provides a mixture of 1.12 g K\(_{2}\)HPO\(_{4}\) and 1.18 g KH\(_{2}\)PO\(_{4}\) in a 5-mL single-dose vial (this equals 22 mmol of potassium and 15 mmol of phosphate). One-half of this vial (2.5 mL) should be added to 1 L of either 0.45% saline or 5% dextrose in water. Two
liters of this solution, infused at a rate of 400 mL/h, will correct the phosphate deficit at the optimal rate of 3 mmol/h while providing 4.4 mEq of potassium per hour. (Additional potassium should be administered as potas-
sium chloride to provide a total of 10–30 mEq of potassium per hour, as noted above.) If the serum phosphate remains below 2.5 mg/dL (0.8 mmol/L) after this infusion, a repeat 5-hour infusion can be given.

F. Hyperchloremic Acidosis During Therapy

Because of the considerable loss of keto acids in the urine
during the initial phase of therapy, substrate for subsequent
regeneration of bicarbonate is lost and correction of the
total bicarbonate deficit is hampered. A portion of the
bicarbonate deficit is replaced with chloride ions infused in
large amounts as saline to correct the dehydration. In most
patients, as the ketoacidosis clears during insulin replace-
ment, a hyperchloremic, low-bicarbonate pattern emerges
with a normal anion gap. This is a relatively benign condition
that reverses itself over the subsequent 12–24 hours
once intravenous saline is no longer being administered.
Using a balanced electrolyte solution with a pH of 7.4 and
98 mEq/L chloride instead of normal saline (pH ~ 5.5;
chloride 154 mEq/L) similar to serum in chloride concen-
tration and pH during resuscitation instead of normal saline has been reported to prevent the hyperchloremic acidosis.

G. Treatment of Associated Infection

Antibiotics are prescribed as indicated (Table 30–5). Cho-
lecystitis and pyelonephritis may be particularly severe in
these patients.

H. Transition to Subcutaneous Insulin Regimen

Once the DKA is controlled and the patient is awake and
able to eat, subcutaneous insulin therapy can be initiated.
The patient with type 1 diabetes may have persistent signif-
icant tissue insulin resistance and may require a total daily
insulin dose of approximately 0.6 unit/kg. The amount of
insulin required in the previous 8 hours can also be helpful in
estimating the initial insulin doses. Half the total daily
dose can be given as a long-acting basal insulin and the
other half as short-acting insulin premeals. The patient
should receive subcutaneous basal insulin and rapid-acting
insulin analog with the first meal and the insulin infusion
discontinued an hour later. The overlap of the subcutaneous
insulin action and insulin infusion is necessary to prevent
relapse of the DKA. In patients with preexisting diabetes,
giving their basal insulin by subcutaneous injection at ini-
tiation of treatment simplifies the transition from intrave-
nous to subcutaneous regimen. The increased insulin
resistance is only present for a few days, and it is important
to reduce both the basal and bolus insulins to avoid hypo-
glycemia. A patient with new-onset type 1 diabetes usually
still has significant beta cell function and may not need any
basal insulin and only very low doses of rapid-acting insulin
before meals after recovery from the ketoacidosis. Patients
with type 2 diabetes and DKA due to severe illness may
initially require insulin therapy but can often transition
back to oral agents during outpatient follow-up.

► Prognosis

Low-dose insulin infusion and fluid and electrolyte
replacement combined with careful monitoring of patients’
clinical and laboratory responses to therapy have dramati-
cally reduced the mortality rates of DKA to less than 5%.
However, this complication remains a significant risk in
the aged who have mortality rates greater than 20% and in
patients in profound coma in whom treatment has been
delayed. Acute myocardial infarction and infarction of the
bowel following prolonged hypotension worsen the out-
look. A serious prognostic sign is end-stage chronic kidney
disease, and prior kidney dysfunction worsens the progno-
sis considerably because the kidney plays a key role in
compensating for massive pH and electrolyte abnormali-
ties. Symptomatic cerebral edema occurs primarily in the
pediatric population. Risk factors for its development
include severe baseline acidosis, rapid correction of hyper-
glycemia, and excess volume administration in the first
4 hours. Onset of headache or deterioration in mental sta-
tus during treatment should lead to consideration of this
complication. Intravenous mannitol at a dosage of 1–2 g/kg
given over 15 minutes is the mainstay of treatment. Excess
crystalloid infusion can precipitate pulmonary edema.
Acute respiratory distress syndrome is a rare complication
of treatment of DKA.

After recovery and stabilization, patients should be
instructed on how to recognize the early symptoms and
signs of ketoacidosis. Urine ketones or capillary blood
beta-hydroxybutyrate should be measured in patients
with signs of infection or in insulin pump-treated patients
when capillary blood glucose remains unexpectedly and
persistently high. When heavy ketonuria and glycosuria
persist on several successive examinations, supplemental
rapid acting insulin should be administered and liquid
foods such as lightly salted tomato juice and broth should
be ingested to replenish fluids and electrolytes. The
patient should be instructed to contact the clinician if
ketonuria persists, and especially if there is vomiting and
inability to keep down fluids. Recurrent episodes of
severe ketoacidosis often indicate poor compliance with
the insulin regimen, and these patients will require inten-
sive counseling.

Savage MW et al. Joint British Diabetes Societies guideline for
the management of diabetic ketoacidosis. Diabet Med. 2011
May;28(5):508–15. [PMID: 21255074]
HYPERGLYCEMIC HYPEROSMOLAR STATE

ESSENTIALS OF DIAGNOSIS

- Hyperglycemia greater than 600 mg/dL (33.3 mmol/L).
- Serum osmolality greater than 310 mOsm/kg.
- No acidosis; blood pH > 7.3.
- Serum bicarbonate greater than 15 mEq/L.
- Normal anion gap (less than 14 mEq/L).

General Considerations

This second most common form of hyperglycemic coma is characterized by severe hyperglycemia in the absence of significant ketosis, with hyperosmolality and dehydration. It occurs in patients with mild or occult diabetes, and most patients are typically middle-aged to elderly. Accurate figures are not available as to its true incidence, but from data on hospital discharges it is rarer than DKA even in older age groups. Underlying chronic kidney disease or heart failure is common, and the presence of either worsens the prognosis. A precipitating event such as infection, myocardial infarction, stroke, or recent operation is often present. Certain medications such as phenytoin, diazoxide, corticosteroids, and diuretics have been implicated in its pathogenesis, as have procedures associated with glucose loading such as peritoneal dialysis.

Pathogenesis

A partial or relative insulin deficiency may initiate the syndrome by reducing glucose utilization of muscle, fat, and liver while inducing hyperglucagonemia and increasing hepatic glucose output. With massive glycosuria, obligatory water loss ensues. If a patient is unable to maintain adequate fluid intake because of an associated acute or chronic illness or has suffered excessive fluid loss, marked dehydration results. As the plasma volume contracts, kidney function becomes impaired, limiting the urinary glucose losses and exacerbating the hyperglycemia. Severe hyperosmolality develops that causes mental confusion and finally coma. It is not clear why ketosis is virtually absent under these conditions of insulin insufficiency, although reduced levels of growth hormone may be a factor, along with portal vein insulin concentrations sufficient to restrain ketogenesis.

Clinical Findings

A. Symptoms and Signs

Onset may be insidious over a period of days or weeks, with weakness, polyuria, and polydipsia. The lack of features of ketoacidosis may retard recognition of the syndrome and delay therapy until dehydration becomes more profound than in ketoacidosis. Reduced intake of fluid is not an uncommon historical feature, due to either inappropriate lack of thirst, nausea, or inaccessibility of fluids to elderly, bedridden patients. A history of ingestion of large quantities of glucose-containing fluids, such as soft drinks or orange juice, can occasionally be obtained. Lethargy and confusion develop as serum osmolality exceeds 310 mOsm/kg, and convulsions and coma can occur if osmolality exceeds 320–330 mOsm/kg. Physical examination confirms the presence of profound dehydration in a lethargic or comatose patient without Kussmaul respirations.

B. Laboratory Findings

Severe hyperglycemia is present, with blood glucose values ranging from 800 mg/dL to 2400 mg/dL (44.4 mmol/L to 133.2 mmol/L) (Table 27–12). In mild cases, where dehydration is less severe, dilutional hyponatremia as well as urinary sodium losses may reduce serum sodium to 120–125 mEq/L, which protects to some extent against extreme hyperosmolality. However, as dehydration progresses, serum sodium can exceed 140 mEq/L, producing serum osmolality readings of 330–440 mOsm/kg. Ketosis and acidosis are usually absent or mild. Prerenal azotemia is the rule, with serum urea nitrogen elevations over 100 mg/dL (35.7 mmol/L) being typical.

Treatment

A. Fluid Replacement

Fluid replacement is of paramount importance in treating nonketotic hyperglycemic coma. The onset of hyperosmolality is more insidious in elderly people without ketosis than in younger individuals with high serum ketone levels, which provide earlier indicators of severe illness (vomiting, rapid deep breathing, acetone odor, etc.). Consequently, diagnosis and treatment are often delayed until fluid deficit has reached levels of 6–10 L.

If hypovolemia is present as evidenced by hypotension and oliguria, fluid therapy should be initiated with 0.9% saline. In all other cases, 0.45% saline appears to be preferable as the initial replacement solution because the body fluids of these patients are markedly hyperosmolar. As much as 4–6 L of fluid may be required in the first 8–10 hours. Careful monitoring of the patient is required for proper sodium and water replacement. An important end point of fluid therapy is to restore urinary output to 50 mL/h or more. Once blood glucose reaches 250 mg/dL (13.9 mmol/L), fluid replacement should include 5% dextrose in either water, 0.45% saline solution, or 0.9% saline solution. The rate of dextrose infusion should be adjusted to maintain glycemic levels of 250–300 mg/dL (13.9–16.7 mmol/L) in order to reduce the risk of cerebral edema.

B. Insulin

Less insulin may be required to reduce the hyperglycemia in nonketotic patients as compared to those with diabetic ketoacidotic coma. In fact, fluid replacement alone can reduce hyperglycemia considerably by correcting the hypovolemia, which then increases both glomerular filtration
and renal excretion of glucose. Insulin treatment should therefore be delayed unless the patient has significant ketonemia (beta-hydroxybutyrate more than 1 mmol/L). Start the insulin infusion rate at 0.05 unit/kg/h (bolus is not needed) and titrate to lower blood glucose levels by 50–70 mg/dL per hour (2.8–3.9 mmol/L/h). Once the patient has stabilized and the blood glucose falls to around 250 mg/dL (13.9 mmol/L), insulin can be given subcutaneously.

C. Potassium

With the absence of acidosis, there may be no initial hyperkalemia unless associated end-stage chronic kidney disease is present. This results in less severe total potassium depletion than in DKA, and less potassium replacement is therefore needed. However, because initial serum potassium is usually not elevated and because it declines rapidly as a result of insulin’s effect on driving potassium intracellularly, it is recommended that potassium replacement be initiated earlier than in ketotic patients, assuming that no chronic kidney disease or oliguria is present. Potassium chloride (10 mEq/L) can be added to the initial bottle of fluids administered if the patient’s serum potassium is not elevated.

D. Phosphate

If severe hypophosphatemia (serum phosphate less than 1 mg/dL [0.32 mmol/L]) develops during insulin therapy, phosphate replacement can be given as described for ketogenic patients (at 3 mmol/h).

Prognosis

The severe dehydration and low output state may predispose the patient to complications such as myocardial infarction, stroke, pulmonary embolism, mesenteric vein thrombosis, and disseminated intravascular coagulation. Fluid replacement remains the primary approach to the prevention of these complications. Low-dose heparin prophylaxis is reasonable but benefits of routine anticoagulation remain doubtful. Rhabdomyolysis is a recognized complication and should be looked for and treated.

The overall mortality rate of hyperglycemic hyperosmolar state coma is more than ten times that of DKA, chiefly because of its higher incidence in older patients, who may have compromised cardiovascular systems or associated major illnesses and whose dehydration is often excessive because of delays in recognition and treatment. (When patients are matched for age, the prognoses of these two hyperglycemic emergencies are reasonably comparable.) When prompt therapy is instituted, the mortality rate can be reduced from nearly 50% to that related to the severity of coexistent disorders.

After the patient is stabilized, the appropriate form of long-term management of the diabetes must be determined. Insulin treatment should be continued for a few weeks but patients usually recover sufficient endogenous insulin secretion to make a trial of diet or diet plus oral agents worthwhile. When the episode occurs in a patient who has known diabetes, then education of the patient and caregivers should be instituted. They should be taught how to recognize situations (nausea and vomiting, infection) that predispose to recurrence of the hyperglycemic, hyperosmolar state, as well as detailed information on how to prevent the escalating dehydration that culminates in hyperosmolar coma (small sips of sugar-free liquids, increase in usual hypoglycemic therapy, or early contact with the clinician).

LACTIC ACIDOSIS

- Severe metabolic acidosis with compensatory hyperventilation.
- Blood pH < 7.30.
- Serum bicarbonate less than 15 mEq/L.
- Anion gap greater than 15 mEq/L.
- Absent serum ketones.
- Serum lactate greater than 5 mmol/L.

General Considerations

Lactic acidosis is characterized by accumulation of excess lactic acid in the blood. Normally, the principal sources of this acid are the erythrocytes (which lack enzymes for aerobic oxidation), skeletal muscle, skin, and brain. Conversion of lactic acid to glucose and its oxidation principally by the liver but also by the kidneys represent the chief pathways for its removal. Hyperlactatemia and acidosis occur when lactate production exceeds lactate consumption. Causes include tissue hypoxia (global or local), disorders that increase epinephrine levels (severe asthma with excess beta-adrenergic agonist use, cardiogenic or hemorrhagic shock, pheochromocytoma), and drugs that impair oxidative phosphorylation (antiretroviral agents and propofol). Most cases of metformin-associated lactic acidosis occur in patients in whom there were contraindications to the use of metformin, in particular kidney failure. Metformin levels are usually greater than 5 mcg/L when metformin is implicated as the cause of lactic acidosis. Other causes of lactic acidosis include several inborn errors of metabolism and the MELAS syndrome (mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes). D-lactic acidosis can occur in patients with short bowel syndrome when unabsorbed carbohydrates are presented as substrate for fermentation by colonic bacteria.
Clinical Findings

A. Symptoms and Signs

The main clinical feature of lactic acidosis is marked hyperventilation. When lactic acidosis is secondary to tissue hypoxia or vascular collapse, the clinical presentation is variable, being that of the prevailing catastrophic illness. However, in the idiopathic, or spontaneous, variety, the onset is rapid (usually over a few hours), blood pressure is normal, peripheral circulation is good, and there is no cyanosis.

B. Laboratory Findings

Plasma bicarbonate and blood pH are quite low, indicating the presence of severe metabolic acidosis. Ketones are usually absent from plasma and urine or at least not prominent. The first clue may be a high anion gap (serum sodium minus the sum of chloride and bicarbonate anions [in mEq/L] should be no greater than 15). A higher value indicates the existence of an abnormal compartment of anions. If this cannot be clinically explained by an excess of keto acids (diabetes), inorganic acids (uremia), or anions from medication overdose (salicylates, methyl alcohol, ethylene glycol), then lactic acidosis is probably the correct diagnosis. (See also Chapter 21.) In the absence of azotemia, hyperphosphatemia may be a clue to the presence of lactic acidosis for reasons that are not clear. The diagnosis is confirmed by a plasma lactic acid concentration of 5 mmol/L or higher (values as high as 30 mmol/L have been reported). Normal plasma values average 1 mmol/L, with a normal lactate/pyruvate ratio of 10:1. This ratio is greatly exceeded in lactic acidosis.1

Treatment

Aggressive treatment of the precipitating cause of lactic acidosis is the main component of therapy, such as ensuring adequate oxygenation and vascular perfusion of tissues. Empiric antibiotic coverage for sepsis should be given after culture samples are obtained in any patient in whom the cause of the lactic acidosis is not apparent (Table 30–5).

Alkalization with intravenous sodium bicarbonate to keep the pH above 7.2 has been recommended by some in the emergency treatment of lactic acidosis; as much as 2000 mEq in 24 hours has been used. However, there is no evidence that the mortality rate is favorably affected by administering bicarbonate, and its use remains controversial. Hemodialysis may be useful in cases where large sodium loads are poorly tolerated and in cases associated with metformin toxicity.

Prognosis

The mortality rate of spontaneous lactic acidosis is high. The prognosis in most cases is that of the primary disorder that produced the lactic acidosis.

1 In collecting samples, it is essential to rapidly chill and separate the blood in order to remove red cells, whose continued glycolysis at room temperature is a common source of error in reports of high plasma lactate. Frozen plasma remains stable for subsequent assay.

THE HYPOGLYCEMIC STATES

Spontaneous hypoglycemia in adults is of two principal types: fasting and postprandial. Symptoms begin at plasma glucose levels in the range of 60 mg/dL (3.3 mmol/L) and impairment of brain function at approximately 50 mg/dL (2.8 mmol/L). Fasting hypoglycemia is often subacute or chronic and usually presents with neuroglycopenia as its principal manifestation; postprandial hypoglycemia is relatively acute and is often heralded by symptoms of neurogenic autonomic discharge (sweating, palpitations, anxiety, tremulousness).

Differential Diagnosis (Table 27–13)

Fasting hypoglycemia may occur in certain endocrine disorders, such as hypopituitarism, Addison disease, or myxedema; in disorders related to liver malfunction, such as acute alcoholism or liver failure; and in instances of end-stage chronic kidney disease, particularly in patients requiring dialysis. These conditions are usually obvious, with hypoglycemia being only a secondary feature. When fasting hypoglycemia is a primary manifestation developing in adults without apparent endocrine disorders or inborn metabolic diseases from childhood, the principal diagnostic possibilities include (1) hyperinsulinism, due to either pancreatic B cell tumors, iatrogenic or surreptitious administration of insulin or sulfonylurea; and (2) hypoglycemia due to extrapancreatic tumors.

Postprandial (reactive) hypoglycemia may be seen after gastrointestinal surgery and is particularly associated with the dumping syndrome after gastrectomy and Roux-en-Y gastric bypass surgery. Occult diabetes very occasionally presents with postprandial hypoglycemia. Rarely, it occurs

with islet cell hyperplasia—the so-called noninsulinoma pancreatic islet cell hyperplasia syndrome.

Alcohol-related hypoglycemia is due to hepatic glycogen depletion combined with alcohol-mediated inhibition of gluconeogenesis. It is most common in malnourished individuals with excessive alcohol intake but can occur in anyone who is unable to ingest food after an acute alcoholic episode followed by gastritis and vomiting.

Immunopathologic hypoglycemia is an extremely rare condition in which anti-insulin antibodies or antibodies to insulin receptors develop spontaneously.

**HYPOGLYCEMIA DUE TO PANCREATIC B CELL TUMORS**

**ESSENTIALS OF DIAGNOSIS**

- Hypoglycemic symptoms—often neuroglycopebic (confusion, blurred vision, anxiety, convulsions).
- Immediate recovery upon administration of glucose.
- Blood glucose less than 45 mg/dL (2.5 mmol/L) with a serum insulin level of 6 microunits/mL or more.

**General Considerations**

Fasting hypoglycemia in an otherwise healthy, well-nourished adult is rare and is most commonly due to an adenoma of the islets of Langerhans. Ninety percent of such tumors are single and benign, but multiple adenomas can occur as well as malignant tumors with functional metastases. Adenomas may be familial, and multiple adenomas have been found in conjunction with tumors of the parathyroids and pituitary (MEN type 1 [MEN 1]). It has been reported that about 30% of sporadic insulinoma tumors have a somatic mutation in the YY1 gene (T372R) that encodes the transcriptional repressor YY1. Over 99% of insulinomas are located within the pancreas and less than 1% in ectopic pancreatic tissue.

**Clinical Findings**

**A. Symptoms and Signs**

The most important prerequisite to diagnosing an insulinoma is simply to consider it, particularly in relatively healthy-appearing persons who have fasting hypoglycemia associated with some degree of central nervous system dysfunction such as confusion or abnormal behavior. A delay in diagnosis can result in unnecessary treatment for psychomotor epilepsy or psychiatric disorders and may cause irreversible brain damage. In long-standing cases, obesity can result as a consequence of overeating to relieve symptoms.

The so-called Whipple triad is characteristic of hypoglycemia regardless of the cause. It consists of (1) a history of hypoglycemic symptoms, (2) an associated low plasma glucose level (40–50 mg/dL), and (3) relief of symptoms upon ingesting fast-acting carbohydrates in approximately 15 minutes. The hypoglycemic symptoms in insulinoma often develop in the early morning or after missing a meal. Occasionally, they occur after exercise.

Patients typically complain of neuroglycopebic symptoms such as blurred vision or diplopia, headache, feelings of detachment, slurred speech, and weakness. Personality and mental changes vary from anxiety to psychotic behavior, and neurologic deterioration can result in convulsions or coma. Hypoglycemic unawareness is very common and adrenergic symptoms of palpitations and sweating may be blunted. With the ready availability of home blood glucose-monitoring systems, patients sometimes present with documented fingerstick blood glucose levels in 40s and 50s at time of symptoms. Access to diabetic medications (sulfonylureas or insulin) should be explored—does a family member have diabetes, or does the patient or family member work in the medical field? Medication-dispensing errors should be excluded—has the patient’s prescription medication changed in shape or color? Patients with insulinoma or factitious hypoglycemia usually have a normal physical examination.

**B. Laboratory Findings**

B cell adenomas do not reduce secretion of insulin in the presence of hypoglycemia, and the critical diagnostic test is to demonstrate inappropriately elevated serum insulin, proinsulin, and C-peptide levels, at a time when plasma glucose level is below 45 mg/dL.

The diagnostic criteria for insulinoma after a 72-hour fast are listed in Table 27–14. Other causes of hyperinsulinemic hypoglycemia include factitious administration of insulin or sulfonylureas. Factitious use of insulin will result in suppression of endogenous insulin secretion and low C-peptide levels. In patients who have injected insulin, the insulin/C-peptide ratio (pmol/L) will be greater than 1. An elevated circulating proinsulin level in the presence of fasting hypoglycemia is characteristic of most B cell adenomas.

and does not occur in factitious hyperinsulinism. Thus, C-peptide levels (by immunochromiluminometric assays [ICMA]) of greater than 200 pmol/L and proinsulin levels (by radioimmunoassay [RIA]) of greater than 5 pmol/L are characteristic of insulinomas. In patients with insulinoma, plasma beta-hydroxybutyrate levels are suppressed to 2.7 mmol/L or less. No single hormone measurement (insulin, proinsulin, C-peptide) is 100% sensitive and specific for the diagnosis of insulinoma, and insulinoma cases have been reported with insulin levels below 3 microunits/mL (ICMA assay) or proinsulin level below 5 pmol/L. These hormonal assays are also not standardized between laboratories, and there can be significant variation in the results. Therefore, the diagnosis should be based on multiple biochemical parameters.

In patients with epigastric distress, a history of renal calculi, or menstrual or erectile dysfunction, a serum calcium, gastrin, or prolactin level may be useful in screening for MEN 1 associated with insulinoma.

C. Diagnostic Tests

If the history is consistent with episodic spontaneous hypoglycemia, patients should be given a home blood glucose monitor and advised to monitor blood glucose levels at the time of symptoms and before consumption of carbohydrates, if this can be done safely. Patients with insulinomas frequently report fingerstick blood glucose levels between 40 mg/dL (2.2 mmol/L) and 50 mg/dL (2.8 mmol/L) at the time of symptoms. The diagnosis, however, cannot be made based on a fingerstick blood glucose. It is necessary to have a low laboratory glucose concomitantly with elevated plasma insulin, proinsulin, and C-peptide levels and a negative sulfonylurea screen. When patients give a history of symptoms after only a short period of food withdrawal or with exercise, then an outpatient assessment can be attempted. The patient should be brought by a family member to the office after an overnight fast and observed in the office. Activity such as walking should be encouraged and fingerstick blood glucose measured repeatedly during observation. If symptoms occur or fingerstick blood glucose is below 50 mg/dL (2.8 mmol/L) then samples for plasma glucose, insulin, C-peptide, proinsulin, sulfonylurea screen, serum ketones, and antibodies to insulin should be sent. If outpatient observation does not result in symptoms or hypoglycemia and if the clinical suspicion remains high, then the patient should undergo an inpatient supervised 72-hour fast. A suggested protocol for the supervised fast is shown in Table 27–15.

In 30% of patients with insulinoma, the blood glucose levels often drop below 45 mg/dL (2.5 mmol/L) after an overnight fast, but some patients require up to 72 hours to develop symptomatic hypoglycemia. However, the term “72-hour fast” is actually a misnomer in most cases since the fast should be immediately terminated as soon as symptoms appear and laboratory confirmation of hypoglycemia is available. In normal male subjects, the blood glucose does not fall below 55–60 mg/dL (3.1–3.3 mmol/L) during a 3-day fast. In contrast, in normal premenopausal women who have fasted for only 24 hours, the plasma glucose may fall normally to such an extent that it can reach values as low as 35 mg/dL (1.9 mmol/L). In these cases, however, the women are not symptomatic, presumably owing to the development of sufficient ketonemia to supply energy needs to the brain. Insulinoma patients, on the other hand, become symptomatic when plasma glucose drops to subnormal levels, since inappropriate insulin secretion restricts ketone formation. Moreover, the demonstration of a nonsuppressed insulin level of 3 microunits/mL or more using an ICMA assay (greater than 6 microunits/mL using an RIA assay) in the presence of hypoglycemia suggests the diagnosis of insulinoma. If hypoglycemia does not develop in a male patient after fasting for up to 72 hours—and particularly when this prolonged fast is terminated with a period of moderate exercise—insulinoma must be considered an unlikely diagnosis.

Stimulation with pancreatic B cell secretagogues such as tolbutamide, glucagon, or leucine has been used to demonstrate exaggerated and prolonged insulin secretion in the presence of insulinomas. However, because insulin-secreting tumors have a wide range of granule content and degrees of differentiation, they are variably responsive to these secretagogues; and a negative response does not necessarily rule out an insulinoma. For these reasons, stimulation tests are not recommended in the diagnostic workup of insulinoma.

An oral glucose tolerance test is of no value in the diagnosis of insulin-secreting tumors. HbA1c levels may be low but there is considerable overlap with normal patients and no particular value is diagnostic.

"Glucose sample should be collected in sodium fluoride containing tube on ice to prevent glycosysis and the plasma separated immediately upon receipt at the laboratory. Arrange for the laboratory to run the glucose samples "stat."
D. Preoperative Localization of B Cell Tumors

After the diagnosis of insulinoma has been unequivocally made by clinical and laboratory findings, studies to localize the tumor should be initiated. The focus of attention should be directed to the pancreas since that is where virtually all insulinomas originate. Ectopic cases are very rare.

Because of the small size of these tumors (averaging 1.5 cm in diameter in one large series), imaging studies do not necessarily identify all of them. A pancreatic dual phase helical CT scan with thin section can identify 82–94% of the lesions. MRI scans with gadolinium can be helpful in detecting a tumor in 85% of cases. One case report suggests that diffusion-weighted MRI can be useful for detecting and localizing small insulinomas, especially for those with no hypervascular pattern. 11-In-octreotide scans for insulinomas, which typically express somatostatin receptor type 3, are positive in only 50–70% of cases. Newer PET/CT scans, using gallium-labeled somatostatin analogs such as DOTA-1-Nal3-octreotide (DOTA-NOC), which have a higher affinity for somatostatin receptor subtypes 2, 3, and 5, and have been reported to be useful in localizing the tumors. Insulinomas express GLP-1 receptors, and radiolabeled GLP-1 receptor agonists such as Lys(40)(Ahx-hydrazinonicotinamide [HYNIC]-[99mTc]NH(2))-exendin-4 for SPECT/CT have also been reported to visualize the tumors. The imaging study used will depend on local availability and local radiologic skill. If the imaging study is normal, then an endoscopic ultrasound should be performed. In experienced hands, about 80–90% of tumors can be detected with this procedure. Fine-needle aspiration of the identified lesion can be attempted to confirm the presence of a neuroendocrine tumor. If the tumor is not identified or the imaging result is equivocal, then the patient should undergo selective calcium-stimulated angiography, which has been reported to localize the tumor to a particular region of the pancreas approximately 90% of the time. In this test, angiography is combined with injections of calcium gluconate into the gastroduodenal, splenic, and superior mesenteric arteries, and insulin levels are measured in the hepatic vein effluent. The procedure is performed after an overnight fast. Calcium gluconate 10% solution diluted to a volume of 5 mL with 0.95% saline is bolused into the selected artery at a dose of 0.0125 mmol calcium/kg (0.005 mmol calcium/kg for obese patients). Small samples of blood (5 mL) are taken from the hepatic effluent at times 0, 30, 60, 90, 120, and 180 seconds after the calcium injection. Fingerstick blood glucose levels are measured at intervals and a dextrose infusion is maintained throughout the procedure to prevent hypoglycemia. Calcium stimulates insulin release from insulinomas but not normal islets, and so a step-up from baseline in insulin levels at 30 or 60 seconds (twofold or greater) regionalizes the source of the hyperinsulinism to the head of the pancreas for the gastroduodenal artery, the uncinate process for the superior mesenteric artery, and the body and tail of the pancreas for the splenic artery calcium infusions. A less than twofold elevation of insulin in the 120-second sample may represent effects of recirculating calcium and is not considered a positive localization. In a single insulinoma, the response is in one artery alone unless the tumor resides in an area fed by two arteries or if there are multiple insulinomas (eg, in MEN 1).

Patients who have diffuse islet hyperplasia (the noninsulinoma pancreatic islet cell hyperplasia syndrome) will have positive responses in multiple arteries. Because diazoxide may interfere with this test, it should be discontinued for at least 48–72 hours before sampling. Patients should be closely monitored during the procedure to avoid hypoglycemia (as well as hyperglycemia, which could affect insulin gradients). These studies combined with careful intraoperative ultrasonography and palpation by a surgeon experienced in insulinoma surgery identifies up to 98% of tumors.

Treatment

The treatment of choice for insulin-secreting tumors is surgical resection. While waiting for surgery, patients should be given oral diazoxide. Divided doses of 300–400 mg/day usually suffice although an occasional patient may require up to 800 mg/day. Side effects include edema due to sodium retention, gastric irritation, and mild hirsutism. Hydrochlorothiazide, 25–50 mg daily, can be used to counteract the sodium retention and edema as well potentiate diazoxide’s hypoglycemic effect.

In patients with a single benign pancreatic B cell adenoma, 90–95% have a successful cure at the first surgical attempt when intraoperative ultrasound is used by a skilled surgeon. Diazoxide should be administered on the day of the surgery because it reduces the risk of hypoglycemia during surgery. Typically, it does not mask the glycemic rise indicative of surgical cure. Blood glucose should be monitored throughout surgery, and 5% or 10% dextrose infusion should be used to maintain euglycemia. In cases where the diagnosis has been established but no adenoma is located after careful palpation and use of intraoperative ultrasound, it is no longer advisable to blindly resect the body and tail of the pancreas, since a nonpalpable tumor missed by ultrasound is most likely embedded within the fleshy head of the pancreas that is left behind with subtotal resections. Most surgeons prefer to close the incision and schedule a selective arterial calcium stimulation with hepatic venous sampling to locate the tumor site prior to a repeat operation. Laparoscopy using ultrasound and enucleation has been successful with a single tumor of the body or tail of the pancreas, but open surgery remains necessary for tumors in the head of the pancreas.

In patients with inoperable functioning islet cell carcinoma with and without hepatic metastasis and in approximately 5–10% of MEN 1 cases when subtotal removal of the pancreas has failed to produce cure, the treatment approach is the same as for other types of pancreatic neuroendocrine tumors (pNETs). Diazoxide is the treatment of choice in preventing hypoglycemia. Frequent carbohydrate feedings (every 2–3 hours) can also be helpful, although weight gain can become a problem. Somatostatin analogs, octreotide or lanreotide, should be considered if diazoxide is ineffective or if there is tumor progression. Surgery or embolization (bland, chemo- and radio-) or thermal ablation (radiofrequency, microwave, and cryo- ablation) can be used to reduce tumor burden and also provide symptomatic relief. Chemotherapy regimens that can be considered include combination of streptozocin, 5-fluorouracil, and doxorubicin; capetitabine and oxaliplatin;
and capcitabine and temozolomide. Targeted therapies against multiple steps in PI3K/AKT/mTor pathway have been shown to be helpful. Everolimus, an inhibitor of mTor, is approved for treatment of advanced pNETs. Sunitinib, a monoclonal antibody against VEGF receptors 2 and 3, PDGFR alpha and beta, and c-kit, has been shown to slow growth of pNETs. Treatment with radioisotopes (indium-111 or yttrium-90 or lutetium-177) linked to a somatostatin analog have been reported to show benefit in a proportion of patients.

NONISLET CELL TUMOR HYPOGLYCEMIA

These rare causes of hypoglycemia include mesenchymal tumors such as retropitoneal sarcomas, hepatocellular carcinomas, adrenocortical carcinomas, and miscellaneous epithelial-type tumors. The tumors are frequently large and readily palpated or visualized on CT scans or MRI.

In many cases the hypoglycemia is due to the expression and release of an incompletely processed insulin-like growth factor 2 (IGF-2) by the tumor.

The diagnosis is supported by laboratory documentation of serum insulin levels below 5 microunit/mL with plasma glucose levels of 45 mg/dL (2.5 mmol/L) or lower. Values for growth hormone and IGF-1 are also decreased. Levels of IGF-2 may be increased but often are “normal” in quantity, despite the presence of the immature, higher-molecular-weight form of IGF-2, which can be detected only by special laboratory techniques.

Not all the patients with nonislet cell tumor hypoglycemia have elevated pro-IGF-2. Ectopic insulin production has been described in bronchial carcinoma, ovarian carcinoma, and small cell carcinoma of the cervix. Hypoglycemia due to IGF-1 released from a metastatic large cell carcinoma of the lung has also been reported. GLP-1–secreting tumors (ovarian and pNETs) can also cause hypoglycemia by stimulating insulin release from normal pancreatic islets.

The prognosis for these tumors is generally poor, and surgical removal should be attempted when feasible. Dietary management of the hypoglycemia is the mainstay of medical treatment, since diazoxide is usually ineffective.

POSTPRANDIAL HYPOGLYCEMIA

1. Hypoglycemia Following Gastric Surgery

Hypoglycemia sometimes develops in patients who have undergone gastric surgery (eg, gastrectomy, vagotomy, pyloroplasty, gastrojejunostomy, Nissan fundoplication, Billroth II procedure, and Roux-en-Y), especially when they consume foods containing high levels of readily absorbable carbohydrates. This late dumping syndrome occurs about 1–3 hours after a meal and is a result of rapid delivery of high concentration of carbohydrates in the proximal small bowel and rapid absorption of glucose. The hyperinsulinemic response to the high carbohydrate load causes hypoglycemia. Excessive release of gastrointestinal hormones such as GLP-1 likely play a role in the hyperinsulinemic response. The symptoms include lightheadedness, sweating, confusion and even loss of consciousness after eating a high carbohydrate meal. To document hypoglycemia, the patient should consume a meal that leads to symptoms during everyday life. An oral glucose tolerance test is not recommended because many normal persons have false-positive test results. There have been case reports of insulinoma and noninsulinoma pancreatic functional hypoglycemia syndrome in patients with hypoglycemia post Roux-en-Y surgery. It is unclear how often this occurs. A careful history may identify patients who have a history of hypoglycemia with exercise or missed meals, and these individuals may require a formal 72-hour fast to rule out an insulinoma.

Treatment for secondary dumping includes dietary modification, but this may be difficult to sustain. Patients can try more frequent meals with smaller portions of less rapidly digested carbohydrates. Alpha-glucosidase therapy may be a useful adjunct to a low carbohydrate diet. Octreotide 50 mcg administered subcutaneously two or three times a day 30 minutes prior to each meal has been reported to improve symptoms due to late dumping syndrome. Treatment with exendin 9-39, a GLP-1 receptor agonist, may prevent post gastric bypass hypoglycemia. Various surgical procedures to delay gastric emptying have been reported to improve symptoms but long-term efficacy studies are lacking.

2. Functional Alimentary Hypoglycemia

Patients have symptoms suggestive of increased sympathetic activity, including anxiety, weakness, tremor, sweating or palpitations after meals. Physical examination and laboratory tests are normal. It is not recommended that patients with symptoms suggestive of increased sympathetic activity undergo either a prolonged oral glucose tolerance test or a mixed meal test. Instead, the patients should be given home blood glucose monitors (with memories) and instructed to monitor fingerstick glucose levels at the time of symptoms. Only patients who have symptoms when their fingerstick blood glucose is low (less than 50 mg/dL) and who have resolution of symptoms when the glucose is raised by eating rapidly released carbohydrate need additional evaluation. Patients who do not have evidence for low glucose levels at time of symptoms are generally reassured by their findings. Counseling and support should be the mainstays in therapy, with dietary manipulation only an adjunct.

3. Occult Diabetes

This condition is characterized by a delay in early insulin release from pancreatic B cells, resulting in initial
exaggeration of hyperglycemia during a glucose tolerance test. In response to this hyperglycemia, an exaggerated insulin release produces a late hypoglycemia 4–5 hours after ingestion of glucose. These patients are often obese and frequently have a family history of diabetes mellitus.

Patients with this type of postprandial hypoglycemia often respond to reduced intake of refined sugars with multiple, spaced, small feedings high in dietary fiber. In the obese, treatment is directed at weight reduction to achieve ideal weight. These patients should be considered to have prediabetes or early diabetes (type 1 or 2) and advised to have periodic medical evaluations.

4. Autoimmune Hypoglycemia

Patients with autoimmune hypoglycemia have early postprandial hyperglycemia followed by hypoglycemia 3–4 hours later. The hypoglycemia is attributed to a dissociation of insulin-antibody immune complexes, releasing free insulin.

The disorder is associated with methimazole treatment for Graves disease, although it can also occur in patients treated with various other sulfhydryl-containing medications (captopril, penicillamine) as well as other drugs such as hydralazine, isoniazid, and procainamide. In addition, it has been reported in patients with autoimmune disorders such as rheumatoid arthritis, systemic lupus erythematosus, and polymyositis as well as in plasma cell myeloma (formerly multiple myeloma) and other plasma cell dyscrasias where paraproteins or antibodies cross-react with insulin. There is also an association with the HLA class II alleles (DRB1*0406, DQA1*0301, and DQB1*0302). These alleles are 10 to 20 times more common in Japanese and Korean populations, which explains why the disorder has been reported mostly in Japanese patients.

High titers of insulin autoantibodies, usually IgG class, can be detected. Insulin, proinsulin, and C-peptide levels may be elevated, but the results may be erroneous because of the interference of the insulin antibodies with the immunoassays for these peptides.

In most cases, the hypoglycemia is transient and usually resolves spontaneously within 3–6 months of diagnosis, particularly when the offending medications are stopped. The most consistent therapeutic benefit in management of this syndrome has been achieved by dietary management with small, frequent low-carbohydrate meals. Prednisone (30–60 mg orally daily) has been used to lower the titer of insulin antibodies.

C-peptide immunoreactivity is pathognomonic of exogenous insulin administration. Insulin and C-peptide are secreted in a 1:1 molar ratio. A large fraction of the endogenous insulin is cleared by the liver, whereas C-peptide, which is cleared by the kidney, has a lower metabolic clearance rate. For this reason, the molar ratio of insulin and C-peptide in a hypoglycemic patient should be less than 1.0 in cases of insulinoma and is greater than 1.0 in cases of exogenous insulin administration. When sulfonylureas, repaglinide, and nateglinide are suspected as a cause of factitious hypoglycemia, a plasma level of these medications to detect their presence may be required to distinguish laboratory findings from those of insulinoma.

FACTITIOUS HYPOGLYCEMIA

Factitious hypoglycemia may be difficult to document. A suspicion of self-induced hypoglycemia is supported when the patient is associated with the health professions or has access to insulin or sulfonylurea medications taken by a diabetic member of the family. The triad of hypoglycemia, high immunoreactive insulin, and suppressed plasma C-peptide immunoreactivity is pathognomonic of exogenous insulin administration. Insulin and C-peptide are secreted in a 1:1 molar ratio. A large fraction of the endogenous insulin is cleared by the liver, whereas C-peptide, which is cleared by the kidney, has a lower metabolic clearance rate. For this reason, the molar ratio of insulin and C-peptide in a hypoglycemic patient should be less than 1.0 in cases of insulinoma and is greater than 1.0 in cases of exogenous insulin administration. When sulfonylureas, repaglinide, and nateglinide are suspected as a cause of factitious hypoglycemia, a plasma level of these medications to detect their presence may be required to distinguish laboratory findings from those of insulinoma.

HYPOGLYCEMIA DUE TO INSULIN RECEPTOR ANTIbODIES

Hypoglycemia due to insulin receptor autoantibodies is an extremely rare syndrome; most cases have occurred in women often with a history of autoimmune disease. Almost all of these patients have also had episodes of insulin-resistant diabetes and acanthosis nigricans. Their hypoglycemia may be either fasting or postprandial and is often severe and is attributed to an agonistic action of the antibody on the insulin receptor. Balance between the antagonistic and agonistic effects of the antibodies determines whether insulin-resistant diabetes or hypoglycemia occurs. Hypoglycemia was found to respond to corticosteroid therapy but not to plasmapheresis or immunosuppression.

MEDICATION-INDUCED HYPOGLYCEMIA

A number of medications apart from the sulfonylureas can occasionally cause hypoglycemia. Common offenders include the fluoroquinolones such as gatifloxacin and levofloxacin, pentamidine, quinine, ACE inhibitors, salicylates and beta-adrenergic blocking agents. The fluoroquinolones, particularly gatifloxacin, have been associated with both hypoglycemia and hyperglycemia. It is thought that the drug acts on the ATP sensitive potassium channels in the beta cell. Hypoglycemia is an early event, and hyperglycemia occurs several days into therapy. Intravenous pentamidine is cytotoxic to beta cells and causes acute hyperinsulinemia and hypoglycemia followed by insulinopenia and hyperglycemia. Fasting patients taking noncardioselective beta-blockers can have an exaggerated hypoglycemic response to starvation. The beta-blockade inhibits fatty acids and gluconeogenesis substrate release and reduces plasma glucagon response. Therapy with ACE inhibitors increases the risk of hypoglycemia in patients who are taking insulin or sulfonylureas presumably because these drugs increase sensitivity to circulating insulin by increasing blood flow to the muscle. Some opioids cause hypoglycemia. Tramadol use has been associated with increased risk of hospitalization for hypoglycemia. Methadone overdose has also been reported to cause...
hypoglycemia and a rapid dose escalation of methadone in cancer patients can lower glucose levels.

Ethanol-associated hypoglycemia may be due to hepatic alcohol dehydrogenase activity depleting NAD. The resultant change in the redox state—increase in NADH to NAD⁺ ratio—causes a partial block at several points in the gluconeogenic pathway. With prolonged starvation, glycogen reserves become depleted within 18–24 hours and hepatic glucose output becomes totally dependent on gluconeogenesis. Under these circumstances, a blood concentration of ethanol as low as 45 mg/dL (9.8 mmol/L) can induce profound hypoglycemia by blocking gluconeogenesis. Neuroglycopenia in a patient whose breath smells of alcohol may be mistaken for alcoholic stupor. Prevention consists of adequate food intake during ethanol ingestion.

Therapy consists of glucose administration to replenish glycogen stores until gluconeogenesis resumes.

When sugar-containing soft drinks are used as mixers to dilute alcohol in beverages (gin and tonic, rum and cola), there seems to be a greater insulin release than when the soft drink alone is ingested and a tendency for more of a late hypoglycemic overswing to occur 3–4 hours later. Prevention would consist of avoiding sugar mixers while ingesting alcohol and ensuring supplementary food intake to provide sustained absorption.

The “Lipid Hypothesis” of cardiovascular disease (CVD)—stating that cholesterol is causal in the development of atherosclerotic cardiovascular disease (ASCVD) and that lowering of cholesterol is associated with lower cardiovascular event rates—is generally accepted throughout the medical community. For patients with known CVD (secondary prevention), studies have shown that cholesterol lowering leads to a consistent reduction in total mortality and in recurrent cardiovascular events in men and women; other studies have documented lowered mortality and events in middle-aged and older patients. Among patients without CVD (primary prevention), the data are generally consistent, with rates of cardiovascular events, heart disease mortality, and all-cause mortality differing among studies. Treatment guidelines have been designed to assist clinicians in selecting patients for cholesterol-lowering therapy based on their overall risk of developing CVD.

There are several genetic disorders that provide insight into the pathogenesis of lipid-related diseases. **Familial hypercholesterolemia**, rare in the homozygous state (about one per million), causes markedly high low-density lipoprotein (LDL) levels and early CVD. The most common genetic defects involve absent or defective LDL receptors, resulting in unregulated LDL metabolism, genetic mutations of apolipoprotein B, or gain of function in proprotein convertase subtilisin/kexin type 9 (PCSK9), a protein that regulates breakdown of LDL receptors. Patients with two abnormal genes (homozygotes) have extremely high levels—up to eight times normal—and present with atherosclerotic disease in childhood. Homozygotes may require liver transplantation or plasmapheresis to correct their severe lipid abnormalities. Those with one defective gene (heterozygotes) have LDL concentrations twice normal; persons with this condition may develop CVD in their 30s or 40s.

Another rare condition is caused by an abnormality of lipoprotein lipase, the enzyme that enables peripheral tissues to take up triglyceride from chylomicrons and very-low-density lipoprotein (VLDL) particles. Patients with this condition, one cause of **familial chylomicronemia syndrome**, have marked hypertriglyceridemia with recurrent pancreatitis and hepatosplenomegaly in childhood.

Numerous other genetic abnormalities of lipid metabolism are named for the abnormality noted when serum is electrophoresed (eg, dysbetalipoproteinemia) or from combinations of lipid abnormalities in families (eg, familial combined hyperlipidemia).

**When to Refer**
- Known genetic lipid disorders.
- Striking family history of hyperlipidemia or premature atherosclerosis.
- Extremely high serum LDL cholesterol or triglycerides, or extremely low serum high-density lipoprotein (HDL) cholesterol.

**LIPID FRACTIONS & THE RISK OF CORONARY HEART DISEASE**

In serum, cholesterol is carried primarily on three different lipoproteins—the VLDL, LDL, and HDL molecules. Total cholesterol equals the sum of these three components:

\[
\text{Total cholesterol} = \text{HDL cholesterol} + \text{VLDL cholesterol} + \text{LDL cholesterol}
\]

Using these assumptions, the Friedewald equation states that LDL cholesterol can be estimated as:

\[
\text{LDL cholesterol} = \frac{(\text{Total cholesterol} - \text{HDL cholesterol}) - (\text{Triglycerides} \times \frac{5}{2.2})}{2.2}
\]

When using SI units, the formula becomes

\[
\text{LDL cholesterol} = \frac{(\text{Total cholesterol} - \text{HDL cholesterol}) - (\text{Triglycerides} \times \frac{5}{2.2})}{2.2}
\]

Modern research has questioned several of the assumptions underlying the Friedewald equation, particularly the...
assumption that VLDL is always best estimated as triglycerides/5, which is inaccurate when triglycerides are above 150 mg/dL and when LDL cholesterol is less than 70 mg/dL. Therefore, many commercial laboratories have switched to the Martin/Hopkins equation, which uses a flexible factor for deriving VLDL from triglycerides (as opposed to always using 5). The Martin/Hopkins equation reduces the systematic underestimation of LDL cholesterol when triglycerides are greater than 150 mg/dL and LDL is less than 70 mg/dL, and is more accurate in estimating LDL from nonfasting blood specimens.

**Non-HDL cholesterol** is increasingly recognized as an important measure of the total quantity of apolipoprotein B–containing atherogenic lipid particles. Non-HDL cholesterol is calculated as: total cholesterol – HDL cholesterol. Advantages of non-HDL cholesterol are that it is less sensitive to fasting status and it is a better predictor of cardiovascular risk compared to LDL cholesterol.

Lipoprotein(a), a subfraction of LDL that is largely genetically determined, has also been recognized as a casual factor in atherosclerosis. Lipoprotein(a) may be useful to measure in patients with a strong family history or with early signs of early ASCVD.

It is difficult to assign a “normal” range for serum lipids. This is because our cholesterol values are vastly higher than our evolutionary ancestors and because mean values vary across the world. In Western populations, cholesterol values are about 20% higher than in Asian populations and exceed 300 mg/dL (7.76 mmol/L) in nearly 5% of adults. About 10% of adults have LDL cholesterol levels above 200 mg/dL (5.17 mmol/L).

**THERAPEUTIC EFFECTS OF LOWERING CHOLESTEROL**

Reducing cholesterol levels in healthy middle-aged men without coronary heart disease (CHD) (in primary prevention studies) reduces their risk in direct proportion to the reduction in LDL cholesterol. Treated adults have statistically significant and clinically important reductions in the rates of myocardial infarctions, strokes, new cases of angina, and need for coronary artery bypass procedures. The West of Scotland Study showed a 31% decrease in myocardial infarctions in middle-aged men treated with pravastatin compared with placebo. The Air Force/Texas Coronary Atherosclerosis Prevention Study (AFCAPS/TexCAPS) study showed similar results with lovastatin. As with any primary prevention interventions, large numbers of healthy patients need to be treated to prevent a single event. The numbers of patients needed to treat (NNT) to prevent one nonfatal myocardial infarction or one coronary artery disease death in these two studies were 46 and 50, respectively. The Anglo-Scandinavian Cardiac Outcomes Trial (ASCOT) study of atorvastatin in persons with hypertension and other risk factors but without CHD demonstrated a 36% reduction in CHD events. The Justification for the Use of Statins in Prevention: An Intervention Trial Evaluating Rosuvastatin (JUPITER) study showed a 44% reduction in a combined end point of myocardial infarction, stroke, revascularization, hospitalization for unstable angina, or death from cardiovascular causes in both men and women. The NNT for 1 year to prevent one event was 169. The Heart Outcomes Prevention Evaluation (HOPE-3) trial of rosuvastatin showed a 24% reduction in cardiovascular events. The NNT over 5.6 years was 91.

Primary prevention studies have found a less consistent effect on total mortality. The West of Scotland study found a 20% decrease in total mortality, tending toward statistical significance. The AFCAPS/TexCAPS study with lovastatin showed no difference in total mortality. The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT-LLT) also showed no reduction either in all-cause mortality or in CHD events when pravastatin was compared with usual care. Subjects treated with atorvastatin in the ASCOT study had a 13% reduction in mortality, but the result was not statistically significant. This study, however, was stopped early due to the marked reduction in CHD events. The JUPITER trial demonstrated a statistically significant 20% reduction in death from any cause. The NNT for 1 year was 400. The HOPE-3 trial showed a 7% reduction in all-cause mortality, but the result was not statistically significant.

In secondary prevention studies among patients with established CVD, the benefits of cholesterol lowering are clearer. Major studies with statins have shown significant reductions in cardiovascular events, cardiovascular deaths, and all-cause mortality in men and women with coronary artery disease. The NNT to prevent a non-fatal myocardial infarction or a coronary artery disease death in these studies was between 12 and 34. Aggressive cholesterol lowering with these agents causes regression of atherosclerotic plaques in some patients, reduces the progression of atherosclerosis in saphenous vein grafts, and can slow or reverse carotid artery atherosclerosis. Results with other classes of medications, particularly those with little effect on LDL or the LDL receptor, have been less consistent. For example, patients treated with gemfibrozil had fewer cardiovascular events, but there was no benefit in all-cause mortality when compared with placebo. The benefits and adverse effects of cholesterol lowering may be specific to each type of drug; the clinician cannot assume that the effects of new drugs with novel mechanisms of action will generalize to other classes of medication.

The disparities in results between primary and secondary prevention studies highlight a critical aspect of clinical cholesterol lowering. The net benefits from cholesterol lowering depend on the underlying risk of ASCVD as well as the competing risks of other diseases. In middle-aged patients with atherosclerosis and high cholesterol, morbid- ity and mortality rates are high, and measures that reduce cholesterol-related risk are more likely to provide a robust net benefit to the patient. In older patients with little ath- erosclerosis and lower cholesterol levels, there may be no meaningful net benefit to cholesterol lowering.

LIPID DISORDERS

Vallejo-Vaz AJ et al. Low-density lipoprotein cholesterol lowering for the primary prevention of cardiovascular disease among men with primary elevations of low-density lipoprotein cholesterol levels of 190 mg/dL or above: analyses from the WOSCOPS (West of Scotland Coronary Prevention Study) 5-year randomized trial and 20-year observational follow-up. Circulation. 2017 Nov 14;136(20):1878–91. [PMID: 28877913]

SECONDARY CONDITIONS THAT AFFECT LIPID METABOLISM

Several factors, including drugs, can influence serum lipids. These are important for two reasons: abnormal lipid levels (or changes in lipid levels) may be the presenting sign of some of these conditions, and correction of the underlying condition may obviate the need to treat an apparent lipid disorder. Thyroid disease, particularly hypothyroidism, is associated with a high LDL. Poorly controlled diabetes mellitus and alcohol use, in particular, are commonly associated with high triglyceride levels that decline with improvements in glycemic control or reduction in alcohol use, respectively. Thus, secondary causes of high blood lipids should be considered in each patient with a lipid disorder before lipid-lowering therapy is started. In most instances, special testing is not needed: a history and physical examination are sufficient.

CLINICAL PRESENTATIONS

Most patients with high cholesterol levels have no specific symptoms or signs. The vast majority of patients with lipid abnormalities are detected by the laboratory, either as part of the workup of a patient with CVD or as part of a preventive screening strategy. Extremely high levels of chylomicrons or VLDL particles (triglyceride level above 1000 mg/dL or 10 mmol/L) result in the formation of eruptive xanthomas (Figure 28–1) (red-yellow papules, especially on the buttocks). High LDL concentrations result in tendinous xanthomas on certain tendons (Achilles, patella, back of the hand). Such xanthomas usually indicate one of the underlying genetic hyperlipidemias. Lipemia retinalis (cream-colored blood vessels in the fundus) is seen with extremely high triglyceride levels (above 2000 mg/dL or 20 mmol/L).

SCREENING & TREATMENT OF HIGH BLOOD CHOLESTEROL

While screening of all children for cholesterol disorders remains controversial, all adults should have their lipids checked before middle age. Patients with CVD and diabetes deserve the most scrutiny of their lipids since these patients are at the highest risk for suffering additional manifestations in the near term and thus have the most to gain from lipid lowering. In such patients, a complete lipid profile (serum total cholesterol, HDL cholesterol, and triglyceride levels) should be obtained. Additional risk reduction measures for atherosclerosis are discussed in Chapter 10; lipid lowering should be just one aspect of a program to reduce the progression and effects of atherosclerosis.

The best screening and treatment strategy for adults who do not have ASCVD is less clear. Several algorithms have been developed to guide the clinician in treatment decisions, but management decisions must always be individualized based on the patient’s risk to maximize net benefit.

The 2018 American Heart Association/American College of Cardiology (AHA/ACC)/Multi-society guidelines recommend screening of all adults aged 20 years or older for high blood cholesterol. The 2016 United States Preventive Services Task Force (USPSTF) guidelines recommend beginning at age 20 years only if there are other
cardiovascular risk factors such as tobacco use, diabetes, hypertension, obesity, or a family history of premature CVD. For men without other risk factors, screening is recommended beginning at age 35 years. For women and for men aged 20 to 35 without increased risk, the USPSTF makes no recommendation for or against routine screening for lipid disorders. Although there is no established interval for screening, screening can be repeated every 5 years for those with average or low risk and more often for those whose levels are close to therapeutic thresholds.

Individuals without CVD should have their 10-year risk of CVD calculated. Although those with LDL cholesterol greater than 190 mg/dL (4.91 mmol/L) are recommended for treatment independent of their 10-year risk of CVD, all other patients are recommended for treatment based on their overall cardiovascular risk. While other calculators (such as SCORE or QRISK) may be more appropriate for other parts of the world, the best method for estimating 10-year risk in the United States is the Pooled Cohort Equations. First introduced in the 2013 ACC/AHA guidelines, the Pooled Cohort Equations include separate equations for white and black patients and estimate the 10-year risk of heart attack, stroke, and cardiovascular death. This represents an improvement over older Framingham 10-year calculator, which includes CHD but not stroke risk. The ACC/AHA risk estimator can be found at http://www.cvriskcalculator.com/, and mobile apps are available for download. While it has been shown to overestimate risk in some modern populations, including those with at least moderate socioeconomic status, the ACC/AHA risk estimator remains an excellent starting point for a risk discussion. Recalibrated versions of the calculator are available for countries across the world.

The 2018 AHA/ACC/Multi-specialty guidelines identify a set of “risk-enhancing factors” that might influence a clinician and patient to favor cholesterol-lowering treatment. Table 28–1 lists these risk-enhancing factors that may be considered, particularly for patients at borderline to intermediate risk (5–20% 10-year cardiovascular risk).

Importantly, the 2018 AHA/ACC/Multi-specialty guidelines also identify the coronary artery calcium score as the single best test for risk stratification. The coronary calcium score is a simple noncontrast cardiac-gated CT scan that takes about 10–15 minutes to do, is associated with approximately 1 mSv of radiation, and costs between $75 and $300. As opposed to the risk-enhancing factors, which may incline a clinician and patient toward treatment, the coronary artery calcium score may also help identify patients who are unlikely to benefit from cholesterol-lowering therapy. For example, when the coronary artery calcium score is zero in the absence of smoking or diabetes, the patient is low risk and less likely to receive net benefit from therapy; instead, the calcium artery calcium score can be repeated in 5 years. The USPSTF does not endorse calcium scoring as a screening test; rather the test should be reserved for situations in which additional data will inform shared decision making and potentially change a therapeutic decision.

Statins are nearly always the first-line therapy. Treatment decisions are based on the presence of clinical CVD or diabetes, LDL cholesterol greater than 190 mg/dL (4.91 mmol/L), patient age, and the estimated 10-year risk of developing CVD. The 2018 AHA/ACC/Multi-specialty guidelines define four groups of patients who benefit from statin medications: (1) individuals with clinical ASCVD; (2) individuals with primary elevation of LDL cholesterol greater than 190 mg/dL (4.91 mmol/L); (3) individuals aged 40–75 with diabetes and LDL greater than or equal to 70 mg/dL (1.81 mmol/L); and (4) individuals aged 40–75 without clinical ASCVD or diabetes, with LDL 70–189 mg/dL (1.81–4.91 mmol/L), and estimated 10-year CVD risk of 7.5% or higher.

Ezetimibe and PCSK9 inhibitors have the strongest recommendations as second-line therapy for patients with (1) CVD whose LDL on statin therapy remains above the 70 mg/dL treatment threshold or (2) possible familial hypercholesterolemia with baseline LDL greater than 190 mg/dL (4.91 mmol/L) whose LDL remains above the 100 mg/dL treatment threshold. In high-risk patients, ezetimibe therapy is favored, while in very high-risk patients, PCSK9 inhibitor therapy should be considered.

### Screening & Treatment in Women

The foregoing screening and treatment guidelines are designed for both men and women. Meta-analysis of studies including women with known heart disease has found that statins prevent recurrent myocardial infarctions in women. Although most experts recommend application of the same primary prevention guidelines for women as for men, clinicians should be aware of the uncertainty in this area. Estimating the 10-year cardiovascular risk is particularly important in women since a larger percentage of women than men will have estimated 10-year cardiovascular risks below 7.5% per year and thus be advised not to take statins unless their LDL is very high (greater than 190 mg/dL [4.91 mmol/L]).
Screening & Treatment in Older Patients

Meta-analysis of evidence relating cholesterol to CVD in older adults suggests that cholesterol is a weak risk factor for CVD for persons over age 75 years. Clinical trials have rarely included such individuals. One exception is the Prospective Study of Pravastatin in the Elderly at Risk (PROSPER). In this study, elderly patients with CVD (secondary prevention) benefited from statin therapy, whereas those without CVD (primary prevention) did not. The 2018 AHA/ACC/Multi-society guidelines suggest continuing statin treatment in patients over age 75 who have CVD. The guidelines, however, suggest selectively treating patients over the age of 75 who do not have evidence of CVD. Individual patient decisions to discontinue statin therapy should be based on overall functional status and life expectancy, comorbidities, and patient preference and should be made in concert with other therapeutic goals and end-of-life decisions.

TREATMENT OF HIGH LDL CHOLESTEROL

Reduction of LDL cholesterol with statins is just one part of a program to reduce the risk of CVD. Other measures—including diet, exercise, smoking cessation, hypertension control, diabetes control, and antithrombotic therapy—are also of central importance. For example, exercise (and weight loss) may reduce the LDL cholesterol and increase the HDL.

The use of medications to raise the HDL cholesterol has not been demonstrated to provide additional benefit. For example, cholesteryl ester transfer protein inhibitors are a class of medicines being investigated to raise HDL levels; however, agents in this class have not been shown to be effective in so doing. The addition of niacin to statins has also been carefully studied in the AIM-HIGH study and the HPS2-THRIVE study in patients at high risk for CVD and shown not to produce any further benefit (ie, to decrease parameters of cardiovascular risk).

Diet Therapy

Studies of nonhospitalized adults have reported only modest cholesterol-lowering benefits of dietary therapy, typically in the range of a 5–10% decrease in LDL cholesterol, and even less over the long term. The effect of diet therapy, however, varies considerably among individuals; some patients will have striking reductions in LDL cholesterol—up to a 25–30% decrease—whereas others will have clinically important increases. Thus, the results of diet therapy should be assessed about 4 weeks after initiation.

Several nutritional approaches to diet therapy are available. Most Americans currently eat over 35% of calories as fat, of which 15% is saturated fat. A traditional cholesterol-lowering diet recommends reducing total fat to 25–30% and saturated fat to less than 7% of calories, with complete elimination of trans fats. These diets replace fat, particularly saturated fat, with carbohydrate. Other diet plans, including the Dean Ornish Diet, the Pritikin Diet, and most vegetarian diets, restrict fat even further. Low-fat, high-carbohydrate diets may, however, result in insulin resistance and reductions in HDL cholesterol.

An alternative strategy is the Mediterranean diet, which maintains total fat at approximately 35–40% of total calories but replaces saturated fat with monounsaturated fat such as that found in canola oil and in olives, peanuts, avocados, and their oils. This diet is equally effective at lowering LDL cholesterol, and is less likely to lead to reductions in HDL cholesterol. Several studies have suggested that this diet may also be associated with reductions in endothelial dysfunction, insulin resistance, and markers of vascular inflammation and may result in better resolution of the metabolic syndrome than traditional cholesterol-lowering diets. A clinical trial demonstrated reduced cardiovascular events in persons on a Mediterranean diet supplemented with additional nuts or extra-virgin olive oil.

Pharmacologic Therapy

There are seven types of medications to consider in patients who require drug treatment of an elevated cholesterol. As discussed above, statins are the cornerstone of nearly all medical regimens, and current guidelines define four groups of patients who benefit from statin medications. The evidence is then strongest for ezetimibe and compared to persons on a less intensive standard Mediterranean diet.

Other dietary changes may also result in beneficial changes in blood lipids. Soluble fiber, such as that found in oat bran or psyllium, may reduce LDL cholesterol by 5–10%. Plant stanols and sterols can reduce LDL cholesterol by 10%. Intake of garlic, soy protein, vitamin C, and pecans may also yield modest reductions of LDL cholesterol. Because oxidation of LDL cholesterol is a potential initiating event in atherogenesis, diets rich in antioxidants, found primarily in fruits and vegetables, may be helpful (see Chapter 29). Studies have suggested that when all of these elements are combined into a single dietary prescription, the impact of diet on LDL cholesterol may approach that of statin medications, lowering LDL cholesterol by close to 30%.

A. Statins (Hydroxymethylglutaryl-Coenzyme A [HMG-CoA] Reductase Inhibitors)

The statins (HMG-CoA reductase inhibitors) work by inhibiting the rate-limiting enzyme in the formation of cholesterol. Cholesterol synthesis in the liver is reduced, with a compensatory increase in hepatic LDL receptors (presumably so that the liver can take more of the cholesterol that it needs from the blood) and a reduction in the circulating LDL cholesterol level by 50% or more at the highest doses. There are also modest increases in HDL levels, substantial decreases in triglyceride levels, and marked reductions in high-sensitivity C-reactive protein levels.

The 2018 AHA/ACC/Multi-specialty guidelines divide statins into two categories: “high-intensity” and “moderate-intensity” statins (Table 28–2). High-intensity statins lower LDL cholesterol by approximately 50%. Examples include high-dose atorvastatin 40–80 mg/day and rosuvastatin 20–40 mg/day (Table 28–3). Moderate-intensity statins lower LDL cholesterol by approximately 30–50%. Examples include simvastatin 20–40 mg/day, pravastatin

4 Plasma lipoprotein apheresis allowed in clinical trial.

5 No plasma lipoprotein apheresis allowed in clinical trial.

HDL, high-density lipoprotein; LDL, low-density lipoprotein; ± variable, if any; others, indicates availability of less expensive generic preparations; OTC, over the counter.
40–80 mg/day, and lovastatin 40 mg/day, as well as low-dose atorvastatin 10–20 mg/day and rosuvastatin 5–10 mg/day. All statins are given once daily in the morning or evening.

Statin-associated muscle aches, with normal serum creatine kinase levels, occur in up to 10% of patients, and often such patients can tolerate the statin upon rechallenge. More serious, but very uncommon, muscle disease includes myositis and rhabdomyolysis, with moderate and marked elevations of serum creatine kinase levels, respectively. Such muscle disease occurs more often when the statin is taken with niacin or a fibrate, as well as with erythromycin, antifungal medications, nefazodone, or cyclosporine. Simvastatin at the highest approved dose (80 mg) is associated with an elevated risk of muscle injury or myopathy; this dose should be used only in patients who have been taking simvastatin at a lower dose for longer than 1 year without muscle toxicity. Liver disease, with elevations of serum transaminases, is another side effect of statin therapy and is again more common in patients who are also taking fibrates or niacin. Manufacturers of statins recommend monitoring liver enzymes before initiating therapy and as clinically indicated thereafter. Liver failure can occur but is extremely uncommon. Finally, statin therapy is associated with mild gastrointestinal symptoms and a 10% increase in risk of developing diabetes mellitus.

B. Ezetimibe

Ezetimibe inhibits the intestinal absorption of dietary and biliary cholesterol across the intestinal wall by inhibiting a cholesterol transporter. The dose of ezetimibe is 10 mg/day orally. Ezetimibe reduces LDL cholesterol between 15% and 20% when used as monotherapy, reduces high-sensitivity C-reactive protein, and can further reduce LDL in patients taking statins in whom the therapeutic goal has not been reached. While beneficial effects of ezetimibe monotherapy on cardiovascular outcomes are available from only a large open-label trial, the double-blind IMPROVE-IT trial showed that adding ezetimibe to a statin resulted in a small incremental 5–10% relative risk reduction in cardiovascular outcomes. At the end of 7 years of study, patients taking ezetimibe-simvastatin had a 2% absolute reduction in cardiovascular events compared to patients taking simvastatin alone. Current guidelines recommend adding ezetimibe therapy to maximally tolerated statin therapy in patients at high risk for CVD whose LDL cholesterol remains above the treatment threshold of 70 mg/dL.

C. Proprotein Convertase Subtilisin/Kexin Type 9 (PCSK9) Inhibitors

PCSK9 inhibitors are fully human monoclonal antibodies that inhibit PCSK9-mediated LDL-receptor degradation and lower LDL cholesterol levels by 50–60% and lipoprotein(a) by up to 20–30%. Two agents, alirocumab and evolocumab, are approved for use in the United States for patients with familial hypercholesterolemia or CVD who require additional lowering of LDL cholesterol. The medications are injected subcutaneously every 2–4 weeks. No significant increase in adverse events has been observed compared to placebo. The FOURIER (Further Cardiovascular Outcomes Research with PCSK9 Inhibition in Subjects with Elevated Risk) trial compared evolocumab with placebo in 27,564 patients with established atherosclerotic disease already taking statin therapy; participants were monitored for a median of 2.2 years. LDL cholesterol was reduced by 59%. Patients receiving the evolocumab plus statin had a 15% reduction in the primary composite endpoint of cardiovascular death, myocardial infarction, stroke, hospital admission for unstable angina, or coronary revascularization and a 20% reduction in the secondary outcome of cardiovascular death, myocardial infarction, or stroke. The ODYSSEY-OUTCOMES study randomized 18,924 patients with recent acute coronary syndrome to alirocumab or placebo, demonstrating a 15% reduction in the primary composite cardiovascular endpoint and a 15% reduction in all-cause mortality in secondary statistical testing after median 2.8-year follow-up.

However, despite encouraging results from multiple clinical trials, initial cost-effectiveness models suggested that PCSK9 inhibitors were not cost-effective. After marked price reductions in 2018 and 2019, PCSK9 inhibitors are closer to being cost-effective; however, guidelines suggest that their relatively high cost must still remain part of the consideration regarding their use. Current guidelines recommend addition of PCSK9 inhibitors to statins at maximally tolerated doses in patients at very high risk for CVD when on-treatment LDL cholesterol remains above 70 mg/dL (or above 100 mg/dL in patients with familial hypercholesterolemia). Patients considered to be at very high risk for CVD include those with recent acute coronary syndrome within 12 months; multiple prior myocardial infarctions or strokes; significant uneventual coronary artery disease; and polyvascular disease (coronary plus cerebrovascular or peripheral vascular disease).

D. Bile Acid–Binding Resins

The bile acid–binding resins include cholestyramine, colesevelam, and colestipol. In the pre-statin era, treatment with these agents reduced the incidence of coronary events in middle-aged men by about 20%, with no significant effect on total mortality. The resins work by binding bile acids in the intestine. The resultant reduction in the enterohepatic circulation causes the liver to increase its production of bile acids, using hepatic cholesterol to do so. Thus, hepatic LDL receptor activity increases, with a decline in plasma LDL levels. The triglyceride level tends to increase slightly in some patients treated with bile acid–binding resins; these resins should be used with caution in patients with elevated triglycerides and probably not at all in patients who have triglyceride levels above 500 mg/dL. The clinician can anticipate a reduction of 15–25% in the LDL cholesterol level, with insignificant effects on the HDL level.

These agents often cause gastrointestinal symptoms, such as constipation and gas. They may interfere with the absorption of fat-soluble vitamins (thereby complicating the management of patients receiving warfarin) and may
bind other drugs in the intestine. Concurrent use of psyllium may ameliorate the gastrointestinal side effects.

**E. Omega-3 Fatty Acid Preparations**

Omega-3 fatty acids are essential fatty acids that must be consumed in the diet and are a prominent feature of Mediterranean-style diets. In pharmacologic doses, omega-3 fatty acid preparations can lower triglycerides by up to 30%, with modest reductions in apolipoprotein-B–containing lipoproteins and high-sensitivity C-reactive protein. Pharmacologic therapy should be differentiated from dietary omega-3 fatty acid supplements. The former is an FDA-approved product usually given at a much higher dose; dietary supplements are variable and not currently regulated.

There is weak evidence that omega-3 fatty acids reduce myocardial infarctions, though with no reduction in total or cardiovascular mortality. Omega-3 ethyl esters have not been associated with cardiovascular event reduction when added to statin therapy. In contrast, icosapent ethyl, which is a highly purified eicosapentaenoic acid (EPA) only preparation, was shown to reduce cardiovascular deaths, nonfatal myocardial infarctions, nonfatal strokes, coronary revascularizations, and unstable angina by 25% in statin-treated patients with triglycerides greater than 135 mg/dL in the 8179 person REDUCE-IT randomized clinical trial. The mechanism of icosapent ethyl is not yet clear but likely involves multiple mechanisms beyond lipid lowering, including antiplatelet activity, anti-inflammatory activity, and arrhythmia prevention.

**F. Fibrac Acid Derivatives**

The fibrates are peroxisome proliferative-activated receptor-alpha (PPAR-alpha) agonists that result in significant reductions of plasma triglycerides and increases in HDL cholesterol. They reduce LDL levels by about 10–15% (although the result is quite variable) and triglyceride levels by about 40% and raise HDL levels by about 15–20%. The fibric acid derivatives or fibrates approved for use in the United States are gemfibrozil and fenofibrate. Ciprofibrate and bezafibrate are also available for use internationally.

Gemfibrozil monotherapy reduced CHD rates in hypercholesterolemic middle-aged men free of coronary disease in the Helsinki Heart Study. The effect was observed only among those who also had lower HDL cholesterol levels and high triglyceride levels. In a Veteran Affairs study, gemfibrozil monotherapy was also shown to reduce cardiovascular events in men with existing CHD whose primary lipid abnormality was a low HDL cholesterol. There was no effect on all-cause mortality.

However, fibrates have not been shown to reduce cardiovascular events in all statin-treated patients with CVD or diabetes. For example, in the ACCORD study, addition of fenofibrate to statin in patients with diabetes and mild triglyceride elevations resulted in no benefit.

The usual dose of gemfibrozil is 600 mg once or twice a day. Side effects include cholelithiasis, hepatitis, and myositis. The incidence of the latter two conditions may be higher among patients also taking other lipid-lowering agents. Fenofibrate, 48–145 mg daily, can be used and has slightly fewer side effects than gemfibrozil. Resins are the only lipid-modifying medication considered safe in pregnancy.

**G. Niacin (Nicotinic Acid)**

Niacin was the first lipid-lowering agent that was associated with a reduction in total mortality. Long-term follow-up of a secondary prevention trial in middle-aged men with previous myocardial infarction disclosed that about half of those who had been previously treated with niacin had died, compared with nearly 60% of the placebo group. This favorable effect on mortality was not seen during the trial itself, though there was a reduction in the incidence of recurrent coronary events. A meta-analysis of 10 randomized trials using niacin in the pre-statin era showed a 27% reduction in cardiovascular events.

Niacin reduces the production of VLDL particles, with secondary reduction in LDL and increases in HDL cholesterol levels. The average effect of full-dose niacin therapy is a 15–25% reduction in LDL cholesterol and a 25–35% increase in HDL cholesterol. Full doses are required to obtain the LDL effect, but the HDL effect is observed at lower doses, eg, 1 g/day. Niacin also reduces triglycerides and can lower lipoprotein(a) (Lp[a]) levels. Intolerance to niacin is common; only 50–60% of patients can take full doses. Niacin causes a prostaglandin-mediated flushing that patients may describe as “hot flashes” or pruritus. It can be decreased with aspirin (81–325 mg/day) or other nonsteroidal anti-inflammatory agents taken an hour before niacin dosing. Extended-release niacin is better tolerated by most patients. Niacin can also exacerbate gout and peptic ulcer disease. Although niacin may increase blood sugar in some patients, clinical trials have shown that it can be safely used in diabetic patients.

In two large clinical trials, AIM-HIGH and HPS2-THRIVE, extended-release niacin did not reduce cardiovascular events when added to statin therapy in high-risk patients.

**Treatment Algorithms**

For patients who require a lipid-modifying medication, an HMG-CoA reductase inhibitor (statin) is recommended. In patients with CVD, this should generally be at its maximally tolerated dose.

Combination therapy is indicated for (1) patients with familial hypercholesterolemia with on-treatment LDL cholesterol that is above 100 mg/dL and (2) patients with existing CVD with on-treatment LDL cholesterol that remains above 70 mg/dL. Patients with homozygous familial hypercholesterolemia may need plasmapheresis and/or special lipid-lowering therapies uniquely approved for this population (Table 28–3). Patients with heterozygous familial hypercholesterolemia may need two or more medications to get below the treatment threshold, while those with CVD less commonly need multiple medications. The 2018 AHA/ACC/Multi-specialty guidelines recommend addition of ezetimibe in high-risk patients, while reserving PCSK9
inhibitor therapy for very high-risk patients or those taking maximally tolerated statins and ezetimibe with LDL cholesterol still not below 70 mg/dL (Figure 28–2).

HIGH BLOOD TRIGLYCERIDES

Patients with very high levels of serum triglycerides (greater than 1000 mg/dL) are at risk for pancreatitis. The pathophysiology is not certain, since pancreatitis never develops in some patients with very high triglyceride levels. Most patients with congenital abnormalities in triglyceride metabolism present in childhood; hypertriglyceridemia-induced pancreatitis first presenting in adults is more commonly due to an acquired problem in lipid metabolism.

Although there are no clear triglyceride levels that predict pancreatitis, most clinicians treat fasting levels above 500 mg/dL (5 mmol/L). The risk of pancreatitis may be more related to the triglyceride level following consumption of a fatty meal. Because postprandial increases in triglyceride are inevitable if fat-containing foods are eaten, fasting triglyceride levels in persons prone to pancreatitis should be kept well below that level.

The primary therapy for high triglyceride levels is dietary, avoiding alcohol, simple sugars, refined starches, and saturated and trans fatty acids, and restricting total calories. Control of secondary causes of high triglyceride levels may also be helpful. In patients with fasting triglycerides greater than or equal to 500 mg/dL (5 mmol/L) despite adequate dietary compliance—and certainly in those with a previous episode of pancreatitis—therapy with a triglyceride-lowering drug (eg, statins, fibric acid derivative, omega-3-acid ethyl esters, or niacin) is indicated. Combinations of these medications may also be used.

Currently, drug treatment for patients with triglycerides greater than 150 mg/dL (1.5 mmol/L) is reserved for those with established CVD with well-controlled LDL cholesterol on maximally tolerated therapy with statins or other agents. Currently, data are strongest for icosapent ethyl.

Nutritional Disorders

NUTRITIONAL DISORDERS

PROTEIN–ENERGY MALNUTRITION

ESSENTIALS OF DIAGNOSIS

- Decreased intake of energy or protein, increased nutrient losses, or increased nutrient requirements.
- Kwashiorkor: caused by protein deficiency.
- Marasmus: caused by combined protein and energy deficiency.
- Protein loss correlates with weight loss: 35–40% total body weight loss is usually fatal.

General Considerations

Protein–energy malnutrition occurs as a result of a relative or absolute deficiency of energy and protein. It may be primary, due to inadequate food intake, or secondary, as a result of other illness. For most developing nations, primary protein–energy malnutrition remains among the most significant health problems. It occurs in two distinct syndromes. Kwashiorkor, caused by a deficiency of protein in the presence of adequate energy, is typically seen in weaning infants at the birth of a sibling in areas where foods containing protein are insufficient. Marasmus, caused by combined protein and energy deficiency, is seen where adequate quantities of food are simply not available.

In industrialized societies, protein–energy malnutrition is most often secondary to other diseases. Kwashiorkor-like secondary protein–energy malnutrition occurs primarily in association with hypermetabolic acute illnesses such as trauma, burns, and sepsis. Marasmus-like secondary protein–energy malnutrition typically results from chronic diseases such as chronic obstructive pulmonary disease (COPD), heart failure, cancer, or AIDS. These two syndromes are estimated to be present in at least 20% of hospitalized patients. A substantially greater number of patients have risk factors that could result in them. In both syndromes, protein–energy malnutrition is caused either by decreased intake of energy and protein or by increased nutrient losses related to the underlying illness. For example, diminished energy intake may result from poor dentition or various gastrointestinal disorders. Increased nutrient losses result from malabsorption, diarrhea, and glycosuria. Increased nutrient requirements occur with fever, surgery, neoplasia, and burns.

Clinical Findings

Clinical manifestations of protein–energy malnutrition range from mild growth retardation and weight loss to a number of distinct clinical syndromes. In the developing world, children manifest marasmus and kwashiorkor. In industrialized nations, clinical manifestations of secondary protein–energy malnutrition are affected by the patient’s nutritional status prior to illness, illness resulting in the protein and energy deficiency, and degree of the deficiency.

Progressive wasting that begins with weight loss and proceeds to more severe cachexia typically develops in most patients with marasmus-like secondary protein–energy malnutrition. In the most severe form of this disorder, most body fat stores disappear and muscle mass decreases, most noticeably in the temporalis and interosseous muscles. Laboratory studies may be unremarkable—serum albumin, for example, may be normal or slightly decreased, rarely decreasing to less than 2.8 g/dL (28 g/L). In contrast, owing to its rapidity of onset, kwashiorkor-like secondary protein–energy malnutrition may develop in patients with normal subcutaneous fat and muscle mass or, if the patient has obesity, even in patients with excess fat and muscle. The serum protein level, however, typically declines and the serum albumin is often less than 2.8 g/dL (28 g/L). Dependent edema, ascites, or anasarca may develop. As with primary protein–energy malnutrition, combinations of the marasmus-like and kwashiorkor-like syndromes can occur simultaneously, typically in patients with progressive chronic disease in whom a superimposed acute illness develops.

Treatment

The treatment of severe protein–energy malnutrition is a slow process requiring great care. Initial efforts should be
OBESITY

Definition & Measurement

Obesity is a multifactorial, chronic disease characterized by an accumulation of visceral and subcutaneous fat. Obesity predisposes to a wide variety of comorbid conditions. The BMI correlates with excess adipose tissue. It is calculated by dividing body weight in kilograms by height in meters squared. The National Institutes of Health (NIH) defines a normal BMI as 18.5–24.9. Overweight is defined as BMI 25–29.9. Class I obesity is 30–34.9, class II obesity is 35–39.9, and class III obesity is BMI greater than or equal to 40. Upper body obesity (excess fat around the waist and flank) is a greater health hazard than lower body obesity (fat in the thighs and buttocks). Patients with obesity and increased abdominal circumference (greater than 102 cm or 40 inches in men and 88 cm or 35 inches in women) or high waist–hip ratios (greater than 1.0 in men and 0.85 in women) have a greater risk of weight-related comorbid conditions and early death than patients with the same BMI and lower ratios. Furthermore, visceral fat within the abdominal cavity is more hazardous to health than subcutaneous fat around the abdomen. US survey data demonstrate that almost 40% of Americans have obesity.

Etiology

Both genetic and environmental factors contribute to the development of obesity. Twin studies have demonstrated that genetics account for 50–90% of the variation in BMI. Only a small percentage of human obesity is thought to be due to single gene mutations. Most human obesity develops from the interactions of multiple genes, environmental factors, and behavior. The rapid increase in obesity in the last several decades points to major roles for environmental and behavioral factors in its development.
Medical Evaluation of the Patient with Obesity

Historical information should be obtained about age at onset, recent weight changes, family history of obesity, occupational history, eating and exercise behavior, cigarette and alcohol use, previous weight loss experience, and psychosocial factors including assessment for depression and eating disorders.

Physical examination should assess the BMI, degree and distribution of body fat, overall nutritional status, and signs of secondary causes of obesity. Less than 1% of patients with obesity have an identifiable secondary cause of obesity. Hypothyroidism and Cushing syndrome are important examples that can be diagnosed by physical examination, laboratory testing, and imaging studies in patients with unexplained recent weight gain. Such patients require endocrinologic evaluation (see Chapter 26). All patients with obesity should be assessed for weight-related comorbid conditions. Blood pressure, waist circumference, fasting glucose, comprehensive metabolic profile, lipid panel, and hemoglobin A1c should be measured as well as other laboratory tests as clinically indicated.

Treatment

Weight loss of 5–10% body weight is sufficient for clinically relevant improvements in many risk factors among patients with obesity and risk reduction appears to be dose-related. Magnitude of weight loss at 1 year is strongly associated with improvements in many parameters including blood sugar, blood pressure, triglycerides, and high-density lipoprotein (HDL) cholesterol. Successful treatment of obesity requires a multidisciplinary approach to counteract the body’s resistance to weight loss. Diet, physical activity, and behavioral modifications are the cornerstones of weight management. Many dietary strategies can be effective for weight loss. Recommendations should be tailored to a patient’s preferences as dietary adherence is associated with greater weight loss and greater reductions in cardiac risk factors. Dietary instructions should emphasize intake of a variety of predominantly “unprocessed” foods, with special attention to limiting foods that provide large amounts of calories without other nutrients, ie, sugary drinks, fast food, junk food and sweets. A Mediterranean diet can be a good option for patients at high cardiovascular risk, since it has been shown to reduce the incidence of major cardiovascular events. A low-glycemic-index diet can curb hunger and decrease cravings by reducing blood sugar fluctuations. Meal replacement diets can also be used effectively to achieve weight loss. Registered dietitians can provide dietary education and customize diet plans.

Long-term changes in eating behavior are required to maintain weight loss and formal behavior modification programs are available. It is important to emphasize planning and self-monitoring, including weighing at regular intervals and keeping a food log to track caloric intake. Self-monitoring not only aids in behavioral change but also provides the practitioner with additional data from which to tailor recommendations. Patients can learn to recognize “eating cues” (emotional, situational, etc) and how to avoid or control them. As weight maintenance can be more challenging than initial weight loss, it is important that patients continue self-monitoring and regular follow up to ensure long-term adherence to their treatment plan.

Exercise offers several advantages for patients trying to lose weight and maintain weight loss. Aerobic exercise directly increases daily energy expenditure and is particularly useful for long-term weight maintenance. Exercise also preserves lean body mass and partially prevents the decrease in basal energy expenditure (BEE) resulting from weight loss. Compared to no treatment, exercise alone results in small amounts of weight loss. Exercise plus diet results in slightly greater weight loss than diet alone. A greater intensity of exercise is associated with a greater amount of weight loss. Up to 1 hour of moderate exercise per day is associated with long-term weight maintenance in individuals who have successfully lost weight.

The American College of Sports Medicine recommends 150 minutes of moderate-intensity aerobic physical activity (such as tennis or brisk walking) per week, 75 minutes of vigorous-intensity aerobic exercise (such as jogging or swimming laps) per week, or an equivalent combination of moderate- and vigorous-intensity aerobic activity. Episodes should last at least 10 minutes and, if possible, be spread out throughout the week. Weight resistance is also recommended at least twice per week. Exercise physiologists, physical therapists, and trainers can provide additional support for patients.

Medications can have unpredictable and variable effects on patients’ weight, so it is important to review patients’ medication regimens and balance the benefits of treatment against the probability of weight gain. Multiple medications are associated with weight gain, including corticosteroids, contraceptives and other hormonal agents as well as certain antidiabetic, antihypertensive, antidepressant, antipsychotic, antiepileptic, and antihistamine agents. Table 29–1 provides an overview of weight-gaining medications as well as potential alternatives. When possible, clinicians should prescribe weight-neutral or weight loss–promoting medications. If there are no alternatives, weight gain can be prevented or lessened by selecting the lowest dose needed to produce clinical efficacy for the shortest duration necessary.

Weight loss achieved by lifestyle modifications alone is often limited and difficult to maintain. As a result, patients may require antiobesity medications, bariatric surgery, devices, or endoscopic bariatric therapies to achieve and maintain clinically significant weight loss.

Antiobesity medications (Table 29–2) can be considered in patients with a BMI 30 or higher or a BMI 27 or higher with weight-related comorbidities. Since obesity is a chronic disease, most medications for weight loss are approved for long-term treatment. Medications approved for weight management should be viewed as additions to diet and exercise for patients who have been unsuccessful with lifestyle changes alone. The six most widely prescribed antiobesity medications approved by the FDA are phentermine, orlistat, phentermine/topiramate extended release (ER), lorcaserin, naltrexone sustained-release (SR)/bupropion SR, and liraglutide 3.0 mg. Table 29–2 provides an overview of these medications.

**Phentermine** is the most commonly prescribed adrenergic agonist and antiobesity medication in the United States; other adrenergic agonists include diethylpropion, benzphetamine, and phendimetrazine. In a 28-week randomized controlled trial, participants taking phentermine 15 mg daily lost an average of 6.0 kg compared with 1.5 kg among those assigned to placebo. The recommended dosage of phentermine is up to 37.5 mg daily, but the dosage should be individualized to achieve response with the lowest effective dose.

**Orlistat** works in the gastrointestinal tract to inhibit intestinal lipase, thus reducing dietary fat absorption. Not unexpectedly, it may cause diarrhea, gas, and cramping and perhaps reduced absorption of fat-soluble vitamins. Orlistat is associated with a 5.8 kg weight loss after 4 years compared to 3.0 kg with placebo. The recommended dose is 120 mg (Xenical, prescription-strength) or 60 mg (Alli, over-the-counter) three times a day with each main meal containing fat.

**Lorcaserin**, a selective serotonin 2C receptor agonist available at a dose of 10 mg orally twice daily or 20 mg ER once daily, is associated with 5.8% weight loss compared to 2.2% with placebo at 52 weeks. In the CAMELLIA-TIMI 61 trial, which enrolled a high-risk population of persons with obesity and overweight, lorcaserin facilitated sustained weight loss without a higher rate of major cardiovascular events compared to placebo.

The combination of **phentermine** and **topiramate ER** (3.75 mg/23 mg orally daily for 14 days, then 7.5 mg/46 mg orally daily, to a maximum dosage of 15 mg/92 mg orally daily) targets two different weight-regulation mechanisms simultaneously. In a 56-week clinical trial, participants taking 15/92 mg lost significantly more weight (9.8 kg) than those assigned to 7.5/46 mg (7.8 kg) or placebo (1.2 kg). The FDA requires a Risk Evaluation and Mitigation Strategy to inform women of reproductive potential and prescribers about a potential increased risk of orofacial clefts.

*(continued)*
Table 29–2. Medications tested in clinical trials for treatment of obesity. (continued)

*P < 0.001 vs. placebo
1Adipex [package insert]. Tulsa, OK: Physicians Total Care, Inc; 2012.

GI, gastrointestinal; GLP-1, glucagon-like peptide-1; MAOI, monoamine oxidase inhibitor; MEN2, multiple endocrine neoplasia syndrome type 2; MTC, medullary thyroid carcinoma; XR, extended release.

in infants exposed to the medication during the first trimester of pregnancy.

The combination of naltrexone SR and bupropion SR (8 mg/90 mg, increasing from 1 tablet orally daily by 1 additional daily tablet each week to a maximum of 2 tablets twice daily) reduces both appetite and food cravings by targeting two areas of the brain: the arcuate nucleus of the hypothalamus and the mesolimbic dopamine reward circuit. Naltrexone 32 mg/bupropion 360 mg is associated with a 6.1% reduction in body weight compared to 1.3% with placebo after 56 weeks. As with all antidepressants, bupropion carries a black box warning related to a potential increase in suicidality among younger patients during the early phase of treatment. Two cardiovascular outcome trials were terminated early.

Liraglutide, an injectable glucagon-like peptide-1 receptor agonist, is approved at a dose of 0.6 mg subcutaneously daily, increasing by 0.6 mg daily each week to a maximum of 3 mg subcutaneously daily. Liraglutide was initially FDA approved in 2010 for the treatment of type 2 diabetes at doses up to 1.8 mg subcutaneously daily. Liraglutide 3.0 mg subcutaneously daily is associated with 6.0% weight loss compared to 2.0% with placebo after 56 weeks. Thyroid C-cell tumors were found in rodents given supratherapeutic doses of liraglutide, but there is no evidence of liraglutide causing C-cell tumors in humans. Liraglutide 1.8 mg subcutaneously daily has been approved for cardiovascular risk reduction in patients with type 2 diabetes at elevated cardiovascular risk and a cardiovascular outcomes trial of liraglutide 3.0 mg is being conducted in patients with obesity.

Bariatric surgery is the most effective treatment for obesity. The three most common bariatric procedures in the United States are the sleeve gastrectomy, the Roux-en-Y gastric bypass, and the laparoscopic adjustable gastric band. Bariatric surgery can be considered in patients with a BMI 40 or higher or with a BMI 35 or higher plus one or more obesity-related complications who are motivated to lose weight but have not achieved sufficient weight loss to address health goals following lifestyle modification, with or without pharmacotherapy. Long-term medical follow up, lifestyle changes, and adherence to a vitamin regimen are crucial to the success of bariatric surgery; however, some patients have difficulty maintaining weight loss and regain some portion of the lost weight.

Sleeve gastrectomy involves removing approximately 70% of the stomach along the greater curvature. The pyloric valve and the small intestine remain intact. The fundus of the stomach, which secretes ghrelin, a hormone that stimulates appetite, is removed. Sleeve gastrectomy is associated with approximately 25% total body weight loss after 1 year. Because this procedure is mainly restrictive, there is a lower risk of nutritional deficiencies. In general, sleeve gastrectomy is associated with fewer complications than both the Roux-en-Y gastric bypass and laparoscopic adjustable gastric band. Early adverse events include bleeding, leakage along the staple line, stenosis, and vomiting. Late complications include gastroesophageal reflux, nutritional deficiencies, and stomach expansion, leading to decreased restriction. Unlike the other two procedures, sleeve gastrectomy is not reversible.

The Roux-en-Y gastric bypass attaches a small pouch created from the proximal stomach to the jejunum, thus bypassing the remainder of the stomach, duodenum, and most of the jejunum. Roux-en-Y gastric bypass is associated with approximately 30–35% total body weight loss at 2 years and greater improvements in comorbid disease markers compared to the two other procedures. Roux-en-Y gastric bypass is associated with a lower rate of gastroesophageal reflux than sleeve gastrectomy and can even alleviate gastroesophageal reflux in patients who have it. Roux-en-Y gastric bypass is often recommended over sleeve gastrectomy for patients with mild or moderate type 2 diabetes because it leads to greater long-term remission; however, both procedures have low efficacy for type 2 diabetes remission among patients with limited pancreatic beta cell reserve. Early adverse events associated with Roux-en-Y gastric bypass include obstruction, stricture, leak, and failure of the staple partition of the upper stomach. Late adverse events include nutritional deficiencies and anastomosis ulceration. Dumping syndrome can develop at any time. Roux-en-Y gastric bypass is technically a reversible procedure; however, it is generally only reversed in extreme circumstances.

The laparoscopic adjustable gastric band is an inflatable device that is placed around the fundus of the stomach to create a small pouch. This procedure is associated with 15% total body weight loss at 2 years. Laparoscopic adjustable gastric band is reversible and less invasive than the other two procedures, but it is associated with more complications than sleeve gastrectomy and Roux-en-Y gastric bypass. The most common adverse events include nausea, vomiting, obstruction, band erosion or migration, and esophageal dysmotility leading to acid reflux.

**When to Refer**

- Patients with a BMI greater than or equal to 30 or a BMI greater than or equal to 27 with weight-related comorbidities may be referred to an obesity medicine specialist.
- Patients with a BMI greater than or equal to 40 (or greater than or equal to 35 with obesity-related morbidities) who have not achieved sufficient weight loss to address health goals following behavioral treatment, with or without pharmacotherapy, may be referred to a bariatric surgeon.

---

In females, absence of at least three consecutive menstrual cycles.

**Clinical Findings**

**A. Symptoms and Signs**

Patients with anorexia nervosa may exhibit severe emaciation and may complain of cold intolerance or constipation. Amenorrhea is almost always present. Bradycardia, hypotension, and hypothermia may be present in severe cases. Examination demonstrates loss of body fat, dry and scaly skin, and increased lanugo body hair. Parotid enlargement and edema may also occur.

**B. Laboratory Findings**

Laboratory findings are variable but may include anemia, leukopenia, electrolyte abnormalities, and elevations of blood urea nitrogen (BUN) and serum creatinine. Serum cholesterol levels are often increased. Endocrine abnormalities include depressed levels of luteinizing and follicle-stimulating hormones and impaired response of luteinizing hormone to luteinizing hormone-releasing hormone.

**Diagnosis & Differential Diagnosis**

The diagnosis is based on weight loss to a body weight 15% below expected, distorted body image, fear of weight gain or of loss of control over food intake and, in females, absence of at least three consecutive menstrual cycles. Other medical or psychiatric illnesses that can account for anorexia and weight loss must be excluded.

Behavioral features required for the diagnosis include intense fear of developing obesity, disturbance of body image, and refusal to exceed a minimal normal weight.

The differential diagnosis includes endocrine and metabolic disorders (eg, panhypopituitarism, Addison disease, hyperthyroidism, and diabetes mellitus); gastrointestinal disorders (eg, Crohn disease and gluten enteropathy); chronic infections (eg, tuberculosis); cancers (eg, lymphoma); and rare central nervous system disorders (eg, hypothalamic tumor).

**Treatment**

The goal of treatment is restoration of normal body weight and improvement in psychological difficulties. Hospitalization may be necessary. Treatment programs conducted by experienced teams are successful in about two-thirds of cases, restoring normal weight and menstruation. The remainder continue to experience difficulties with eating behaviors and psychiatric problems. About 2% to 6% of patients die of the complications of the disorder or commit suicide.

Various treatment methods have been used without clear evidence of superiority of one over another. Supportive care by clinicians and family is probably the most important feature of therapy. Cognitive-behavioral therapy, intensive psychotherapy, and family therapy may be tried. A variety of medications including tricyclic antidepressants, selected serotonin reuptake inhibitors (SSRIs), and lithium carbonate are effective in some cases; however, clinical trial results have been disappointing. Patients with severe malnutrition must be hemodynamically stabilized and may require enteral or parenteral feeding. Forced

**General Considerations**

Anorexia nervosa typically begins in the years between adolescence and young adulthood. Ninety percent of patients are female, most of middle and upper socioeconomic status.

The prevalence of anorexia nervosa is greater than previously suggested. Many adolescent girls have features of the disorder without the severe weight loss.

The cause of anorexia nervosa is not known. Although multiple endocrinologic abnormalities exist in these patients, most authorities believe they are secondary to malnutrition and not primary disorders. Most experts favor a primary psychiatric origin, but no hypothesis explains all cases. The patient characteristically comes from a family whose members are highly goal-oriented. The parents may be directive and concerned with slimness and physical fitness, and family conversation often centers around dietary matters. One theory holds that the patient’s refusal to eat is an attempt to regain control of one’s body in defiance of parental control. The patient’s unwillingness to inhabit an “adult body” may also represent a rejection of adult responsibilities and the implications of adult interpersonal relationships. Patients are often perfectionistic in behavior and exhibit obsessional personality characteristics.

**ESSENTIALS OF DIAGNOSIS**

- Disturbance of body image and intense fear of becoming fat.
- Weight loss leading to body weight 15% below expected.
- In females, absence of three consecutive menstrual cycles.
When to Admit

General Considerations

- Clinical Findings
  - Failure to improve with outpatient management.
  - Uncontrolled episodes of binge eating at least twice weekly for 3 months.
  - Signs of hypovolemia, major electrolyte disorders, and severe protein–energy malnutrition.
  - Failure to improve with outpatient management.

When to Refer

- Adolescents and young adults with otherwise unexplained profound weight loss should be evaluated by a psychiatrist.
- All patients with diagnosed anorexia nervosa should be co-managed with a psychiatrist.

When to Admit

- Signs of hypovolemia, major electrolyte disorders, and severe protein–energy malnutrition.
- Failure to improve with outpatient management.

Like anorexia nervosa, bulimia nervosa is predominantly a disorder of young, white, middle- and upper-class women. It is more difficult to detect than anorexia, and some studies have estimated that the prevalence may be as high as 19% in college-aged women.

Clinical Findings

Patients with bulimia nervosa typically consume large quantities of easily ingested high-calorie foods, usually in secrecy. Some patients may have several such episodes a day over multiple days; others report regular and persistent patterns of binge eating. Binging is usually followed by vomiting, cathartics, or diuretics and accompanied by feelings of guilt or depression. Periods of binging may be followed by intervals of self-imposed starvation. Body weight may fluctuate but generally is within 20% of desirable weight.

Some patients with bulimia nervosa also have a cryptic form of anorexia nervosa with significant weight loss and amenorrhea. Family and psychological issues are generally similar to those of patients with anorexia nervosa. Bulimic patients, however, have a higher incidence of premorbid obesity, greater use of cathartics and diuretics, and more impulsive or antisocial behavior. Menstruation is usually preserved.

Medical complications are numerous. Gastric dilatation and pancreatitis have been reported after binges. Vomiting can result in poor dentition, pharyngitis, esophagitis, aspiration, and electrolyte abnormalities. Cathartic and diuretic abuse can also cause electrolyte abnormalities or dehydration. Constipation is common.

Treatment

Treatment of bulimia nervosa requires supportive care and psychotherapy. Individual, group, family, and behavioral therapy have all been utilized. Antidepressant medications may be helpful. The best results have been with fluoxetine and other SSRIs. Although death from bulimia is rare, the long-term psychiatric prognosis in severe bulimia is worse than that in anorexia nervosa.

When to Refer

All patients with diagnosed bulimia should be co-managed with a psychiatrist.

BULIMIA NERVOSA

ESSENTIALS OF DIAGNOSIS

- Uncontrolled episodes of binge eating at least twice weekly for 3 months.
- Recurrent inappropriate compensation to prevent weight gain such as self-induced vomiting, laxatives, diuretics, fasting, or excessive exercise.
- Overconcern with weight and body shape.

General Considerations

Bulimia nervosa is the episodic uncontrolled ingestion of large quantities of food followed by recurrent inappropriate compensatory behavior to prevent weight gain, such as self-induced vomiting, diuretic or cathartic use, strict dieting, or vigorous exercise.
THIAMINE (B₁) DEFICIENCY

**ESSENTIALS OF DIAGNOSIS**

- Most common in patients with chronic alcoholism.
- Early symptoms of anorexia, muscle cramps, paresthesias, irritability.
- Advanced syndromes of high-output heart failure ("wet beriberi"), peripheral nerve disorders, and Wernicke-Korsakoff syndrome ("dry beriberi").

**General Considerations**

Most thiamine deficiency in the United States is due to chronic alcoholism, with poor dietary intake of thiamine and impaired thiamine absorption, metabolism, and storage. Thiamine deficiency is also associated with malabsorption, dialysis, and other causes of chronic protein–calorie undernutrition. Thiamine deficiency can be precipitated in patients with marginal thiamine status given intravenous dextrose solutions.

**Clinical Findings**

Early manifestations of thiamine deficiency include anorexia, muscle cramps, paresthesias, and irritability. Advanced deficiency primarily affects the cardiovascular system ("wet beriberi") or the nervous system ("dry beriberi"). Wet beriberi occurs in thiamine deficiency accompanied by severe physical exertion and high carbohydrate intake. Dry beriberi occurs in thiamine deficiency accompanied by inactivity and low-calorie intake. 

**Wet beriberi** is characterized by marked peripheral vasodilation resulting in high-output heart failure with dyspnea, tachycardia, cardiomegaly, pulmonary edema, and peripheral edema with warm extremities mimicking cellulitis.

**Dry beriberi** involves both the peripheral and the central nervous systems. Peripheral nerve involvement is typically a symmetric motor and sensory neuropathy with pain, paresthesias, and loss of reflexes. The legs are affected more than the arms. Central nervous system involvement results in Wernicke-Korsakoff syndrome. Wernicke encephalopathy consists of nystagmus progressing to ophthalmoplegia, truncal ataxia, and confusion. Korsakoff syndrome includes amnesia, confabulation, and impaired learning.

**Diagnosis**

In most instances, the clinical response to empiric thiamine therapy is used to support a diagnosis of thiamine deficiency. The most commonly used biochemical tests measure thiamine concentration directly, while other assays measure erythrocyte transketolase activity and urinary thiamine excretion. Normal thiamine values typically range from 70 nmol/L to 180 nmol/L.

**Treatment**

Thiamine deficiency is treated with large parenteral doses of thiamine. Fifty to 100 mg/day is administered intravenously for the first few days, followed by daily oral doses of 5–10 mg/day. All patients should simultaneously receive therapeutic doses of other water-soluble vitamins. Although treatment results in complete resolution in half of patients (one-fourth immediately and another one-fourth over days), the other half obtain only partial resolution or no benefit.

**When to Refer**

Patients with signs of dry beriberi or Wernicke-Korsakoff syndrome should be referred to a neurologist. Patients with signs of wet beriberi should be referred to a cardiologist.

**THIAMINE TOXICITY**

There is no known toxicity of thiamine.

**RIBOFLAVIN (B₂) DEFICIENCY**

**Clinical Findings**

Riboflavin deficiency almost always occurs in combination with deficiencies of other vitamins. Dietary inadequacy, interactions with a variety of medications, alcoholism, and other causes of protein–calorie undernutrition are the most common causes of riboflavin deficiency.

Manifestations of riboflavin deficiency include cheilosis, angular stomatitis, glossitis, seborrheic dermatitis, weakness, corneal vascularization, and anemia.

**Diagnosis**

Riboflavin deficiency can be confirmed by measuring the riboflavin-dependent enzyme erythrocyte glutathione reductase. Activity coefficients greater than 1.2–1.4 are suggestive of riboflavin deficiency. Urinary riboflavin excretion and serum levels of plasma and red cell flavins can also be measured.

**Treatment**

Riboflavin deficiency is usually treated empirically when the diagnosis is suspected. It is easily treated with foods...
such as meat, fish, and dairy products or with oral preparations of the vitamin. Administration of 5–15 mg/day until clinical findings are resolved is usually adequate. Riboflavin can also be given parenterally, but it is poorly soluble in aqueous solutions.

**RIBOFLAVIN TOXICITY**

There is no known toxicity of riboflavin.

**NIACIN DEFICIENCY**

**General Considerations**

"Niacin" is a generic term for nicotinic acid and other derivatives with similar nutritional activity. Unlike most other vitamins, niacin can be synthesized from the amino acid tryptophan. Niacin is an essential component of the co-enzymes nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP), which are involved in many oxidation-reduction reactions. The major food sources of niacin are proteins containing tryptophan and numerous cereals, vegetables, and dairy products.

Historically, niacin deficiency occurred when corn, which is relatively deficient in both tryptophan and niacin, was the major source of calories. Currently, niacin deficiency is more commonly due to alcoholism and nutrient–drug interactions. Niacin deficiency can also occur in inborn errors of metabolism. Niacin in the form of nicotinic acid is used therapeutically for the treatment of hypercholesterolemia and hypertriglyceridemia. Niacinamide (the form of niacin usually used to treat niacin deficiency) does not exhibit the lipid-lowering effects of nicotinic acid.

**Clinical Findings**

As with other B vitamins, early manifestations of niacin deficiency are nonspecific—anorexia, weakness, irritability, mouth soreness, glossitis, stomatitis, and weight loss. More advanced deficiency results in the classic triad of pellagra: dermatitis, diarrhea, and dementia. The dermatitis is symmetric, involving sun-exposed areas. Skin lesions are dark, dry, and scaling. The dementia begins with insomnia, irritability, and apathy and progresses to confusion, memory loss, hallucinations, and psychosis. The diarrhea can be severe and may result in malabsorption due to atrophy of the intestinal villi. Advanced pellagra can result in death.

**Diagnosis**

In early deficiency, diagnosis requires a high index of suspicion and attempts at confirmation of niacin deficiency. Niacin metabolites, particularly N-methylnicotinamide, can be measured in the urine. Low levels suggest niacin deficiency but may also be found in patients with generalized under-nutrition. Serum and red cell levels of NAD and NADP are also low but are similarly nonspecific. In advanced cases, the diagnosis of pellagra can be made on clinical grounds.

**Treatment**

Niacin deficiency can be effectively treated with oral niacin, usually given as nicotinamide (10–150 mg/day).

**NIACIN TOXICITY**

At the high doses of niacin used to treat hyperlipidemia, side effects are common. These include cutaneous flushing (partially prevented by pretreatment with aspirin, 81–325 mg/day, and use of extended-release preparations) and gastric irritation. Elevation of liver enzymes, hyperglycemia, and gout are less common untoward effects.

**VITAMIN B₆ DEFICIENCY**

Vitamin B₆ deficiency most commonly occurs as a result of alcoholism or interactions with medications, especially isoniazid, cycloserine, penicillamine, and oral contraceptives. A number of inborn errors of metabolism and other pyridoxine-responsive syndromes, particularly pyridoxine-responsive anemia, are not clearly due to vitamin deficiency but commonly respond to high doses of the vitamin. Patients with common variable immunodeficiency may have concomitant vitamin B₆ deficiency.

**Clinical Findings**

Vitamin B₆ deficiency results in clinical symptoms similar to those of other B vitamin deficiencies, including mouth soreness, glossitis, cheilosis, weakness, and irritability. Severe deficiency can result in peripheral neuropathy, anemia, and seizures.

**Diagnosis**

The diagnosis of vitamin B₆ deficiency can be confirmed by measurement of pyridoxal phosphate in blood. Normal levels vary per laboratory but are typically greater than 5.0 ng/mL.

**Treatment**

Vitamin B₆ deficiency can be effectively treated with vitamin B₆ supplements (10–20 mg/day orally). Some patients taking medications that interfere with pyridoxine metabolism (such as isoniazid) may need doses as high as 50–100 mg/day orally to prevent vitamin B₆ deficiency. This is particularly true for patients who are more likely to have diets marginally adequate in vitamin B₆, such as older
patients, patients with alcoholism, or patients with lower socioeconomic status. Inborn errors of metabolism and pyridoxine-responsive syndromes often require doses up to 600 mg/day orally.

VITAMIN B<sub>6</sub> TOXICITY

A sensory neuropathy, at times irreversible, occurs in patients receiving large doses of vitamin B<sub>6</sub> (200–2000 mg/day).

VITAMIN B<sub>12</sub> & FOLATE

Vitamin B<sub>12</sub> (cobalamin) and folate are discussed in Chapter 13.

VITAMIN C (Ascorbic Acid) DEFICIENCY

Most cases of vitamin C deficiency seen in the United States are due to dietary inadequacy in patients with lower socioeconomic status, older patients, and patients with chronic alcoholism. Patients with chronic illnesses such as cancer and chronic kidney disease and individuals who smoke cigarettes are also at risk.

Clinical Findings

Early manifestations of vitamin C deficiency are nonspecific and include malaise and weakness. In more advanced stages, the typical features of scurvy develop. Manifestations include perifollicular hemorrhages, perifollicular hyperkeratotic papules, petechiae and purpura, splinter hemorrhages, bleeding gums, hemarthroses, and subperiosteal hemorrhages. Anemia is common, and wound healing is impaired. The late stages of scurvy are characterized by edema, oliguria, neuropathy, intracerebral hemorrhage, and death.

Diagnosis

The diagnosis of advanced scurvy can be made clinically on the basis of the skin lesions in the proper clinical situation. Atraumatic hemarthrosis is also highly suggestive. The diagnosis can be confirmed with decreased plasma ascorbic acid levels, typically below 0.2 mg/dL.

Treatment

Adult scurvy can be treated with ascorbic acid 300–1000 mg/day orally. Improvement typically occurs within days.

VITAMIN C TOXICITY

Very large doses of vitamin C can cause gastric irritation, flatulence, or diarrhea. Oxalate kidney stones are of theoretical concern because ascorbic acid is metabolized to oxalate, but stone formation has not been frequently reported. Vitamin C can also confound common diagnostic tests by causing false-negative results for some fecal occult blood tests and both false-negative and false-positive results for urine glucose.

VITAMIN A DEFICIENCY

Clinical Findings

Vitamin A deficiency is one of the most common vitamin deficiency syndromes, particularly in developing countries. In many such regions, it is the most common cause of blindness. In the United States, vitamin A deficiency is usually due to fat malabsorption syndromes or mineral oil laxative abuse and occurs most commonly in older adults and individuals of lower socioeconomic status.

Night blindness is the earliest symptom. Dryness of the conjunctiva (xerosis) and the development of small white patches on the conjunctiva (Bitot spots) are early signs. Ulceration and necrosis of the cornea (keratomalacia), perforation, endophthalmitis, and blindness are late manifestations. Xerosis and hyperkeratinization of the skin and loss of taste may also occur.

Diagnosis

Abnormalities of dark adaptation are strongly suggestive of vitamin A deficiency. Serum levels below the normal range of 30–65 mg/dL are commonly seen in advanced deficiency.

Treatment

Night blindness, poor wound healing, and other signs of early deficiency can be effectively treated with vitamin A 30,000 international units orally daily for 1 week. Advanced deficiency with corneal damage calls for administration of 20,000 international units/kg orally for at least 5 days. The potential antioxidant effects of beta-carotene can be achieved with supplements of 25,000–50,000 international units of beta-carotene.

VITAMIN A TOXICITY

Excess intake of beta-carotene (hypercarotenosis) results in staining of the skin a yellow-orange color but is otherwise benign. Skin changes are most marked on the palms and soles, while the scleras remain white, clearly distinguishing hypercarotenosis from jaundice.

Excessive vitamin A (hypervitaminosis A), on the other hand, can be quite toxic. Chronic toxicity usually occurs after ingestion of daily doses of over 50,000 international
VITAMIN D

Vitamin D is discussed in Chapter 26.

VITAMIN E DEFICIENCY

Clinical Findings

Clinical deficiency of vitamin E is most commonly due to severe malabsorption or abetalipoproteinemia in adults and chronic cholestatic liver disease, biliary atresia, or cystic fibrosis in children. Manifestations of deficiency include areflexia, disturbances of gait, decreased vibration and proprioception, and ophthalmoplegia.

Diagnosis

Plasma vitamin E levels can be measured; normal levels are 0.5–0.7 mg/dL or higher. Since vitamin E is normally transported in lipoproteins, the serum level should be interpreted in relation to circulating lipid levels.

Treatment

The optimum therapeutic dose of vitamin E has not been clearly defined. Large doses, often administered parenterally, can be used to improve the neurologic complications seen in abetalipoproteinemia and cholestatic liver disease. Several trials of supplemental vitamin E have shown slower cognitive decline in patients with Alzheimer disease. Vitamin E supplementation may also provide benefit in patients with nonalcoholic fatty liver disease.

VITAMIN E TOXICITY

Clinical trials have suggested an increase in all-cause mortality with high dose (400 international units/day or more) vitamin E supplements. Large doses of vitamin E can also increase the vitamin K requirement and can result in bleeding in patients taking oral anticoagulants.

VITAMIN K

Vitamin K is discussed in Chapter 14.

DIETS THAT ALTER CONSISTENCY

Clear Liquid Diet

This diet provides adequate water, 500–1000 kcal as simple sugar, and some electrolytes. It is fiber free and requires minimal digestion or intestinal motility.

A clear liquid diet is useful for patients with resolving postoperative ileus, acute gastroenteritis, partial intestinal obstruction, and as preparation for diagnostic gastrointestinal procedures. It is commonly used as the first diet for patients who have been taking nothing by mouth for long periods. Because of the low calorie and minimal protein content of the clear liquid diet, it is used only for short periods.

Full Liquid Diet

The full liquid diet provides adequate water and can be designed to provide adequate calories and protein. Vitamins and minerals—especially folic acid, iron, and vitamin B<sub>6</sub>—may be inadequate and should be provided in the form of supplements. Dairy products and soups are used to supplement clear liquids. Commercial oral supplements can also be incorporated into the diet or used alone.

This diet is low in residue and can be used in many instances instead of the clear liquid diet described above—especially in patients with difficulty chewing or swallowing, with partial obstructions, or in preparation for some diagnostic procedures. Full liquid diets are commonly used following clear liquid diets to advance diets in patients who have been taking nothing by mouth for long periods.
Soft Diets

Soft diets are designed for patients unable to chew or swallow hard or coarse food. Tender foods are used, and most raw fruits and vegetables as well as coarse breads and cereals are eliminated. Soft diets are commonly used to assist in progression from full liquid diets to regular diets in postoperative patients, in patients who are too weak or those whose dentition is too poor to handle a regular diet, in head and neck surgical patients, in patients with esophageal strictures, and in other patients who have difficulty with chewing or swallowing.

The soft diet can be designed to meet all nutritional requirements.

DIETS THAT RESTRICT NUTRIENTS

Diet can be designed to restrict (or eliminate) virtually any nutrient or food component. The most commonly used restricted diets are those that limit sodium, fat, carbohydrate, and protein. Other restrictive diets include gluten restriction in gluten enteropathy, potassium and phosphate reduction in chronic kidney disease, and various elimination diets for food allergies.

Sodium-Restricted Diets

Low-sodium diets are useful in the management of hypertension and in conditions in which sodium retention and edema are prominent features, particularly heart failure, chronic liver disease, and chronic kidney disease. Sodium restriction may be beneficial with or without diuretic therapy. When used in conjunction with diuretics, sodium restriction allows lower dosage of the diuretic medication and may prevent side effects. Potassium excretion, in particular, is directly related to distal renal tubule sodium delivery, and sodium restriction will decrease diuretic-related potassium losses.

Typical American diets contain 4–6 g (175–260 mEq) of sodium per day. A no-added-salt diet contains approximately 3 g (132 mEq) of sodium per day. Further restriction can be achieved with diets of 2 or 1 g of sodium per day. Diets with more severe restriction are poorly accepted by patients and are rarely used. Current Institute of Medicine guidelines recommend 2.3 g of sodium per day, which is approximately 1 teaspoon of salt.

Dietary sodium includes sodium naturally occurring in foods, sodium added during food processing, and sodium added by the consumer during cooking and at the table. About 80% of the current US dietary intake is from processed and pre-prepared foods. Diets designed for 2.3 g of sodium per day require elimination of most processed foods, added salt, and foods with particularly high sodium content. Many patients with mild hypertension will achieve significant reductions in blood pressure (approximately 5 mm Hg diastolic) with this degree of sodium restriction.

Diets allowing 1 g of sodium require further restriction of commonly eaten foods. Special “low-sodium” products are available to facilitate such diets. These diets are difficult for most people to follow and are generally reserved for hospitalized patients, most commonly those with severe liver disease and ascites.

Fat-Restricted Diets & Low-Saturated-Fat Diets

Traditional fat-restricted diets are useful in the treatment of fat malabsorption syndromes. Such diets will improve the symptoms of diarrhea with steatorrhea independently of the primary physiologic abnormality by limiting the quantity of fatty acids that reach the colon. The degree of fat restriction necessary to control symptoms must be individualized. Patients with severe malabsorption can be limited to 40–60 g of fat per day. Diets containing 60–80 g of fat per day can be designed for patients with less severe abnormalities.

Fat-restricted diets that specifically restrict saturated fats are the mainstay of dietary treatment of hyperlipidemia with elevated low-density lipoprotein cholesterol (see Chapter 28). Similar diets are often recommended for the prevention of coronary artery disease (see Chapter 10). The large Women’s Health Initiative Dietary Modification Trial, however, did not show any significant benefit of a low-fat diet on weight control or prevention of cardiovascular disease or cancer. In contrast, a study of Mediterranean diets, supplemented by nuts or extra-virgin olive oil, did demonstrate a reduction in cardiovascular events.

The aim of low-fat diets is to restrict total fat to less than 30% of calories and to achieve a normal body weight by caloric restriction and increased physical activity. Saturated fat is restricted to 7% of calories. Saturated fat and total fat can be restricted further, but studies suggest that more extreme restriction offers little further advantage in overall modification of serum lipids. Low-fat diets can be augmented with the addition of plant stanoles and sterols and with soluble dietary fiber to further reduce serum lipids.

Carbohydrate-Restricted Diets

Low carbohydrate diets restrict carbohydrate intake to at most 50–100 g/day (sometimes even lower). The consumption of foods that contain higher protein and fat with a lower carbohydrate content has been shown to promote satiety. Carbohydrate-restricted diets, including low glycemic index diets (see Chapter 27), can be particularly helpful for patients with type 2 diabetes and other forms of insulin resistance to reduce both blood sugar and weight. There have been several studies investigating the efficacy of low-fat versus low-carbohydrate diets for weight loss with no clear benefit of one versus the other.

Protein-Restricted Diets

Protein-restricted diets are most commonly used in patients with hepatic encephalopathy due to chronic liver disease and in patients with advanced chronic kidney disease to slow the progression of early disease and to decrease symptoms of uremia in more severe disease. Patients with selected inborn errors of amino acid metabolism and other abnormalities resulting in hyperammonemia also require restriction of protein or of specific amino acids.

Protein restriction is intended to limit the production of nitrogenous waste products. Energy intake must be adequate to facilitate the efficient use of dietary protein.
Proteins must be of high biologic value and be provided in sufficient quantity to meet minimal requirements. For most patients, the diet should contain at least 0.6 g/kg/day of protein. Patients with encephalopathy who do not respond to this degree of restriction are unlikely to respond to more severe restriction.

**DIETS THAT SUPPLEMENT NUTRIENTS**

**High-Fiber Diet**

Dietary fiber is a diverse group of plant constituents that is resistant to digestion by the human digestive tract. Guidelines suggest that men should eat 30–38 g/day and women 21–25 g/day. Typical US diets, however, contain about half of that amount. Epidemiologic evidence has suggested that populations consuming greater quantities of fiber have a lower incidence of certain gastrointestinal disorders, including diverticulitis and, in some studies, colon cancer and a lower risk of cardiovascular disease. A meta-analysis of 22 studies suggested that each 7 g of dietary fiber was associated with a 9% decrease in first cardiovascular event.

Diets high in dietary fiber (21–38 g/day) are also commonly used in the management of a variety of gastrointestinal disorders, particularly irritable bowel syndrome and recurrent diverticulitis. Diets high in fiber, particularly soluble fiber, may also be useful to reduce blood sugar in patients with diabetes and to reduce cholesterol levels in patients with hypercholesterolemia. Good sources of soluble fiber are oats, nuts, seeds, legumes, and most fruits. Foods with insoluble fiber include whole wheat, brown rice, other whole grains, and most vegetables. For some patients, the addition of psyllium seed (2 tsp per day) or natural bran (one-half cup per day) may be a useful adjunct to increase dietary fiber.

**High-Potassium Diets**

Potassium-supplemented diets are used most commonly to compensate for potassium losses caused by diuretics. Although potassium losses can be partially prevented by using lower doses of diuretics, concurrent sodium restriction, and potassium-sparing diuretics, some patients require additional potassium to prevent hypokalemia. High-potassium diets may also have a direct antihypertensive effect. Typical American diets contain about 3 g (80 mEq) of potassium per day. High-potassium diets commonly contain 4.5–7 g (120–180 mEq) of potassium per day.

Most fruits, vegetables, and their juices contain high concentrations of potassium. Supplemental potassium can also be provided with potassium-containing salt substitutes (up to 20 mEq in one-quarter tsp) or as potassium chloride in solution or capsules, but this is rarely necessary if the above measures are followed to prevent potassium losses and to supplement dietary potassium.

**High-Calcium Diets**

Additional intake of dietary calcium has been recommended for the prevention of postmenopausal osteoporosis, the prevention and treatment of hypertension, and the prevention of colon cancer. The Women’s Health Initiative, however, suggested that calcium and vitamin D supplementation did not prevent fractures or colon cancer. Observational studies have also suggested that calcium supplements, especially when taken without vitamin D, may be associated with an increased risk of coronary heart disease. The recommended dietary allowance for the total calcium intake (from food and supplements) in adults ranges from 1000 mg/day to 1200 mg/day. Average American daily intakes are approximately 700 mg/day.

Dairy products are the primary dietary sources of calcium in the United States. An 8-ounce glass of milk, for example, contains approximately 300 mg of calcium. Patients with lactose intolerance who cannot tolerate liquid dairy products may be able to use lactose-free milk, take supplemental lactase enzyme supplements, or tolerate non-lactose products such as yogurt and aged cheeses. Leafy green vegetables and canned fish with bones also contain high concentrations of calcium, although the latter is also high in sodium.

**NUTRITIONAL SUPPORT**

Nutritional support is the provision of nutrients to patients who cannot meet their nutritional requirements by eating standard diets. Nutrients may be delivered enterally, using oral nutritional supplements, nasogastric and nasoduodenal feeding tubes, and tube enterostomies, or parenterally, using lower doses of diuretics, concurrent sodium restriction, and potassium-sparing diuretics, some patients require additional potassium to prevent hypokalemia. High-potassium diets may also have a direct antihypertensive effect. Typical American diets contain about 3 g (80 mEq) of potassium per day. High-potassium diets commonly contain 4.5–7 g (120–180 mEq) of potassium per day.

Most fruits, vegetables, and their juices contain high concentrations of potassium. Supplemental potassium can also be provided with potassium-containing salt substitutes (up to 20 mEq in one-quarter tsp) or as potassium chloride in solution or capsules, but this is rarely necessary if the above measures are followed to prevent potassium losses and to supplement dietary potassium.

The precise indications for nutritional support remain controversial. Most authorities agree that nutritional support is indicated for at least four groups of adult patients: (1) those with inadequate bowel syndromes, (2) those with severe prolonged hypercatabolic states (eg, due to extensive burns, multiple trauma, mechanical ventilation), (3) those requiring...
NUTRITIONAL SUPPORT METHODS

Nutritional Support Methods

Selection of the most appropriate nutritional support method involves consideration of gastrointestinal function, the anticipated duration of nutritional support, and the ability of each method to meet the patient’s nutritional requirements. The method chosen should meet the patient’s nutritional needs with the lowest risk and lowest cost possible. For most patients, enteral feeding is safer and cheaper and offers significant physiologic advantages. An algorithm for selection of the most appropriate nutritional support method is presented in Figure 29–1.

Prior to initiating specialized enteral nutritional support, efforts should be made to supplement food intake. Attention to patient food preferences, timing of meals in relation to diagnostic procedures and required interventions, and the use of foods brought to the hospital by family and friends can often increase oral intake. Patients unable to eat enough at regular mealtimes to meet nutritional requirements can be given oral supplements as snacks or to replace low-calorie beverages. Oral supplements of differing nutritional composition are available for the purpose of individualizing the diet in accordance with specific clinical requirements. Fiber and lactose content, caloric density, protein level, amino acid profiles, vitamin K, and calcium can all be modified as necessary.

Patients unable to take adequate oral nutrients who have functioning gastrointestinal tracts and who meet the criteria for nutritional support are candidates for liquid artificial nutrition ("tube feedings"). Small-bore feeding tubes are placed via the nose into the stomach or duodenum. Patients able to sit up in bed who can protect their airways can be fed into the stomach. Because of the increased risk of aspiration, patients who cannot adequately protect their airways should be fed nasoduodenally (though, as noted below, this may not prevent all aspirations, particularly if the pylorus is patent). Feeding tubes can usually be passed into the duodenum by leaving an extra length of tubing in the stomach and placing the patient in the right decubitus position. Metoclopramide, 10 mg intravenously, can be given 20 minutes prior to insertion and continued every 6 hours thereafter to facilitate passage through the pylorus. Occasionally, patients will require fluoroscopic or endoscopic guidance to insert the tube distal to the pylorus. Placement of nasogastric and, particularly, nasoduodenal tubes should be confirmed radiographically before delivery of feeding solutions.

Liquid artificial nutrition can also be accomplished by placing tubes directly into the gastrointestinal tract using tube enterostomies. Most tube enterostomies are placed in patients who require long-term enteral nutritional support. Gastrostomies have the advantage of allowing bolus feedings, while jejunostomies require continuous infusions. Gastrostomies—like nasogastric feeding—should be used only in patients at low risk for aspiration. Gastrostomies can also be placed percutaneously with the aid of endoscopy. These tubes can then be advanced into the jejunum. Tube enterostomies can also be placed surgically.

Patients who require nutritional support but whose gastrointestinal tracts are nonfunctional should receive parenteral nutritional support. Most patients receive parenteral feedings via a central vein—most commonly the subclavian vein. Peripheral veins can be used in some patients, but this method involves consideration of gastrointestinal function, the anticipated duration of nutritional support, and the ability of each method to meet the patient’s nutritional requirements. The method chosen should meet the patient’s nutritional needs with the lowest risk and lowest cost possible. For most patients, enteral feeding is safer and cheaper and offers significant physiologic advantages. An algorithm for selection of the most appropriate nutritional support method is presented in Figure 29–1.

Prior to initiating specialized enteral nutritional support, efforts should be made to supplement food intake. Attention to patient food preferences, timing of meals in relation to diagnostic procedures and required interventions, and the use of foods brought to the hospital by family and friends can often increase oral intake. Patients unable to eat enough at regular mealtimes to meet nutritional requirements can be given oral supplements as snacks or to replace low-calorie beverages. Oral supplements of differing nutritional composition are available for the purpose of individualizing the diet in accordance with specific clinical requirements. Fiber and lactose content, caloric density, protein level, amino acid profiles, vitamin K, and calcium can all be modified as necessary.

Patients unable to take adequate oral nutrients who have functioning gastrointestinal tracts and who meet the criteria for nutritional support are candidates for liquid artificial nutrition ("tube feedings"). Small-bore feeding tubes are placed via the nose into the stomach or duodenum. Patients able to sit up in bed who can protect their airways can be fed into the stomach. Because of the increased risk of aspiration, patients who cannot adequately protect their airways should be fed nasoduodenally (though, as noted below, this may not prevent all aspirations, particularly if the pylorus is patent). Occasionally, patients will require fluoroscopic or endoscopic guidance to insert the tube distal to the pylorus. Placement of nasogastric and, particularly, nasoduodenal tubes should be confirmed radiographically before delivery of feeding solutions.

Liquid artificial nutrition can also be accomplished by placing tubes directly into the gastrointestinal tract using tube enterostomies. Most tube enterostomies are placed in patients who require long-term enteral nutritional support. Gastrostomies have the advantage of allowing bolus feedings, while jejunostomies require continuous infusions. Gastrostomies—like nasogastric feeding—should be used only in patients at low risk for aspiration. Gastrostomies can also be placed percutaneously with the aid of endoscopy. These tubes can then be advanced into the jejunum. Tube enterostomies can also be placed surgically.

Patients who require nutritional support but whose gastrointestinal tracts are nonfunctional should receive parenteral nutritional support. Most patients receive parenteral feedings via a central vein—most commonly the subclavian vein. Peripheral veins can be used in some patients, but this

![Figure 29–1. Nutritional support method decision tree.](image-url)
is rarely tolerated for more than a few weeks because of the high osmolality of parenteral solutions.

**Peripheral vein nutritional support** is most commonly used in patients with nonfunctioning gastrointestinal tracts who require immediate support but whose clinical status is expected to improve within 1–2 weeks, allowing enteral feeding. Peripheral vein nutritional support is administered via standard intravenous lines. Solutions should always include lipid and dextrose in combination with amino acids to provide adequate nonprotein calories. Serious side effects are infrequent, but there is a high incidence of phlebitis and infiltration of intravenous lines.

**Central vein nutritional support** is delivered via intravenous catheters placed percutaneously using aseptic technique. Proper placement in the superior vena cava is documented radiographically before the solution is infused. Catheters must be carefully maintained by experienced nursing personnel and used solely for nutritional support to prevent infection and other catheter-related complications.

### NUTRITIONAL REQUIREMENTS

Each patient’s nutritional requirements should be determined independently of the method of nutritional support. In most situations, solutions of equal nutrient value can be designed for delivery via enteral and parenteral routes, but differences in absorption must be considered. A complete nutritional support solution must contain water, energy, amino acids, electrolytes, vitamins, minerals, and essential fatty acids.

#### Water

For most patients, water requirements can be calculated by allowing 1500 mL for the first 20 kg of body weight plus 20 mL for every kilogram over 20. Additional losses should be replaced as they occur. For average-sized adult patients, fluid needs are about 30–35 mL/kg, or approximately 1 mL/kcal of energy required.

#### Energy

Energy requirements can be estimated by one of three methods: (1) by using standard equations to calculate BEE plus additional calories for activity and illness, (2) by applying a simple calculation based on calories per kilogram of body weight, or (3) by measuring energy expenditure with indirect calorimetry.

BEE can be estimated by the **Harris–Benedict equation**: for men, 

$$\text{BEE} = 666 + (13.7 \times \text{weight in kg}) + (5 \times \text{height in cm}) - (6.8 \times \text{age in years})$$

For women, 

$$\text{BEE} = 655 + (9.5 \times \text{weight in kg}) + (1.8 \times \text{height in cm}) - (4.7 \times \text{age in years})$$

For undernourished patients, actual body weight should be used; for patients with obesity, ideal body weight should be used. For most patients, an additional 20–50% of BEE is administered as nonprotein calories to accommodate energy expenditures during activity or relating to the illness. Occasional patients are noted to have energy expenditures greater than 150% of BEE.

Energy requirements can be estimated also by multiplying actual body weight in kilograms (for patients with obesity, ideal body weight) by 30–35 kcal.

Both of these methods provide imprecise estimates of actual energy expenditures, especially for the markedly underweight, overweight, and critically ill patient. Studies using indirect calorimetry have demonstrated that as many as 30–40% of patients will have measured expenditures 10% above or below estimated values. For a more accurate determination of energy expenditure, indirect calorimetry can be used.

#### Protein

Protein and energy requirements are closely related. If adequate calories are provided, most patients can be given 0.8–1.2 g of protein per kilogram per day. Patients undergoing moderate to severe stress should receive up to 1.5 g/kg/day. As in the case of energy requirements, actual weights should be used for normal and underweight patients and ideal weights for patients with significant obesity.

Patients who are receiving protein without adequate calories will catabolize protein for energy rather than utilizing it for protein synthesis. Thus, when energy intake is low, excess protein is needed for nitrogen balance. If both energy and protein intakes are low, extra energy will have a more significant positive effect on nitrogen balance than extra protein.

#### Electrolytes & Minerals

Requirements for sodium, potassium, and chloride vary widely. Most patients require 45–145 mEq/day of each. The actual requirement in individual patients will depend on the patient’s cardiovascular, renal, endocrine, and gastrointestinal status as well as measurements of serum concentration.

Patients receiving enteral nutritional support should receive adequate vitamins and minerals according to the recommended daily allowances. Most premixed enteral solutions provide adequate vitamins and minerals as long as adequate calories are administered.

Patients receiving parenteral nutritional support require smaller amounts of minerals: calcium, 10–15 mEq/day; phosphorus, 15–20 mEq per 1000 nonprotein calories; and magnesium, 16–24 mEq/day. Most patients receiving nutritional support do not require supplemental iron because body stores are adequate. Iron nutrition should be monitored closely by following the hemoglobin concentration, mean corpuscular volume, and iron studies. Parenteral administration of iron is associated with a number of adverse effects and should be reserved for iron-deficient patients unable to take oral iron.

Patients receiving parenteral nutritional support should be given the trace elements zinc (about 5 mg/day) and copper (about 2 mg/day). Patients with diarrhea will require additional zinc to replace fecal losses. Additional trace elements—especially chromium, manganese, and selenium—are provided to patients receiving long-term parenteral nutrition.

Parenteral vitamins are provided daily. Standardized multivitamin solutions are currently available to provide adequate quantities of vitamins A, B₁₂, C, D, E, thiamine, riboflavin, niacin, pantothenic acid, pyridoxine, folic acid,
and biotin. Vitamin K is not given routinely but administered when the prothrombin time becomes abnormal.

**Essential Fatty Acids**

Patients receiving nutritional support should be given 2–4% of their total calories as linoleic acid to prevent essential fatty acid deficiency. Most prepared enteral solutions contain adequate linoleic acid. Patients receiving parenteral nutrition should be given at least 250 mL of a 20% intravenous fat (emulsified soybean or safflower oil) about two or three times a week. Intravenous fat can also be used as an energy source in place of dextrose.

## ENTEGRAL NUTRITIONAL SUPPORT SOLUTIONS

Most patients who require enteral nutritional support can be given commercially prepared enteral solutions (Table 29–3). Nutritionally complete solutions have been designed to provide adequate proportions of water, energy, protein, and micronutrients. Nutritionally incomplete solutions are also available to provide specific macronutrients (eg, protein, carbohydrate, and fat) to supplement complete solutions for patients with unusual requirements or to design solutions that are not available commercially.

Nutritionally complete solutions are characterized as follows: (1) by osmolality (isotonic or hypertonic), (2) by lactose content (present or absent), (3) by the molecular form of the protein component (intact proteins; peptides or amino acids), (4) by the quantity of protein and calories provided, and (5) by fiber content (present or absent). For most patients, isotonic solutions containing no lactose or fiber are preferable. Such solutions generally contain moderate amounts of fat and intact protein. Most commercial isotonic solutions contain 1000 kcal and about 37–45 g of protein per liter.

Solutions containing hydrolyzed proteins or crystalline amino acids and with no significant fat content are called elemental solutions, since macronutrients are provided in their most “elemental” form. These solutions have been designed for patients with malabsorption, particularly pancreatic insufficiency and limited fat absorption. Elemental diets are extremely hypertonic and often result in more severe diarrhea. Their use should be limited to patients who cannot tolerate isotonic solutions.

Although formulas have been designed for specific clinical situations—solutions containing primarily essential amino acids (for advanced chronic kidney disease), medium-chain triglycerides (for fat malabsorption), more fat (for respiratory failure and CO2 retention), and more branched-chain amino acids (for hepatic encephalopathy and severe trauma)—they have not been shown to be superior to standard formulas for most patients.

Enteral solutions should be administered via continuous infusion, preferably with an infusion pump. Isotonic feedings should be started at full strength at about 25–33% of the estimated final infusion rate. Feedings can be advanced by similar amounts every 12 hours as tolerated. Hypertonic feedings should be started at half strength. The strength and the rate can then be advanced every 6 hours as tolerated.

## COMPLICATIONS OF ENTERAL NUTRITIONAL SUPPORT

Minor complications of enteral nutritional support occur in 10–15% of patients. Gastrointestinal complications include diarrhea (most common), inadequate gastric emptying, emesis, esophagitis, and occasionally gastrointestinal bleeding. Diarrhea associated with enteral nutritional support may be due to intolerance to the osmotic load or to one of the macronutrients (eg, fat, lactose) in the solution. Patients being fed in this way may also have diarrhea from other causes (as side effects of antibiotics or other drugs, associated with infection, etc), and these possibilities should always be investigated in appropriate circumstances.

Mechanical complications of enteral nutritional support are potentially the most serious. Of particular importance is aspiration. All patients receiving nasogastric tube feedings are at risk for this life-threatening complication. Limiting nasogastric feedings to those patients who can adequately protect their airway and careful monitoring of patients being fed by tube should limit these serious complications to 1–2% of cases. Minor mechanical complications are common and include tube obstruction and dislodgment.
Metabolic complications during enteral nutritional support are common but are easily managed in most cases. The most important problem is hypernatremic dehydration, most commonly seen in elderly patients given excessive protein intake who are unable to respond to thirst. Abnormalities of potassium, glucose, CO₂ production, and acid–base balance may also occur.

PARENTERAL NUTRITIONAL SUPPORT SOLUTIONS

Parenteral nutritional support solutions can be designed to deliver adequate nutrients to most patients. The basic parenteral solution is composed of dextrose, amino acids, and water. Electrolytes, minerals, trace elements, vitamins, and medications can also be added. Most commercial solutions contain the monohydrate form of dextrose that provides 3.4 kcal/g. Crystalline amino acids are available in a variety of concentrations, so that a broad range of solutions can be made up that will contain specific amounts of dextrose and amino acids as required.

Typical solutions for central vein nutritional support contain 25–35% dextrose and 2.75–6% amino acids depending upon the patient's estimated nutrient and water requirements. These solutions typically have osmolalities in excess of 1800 mOsm/L and require infusion into a central vein. A typical formula for patients without organ failure is shown in Table 29–4.

Solutions with lower osmolalities can also be designed for infusion into peripheral veins. Typical solutions for peripheral infusion contain 5–10% dextrose and 2.75–4.25% amino acids. These solutions have osmolalities between 800 and 1200 mOsm/L and result in a high incidence of thrombophlebitis and line infiltration. These solutions will provide adequate protein for most patients but inadequate energy. Additional energy must be provided in the form of emulsified soybean or safflower oil. Such intravenous fat solutions are isosmotic and well tolerated by peripheral veins.

Table 29–4. Typical parenteral nutrition solution (for stable patients without organ failure).

Typical patients are given 200–500 mL of a 20% solution each day. As much as 60% of total calories can be administered in this manner.

Intravenous fat can also be provided to patients receiving central vein nutritional support. In this instance, dextrose concentrations should be decreased to provide a fixed concentration of energy. Intravenous fat has been shown to be equivalent to intravenous dextrose in providing energy to spare protein. Intravenous fat is associated with less glucose intolerance, less production of carbon dioxide, and less fatty infiltration of the liver and has been increasingly utilized in patients with hyperglycemia, respiratory failure, and liver disease. Intravenous fat has also been increasingly used in patients with large estimated energy requirements. The maximum glucose utilization rate is approximately 5–7 mg/min/kg. Patients who require additional calories can be given them as fat to prevent excess administration of dextrose. Intravenous fat can also be used to prevent essential fatty acid deficiency. The optimal ratio of carbohydrate and fat in parenteral nutritional support has not been determined.

Infusion of parenteral solutions should be started slowly to prevent hyperglycemia and other metabolic complications. Typical solutions are given initially at a rate of 50 mL/h and advanced by about the same amount every 24 hours until the desired final rate is reached.

**Common Causes**

- High chloride administration
- Severe, undetected hyperglycemia
- Decrease chloride concentration
- Insulin, hydration, potassium
- Diarrhea, small bowel fistulas
- Oral fat

**Possible Solutions**

- Increase concentration
- Lipid trapping in hepatocytes, fatty liver
- Decrease amino acid concentration
- Excessive protein administration
- Decrease dextrose infusion

**Solutions**

- Biliary stasis
- Increase concentration
- Biliary fistulas

Patients with positive nitrogen balances can be continued on their current regimens; patients with negative balances should receive moderate increases in calorie and protein intake and then be reassessed. Monitoring for metabolic complications includes daily measurements of electrolytes; serum glucose, phosphorus, magnesium, calcium, and creatinine; and BUN until the patient is stabilized. Once the patient is stabilized, electrolytes, phosphorus, calcium, magnesium, and glucose should be obtained at least twice weekly. Red blood cell folate, zinc, and copper should be checked at least once a month.

COMMON PROBLEMS IN INFECTIOUS DISEASES

FEVER OF UNKNOWN ORIGIN (FUO)

ESSENTIALS OF DIAGNOSIS

- Illness of at least 3 weeks in duration.
- Fever over 38.3°C on several occasions.
- Diagnosis has not been made after three outpatient visits or 3 days of hospitalization.

General Considerations

The intervals specified in the criteria for the diagnosis of FUO are arbitrary ones intended to exclude patients with protracted but self-limited viral illnesses and to allow time for the usual radiographic, serologic, and cultural studies to be performed. The criteria for FUO are met when a diagnosis has not been made after three outpatient visits or 3 days of hospitalization.

The recently added categories of FUO include complications of current health care scenarios: (1) Hospital-associated FUO refers to the hospitalized patient with fever of 38.3°C or higher on several occasions, due to a process not present or incubating at the time of admission, in whom initial cultures are negative and the diagnosis remains unknown after 3 days of investigation (see Health Care–Associated Infections below); (2) neutropenic FUO includes patients with fever of 38.3°C or higher on several occasions with less than 500 neutrophils per microliter in whom initial cultures are negative and the diagnosis remains uncertain after 3 days (see Health Care–Associated Infections below); (3) HIV-associated FUO pertains to HIV-positive patients with fever of 38.3°C or higher who have been febrile for 4 weeks or more as an outpatient or 3 days as an inpatient, in whom the diagnosis remains uncertain after 3 days of investigation with at least 2 days for cultures to incubate (see Chapter 31). Although not usually considered separately, FUO in solid organ transplant recipients and FUO in the returning traveler are common scenarios, each with a unique differential diagnosis, and are also discussed in this chapter.

For a general discussion of fever, see the section on fever and hyperthermia in Chapter 2.

A. Common Causes

Most cases represent unusual manifestations of common diseases and not rare or exotic diseases—e.g., tuberculosis, endocarditis, gallbladder disease, and HIV (primary infection or opportunistic infection) are more common causes of FUO than Whipple disease or familial Mediterranean fever.

B. Age of Patient

In adults, infections (25–40% of cases) and cancer (25–40% of cases) account for the majority of FUOs. In children, infections are the most common cause of FUO (30–50% of cases) and cancer a rare cause (5–10% of cases). Autoimmune disorders occur with equal frequency in adults and children (10–20% of cases), but the diseases differ. Juvenile rheuomatoid arthritis is particularly common in children, whereas systemic lupus erythematosus, granulomatosis with polyangiitis (formerly Wegener granulomatosis), and polyarteritis nodosa are more common in adults. Still disease, giant cell arteritis, and polymyalgia rheumatica occur exclusively in adults. In adults over 65 years of age, multisystem immune-mediated diseases such as temporal arteritis, polymyalgia rheumatica, sarcoidosis, rheumatoid arthritis, and granulomatosis with polyangiitis account for 25–30% of all FUOs.

C. Duration of Fever

The cause of FUO changes dramatically in patients who have been febrile for 6 months or longer. Infection, cancer, and autoimmune disorders combined account for only 20% of FUOs in these patients. Instead, other entities such as granulomatous diseases (granulomatosis hepatitis, Crohn disease, ulcerative colitis) and factitious fever become important causes. One-fourth of patients who say they have been febrile for 6 months or longer actually have no true fever or underlying disease. Instead, the usual
normal circadian variation in temperature (temperature 0.5–1°C higher in the afternoon than in the morning) is interpreted as abnormal. Patients with episodic or recurrent fever (ie, those who meet the criteria for FUO but have fever-free periods of 2 weeks or longer) are similar to those with prolonged fever. Infection, malignancy, and autoimmune disorders account for only 20–25% of such fevers, whereas various miscellaneous diseases (Crohn disease, familial Mediterranean fever, allergic alveolitis) account for another 25%. Approximately 50% of cases remain undiagnosed but have a benign course with eventual resolution of symptoms.

D. Immunologic Status

In the neutropenic patient, fungal infections and occult bacterial infections are important causes of FUO. In the patient taking immunosuppressive medications (particularly organ transplant patients), cytomegalovirus (CMV) infections are a frequent cause of fever, as are fungal infections, nocardiosis, Pneumocystis jirovecii pneumonia, and mycobacterial infections.

E. Classification of Causes of FUO

Most patients with FUO will fit into one of five categories.

1. Infection—Both systemic and localized infections can cause FUO. Tuberculosis and endocarditis are the most common systemic infections associated with FUO, but mycoses, viral diseases (particularly infection with Epstein-Barr virus and CMV), toxoplasmosis, brucellosis, Q fever, cat-scratch disease, salmonellosis, malaria, and many other less common infections have been implicated. Primary infection with HIV or opportunistic infections associated with AIDS—particularly mycobacterial infections—can also present as FUO. The most common form of localized infection causing FUO is an occult abscess. Liver, spleen, kidney, brain, and bone abscesses may be difficult to detect. A collection of pus may form in the peritoneal cavity or in the subdiaphragmatic, subhepatic, paracolic, or other areas. Cholangitis, osteomyelitis, urinary tract infection, dental abscess, or paranasal sinusitis may cause prolonged fever.

2. Neoplasms—Many cancers can present as FUO. The most common are lymphoma (both Hodgkin and non-Hodgkin) and leukemia. Posttransplant lymphoproliferative disorders may also present with fever. Other diseases of lymph nodes, such as angioimmunoblastic lymphoma and Castleman disease, can also cause FUO. Primary and metastatic tumors of the liver are frequently associated with fever, as are renal cell carcinomas. Atrial myxoma is an often forgotten neoplasm that can result in fever. Chronic lymphocytic leukemia and multiple myeloma are rarely associated with fever, and the presence of fever in patients with these diseases should prompt a search for infection.

3. Autoimmune disorders—Still disease, systemic lupus erythematosus, cryoglobulinemia, and polyarteritis nodosa are the most common causes of autoimmune-associated FUO. Giant cell arteritis and polymyalgia rheumatica are seen almost exclusively in patients over 50 years of age and are nearly always associated with an elevated erythrocyte sedimentation rate (greater than 40 mm/h).

4. Miscellaneous causes—Many other conditions have been associated with FUO but less commonly than the foregoing types of illness. Examples include thyroiditis, sarcoidosis, Whipple disease, familial Mediterranean fever, recurrent pulmonary emboli, alcoholic hepatitis, drug fever, and factitious fever.

5. Undiagnosed FUO—Despite extensive evaluation, the diagnosis remains elusive in 15% or more of patients. Of these patients, the fever abates spontaneously in about 75% with no diagnosis; in the remainder, more classic manifestations of the underlying disease appear over time.

Clinical Findings

Because the evaluation of a patient with FUO is costly and time-consuming, it is imperative to first document the presence of fever. This is done by observing the patient while the temperature is being taken to ascertain that fever is not factitious (self-induced). Associated findings that accompany fever include tachycardia, chills, and piloerection. A thorough history—including family, occupational, social (sexual practices, use of injection drugs), dietary ( unpasteurized products, raw meat), exposures (animals, chemicals), and travel—may give clues to the diagnosis. Repeated physical examination may reveal subtle, evanescent clinical findings essential to diagnosis.

A. Laboratory Tests

In addition to routine laboratory studies, blood cultures should always be obtained, preferably when the patient has not taken antibiotics for several days, and should be held by the laboratory for 2 weeks to detect slow-growing organisms. Cultures on special media are requested if Legionella, Bartonella, or nutritionally deficient streptococci are possible pathogens. “Screening tests” with immunologic or microbiologic serologies (“febrile agglutinins”) are of low yield and should not be done. If the history or physical examination suggests a specific diagnosis, specific serologic tests with an associated fourfold rise or fall in titer may be useful. Because infection is the most common cause of FUO, other body fluids are usually cultured, ie, urine, sputum, stool, cerebrospinal fluid, and morning gastric aspirates (if one suspects tuberculosis). Direct examination of blood smears may establish a diagnosis of malaria or relapsing fever (Borrelia).

B. Imaging

All patients with FUO should have a chest radiograph. Studies such as sinus CT, upper gastrointestinal series with small bowel follow-through, barium enema, proctosigmoidoscopy, and evaluation of gallbladder function are reserved for patients who have symptoms, signs, or a history that suggest disease in these body regions. CT scan of the abdomen and pelvis is also frequently performed and is particularly useful for looking at the liver, spleen, and retroperitoneum. When the CT scan is abnormal, the findings often lead to a specific diagnosis. A normal CT scan is
not quite as useful; more invasive procedures such as biopsy or exploratory laparotomy may be needed. The role of MRI in the investigation of FUO has not been evaluated. In general, however, MRI is better than CT for detecting lesions of the nervous system and is useful in diagnosing various vasculitides. Ultrasound is sensitive for detecting lesions of the kidney, pancreas, and biliary tree. Echocardiography should be used if one is considering endocarditis or atrial myxoma. Transesophageal echocardiography is more sensitive than surface echocardiography for detecting valvular lesions, but even a negative transesophageal study does not exclude endocarditis (10% false-negative rate). The usefulness of radionuclide studies in diagnosing FUO is variable. Some experts use positron emission tomography (PET) in conjunction with CT scans early in the investigation of FUO. However, more studies are needed before this practice can be more fully integrated into clinical practice. Theoretically, a gallium or PET scan would be more helpful than an indium-labeled white blood cell scan because gallium and fluorodeoxyglucose may be useful for detecting infection, inflammation, and neoplasm whereas the indium scan is useful only for detecting infection. Indium-labeled immunoglobulin may prove to be useful in detecting infection and neoplasm and can be used in the neutropenic patient. It is not sensitive for lesions of the liver, kidney, and heart because of high background activity. In general, radionuclide scans are plagued by high rates of false-positive and false-negative results that are not useful when used as screening tests and, if done at all, are limited to those patients whose history or examination suggests local inflammation or infection.

C. Biopsy

Invasive procedures are often required for diagnosis. Any abnormal finding should be aggressively evaluated. Headache calls for lumbar puncture to rule out meningitis; skin rash should be biopsied for cutaneous manifestations of collagen vascular disease or infection; and enlarged lymph nodes should be aspirated or biopsied for neoplasm and sent for culture. Bone marrow aspiration with biopsy is a relatively low-yield procedure (15–25%; except in HIV-positive patients, in whom mycobacterial infection is a common cause of FUO), but the risk is low and the procedure should be done if other less invasive tests have not yielded a diagnosis, particularly in persons with hematologic abnormalities. Liver biopsy will yield a specific diagnosis in 10–15% of patients with FUO and should be considered in any patient with abnormal liver tests even if the liver is normal in size. CT scanning and MRI have decreased the need for exploratory laparotomy; however, surgical visualization and biopsies should be considered when there is continued deterioration or lack of diagnosis.

Treatment

Although an empiric course of antimicrobials is sometimes considered for FUO, it is rarely helpful and may impact infectious diseases diagnoses (eg, by reducing the sensitivity of blood cultures).

When to Refer

- Any patient with FUO and progressive weight loss and other constitutional signs.
- Any immunocompromised patient (eg, transplant recipients and HIV-infected patients).
- Infectious diseases specialists may also be able to coordinate and interpret specialized testing (eg, Q fever serologies) with outside agencies, such as the US Centers for Disease Control and Prevention.

When to Admit

- Any patient who is rapidly declining with weight loss where hospital admission may expedite workup.
- If FUO is present in immunocompromised patients, such as those who are neutropenic from recent chemotherapy or those who have undergone transplantation (particularly in the previous 6 months).

Mulders-Manders CM et al. Long-term prognosis, treatment, and outcome of patients with fever of unknown origin in whom no diagnosis was made despite extensive investigation: a questionnaire based study. Medicine (Baltimore). 2018 Jun;97(23):e11241. [PMID: 29920554]
be important pathogens in the compromised patient (e.g., *Staphylococcus epidermidis*, *Corynebacterium jeikeium*, *Propionibacterium acnes*, *Bacillus* species). Therefore, culture results must be interpreted with caution, and isolates should not be disregarded as solely contaminants. Although the type of immunodeficiency is associated with specific infectious disease syndromes, any pathogen can cause infection in any immunosuppressed patient at any time. Thus, a systematic evaluation is required to identify a specific organism.

### A. Impaired Humoral Immunity

Defects in humoral immunity are often congenital, although hypogammaglobulinemia can occur in multiple myeloma, chronic lymphocytic leukemia, small lymphocyte lymphoma, and in patients who have undergone splenectomy. Patients with ineffective humoral immunity lack opsonizing antibodies and are at particular risk for infection with encapsulated organisms, such as *Haemophilus influenzae*, *Neisseria meningitidis*, and *Streptococcus pneumoniae*. Although rituximab is normally thought of as being linked to impaired cellular immunity, it has been associated with the development of *Pneumocystis jirovecii* infection and progressive multifocal leukoencephalopathy (PML) as well as with hepatitis B reactivation.

### B. Granulocytopenia (Neutropenia)

Granulocytopenia is common following hematopoietic cell transplantation (“stem cell transplantation”) and among patients with solid tumors—as a result of myelosuppressive chemotherapy—and in acute leukemias. The risk of infection begins to increase when the absolute granulocyte count falls below 1000/mcL, with a dramatic increase in frequency and severity when the granulocyte count falls below 100/mcL. The infection risk is also increased with a rapid rate of decline of neutrophils and with a prolonged period of neutropenia. The granulocytopenic patient is particularly susceptible to infections with gram-negative enteric organisms, *Pseudomonas*, gram-positive cocci (particularly *Staphylococcus aureus*, *S. epidermidis*, and viridans streptococci), *Candida*, *Aspergillus*, and other fungi that have recently emerged as pathogens such as *Trichosporon*, *Scedosporium*, *Fusarium*, and the mucormycoses.

### C. Impaired Cellular Immunity

Patients with cellular immune deficiency encompass a large and heterogeneous group, including patients with HIV infection (see Chapter 31); patients with lymphoreticular malignancies, such as Hodgkin disease; and patients receiving immunosuppressive medications, such as corticosteroids, cyclosporine, tacrolimus, and other cytotoxic medications. This latter group—those who are immunosuppressed as a result of medications—includes patients who have undergone solid organ transplantation, many patients receiving therapy for solid tumors, and patients receiving prolonged high-dose corticosteroid treatment (e.g., for asthma, temporal arteritis, systemic lupus erythematosus). Patients taking tumor necrosis factor (TNF) inhibitors, such as etanercept and infliximab, are also included in this category. Patients with cellular immune dysfunction are susceptible to infections by a large number of organisms, particularly ones that replicate intracellularly. Examples include bacteria, such as *Listeria*, *Legionella*, *Salmonella*, and *Mycobacterium*; viruses, such as herpes simplex, varicella, and CMV; fungi, such as *Cryptococcus*, *Coccidioides*, *Histoplasma*, and *Pneumocystis*; and protozoa, such as *Toxoplasma*.

### D. Hematopoietic Cell Transplant Recipients

The length of time it takes for complications to occur in hematopoietic cell transplant recipients can be helpful in determining the etiologic agent. In the early (preengraftment) posttransplant period (days 1–21), patients will become severely neutropenic for 7–21 days. Patients are at risk for gram-positive (particularly catheter-related) and gram-negative bacterial infections, as well as herpes simplex virus, respiratory syncytial virus, and fungal infections. In contrast to solid organ transplant recipients, the source of fever is unknown in 60–70% of hematopoietic cell transplant patients. Between 3 weeks and 3 months posttransplant, infections with CMV, adenovirus, *Aspergillus*, and *Candida* are most common. *P. jiroveci* pneumonia is possible, particularly in patients who receive additional immunosuppressive therapy for treatment of graft-versus-host disease. Patients continue to be at risk for infectious complications beyond 3 months following transplantation, particularly those who have received allogeneic transplantation and those who are taking immunosuppressive therapy for chronic graft-versus-host disease. Varicella-zoster is common, and *Aspergillus* and CMV infections are increasingly seen in this period as well.

### E. Solid Organ Transplant Recipients

The length of time it takes for infection to occur following solid organ transplantation can also be helpful in determining the infectious origin. Immediate postoperative infections often involve the transplanted organ. Following lung transplantation, pneumonia and mediastinitis are particularly common; following liver transplantation, intra-abdominal abscess, cholangitis, and peritonitis may be seen; after kidney transplantation, urinary tract infections, perinephric abscesses, and infected lymphoceles can occur. Most infections that occur in the first 2–4 weeks posttransplant are related to the operative procedure and to hospitalization itself (wound infection, intravenous catheter infection, urinary tract infection from a Foley catheter) or are related to the transplanted organ. In rare instances, donor-derived infections (e.g., West Nile virus, tuberculosis) may present during this time period. Compensated organ transplants obtained abroad through “medical tourism” can introduce additional risk of infections, which vary by country and by transplant setting. Infections that occur between the first and sixth months are often related to immunosuppression. During this period, reactivation of viruses, such as herpes simplex, varicella-zoster, and CMV is quite common. Opportunistic infections with fungi (e.g., *Candida*, *Aspergillus*, *Cryptococcus*, *Pneumocystis*), *Listeria monocytogenes*, *Nocardia*, and *Toxoplasma* are also
common. After 6 months, if immunosuppression has been reduced to maintenance levels, infections that would be expected in any population occur. Patients with poorly functioning allografts receiving long-term immunosuppression therapy continue to be at risk for opportunistic infections.

**F. Tumor Necrosis Factor Inhibitor Recipients**

Patients taking TNF inhibitors have specific defects that increase risk of bacterial, mycobacterial (particularly tuberculosis), viral (HBV reactivation and HCV progression), and fungal infections (Pneumocystis, molds, and endemic mycoses). Infection risk may be highest shortly after therapy is initiated (within the first 3 months) and with a higher dose of medications.

**G. Recipients of Other Biologics**

In addition to TNF inhibitors, other biologics target a variety of immunologic pathways that are involved in immunologic mediated disease and in cancer replication. Disruption of these pathways include, but are not limited to impact on B cells, T cells, complement and leukocytes. This may result in not only serious infections, but the development of autoimmune disease and malignancies as well. Some medications have been observed to have specific associations with opportunistic infections (eg, natalizumab and PML, or eculizumab and meningococcal disease). Other biologics such as chimeric antigen receptor T cells may have unintended infectious risks that are currently unknown, or may have adverse effects that mimic infection (eg, cytokine release syndrome). As more biologics are developed and used, clinicians must remain vigilant for the possibility of serious infectious disease risk.

**H. Other Immunocompromised States**

A large group of patients who are not specifically immunodeficient are at increased risk for infection due to debilitating injury (eg, burns or severe trauma), invasive procedures (eg, chronic central intravenous catheters, Foley catheters, dialysis catheters), central nervous system dysfuncion (which predisposes patients to aspiration pneumonia and decubitus ulcers), obstructing lesions (eg, pneumonia due to an obstructed bronchus, pyelonephritis due to nephrolithiasis, cholangitis secondary to cholelithiasis), and use of broad-spectrum antibiotics. Patients with diabetes mellitus have alterations in cellular immunity, resulting in mucormycosis, emphysematous pyelonephritis, and foot infections.

**Clinical Findings**

**A. Laboratory Findings**

Routine evaluation includes complete blood count with differential, chest radiograph, and blood cultures; urine and respiratory cultures should be obtained if indicated clinically or radiographically. Any focal complaints (localized pain, headache, rash) should prompt imaging and cultures appropriate to the site.

Patients who remain febrile without an obvious source should be evaluated for viral infection (serum CMV antigen test or polymerase chain reaction), abscesses (which usually occur near previous operative sites), candidiasis involving the liver or spleen, or aspergillosis. Serologic evaluation may be helpful if toxoplasmosis or an endemic fungal infection (coccidioidomycosis, histoplasmosis) is a possible cause. Antigen-based assays may be useful for the diagnosis of aspergillosis (detected by galactomannan level in serum or bronchoalveolar lavage fluid), or other invasive fungal disease, including *Pneumocystis* infection (serum $[1 \rightarrow 3]$-beta-D-glucan level).

**B. Special Diagnostic Procedures**

Special diagnostic procedures should also be considered. The cause of pulmonary infiltrates can be easily determined with simple techniques in some situations—eg, induced sputum yields a diagnosis of *Pneumocystis* pneumonia in 50–80% of AIDS patients with this infection. In other situations, more invasive procedures may be required (bronchoalveolar lavage, transbronchial biopsy, open lung biopsy). Skin, liver, or bone marrow biopsy may be helpful in establishing a diagnosis. Next generation DNA-sequencing analysis is an increasingly used and validated option for diagnosis of infectious diseases in immunocompromised persons.

**Differential Diagnosis**

Transplant rejection, organ ischemia and necrosis, thrombophlebitis, and lymphoma (posttransplant lymphoproliferative disease) may all present as fever and must be considered in the differential diagnosis.

**Prevention**

While prophylactic antimicrobial medications are used commonly, the optimal medications or dosage regimens are debated. *Hand washing is the simplest and most effective means of decreasing hospital-associated infections*, especially in the compromised patient. Invasive devices such as central and peripheral lines and Foley catheters are potential sources of infection. Some centers use laminar airflow isolation or high-efficiency particulate air (HEPA) filtering in hematopoietic cell transplant patients. Rates of infection and episodes of febrile neutropenia, but not mortality, are decreased if colony-stimulating factors are used (typically in situations where the risk of febrile neutropenia is 20% or higher) during chemotherapy or during stem-cell transplantation.

**A. Pneumocystis & Herpes Simplex Infections**

Trimethoprim-sulfamethoxazole (TMP-SMZ), one double-strength tablet orally three times a week, one double-strength tablet twice daily on weekends, or one single-strength tablet daily for 3–6 months, is frequently used to prevent *Pneumocystis* infections in transplant patients. In patients allergic to TMP-SMZ, dapsone, 50 mg orally daily or 100 mg three times weekly, is recommended. Glucose-6-phosphate dehydrogenase (G6PD) levels should be assessed before dapsone is instituted. Acyclovir prevents herpes simplex infections in bone marrow and solid organ transplant recipients and is given to seropositive patients who are not receiving ganciclovir or valganciclovor for
CMV prophylaxis. The usual dose is 200 mg orally three times daily for 4 weeks (hematoopoietic cell transplants) to 12 weeks (other solid organ transplants).

**B. CMV**

No uniformly accepted approach has been adopted for prevention of CMV. Prevention strategies often depend on the serologic status of the donor and recipient and the organ transplanted, which determines the level of immunosuppression after transplant. In solid organ transplants (liver, kidney, heart, lung), the greatest risk of developing CMV disease is in seronegative recipients who receive organs from seropositive donors. These high-risk patients usually receive oral valganciclovir, 900 mg daily for 3–6 months (longer in lung transplant recipients). Other solid organ transplant recipients (seropositive recipients) are at lower risk for developing CMV disease, but still usually receive oral valganciclovir for 3 months. The lowest-risk group for the development of CMV disease is in seronegative patients who receive organs from seronegative donors. Typically, no CMV prophylaxis is used in this group. Ganciclovir and valganciclovir also prevent herpes virus reactivation. Because immunosuppression is increased during periods of rejection, patients treated for rejection usually receive CMV prophylaxis during rejection therapy. Alternatively, in a preemptive approach, patients can be monitored without specific prophylaxis by having blood sampled weekly to look for CMV by polymerase chain reaction techniques. If CMV is detected, then therapy is instituted with oral valganciclovir, 900 mg orally twice daily for a minimum of 2–3 weeks.

Recipients of hematopoietic cell transplants are more severely immunosuppressed than recipients of solid organ transplants, are at greater risk for developing serious CMV infection (usually CMV reactivation), and thus usually receive more aggressive prophylaxis. Like in solid organ transplant recipients, two approaches have been used: *universal prophylaxis* or *preemptive therapy*. In the former, all high-risk patients (seropositive patients who receive allogeneic transplants) may receive oral valganciclovir, 900 mg daily to day 100. However, valganciclovir is associated with significant bone marrow toxicity. Letermovir is being used increasingly, and it is not associated with bone marrow toxicity. Universal prophylaxis may be costly. Because of the possibility of bone marrow toxicity and the expense, many clinicians traditionally preferred the preemptive approach over the universal prophylaxis approach for recipients of hematopoietic stem cell transplants. However, while this preemptive approach is effective, it does miss a small number of patients in whom CMV disease would have been prevented had prophylaxis been used. Other preventive strategies include use of CMV-negative or leukocyte-depleted blood products for CMV-seronegative recipients.

**C. Other Organisms**

Routine decontamination of the gastrointestinal tract to prevent bacteremia in the neutropenic patient is not recommended. The use of prophylactic antibiotics in the febrile, asymptomatic neutropenic patient is debated, although many centers have adopted this strategy. Rates of bacteremia are decreased, but overall mortality is not affected and emergence of resistant organisms takes place. Use of intravenous immunoglobulin is reserved for the small number of patients with severe hypogammaglobulinemia following hematopoietic stem cell transplantation and should not be routinely administered to all transplant patients.

Prophylaxis with antifungal agents to prevent invasive mold (primarily *Aspergillus*) and yeast (primarily *Candida*) infections is routinely used, but the optimal agent, dose, and duration are also debated. Lipid-based preparations of amphotericin B, aerosolized amphotericin B, intravenous and oral fluconazole or voriconazole, and oral posaconazole solution and tablets are all prophylactic options in the neutropenic patient. Because voriconazole is superior to amphotericin for documented *Aspergillus* infections and because posaconazole prophylaxis (compared with fluconazole) has been shown to result in fewer cases of invasive aspergillosis among allogeneic stem cell transplant recipients with graft-versus-host disease, one approach to prophylaxis is to use oral fluconazole (400 mg/day) for patients at low risk for developing fungal infections (those who receive autologous stem cell transplants) and oral voriconazole (200 mg twice daily) or oral posaconazole (200 mg suspension three times daily or 300 mg [three 100-mg tablets] sustained-release tablets once daily) for those at high risk (allogeneic transplants, graft-versus-host disease) at least until engraftment (usually 30 days). In solid organ transplant recipients, the risk of invasive fungal infection varies considerably (1–2% in liver, pancreas, and kidney transplants and 6–8% in heart and lung transplants). Whether universal prophylaxis or observation with preemptive therapy is the best approach has not been determined. Although fluconazole is effective in preventing yeast infections, emergence of fluconazole-resistant *Candida* and molds (*Fusarium*, *Aspergillus*, *Macor*) has raised concerns about its routine use as a prophylactic agent in the general solid organ transplant population. However, liver transplant recipients with additional risk factors, such as having undergone a cholecdochojejunostomy, having had a high transfusion requirement or having developed kidney disease, may benefit from abbreviated postoperative *Candida* prophylaxis.

Given the high risk of reactivation of tuberculosis in patients taking TNF inhibitors, all patients should be screened for latent tuberculosis infection (LTBI) with a tuberculin skin test or an interferon-gamma release assay prior to the start of therapy. If LTBI is diagnosed, treatment with the TNF inhibitors should be delayed until treatment for LTBI is completed. There is also a marked risk of reactivation of hepatitis B and hepatitis C in patients taking TNF inhibitors; patients should also be screened for these viruses when TNF inhibitor treatment is being considered. Providers should also ensure that patients’ vaccinations are up-to-date before starting TNF inhibitors therapy.

**Treatment**

**A. General Measures**

Because infections in the immunocompromised patient can be rapidly progressive and life-threatening, diagnostic procedures must be performed promptly, and empiric therapy is usually instituted.
When to Refer

Patients with potential drug toxicities and drug interactions should be referred based on the need to empirically treat with a macrolide or fluoroquinolone. Patients with latent tuberculosis, HBV, and HCV infections should be referred to empiric treatment with a macrolide or fluoroquinolone (empiric treatment with a macrolide or fluoroquinolone is usually necessary). If a source is not identified, the main concern is the potential for superinfection. In the organ transplant setting, if the transplant is expected to persist for less than 10 days, no antimicrobials are used with the intent of providing synergy or tailoring therapy to the infection. However, if a source is identified, the main concern is the potential for superinfection. In the organ transplant setting, if the transplant is expected to persist for more than 10 days, antimicrobial agents are used with the intent of providing synergy or tailoring therapy to the infection. For example, in the febrile neutropenic patient, an algorithmic approach to therapy is often used. Febrile neutropenic patients should be empirically treated with broad-spectrum agents active against selected gram-positive bacteria, *Staphylococcus aureus* (MRSA), *S. epidermidis*, enterococcus, and resistant viridans streptococci. Continued neutropenic fever necessitates broadening of antibacterial coverage from cefepime to agents such as imipenem 500 mg every 6 hours or meropenem 1 g every 8 hours intravenously with or without tobramycin 5–7 mg/kg intravenously every 24 hours. Antifungal agents (such as voriconazole, 200 mg intravenously or orally every 12 hours, or caspofungin, 50 mg daily intravenously) should be added if fevers continue after 5–7 days of broad-spectrum antibiotic therapy. Regardless of whether the patient becomes afebrile, *therapy is continued until resolution of neutropenia*. Failure to continue antibiotics through the period of neutropenia has been associated with increased morbidity and mortality.

Patients with fever and low-risk neutropenia (neutropenia expected to persist for less than 10 days, no comorbid complications requiring hospitalization, and cancer adequately treated) can be treated with oral antibiotic regimens, such as ciprofloxacin, 750 mg every 12 hours, or amoxicillin-clavulanic acid, 500 mg every 8 hours. Antibiotics are continued as long as the patient is neutropenic even if a source is not identified. In the organ transplant patient with interstitial infiltrates, the main concern is infection with *Pneumocystis* or *Legionella* species, so that empiric treatment with a macrolide or fluoroquinolone (*Legionella*) and TMP-SMZ, 15 mg/kg/day orally or intravenously, based on trimethoprim component (*Pneumocystis*) would be reasonable in those patients not receiving TMP-SMZ prophylaxis. If the patient does not respond to empiric treatment, a decision must be made to add more antimicrobial agents or perform invasive procedures (see above) to make a specific diagnosis. By making a definite diagnosis, therapy can be specific, thereby reducing selection pressure for resistance and superinfection.

### When to Refer

- Any immunocompromised patient with an opportunistic infection.
- Patients with potential drug toxicities and drug interactions related to antimicrobials where alternative agents are sought.
- Patients with latent tuberculosis, HBV, and HCV infection in whom therapy with TNF inhibitors is planned.

### When to Admit

Immunocompromised patients who are febrile, or those without fevers in whom an infection is suspected, particularly in the following groups: solid-organ or hematopoietic stem cell transplant recipient (particularly in the first 6 months), neutropenic patients, patients receiving TNF inhibitors, and transplant recipients who have had recent rejection episodes (including graft-versus-host disease).

HEALTH CARE–ASSOCIATED INFECTIONS

**General Considerations**

Worldwide, approximately 10% of patients acquire a health care–associated infection, resulting in prolongation of the hospital stay, increase in cost of care, and significant morbidity and mortality. The most common infections are urinary tract infections, usually associated with Foley catheters or urologic procedures; bloodstream infections, most commonly from indwelling catheters but also from secondary sites, such as surgical wounds, abscesses, pneumonia, the genitourinary tract, and the gastrointestinal tract; pneumonia in intubated patients or those with altered levels of consciousness; surgical wound infections; MRSA infections; and *Clostridiodes difficile* colitis.

Some general principles are helpful in preventing, diagnosing, and treating health care–associated infections:

1. Many infections are a direct result of the use of *invasive devices* for monitoring or therapy, such as intravenous catheters, Foley catheters, shunts, surgical drains, catheters placed by interventional radiology for drainage, nasogastric tubes, and orotracheal or nasotracheal tubes for ventilatory support. Early *removal of such devices reduces the possibility of infection*.  
2. Patients in whom health care–associated infections develop are often critically ill, have been hospitalized for extended periods, and have received several courses of broad-spectrum antibiotic therapy. As a result, health care–associated infections are often due to *multidrug resistant pathogens* and differ from those encountered in community-acquired infections. For example, *S. aureus* and *S. epidermidis* (a frequent cause of prosthesis device infection) are often resistant to methicillin and most cephalosporins (*ceftiofur* is active against MRSA) and require vancomycin for therapy; *Enterococcus faecium* resistant to ampicillin and vancomycin; gram-negative infections caused by *Pseudomonas, Citrobacter, Enterobacter, Acinetobacter, Stenotrophomonas*, extended-spectrum beta-lactamases (ESBL)–producing *E. coli*, and *Klebsiella* may be resitant to most antibacterials. When choosing antibiotics to treat the seriously ill patient with a health care–associated infection, antimicrobial history and the “local ecology” must be considered. In the most seriously ill patients, broad-spectrum coverage with vancomycin and a carbapenem with or without an aminoglycoside is recommended. Once a pathogen is isolated and susceptibility is known, the most narrow-spectrum, least toxic, most cost-effective regimen should be used.

Widespread use of antimicrobial medications contributes to the selection of drug-resistant organisms; thus, **every effort should be made to limit the spectrum of coverage and unnecessary duration.** All too often, unreliable or uninterpretable specimens are obtained for culture that result in unnecessary use of antibiotics. The best example of this principle is the diagnosis of line-related or bloodstream infection in the febrile patient. To avoid unnecessary use of antibiotics, thoughtful consideration of culture results is mandatory. A positive wound culture without signs of inflammation or infection, a positive sputum culture without pulmonary infiltrates on chest radiograph, or a positive urine culture in a catheterized patient without symptoms or signs of pyelonephritis are all likely to represent *colonization*, not infection.

**Clinical Findings**

### A. Symptoms and Signs

Catheter-associated infections have a variable presentation, depending on the type of catheter used (peripheral or central venous catheters, nontunneled or tunneled). Local signs of infection may be present at the insertion site, with pain, erythema, and purulence. Fever is often absent in uncomplicated infections and if present, may indicate more disseminated disease such as bacteremia, cellulitis, and septic thrombophlebitis. Often signs of infection at the insertion site are absent.

1. **Fever in an intensive care unit patient**—Fever complicates up to 70% of patients in intensive care units, and the etiology of the fever may be infectious or noninfectious. Common infectious causes include catheter-associated infections, hospital-acquired and ventilator-associated pneumonia (see Chapter 9), surgical site infections, urinary tract infections, and sepsis. Clinically relevant sinusitis is relatively uncommon in the patient in the intensive care unit.

An important noninfectious cause is thromboembolic disease. Fever in conjunction with refractory hypotension and shock may suggest sepsis; however, adrenal insufficiency, thyroid storm, and transfusion reaction may have a similar clinical presentation. Drug fever is difficult to diagnose and is usually a diagnosis of exclusion unless there are other signs of hypersensitivity, such as a typical maculopapular rash (most common with beta-lactams).

2. **Fever in the postoperative patient**—Postoperative fever is very common and noninfectious fever resolves spontaneously. Timing of the onset of the fever in relation to the surgical procedure may be of diagnostic benefit.

### A. Immediate fever (in the first few hours after surgery)—Immediate fever can be due to medications that were given perioperatively, to surgical trauma, or to...
Infections that were present before surgery. Necrotizing fasciitis due to group A streptococci or mixed organisms may present in this period. Malignant hyperthermia is rare and presents 30 minutes to several hours following inhalational anesthesia and is characterized by extreme hyperthermia, muscle rigidity, rhabdomyolysis, electrolyte abnormalities, and hypotension. Aggressive cooling and dantrolene are the mainstays of therapy. Aspiration of acidic gastric contents during surgery can result in a chemical pneumonitis (Mendelson syndrome) that develops rapidly, is transient, and does not require antibiotics. Fever due to surgical trauma usually resolves in 2–3 days; however, it may be longer in more complicated operative cases and in patients with head trauma.

B. Acute fever (within 1 week of surgery)—Acute fever is usually due to common causes of hospital-associated infections, such as ventilator-associated pneumonia (including aspiration pneumonia in patients with decreased gag reflex) and line infections. Noninfectious causes include alcohol withdrawal, gout, pulmonary embolism, and pancreatitis. Atelectasis following surgery is commonly invoked as a cause of postoperative fever but there is no good evidence to support a causal association between the presence or degree of atelectasis and fever.

C. Subacute fever (at least 1 week after surgery)—Surgical site infections commonly present at least 1 week after surgery. The type of surgery that was performed predicts specific infectious etiologies. Patients undergoing cardiothoracic surgery may be at higher risk for pneumonia and deep and superficial sternal wound infections. Meningitis without typical signs of meningismus may complicate neurosurgical procedures. Postoperative deep abdominal abscesses may require drainage.

B. Laboratory Findings

Blood cultures are universally recommended, and chest radiographs are frequently obtained. A properly prepared sputum Gram stain and semi-quantitative sputum cultures may be useful in selected patients where there is a high pretest probability of pneumonia but multiple exclusion criteria probably limit generalizability in most patients, such as immunocompromised patients and those with drug resistance. Other diagnostic strategies will be dictated by the clinical context (eg, transesophageal echocardiogram in a patient with *S aureus* bacteremia).

Any fever in a patient with a central venous catheter should prompt the collection of blood. The best method to evaluate bacteremia is to gather at least two peripherally obtained blood cultures. Blood cultures from unidentified sites, a single blood culture from any site, or a blood culture through an existing line will often be positive for coagulase-positive staphylococci, particularly *S epidermidis*, often resulting in the inappropriate use of vancomycin. Unless two separate venipuncture cultures are obtained—not through catheters—interpretation of results is impossible, and unnecessary therapy often results. Each “pseudobacteremia” increases laboratory costs, antibiotic use, and length of stay. Microbiologic evaluation of the removed catheter can sometimes be helpful, but only in addition to (not instead of) blood cultures drawn from peripheral sites. The differential time to positivity measures the difference in time that cultures simultaneously drawn through a catheter and a peripheral site become positive. A positive test (at least 120 minutes’ difference in time) supports a catheter-related bloodstream infection, while a negative test suggests catheters may be retained.

Complications

Complications such as septic thrombophlebitis, endocarditis, or metastatic foci of infection (particularly with *S aureus*) may be suspected in patients with persistent bacteremia and fever despite removal of the infected catheter. Additional studies such as venous Doppler studies, transesophageal echocardiogram, and chest radiographs may be indicated, and 4–6 weeks of antibiotics may be needed. In the case of septic thrombophlebitis, anticoagulation with heparin is also recommended if there are no contraindications.

Differential Diagnosis

Although most fevers are due to infections, about 25% of patients will have fever of noninfectious origin, including drug fever, nonspecific postoperative fevers (tissue damage or necrosis), hemoptysis, pancreatitis, pulmonary embolism, myocardial infarction, and ischemic bowel disease.

Prevention

The concept of universal precautions emphasizes that all patients are treated as though they have a potential blood-borne transmissible disease, and thus all body secretions are handled with care to prevent spread of disease. Body substance isolation requires use of gloves whenever a health care worker anticipates contact with blood or other body secretions. Even though gloves are worn, health care workers should routinely wash their hands, since it is the easiest and most effective means of preventing hospital-associated infections. Application of a rapid drying, alcohol-based antiseptic is simple, takes less time than traditional hand washing with soap and water, is more effective at reducing hand colonization, and promotes compliance with hand decontamination. For prevention of transmission of *C difficile* infection, hand washing is more effective than alcohol-based antiseptics. Consequently, even after removing gloves, providers should always wash hands in cases of proven or suspected *C difficile* infection.

Peripheral intravenous lines should be replaced no more frequently than every 3–4 days. Some clinicians replace only when clinically indicated or if the line was put in emergently. Arterial lines and lines in the central venous circulation (including those placed peripherally) can be left in place indefinitely and are changed or removed when they are clinically suspected of being infected, when they are nonfunctional, or when they are no longer needed. Using sterile barrier precautions (including cap, mask, gown, gloves, and drape) is recommended while inserting central venous catheters. Antibiotic-impregnated (minocycline plus rifampin or chlorhexidine plus silver sulfadiazine) venous catheters reduce line infections. Silver alloy–impregnated Foley catheters reduce the incidence of catheter-associated bacteriuria,
but not consistently catheter-associated urinary tract infections. Best practices to prevent ventilator-associated pneumonia include avoiding intubation if possible, minimizing and daily interruption of sedation, pooling/draining of subglottic secretions above the tube cuff, and elevating the head of the bed. Silver-coated endotracheal tubes may reduce the incidence of ventilator-associated pneumonia but has limited impact on hospital stay duration or mortality, so they are not generally recommended. Catheter-related urinary tract infections and intravenous catheter-associated infections are not Medicare-reimbursable conditions in the United States. Preoperative skin preparation with chlorhexidine and alcohol (versus povidone-iodine) reduces the incidence of infection following surgery. Another strategy that can prevent surgical-site infections is the identification and treatment of *S aureus* nasal carriers with 2% mupirocin nasal ointment and chlorhexidine soap. Daily bathing of ICU patients with chlorhexidine-impregnated washcloths versus soap and water results in lower incidence of health care-associated infections and colonization. Selective decontamination of the digestive tract with nonabsorbable or parenteral antibiotics, or both, may prevent hospital-acquired pneumonia and decrease mortality but is in limited use because of the concern of the development of antibiotic resistance. Prevention bundles (implementing more than one intervention concomitantly) are commonly used as a practical strategy to enhance care in the healthcare setting.

Attentive nursing care (positioning to prevent pressure injuries, wound care, elevating the head during tube feedings to prevent aspiration) is critical in preventing hospital-associated infections. In addition, monitoring of high-risk areas by hospital epidemiologists is critical in the prevention of infection. Some guidelines advocate rapid screening (active surveillance cultures) for MRSA on admission to acute care facilities among certain subpopulations of patients (eg, those recently hospitalized, admission to the intensive care unit, patients undergoing hemodialysis). However, outside the setting of an MRSA outbreak, it is not clear whether this strategy decreases the incidence of hospital-associated MRSA infections.

Vaccines, including hepatitis A, hepatitis B, and the varicella, pneumococcal, and influenza vaccinations, are important adjuncts. (See section below titled Immunization Against Infectious Diseases.)

> Treatment

A. Fever in an Intensive Care Unit Patient

Unless the patient has a central neurologic injury with elevated intracranial pressure or has a temperature higher than 41°C, there is less physiologic need to maintain euthermia. Empiric broad-spectrum antibiotics (see Table 30–5) are recommended for neutropenic and other immunocompromised patients and in patients who are clinically unstable.

B. Catheter-Associated Infections

Factors that inform treatment decisions include the type of catheter, the causative pathogen, the availability of alternate catheter access sites, the need for ongoing intravascular access, and the severity of disease.

In general, catheters should be removed if there is purulence at the exit site; if the organism is *S aureus*, gram-negative rods, or *Candida* species; if there is persistent bacteremia (more than 48 hours while receiving antibiotics); or if complications, such as septic thrombophlebitis, endocarditis, or other metastatic disease exist. Central venous catheters may be exchanged over a guidewire provided there is no erythema or purulence at the exit site and the patient does not appear to be septic. Methicillin-resistant, coagulate-negative staphylococci are the most common pathogens; thus, empiric therapy with vancomycin, 15 mg/kg/dose intravenously twice daily, should be given assuming normal kidney function. Empiric gram-negative coverage should be used in patients who are immunocompromised or who are critically ill (see Table 30–5).

Antibiotic treatment duration depends on the pathogen and the extent of disease. For uncomplicated bacteremia, 5–7 days of therapy is usually sufficient for coagulate-negative staphylococci, even if the original catheter is retained. Fourteen days of therapy is generally recommended for uncomplicated bacteremia caused by gram-negative rods, *Candida* species, and *S aureus*. Antibiotic lock therapy involves the instillation of supratherapeutic concentrations of antibiotics with heparin in the lumen of catheters. The purpose is to achieve adequate concentrations of antibiotics to kill microbes in the biofilm. Antibiotic lock therapy can be used for catheter-related bloodstream infections caused by both gram-positive and gram-negative bacterial pathogens and when the catheter is being retained in a salvage situation.

> When to Refer

- Any patient with multidrug-resistant infection.
- Any patient with fungemia or persistent bacteremia.
- Patients with multisite infections.
- Patients with impaired or fluctuating kidney function for assistance with dosing of antimicrobials.
- Patients with refractory or recurrent *C difficile* colitis.

Harris PNA et al; MERINO Trial Investigators and the Australasian Society for Infectious Disease Clinical Research Network (ASID-CRN). Effect of piperacillin–tazobactam vs meropenem on 30-day mortality for patients with *E coli* or *Klebsiella pneumoniae* bloodstream infection and ceftriaxone resistance: a randomized clinical trial. JAMA. 2018 Sep 11;320(10):984–94. [PMID: 30208454]

**ESSENTIALS OF DIAGNOSIS**

- Central nervous system infection is a medical emergency.
- Symptoms and signs common to all central nervous system infections include headache, fever, sensorial disturbances, neck and back stiffness, positive Kernig and Brudzinski signs, and cerebrospinal fluid abnormalities.

**General Considerations**

Infections of the central nervous system can be caused by almost any infectious agent, including bacteria, mycobacteria, fungi, spirochetes, protozoa, helminths, and viruses.

**Table 30–1.** Typical cerebrospinal fluid findings in various central nervous system diseases.

<sup>1</sup>Cerebrospinal fluid glucose must be considered in relation to blood glucose level. Normally, cerebrospinal fluid glucose is 20–30 mg/dL lower than blood glucose, or 50–70% of the normal value of blood glucose.

<sup>2</sup>Organisms in smear or culture of cerebrospinal fluid; counterimmunoelectrophoresis or latex agglutination may be diagnostic.

<sup>3</sup>Polymerophonuclear neutrophils may predominate early.

<sup>4</sup>Viral isolation from cerebrospinal fluid early; antibody titer rise in paired specimens of serum; polymerase chain reaction for herpesvirus.

<sup>5</sup>May occur in mastoiditis, brain abscess, epidural abscess, sinusitis, septic thrombus, brain tumor. Cerebrospinal fluid culture results usually negative.

---

**Etiologic Classification**

Central nervous system infections can be divided into several categories that usually can be readily distinguished from each other by cerebrospinal fluid examination as the first step toward etiologic diagnosis (Table 30–1).

**A. Purulent Meningitis**

Patients with bacterial meningitis usually seek medical attention within hours or 1–2 days after onset of symptoms. The organisms responsible depend primarily on the age of the patient as summarized in Table 30–2. The diagnosis is usually based on the Gram-stained smear (positive in 60–90%) or culture (positive in over 90%) of the cerebrospinal fluid.

**B. Chronic Meningitis**

The presentation of chronic meningitis is less acute than purulent meningitis. Patients with chronic meningitis usually have a history of symptoms lasting weeks to months. The most common pathogens are *Mycobacterium tuberculosis*, atypical mycobacteria, fungi (*Cryptococcus, Coccidioides, Histoplasma*), and spirochetes (*Treponema pallidum* and *Borrelia burgdorferi*). The diagnosis is made by culture or in some cases by serologic tests (*cryptococcosis, coccidioidomycosis, syphilis, Lyme disease*).

**C. Aseptic Meningitis**

Aseptic meningitis—a much more benign and self-limited syndrome than purulent meningitis—is caused principally by viruses, especially herpes simplex virus and the enterovirus group (including coxsackieviruses and echoviruses). Infectious mononucleosis may be accompanied by aseptic meningitis. Leptospiral infection is also usually placed in...
the aseptic group because of the lymphocytic cellular response and its relatively benign course. This type of meningitis also occurs during secondary syphilis and disseminated Lyme disease. Prior to the routine administration of measles-mumps-rubella (MMR) vaccines, mumps was the most common cause of viral meningitis. Drug-induced aseptic meningitis has been reported with nonsteroidal anti-inflammatory drugs, sulfonamides, and certain monoclonal antibodies.

### D. Encephalitis

Encephalitis (due to herpesviruses, arboviruses, rabies virus, flaviviruses [West Nile encephalitis, Japanese encephalitis], and many others) produces disturbances of the sensorium, seizures, and many other manifestations. Patients are more ill than those with aseptic meningitis. Cerebrospinal fluid may be entirely normal or may show some lymphocytes and, in some instances, (eg, herpes simplex) red cells as well. Influenza has been associated with encephalitis, but the relationship is not clear. An autoimmune form of encephalitis associated with N-methyl-D-aspartate receptor antibodies should be suspected in younger patients with encephalitis and associated seizures, movement disorders, and psychosis.

### E. Partially Treated Bacterial Meningitis

Previous effective antibiotic therapy given for 12–24 hours will decrease the rate of positive cerebrospinal fluid Gram stain results by 20% and culture by 30–40% but will have little effect on cell count, protein, or glucose. Occasionally, previous antibiotic therapy will change a predominantly polymorphonuclear response to a lymphocytic pleocytosis, and some of the cerebrospinal fluid findings may be similar to those seen in aseptic meningitis.

### F. Neighborhood Reaction

As noted in Table 30–1, this term denotes a purulent infectious process in close proximity to the central nervous system that spills some of the products of the inflammatory process—white blood cells or protein—into the cerebrospinal fluid. Such an infection might be a brain abscess, osteomyelitis of the vertebrae, epidural abscess, subdural empyema, or bacterial sinusitis or mastoiditis.

### G. Noninfectious Meningeal Irritation

Carcinomatous meningitis, sarcoidosis, systemic lupus erythematosus, chemical meningitis, and certain medications—nonsteroidal anti-inflammatory drugs, OKT3, TMP-SMZ, and others—can also produce symptoms and signs of meningeval irritation with associated cerebrospinal fluid pleocytosis, increased protein, and low or normal glucose. Meningismus with normal cerebrospinal fluid findings occurs in the presence of other infections such as pneumonia and shigellosis.

### H. Brain Abscess

Brain abscess presents as a space-occupying lesion; symptoms may include vomiting, fever, change of mental status, or focal neurologic manifestations. When brain abscess is suspected, a CT scan should be performed. If positive, lumbar puncture should not be performed since results rarely provide clinically useful information and herniation can occur. The bacteriology of brain abscess is usually polymicrobial and includes S aureus, gram-negative bacilli, streptococci, and mouth anaerobes (including anaerobic streptococci and Prevotella species).
I. Health Care–Associated Meningitis

This infection may arise as a result of invasive neurosurgical procedures (eg, craniotomy, internal or external ventricular catheters, external lumbar catheters), complicated head trauma, or hospital-acquired bloodstream infections. Outbreaks have been associated with contaminated epidural or paraspinal corticosteroid injections. In general, the microbiology is distinct from community-acquired meningitis, with gram-negative organisms (eg, *Pseudomonas*), *S aureus*, and coagulase-negative staphylococci and, in the outbreaks associated with contaminated corticosteroids, mold and fungi (*Exserohilum rostratum* and *Aspergillus fumigatus*) playing a larger role.

▶ Clinical Findings

A. Symptoms and Signs

The classic triad of fever, stiff neck, and altered mental status has a low sensitivity (44%) for bacterial meningitis. However, nearly all patients with bacterial meningitis have at least two of the following symptoms—fever, headache, stiff neck, or altered mental status.

B. Laboratory Tests

Evaluation of a patient with suspected meningitis includes a blood count, blood culture, lumbar puncture followed by careful study and culture of the cerebrospinal fluid, and a chest film. The fluid must be examined for cell count, glucose, and protein, and a smear stained for bacteria (and acid-fast organisms when appropriate) and cultured for pyogenic organisms and for mycobacteria and fungi when indicated. Latex agglutination tests can detect antigens of encapsulated organisms (*S pneumoniae*, *H influenzae*, *N meningitidis*, and *Cryptococcus neoformans*) but are rarely used except for detection of *Cryptococcus* or in partially treated patients. Polymerase chain reaction (PCR) testing of cerebrospinal fluid has been used to detect bacteria (*S pneumoniae*, *H influenzae*, *N meningitidis*, and *Cryptococcus neoformans*) but are rarely used except for detection of *Cryptococcus* or in partially treated patients. The greatest experience is with PCR for herpes simplex, varicella-zoster, CMV, Epstein-Barr virus, and enteroviruses in patients with meningitis. These tests are very sensitive (greater than 95%) and specific. In addition to its use in meningitis, molecular methods such as PCR and next-generation sequencing are being used increasingly for the diagnosis of encephalitis, transverse myelitis, and brain abscess. In general, molecular diagnostic tests may provide a more sensitive and rapid alternative to traditional culture and serology methods. However, it is difficult to ascertain the true sensitivity of many molecular tests for CNS infections given the absence of a gold standard. In some cases, tests to detect several organisms may not be any more sensitive than culture (or serology), but the real value is the rapidity with which results are available, ie, hours compared with days or weeks.

C. Lumbar Puncture and Imaging

Since performing a lumbar puncture in the presence of a space-occupying lesion (brain abscess, subdural hematoma, subdural empyema, necrotic temporal lobe from herpes encephalitis) may result in brainstem herniation, a CT scan is performed prior to lumbar puncture if a space-occupying lesion is suspected on the basis of papilledema, seizures, or focal neurologic findings. Other indications for CT scan are an immunocompromised patient or moderately to severely impaired level of consciousness. If delays are encountered in obtaining a CT scan and bacterial meningitis is suspected, blood cultures should be drawn and antibiotics and corticosteroids administered even before cerebrospinal fluid is obtained for culture to avoid delay in treatment (Table 30–1).

Antibiotics given within 4 hours of obtaining cerebrospinal fluid probably do not affect culture results. MRI with contrast of the epidural injection site and surrounding areas is recommended (sometimes repeatedly) for those with symptoms following a possibly contaminated corticosteroid injection to exclude epidural abscess, phelegmon, vertebral osteomyelitis, discitis, or arachnoiditis.

▶ Treatment

Although it is difficult to prove with existing clinical data that early antibiotic therapy improves outcome in bacterial meningitis, prompt therapy is still recommended. In purulent meningitis, the identity of the causative microorganism may remain unknown or doubtful for a few days and initial antibiotic treatment as set forth in Table 30–2 should be directed against the microorganisms most common for each age group.

The duration of therapy for bacterial meningitis varies depending on the etiologic agent: *H influenzae*, 7 days; *N meningitidis*, 3–7 days; *S pneumoniae*, 10–14 days; *L monocytogenes*, 14–21 days; and gram-negative bacilli, 21 days.

For adults with pneumococcal meningitis, dexamethasone 10 mg administered intravenously 15–20 minutes before or simultaneously with the first dose of antibiotics and continued every 6 hours for 4 days decreases morbidity and mortality. Patients most likely to benefit from corticosteroids are those infected with gram-positive organisms (*Streptococcus pneumoniae* or *S suis*), and those who are HIV negative. It is unknown whether patients with meningitis due to *N meningitidis* and other bacterial pathogens benefit from the use of adjunctive corticosteroids. Increased intracranial pressure due to brain edema often requires therapeutic attention. Hyperventilation, mannitol (25–50 g intravenously as a bolus), and even drainage of cerebrospinal fluid by repeated lumbar punctures or by placement of intraventricular catheters have been used to control cerebral edema and increased intracranial pressure. Dexamethasone (4 mg intravenously every 4–6 hours) may also decrease cerebral edema.

Therapy of brain abscess consists of drainage (excision or aspiration) in addition to 3–4 weeks of systemic antibiotics directed against organisms isolated. An empirical regimen often includes metronidazole, 500 mg intravenously or orally every 8 hours, plus ceftriaxone, 2 g intravenously every 12 hours, with or without vancomycin, 10–15 mg/kg/dose intravenously every 12 hours. Vancomycin trough serum levels should be greater than 15 mcg/mL in such patients. In cases where abscesses are smaller than 2 cm,
where there are multiple abscesses that cannot be drained, or if an abscess is located in an area where significant neurologic sequelae would result from drainage, antibiotics for 6–8 weeks can be used without drainage.

In addition to antibiotics, in cases of health care–associated meningitis associated with an external intraventricular catheter, the probability of cure is increased if the catheter is removed. In infections associated with internal ventricular catheters, removal of the internal components and insertion of an external drain is recommended. After collecting cerebrospinal fluid, epidural aspirate, or other specimens for culture, empiric antifungal therapy with voriconazole as well as routine empiric treatment for other pathogens (as above) is recommended until the specific cause of the patient’s central nervous system or parameningeal infection has been identified. In addition, early consultation with a neurosurgeon is recommended for those found to have an epidural abscess, phlegmon, vertebral osteomyelitis, discitis, or arachnoiditis to discuss possible surgical management (eg, debridement).

Therapy of other types of meningitis is discussed elsewhere in this book (fungal meningitis, Chapter 36; syphilis and Lyme borreliosis, Chapter 34; tuberculous meningitis, Chapter 33; herpes encephalitis, Chapter 32).

When to Refer

- Patients with acute meningitis, particularly if culture negative or atypical (eg, fungi, syphilis, Lyme disease, M tuberculosis), or if the patient is immunosuppressed.
- Patients with chronic meningitis.
- All patients with brain abscesses and encephalitis.
- Patients with suspected hospital-acquired meningitis (eg, in patients who have undergone recent neurosurgery or epidural or paraspinal corticosteroid injection).
- Patients with recurrent meningitis.

When to Admit

- Patients with suspected acute meningitis, encephalitis, and brain or paraspinal abscess should be admitted for urgent evaluation and treatment.
- There is less urgency to admit patients with chronic meningitis; these patients may be admitted to expedite diagnostic procedures and coordinate care, particularly if no diagnosis has been made in the outpatient setting.

ESSENTIALS OF DIAGNOSIS

- Cat and human bites have higher rates of infection than dog bites.
- Hand bites are particularly concerning for the possibility of closed-space infection.
- Antibiotic prophylaxis indicated for noninfected bites of the hand and hospitalization required for infected hand bites.
- All infected wounds need to be cultured to direct therapy.

General Considerations

About 1000 dog bite injuries require emergency department attention each day in the United States, most often in urban areas. Dog bites occur most commonly in the summer months. Biting animals are usually known by their victims, and most biting incidents are provoked (ie, bites occur while playing with the animal or after surprising the animal while eating or waking it abruptly from sleep). Failure to elicit a history of provocation is important, because an unprovoked attack raises the possibility of rabies. Human bites are usually inflicted by children while playing or fighting; in adults, bites are associated with alcohol use and closed-fist injuries that occur during fights.

The animal inflicting the bite, the location of the bite, and the type of injury inflicted are all important determinants of whether they become infected. Cat bites are more likely to become infected than human bites—between 30% and 50% of all cat bites become infected. Infections following human bites are variable. Bites inflicted by children rarely become infected because they are superficial, and bites by adults become infected in 15–30% of cases, with a particularly high rate of infection in closed-fist injuries. Dog bites, for unclear reasons, become infected only 5% of the time. Bites of the head, face, and neck are less likely to become infected than bites on the extremities. “Through and through” bites (eg, involving the mucosa and the skin) have an infection rate similar to closed-fist injuries. Puncture wounds become infected more frequently than lacerations, probably because the latter are easier to irrigate and debride.

The bacteriology of bite infections is polymicrobial. Following dog and cat bites, over 50% of infections are caused by aerobes and anaerobes and 36% are due to aerobes alone. Pure anaerobic infections are rare. Pasteurella species are the most common staphylococci, phlegmone, Moraxella, and Neisseria; the most common anaerobes are Fusobacterium, Bacteroides, Porphyromonas, and Prevotella. The median number of isolates following human bites is four (three aerobes and one anaerobe). Like dog and cat bites, infections caused by most human bites are a mixture of aerobes and anaerobes (54%) or are due to

Treatment

A. Local Care

Vigorous cleansing and irrigation of the wound as well as debridement of necrotic material are the most important factors in decreasing the incidence of infections. Radiographs should be obtained to look for fractures and the presence of foreign bodies. Careful examination to assess the extent of the injury (tendon laceration, joint space penetration) is critical to appropriate care.

B. Suturing

If wounds require closure for cosmetic or mechanical reasons, suturing can be done. However, one should never suture an infected wound, and wounds of the hand should generally not be sutured since a closed-space infection of the hand can result in loss of function.

C. Prophylactic Antibiotics

Prophylaxis is indicated in high-risk bites and in high-risk patients. Cat bites in any location and hand bites by any animal, including humans, should receive prophylaxis. Individuals with certain comorbidities (diabetes, liver disease) are at increased risk for severe complications and should receive prophylaxis even for low-risk bites, as should patients without functional spleens who are at increased risk for overwhelming sepsis (primarily with Capnocytophaga species). Amoxicillin-clavulanate (Augmentin) 500 mg orally three times daily for 5–7 days is the regimen of choice. For patients with serious allergy to penicillin, a combination of clindamycin 300 mg orally three times daily together with one of the following is recommended for 5–7 days: doxycycline 100 mg orally twice daily, or double-strength TMP-SMZ orally twice daily, or a fluoroquinolone (ciprofloxacin 500 mg orally twice daily or levofloxacin 500–750 mg orally once daily). Moxifloxacin, a fluoroquinolone with good aerobic and anaerobic activity, may be suitable as monotherapy at 400 mg orally once daily for 5–7 days. Agents such as dicloxacillin, cephalaxin, macrolides, and clindamycin should not be used alone because they lack activity against Pasteurella species. TMP-SMZ has poor activity against anaerobes and should only be used in combination with clindamycin.

Because the risk of HIV transmission is so low following a bite, routine postexposure prophylaxis is not recommended. Each case should be evaluated individually and consideration for prophylaxis should be given to those who present within 72 hours of the incident, the source is known to be HIV infected, and the exposure is high risk.

D. Antibiotics for Documented Infection

For wounds that are infected, antibiotics are clearly indicated. How they are given (orally or intravenously) and the need for hospitalization are individualized clinical decisions. The most commonly encountered pathogens require treatment with ampicillin-sulbactam (Unasyn), 1.5–3 g intravenously every 6–8 hours; or amoxicillin-clavulanate (Augmentin), 500 mg orally three times daily; or with ertapenem, 1 g intravenously daily. For the patient with severe penicillin allergy, a combination of clindamycin 600–900 mg intravenously every 8 hours plus a fluoroquinolone (ciprofloxacin, 400 mg intravenously every 12 hours; levofloxacin, 500–750 mg intravenously once daily) or TMP-SMZ (10 mg/kg of trimethoprim daily in two or three divided doses) is indicated. Duration of therapy is usually 2–3 weeks unless complications such as septic arthritis or osteomyelitis is present; if these complications are present, therapy should be extended to 4 and 6 weeks, respectively.

E. Tetanus and Rabies

All patients must be evaluated for the need for tetanus (see Chapter 33) and rabies (see Chapter 32) prophylaxis.

When to Refer

- If septic arthritis or osteomyelitis is suspected.
- For exposure to bites by dogs, cats, reptiles, amphibians, and rodents.
- When rabies is a possibility.

When to Admit

- Patients with infected hand bites.
- Deep bites, particularly if over joints.

SEXUALLY TRANSMITTED DISEASES

- All sexually transmitted diseases (STDs) have subclinical or latent periods, and patients may be asymptomatic.
- Simultaneous infection with several organisms is common.
- All patients who seek STD testing should be screened for syphilis and HIV.
**General Considerations**

The most common STDs are gonorrhea,* syphilis,* human papillomavirus (HPV)–associated condyloma acuminatum, chlamydia genital infections,* herpesvirus genital infections, trichomonas vaginitis, chancroid,* granuloma inguinale, scabies, louse infestation, and bacterial vaginosis (among women who have sex with women). However, shigellosis*; hepatitis A, B, and C*; amebiasis; giardiasis*; cryptosporidiosis*; salmonellosis*; and campylobacteriosis may also be transmitted by sexual (oral-anal) contact, especially in men who have sex with men. Ebola virus and Zika virus have both been associated with sexual transmission. Both homosexual and heterosexual contact are risk factors for the transmission of HIV (see Chapter 31). All STDs have *subclinical* or *latent phases* that play an important role in long-term persistence of the infection or in its transmission from infected (but largely asymptomatic) persons to other contacts. Simultaneous infection by several different agents is common.

Infections typically present in one of several ways, each of which has a defined differential diagnosis, which should prompt appropriate diagnostic tests.

**A. Genital Ulcers**

Common etiologies include herpes simplex virus, primary syphilis, and chancroid. Other possibilities include lymphogranuloma venereum (see Chapter 33), granuloma inguinale caused by *Klebsiella granulomatis* (see Chapter 33), as well as lesions caused by infection with Epstein-Barr virus and HIV. Noninfectious causes are Behçet disease (see Chapter 20), neoplasm, trauma, drugs, and irritants.

**B. Urethritis With or Without Urethral Discharge**

The most common infections causing urethral discharge are *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. *N gonorrhoeae* and *C trachomatis* are also frequent causes of prostatitis among sexually active men. Other sexually transmitted infections that can cause urethritis include *Mycoplasma genitalium* and, less commonly, *Ureaplasma urealyticum* and *Trichomonas vaginalis*. Noninfectious causes of urethritis include reactive arthritis with associated urethritis.

**C. Vaginal Discharge**

Common causes of vaginitis are bacterial vaginosis (caused by overgrowth of anaerobes such as *Gardnerella vaginalis*), candidiasis, and *T vaginalis* (see Chapter 18). Less common infectious causes of vaginitis include HPV–associated condyloma acuminata and group A streptococcus. Noninfectious causes are physiologic changes related to the menstrual cycle, irritants, and lichen planus. Even though *N gonorrhoeae* and *C trachomatis* are frequent causes of cervicitis, they rarely produce vaginal discharge.

*Reportable to public health authorities.

**Screening & Prevention**

All persons who seek STD testing should undergo routine screening for HIV infection, using rapid HIV testing (if patients may not follow up for results obtained by standard methods) or nucleic acid amplification followed by confirmatory serology (if primary HIV infection may be a possibility) as indicated. Patients in whom certain STDs have been diagnosed and treated (chlamydia or gonorrhea, and trichomonas in women) are at a high risk for reinfection and should be encouraged to be rescreened for STDs at 3 months following the initial STD diagnosis.

Asymptomatic patients often request STD screening at the time of initiating a new sexual relationship. Routine HIV testing and hepatitis B serology testing should be offered to all such patients. In sexually active women who have not been recently screened, cervical Papanicolaou testing and nucleic acid amplification testing of a urine specimen for gonorrhea and chlamydia are recommended. Among men who have sex with men, additional screening is recommended for syphilis; hepatitis A; urethral, pharyngeal, and rectal gonorrhea; as well as urethral and rectal chlamydia. Nucleic acid amplification testing is recommended for gonorrhea or chlamydia. There are no recommendations to screen heterosexual men for urethral chlamydia, but this could be considered in STD clinics, adolescent clinics, or correctional facilities. The periodicity of screening thereafter depends on sexual risk, but most screening should be offered at least annually to sexually active adults (particularly to those 25 years old and under). Clinicians should also evaluate transgender men and women for STD screening, based on current anatomy and behaviors practiced. If not immune, hepatitis B vaccination is recommended for all sexually active adults, and hepatitis A vaccination in men who have sex with men. Persons between the ages of 9 and 26 should be routinely offered vaccination against HPV (9-valent).

The risk of developing an STD following a sexual assault is difficult to accurately ascertain given high rates of baseline infections and poor follow-up. Victims of assault have a high baseline rate of infection (*N gonorrhoeae*, 6%; *C trachomatis*, 10%; *T vaginalis*, 15%; and bacterial vaginosis, 34%), and the risk of acquiring infection as a result of the assault is significant, but is often lower than the pre-existing rate (*N gonorrhoeae*, 6–12%; *C trachomatis*, 4–17%; *T vaginalis*, 12%; syphilis, 0.5–3%; and bacterial vaginosis, 19%). Victims should be evaluated within 24 hours after the assault, and nucleic acid amplification tests for *N gonorrhoeae* and *C trachomatis* should be performed. Vaginal secretions are obtained for *Trichomonas* wet mount and culture, or point-of-care testing. If a discharge is present, if there is itching, or if secretions are malodorous, a wet mount should be examined for *Candida* and bacterial vaginosis. In addition, a blood sample should be obtained for immediate serologic testing for syphilis, hepatitis B, and HIV. Follow-up examination for STDs should be repeated within 1–2 weeks, since concentrations of infecting organisms may not have been sufficient to produce a positive test at the time of initial examination. If prophylactic treatment was given (may include postexposure hepatitis B vaccination without hepatitis B immune
glovin; treatment for chlamydial, gonorrheal, or trichomonal infection; and emergency contraception), tests should be repeated only if the victim has symptoms. If prophylaxis was not administered, the individual should be seen in 1 week so that any positive tests can be treated. Follow-up serologic testing for syphilis and HIV infection should be performed in 6, 12, and 24 weeks if the initial tests are negative. The usefulness of presumptive therapy is controversial, with some feeling that all patients should receive it and others that it should be limited to those in whom follow-up cannot be ensured or to patients who request it.

Although seroconversion to HIV has been reported following sexual assault when this was the only known risk, this risk is believed to be low. The likelihood of HIV transmission from vaginal or anal receptive intercourse when the source is known to be HIV positive is 1 per 1000 and 5 per 1000, respectively. Although prophylactic antiretroviral therapy has not been studied in this setting, the Department of Health and Human Services recommends the prompt institution of postexposure prophylaxis with antiretroviral therapy if the person seeks care within 72 hours of the assault, the source is known to be HIV positive, and the exposure presents a substantial risk of transmission.

In addition to screening asymptomatic patients with STDs, other strategies for preventing further transmission include evaluating sex partners and administering preexposure vaccination of preventable STDs to individuals at risk; other strategies include the consistent use of male and female condoms and male circumcision. Adult male circumcision has been shown to decrease the transmission of HIV by 50%, and of herpes simplex virus and HPV by 30% in heterosexual couples in sub-Saharan Africa. For each patient, there are one or more sexual contacts who require diagnosis and treatment. Prompt treatment of contacts by giving antibiotics to the index case to distribute to all sexual contacts (patient-delivered therapy) is an important strategy for preventing further transmission and to prevent reinfection of the index case.

Note that vaginal spermicides and condoms containing nonoxynol-9 provide no additional protection against STDs. Early initiation of antiretroviral therapy in HIV-infected individuals can prevent HIV acquisition in an uninfected sex partner. Also, preexposure prophylaxis with a once-daily pill containing emtricitabine plus tenofovir disoproxil fumarate (TDF) has been shown to be effective in preventing HIV infection among high-risk men who have sex with men, heterosexual women and men, transgender women, and persons who inject drugs.

### When to Refer

- Patients with a new diagnosis of HIV.
- Patients with persistent, refractory, or recurrent STDs, particularly when drug resistance is suspected.

### INFECTIONS IN PERSONS WHO INJECT DRUGS

#### Essentials of Diagnosis

- Common infections that occur with greater frequency in persons who inject drugs include:
  - Skin infections, aspiration pneumonia, tuberculosis.
  - Hepatitis A, B, C, D; STDs; HIV/AIDS.
  - Pulmonary septic emboli, infective endocarditis.
  - Osteomyelitis and septic arthritis.

- **General Considerations**

  There is a high incidence of infection among drug users, particularly among people who inject drugs. Increased risk of infection is likely associated with poor hygiene and colonization with potentially pathogenic organisms, contamination of drugs and equipment, increased sexual risk behaviors, and impaired immune defenses. The use of parenterally administered recreational drugs has increased enormously in recent years, fueled in part by an epidemic of prescription opioid misuse and abuse. More than 2 million persons in North America are estimated to have used injection drugs in the past year.

  **Skin infections** are associated with poor hygiene and use of nonsterile technique when injecting drugs. *S aureus* (including community-acquired methicillin-resistant strains) and oral flora (streptococci, *Eikenella, Fusobacterium, Peptostreptococcus*) are the most common organisms, with enteric gram-negatives generally more likely seen in those who inject into the groin. Cellulitis and subcutaneous abscesses occur most commonly, particularly in association with subcutaneous (“skin-popping”) or intramuscular injections and the use of cocaine and heroin mixtures (probably due to ischemia). Myositis, clostridial myonecrosis, and necrotizing fasciitis occur infrequently but are life-threatening. Wound botulism in association with black tar heroin occurs sporadically but often in clusters.

When to Admit

- Persons who inject drugs with fever.
- Patients with persistent bacteremia.
- Patients with abscesses or progressive skin and soft tissue infections.

Treatment

Any patient with suspected or proven infective endocarditis and its complications (lung abscess, empyema, brain abscess) result from altered consciousness associated with drug use. Mixed aerobic and anaerobic mouth flora are usually involved.

Tuberculosis also occurs in persons who use drugs, and infection with HIV has fostered the spread of tuberculosis in this population. Morbidity and mortality rates are increased in HIV-infected individuals with tuberculosis. Classic radiographic findings are often absent; tuberculosis is suspected in any patient with infiltrates who does not respond to antibiotics.

Hepatitis is very common among persons who inject drugs and is transmissible both by the parenteral (hepatitis B, C, and D) and by the fecal-oral route (hepatitis A). Multiple episodes of hepatitis with different agents can occur.

Pulmonary septic emboli may originate from venous thrombi or right-sided endocarditis.

STDs are not directly related to drug use, but the practice of exchanging sex for drugs has resulted in an increased frequency of STDs. Syphilis, gonorrhea, and chancroid are the most common.

HIV/AIDS has a high incidence among persons who inject drugs and their sexual contacts and among the offspring of infected women (see Chapter 31).

Infective endocarditis in persons who inject drugs is most commonly caused by S aureus, Candida (usually C albicans or C parapsilosis), Enterococcus faecalis, other streptococci, and gram-negative bacteria (especially Pseudomonas and Serratia marcescens). See Chapter 33.

Other vascular infections include septic thrombophlebitis and mycotic aneurysms. Mycotic aneurysms resulting from direct trauma to a vessel with secondary infection most commonly occur in femoral arteries and less commonly in arteries of the neck. Aneurysms resulting from hematogenous spread of organisms frequently involve intracerebral vessels and thus are seen in association with endocarditis.

Osteomyelitis and septic arthritis involving vertebral bodies, sternoclavicular joints, the pubic symphysis, the sacroiliac joints, and other sites usually result from hematogenous distribution of injected organisms or septic venous thrombi. Pain and fever precede radiographic changes, sometimes by several weeks. While S aureus—often methicillin-resistant—is most common, Serratia, Pseudomonas, Candida (often not C albicans), and other pathogens rarely encountered in spontaneous bone or joint disease are found in persons who inject drugs.

When to Refer

- Any patient with suspected or proven infective endocarditis.
- Patients with persistent bacteremia.

When to Admit

- Persons who inject drugs with fever.
- Patients with abscesses or progressive skin and soft tissue infection that require debridement.

Aspiration pneumonia and its complications (lung abscess, empyema, brain abscess) result from altered consciousness associated with drug use. Mixed aerobic and anaerobic mouth flora are usually involved.

Hepatitis is very common among persons who inject drugs and is transmissible both by the parenteral (hepatitis B, C, and D) and by the fecal-oral route (hepatitis A). Multiple episodes of hepatitis with different agents can occur.

Pulmonary septic emboli may originate from venous thrombi or right-sided endocarditis.

STDs are not directly related to drug use, but the practice of exchanging sex for drugs has resulted in an increased frequency of STDs. Syphilis, gonorrhea, and chancroid are the most common.

HIV/AIDS has a high incidence among persons who inject drugs and their sexual contacts and among the offspring of infected women (see Chapter 31).

Infective endocarditis in persons who inject drugs is most commonly caused by S aureus, Candida (usually C albicans or C parapsilosis), Enterococcus faecalis, other streptococci, and gram-negative bacteria (especially Pseudomonas and Serratia marcescens). See Chapter 33.

Other vascular infections include septic thrombophlebitis and mycotic aneurysms. Mycotic aneurysms resulting from direct trauma to a vessel with secondary infection most commonly occur in femoral arteries and less commonly in arteries of the neck. Aneurysms resulting from hematogenous spread of organisms frequently involve intracerebral vessels and thus are seen in association with endocarditis.

Osteomyelitis and septic arthritis involving vertebral bodies, sternoclavicular joints, the pubic symphysis, the sacroiliac joints, and other sites usually result from hematogenous distribution of injected organisms or septic venous thrombi. Pain and fever precede radiographic changes, sometimes by several weeks. While S aureus—often methicillin-resistant—is most common, Serratia, Pseudomonas, Candida (often not C albicans), and other pathogens rarely encountered in spontaneous bone or joint disease are found in persons who inject drugs.

Treatment

A common and difficult clinical problem is management of a person known to inject drugs who presents with fever. In general, after obtaining appropriate cultures (blood, urine, and sputum if the chest radiograph is abnormal), empirical therapy is begun. If the chest radiograph is suggestive of a community-acquired pneumonia (consolidation), therapy for outpatient pneumonia is begun with ceftriaxone, 1 g intravenously every 24 hours, plus either azithromycin (500 mg orally or intravenously every 24 hours) or doxycycline (100 mg orally or intravenously twice daily). If the chest radiograph is suggestive of septic emboli (nodular infiltrates), therapy for presumed endocarditis is initiated, usually with vancomycin 15 mg/kg/dose every 12 hours intravenously (due to the high prevalence of MRSA and the possibility of enterococcus). If the chest radiograph is normal and no focal site of infection can be found, endocarditis is presumed. While awaiting the results of blood cultures, empiric treatment with vancomycin is started. If blood cultures are positive for organisms that frequently cause endocarditis in drug users (see above), endocarditis is presumed to be present and treated accordingly. If blood cultures are positive for an organism that is an unusual cause of endocarditis, evaluation for an occult source of infection should go forward. In this setting, a transesophageal echocardiogram may be quite helpful since it is 90% sensitive in detecting vegetations and a negative study is strong evidence against endocarditis. If blood cultures are negative and the patient responds to antibiotics, therapy should be continued for 7–14 days (oral therapy can be given once an initial response has occurred). In every patient, careful examination for an occult source of infection (eg, genitourinary, dental, sinus, gallbladder) should be done. Given the intersecting epidemics of opioid use disorder and the infectious complications that arise, clinicians must also be prepared to integrate treatment of opioid use disorder whenever possible.
ACUTE INFECTIOUS DIARRHEA

ESSENTIALS OF DIAGNOSIS

- **Acute diarrhea:** lasts less than 2 weeks
- **Chronic diarrhea:** lasts longer than 2 weeks.
- **Mild diarrhea:** 3 or fewer stools per day.
- **Moderate diarrhea:** 4 or more stools per day with local symptoms (abdominal cramps, nausea, tenesmus).
- **Severe diarrhea:** 4 or more stools per day with systemic symptoms (fever, chills, dehydration).

**General Considerations**

Acute diarrhea can be caused by a number of different factors, including emotional stress, food intolerance, inorganic agents (eg, sodium nitrite), organic substances (eg, mushrooms, shellfish), medications, and infectious agents (including viruses, bacteria, and protozoa) (Table 30–3). From a diagnostic and therapeutic standpoint, it is helpful to classify infectious diarrhea into syndromes that produce inflammatory or bloody diarrhea and those that are noninflammatory, nonbloody, or watery. In general, the term “inflammatory diarrhea” suggests colonic involvement by invasive bacteria or parasites by toxin production. Patients complain of frequent bloody or bloody stools, often associated with fever, abdominal cramps, tenesmus, and fecal urgency. Common causes of this syndrome include *Shigella*, *Salmonella*, *Campylobacter*, *Yersinia*, invasive strains of *Escherichia coli*, and other Shiga-toxin–producing strains of *E coli* (STEC), *Entamoeba histolytica*, and *C difficile*. Tests for fecal leukocytes or the neutrophil marker lactoferrin are frequently positive, and definitive etiologic diagnosis requires stool culture. **Noninflammatory diarrhea** is generally milder and is caused by viruses or toxins that affect the small intestine and interfere with salt and water balance, resulting in large-volume watery diarrhea, often with nausea, vomiting, and cramps. Common causes of this syndrome include viruses (eg, rotavirus, norovirus, astrovirus, enteric adenoviruses), vibriones (*Vibrio cholerae, Vibrio para-haemolyticus*), enterotoxin–producing *E coli*, *Giardia lamblia*, cryptosporidia, and agents that can cause food-borne gastroenteritis. In developed countries, viruses (particularly norovirus) are an important cause of hospitalizations due to acute gastroenteritis among adults.

The term “food poisoning” denotes diseases caused by toxins present in consumed foods. When the incubation period is short (1–6 hours after consumption), the toxin is usually preformed. Vomiting is usually a major complaint, and fever is usually absent. Examples include intoxication from *S aureus* or *Bacillus cereus*, and toxin can be detected in the food. When the incubation period is longer—between 8 hours and 16 hours—the organism is present in the food and produces toxin after being ingested. Vomiting is less prominent, abdominal cramping is frequent, and fever is often absent. The best example of this disease is that due to *Clostridium perfringens*. Toxin can be detected in food or stool specimens.

The inflammatory and noninflammatory diarrheas discussed above can also be transmitted by food and water and usually have incubation periods between 12 and 72 hours. *Cyclospora*, cryptosporidia, and *Isospora* are protozoans capable of causing disease in both immunocompetent and immunocompromised patients. Characteristics of disease include profuse watery diarrhea that is prolonged but usually self-limited (1–2 weeks) in the immunocompetent patient but can be chronic in the compromised host. Epidemiologic features may be helpful in determining etiology. Recent hospitalization or antibiotic use suggests *C difficile*; recent foreign travel suggests *Salmonella*, *Shigella*, *Campylobacter*, *E coli*, or *V cholerae*; undercooked hamburger suggests STEC; outbreak in long-term care facility, school, or cruise ship suggests norovirus (including newly identified strains, eg, GII.4 Sydney); and fried rice consumption is associated with *B cereus* toxin. Prominent features of some of these causes of diarrhea are listed in Table 30–3.

**Treatment**

A. General Measures

In general, most cases of acute gastroenteritis are self-limited and do not require therapy other than supportive measures. Treatment usually consists of replacement of fluids and electrolytes and, very rarely, management of hypovolemic shock and respiratory compromise. In mild diarrhea, increasing ingestion of juices and clear soups is adequate. In more severe cases of dehydration (postural lightheadedness, decreased urination), oral glucose-based rehydration solutions can be used (Ceralyte, Pedialyte).

B. Specific Measures

In immunocompetent adults, empiric antimicrobial therapy for bloody diarrhea while waiting for results is recommended only with the following circumstances: (1) documented fever, abdominal pain, bloody diarrhea, and bacillary dysentery (frequent scant bloody stools, fever, abdominal cramps, tenesmus) presumptively due to *Shigella*; and (2) returning travelers with a temperature of at least 38.5°C or signs of sepsis.

Either a fluoroquinolone or azithromycin should be used as empiric antimicrobial therapy for bloody diarrhea. Empiric antibacterial treatment should be considered in immunocompromised people with severe illness and bloody diarrhea. Loperamide may be given to immunocompetent adults with acute watery diarrhea, but should be avoided with *Shigella* infection or in suspected or proven toxic megacolon. Therapeutic recommendations for specific agents can be found elsewhere in this book.

Table 30–3. Acute bacterial diarrheas and "food poisoning" (listed in alphabetical order).

<td>Fever, diarrhea that can be bloody, cramps. Usually self-limited in 2–10 days. Treat with azithromycin or fluoroquinolones for severe disease. May be associated with Guillain-Barré syndrome.</td>
</tr>
<tr>
<td><em>Clostridium botulinum</em></td>
<td>12–72 hours</td>
<td>±</td>
<td>–</td>
<td>–</td>
<td>Clostridia grow in anaerobic acidic environment eg, canned foods, fermented fish, foods held warm for extended periods.</td>
<td>Stool, serum, and food can be tested for toxin. Stool and food can be cultured.</td>
<td>Diplopia, dysphagia, dysphonia, respiratory embarrassment. Treatment requires clear airway, ventilation, and intravenous polyvalent antitoxin (see text). Symptoms can last for days to months.</td>
</tr>
<tr>
<td><em>Clostridioides difficile</em></td>
<td>Usually occurs after 7–10 days of antibiotics. Can occur after a single dose or several weeks after completion of antibiotics.</td>
<td>–</td>
<td>+++</td>
<td>++</td>
<td>Associated with antibacterial drugs; clindamycin and beta-lactams most commonly implicated. Fluoroquinolones associated with hypervirulent strains.</td>
<td>Stool tested for toxin.</td>
<td>Abrupt onset of diarrhea that may be bloody; fever. Vancomycin 125 mg orally four times per day or fidaxomicin 200 mg twice daily for 10 days recommended over metronidazole.</td>
</tr>
<tr>
<td><em>Clostridium perfringens</em></td>
<td>8–16 hours</td>
<td>±</td>
<td>+++</td>
<td>–</td>
<td>Clostridia grow in rewarmed meat and poultry dishes and produce an enterotoxin.</td>
<td>Stools can be tested for enterotoxin or cultured.</td>
<td>Abrupt onset of profuse diarrhea, abdominal cramps, nausea; vomiting occasionally. Recovery usual without treatment in 24–48 hours. Supportive care; antibiotics not needed.</td>
</tr>
<tr>
<td>Enterohemorrhagic <em>Escherichia coli</em>, including Shiga-toxin–producing <em>E coli</em> strains (STEC)</td>
<td>1–8 days</td>
<td>+</td>
<td>+++</td>
<td>–</td>
<td>Undercooked beef, especially hamburger; unpasteurized milk and juice; raw fruits and vegetables.</td>
<td>Shiga-toxin–producing <em>E coli</em> can be cultured on special medium. Other toxins can be detected in stool.</td>
<td>Usually abrupt onset of diarrhea, often bloody; abdominal pain. In adults, it is usually self-limited to 3–5 days. In children, it is associated with hemolytic-uremic syndrome (HUS). Antibiotic therapy may increase risk of HUS. Plasma exchange may help patients with STEC–associated HUS.</td>
</tr>
<tr>
<td>Enterotoxigenic <em>E coli</em> (ETEC)</td>
<td>1–3 days</td>
<td>±</td>
<td>+++</td>
<td>±</td>
<td>Water, food contaminated with feces.</td>
<td>Stool culture. Special tests required to identify toxin–producing strains.</td>
<td>Watery diarrhea and abdominal cramps, usually lasting 3–7 days. In travelers, fluoroquinolones shorten disease.</td>
</tr>

</tr>
</tbody>
</table>

PCR, polymerase chain reaction.
The incubation period may be helpful in diagnosis. Less than 3 weeks following exposure may suggest dengue, leptospirosis, and yellow fever; more than 3 weeks suggest typhoid fever, malaria, and tuberculosis.

**General Considerations**

The differential diagnosis of fever in the returning traveler is broad, ranging from self-limited viral infections to life-threatening illness. The evaluation is best done by identifying whether a particular syndrome is present, then refining the differential diagnosis based on an exposure history. The travel history should include directed questions regarding geography (rural versus urban, specific country visited), time of year, animal or arthropod contact, unprotected sexual intercourse, ingestion of untreated water or raw foods, historical or pretravel immunizations, and adherence to malaria prophylaxis.

**Etiologies**

The most common infectious causes of fever—excluding simple causes such as upper respiratory infections, bacterial pneumonia and urinary tract infections—in returning travelers are malaria (see Chapter 35), diarrhea (see next section), and dengue (see Chapter 32). Others include mononucleosis (associated with Epstein-Barr virus or cytomegalovirus), respiratory infections, including seasonal influenza, influenza A/H1N1 “swine” influenza, and influenza A/H5N1 or A/H7N9 “avian” influenza (see Chapter 32); leptospirosis (see Chapter 34); typhoid fever (see Chapter 33); and rickettsial infections (see Chapter 32). Foreign travel is increasingly recognized as a risk factor for colonization and disease with resistant pathogens, such as ESBL-producing gram-negative organisms. Systemic febrile illnesses without a diagnosis also occur commonly, particularly in travelers returning from sub-Saharan Africa or Southeast Asia.

**A. Fever and Rash**

Potential etiologies include dengue, Ebola, Chikungunya, and Zika viruses, viral hemorrhagic fever, leptospirosis, meningococcemia, yellow fever, typhus, *Salmonella typhi*, and acute HIV infection.

**B. Pulmonary Infiltrates**

Tuberculosis, ascaris, *Paragonimus*, and *Strongyloides* can all cause pulmonary infiltrates.

**C. Meningoencephalitis**

Etiologies include *N meningitidis*, leptospirosis, arboviruses, rabies, and (cerebral) malaria.

**D. Jaundice**

Consider hepatitis A, yellow fever, hemorrhagic fever, leptospirosis, and malaria.

**E. Fever Without Localizing Symptoms or Signs**

Malaria, typhoid fever, acute HIV infection, rickettsial illness, visceral leishmaniasis, trypanosomiasis, and dengue are possible etiologies.

**F. Traveler’s Diarrhea**

See next section.

**Clinical Findings**

Fever and rash in the returning traveler should prompt blood cultures and serologic tests based on the exposure history. The workup of a pulmonary infiltrate should include the placement of a PPD or use of an interferon-gamma release assay, examination of sputum for acid-fast bacilli and possibly for ova and parasites. Patients with evidence of meningoencephalitis should receive lumbar puncture, blood cultures, thick/thin smears of peripheral blood, history-guided serologies, and a nape biopsy (if rabies is suspected). Jaundice in a returning traveler should be evaluated for hemolysis (for malaria), and the following tests should be performed: liver biochemical tests, thick/thin smears of peripheral blood, and directed serologic testing. The workup of traveler’s diarrhea is presented in the following section. Finally, patients with fever but no localizing signs or symptoms should have blood cultures performed. Routine laboratory studies usually include complete blood count with differential, electrolytes, liver biochemical tests, urinalysis, and blood cultures. Thick and thin peripheral blood smears should be done (and repeated in 12–24 hours if clinical suspicion remains high) for malaria if there has been travel to endemic areas. Other studies are directed by the results of history, physical examination, and initial laboratory tests. They may include stool for ova and parasites, chest radiograph, HIV test, and specific serologies (eg, dengue, leptospirosis, rickettsial disease, schistosomiasis, *Strongyloides*). Bone marrow biopsy to diagnose typhoid fever could be helpful in the appropriate patient.
TRAVELER’S DIARRHEA

**ESSENTIALS OF DIAGNOSIS**

- Usually a benign, self-limited disease occurring about 1 week into travel.
- Prophylaxis **not** recommended unless there is a comorbid disease (inflammatory bowel syndrome, HIV, immunosuppressive medication).
- Single-dose therapy of a fluoroquinolone usually effective if significant symptoms develop.

**General Considerations**

Whenever a person travels from one country to another—particularly if the change involves a marked difference in climate, social conditions, or sanitation standards and facilities—diarrhea may develop within 2–10 days. Bacteria cause 80% of cases of traveler’s diarrhea, with enterotoxigenic *E. coli*, *Shigella* species, and *Campylobacter jejuni* being the most common pathogens. Less common are *Aeromonas*, *Salmonella*, *noncholera vibriones*, *E. histolytica*, and *G. lamblia*. Contributory causes include unusual food and drink, change in living habits, occasional viral infections (adenoviruses or rotaviruses), and change in bowel flora. Chronic watery diarrhea may be due to amebiasis or giardiasis or, rarely, tropical sprue.

**When to Refer**

Travelers with fever, particularly if immunocompromised.

**When to Admit**

Any evidence of hemorrhage, respiratory distress, hemodynamic instability, and neurologic deficits.

**Clinical Findings**

**A. Symptoms and Signs**

There may be up to ten or even more loose stools per day, often accompanied by abdominal cramps and nausea, occasionally by vomiting, and rarely by fever. The stools are usually watery and not associated with fever when caused by enterotoxigenic *E. coli*. With invasive bacterial pathogens (*Shigella*, *Campylobacter*, *Salmonella*), stools can be bloody and fever may be present. The illness usually subsides spontaneously within 1–5 days, although 10% remain symptomatic for 1 week or longer, and symptoms persist for longer than 1 month in 2%. Traveler’s diarrhea is also a significant risk factor for developing irritable bowel syndrome.

**B. Laboratory Findings**

In patients with fever and bloody diarrhea, stool culture is indicated, but in most cases, cultures are reserved for those who do not respond to antibiotics.

**Prevention**

**A. General Measures**

Avoidance of fresh foods and water sources that are likely to be contaminated is recommended for travelers to developing countries, where infectious diarrheal illnesses are endemic.

**B. Specific Measures**

Because not all travelers will have diarrhea and because most episodes are brief and self-limited, the currently recommended approach is to provide the traveler with a supply of antimicrobials. Prophylaxis is recommended for those with significant underlying disease (inflammatory bowel disease, AIDS, diabetes mellitus, heart disease in older adults, conditions requiring immunosuppressive medications) and for those whose full activity status during the trip is so essential that even short periods of diarrhea would be unacceptable.

Prophylaxis is started upon entry into the destination country and is continued for 1 or 2 days after leaving. For stays of more than 3 weeks, prophylaxis is not recommended because of the cost and increased toxicity. For prophylaxis, several oral antimicrobial once-daily regimens are effective, such as ciprofloxacin, 500 mg, or rifaximin, 200 mg. Bismuth subsalicylate is effective but turns the tongue and the stools black and can interfere with doxycycline absorption, which may be needed for malaria prophylaxis; it is rarely used.

**Treatment**

For most individuals, the affliction is short-lived, and symptomatic therapy with loperamide is all that is required, provided the patient is not systemically ill (fever 39°C or higher) and does not have dysentery (bloody stools), in which case antimotility agents should be avoided. Packages of oral rehydration salts to treat dehydration are available over the counter in the United States (Infalyte, Pedialyte, others) and in many foreign countries.

When treatment is necessary, in areas where toxin-producing bacteria are the major cause of diarrhea (Latin America and Africa), loperamide (4 mg oral loading dose,
then 2 mg after each loose stool to a maximum of 16 mg/day)
with a single oral dose of ciprofloxacin (750 mg), levofloxa-
cin (500 mg), or ofloxacin (200 mg), cures most cases of
traveler’s diarrhea. If diarrhea is associated with bloody stools
or persists despite a single dose of a fluoroquinolone, 1000 mg
of azithromycin should be taken. In pregnant women and in
areas where invasive bacteria more commonly cause diar-
rhea (Indian subcontinent, Asia, especially Thailand where
fluoroquinolone-resistant Campylobacter is prevalent), azithromycin is the medication of choice. Rifaximin, a non-
absorbable agent, is also approved for therapy of traveler’s
diarrhea at a dose of 200 mg orally three times per day or
400 mg twice a day for 3 days. Because luminal concentra-
tions are high, but tissue levels are insufficient, it should not
be used in situations where there is a high likelihood of inva-
sive disease (eg, fever, systemic toxicity, or bloody stools).

► When to Refer
- Cases refractory to treatment.
- Persistent infection.
- Immunocompromised patient.

► When to Admit
 Patients who are severely dehydrated or hemodynamically
unstable should be admitted to the hospital.

¹Fluoroquinolones include ciprofloxacin, levofloxacin, moxifloxacin, and others. Gemifloxacin, levofloxacin, and moxifloxacin, the so-called respiratory fluoroquinolones, demonstrate the most reliable activity against penicillin-resistant *S pneumoniae* and other respiratory infection pathogens. Delafloxacin is predictably active against methicillin-resistant *S aureus* (MRSA).

²Azithromycin is the preferred macrolide due to increased safety profile and minimal drug interaction potential.

³All tetracyclines have similar activity against most microorganisms. Minocycline (the most active tetracycline) and doxycycline are more active than tetracycline against *S aureus*.

⁴TMP-SMZ is a mixture of 1 part trimethoprim and 5 parts sulfamethoxazole.

⁵Test of cure required if ceftriaxone not used.

⁶Penicillin G is preferred for parenteral injection; penicillin V for oral administration.

⁷Addition of gentamicin indicated only for severe enterococcal infections (eg, endocarditis, meningitis).

⁸Linezolid, tedizolid, daptomycin, teicoplanin, dalbavancin, and oritavancin should be reserved for the treatment of vancomycin-resistant isolates or in patients intolerant of vancomycin.

⁹Most intravenous cephalosporins (with the exception of ceftazidime) are active against streptococci and staphylococci.

¹⁰Parenteral nafcillin or oxacillin; oral dicloxacillin, cloxacillin, or oxacillin.

¹¹Infections caused by isolates with intermediate resistance may respond to high dose penicillin or ceftriaxone or the respiratory fluoroquinolones (gemifloxacin, levofloxacin, and moxifloxacin). Infections caused by highly penicillin-resistant isolates should be treated with vancomycin. Penicillin-resistant pneumococci are often resistant to macrolides, tetracyclines, and TMP-SMZ.

¹²Aminoglycosides—gentamicin, tobramycin, amikacin, netilmicin—should be chosen on the basis of local patterns of susceptibility.

¹³Extended beta-lactamase–producing (ESBL) isolates should be treated with a carbapenem. If a carbapenem cannot be used, ceftazidime-avibactam or possibly ceftolozane-tazobactam can be considered.

¹⁴Ceftolozane-tazobactam and occasionally ceftazidime-avibactam may be active against multidrug-resistant *P aeruginosa*.

¹⁵Consider in cases of infection due to carbapenemase-producing Enterobacteriaceae.

¹⁶Resistance is common and susceptibility testing must be performed.

¹⁷Ciprofloxacin has inferior antichlamydial activity compared with levofloxacin or ofloxacin. ±, alone or combined with.
A. Etiologic Diagnosis

Based on the organ system involved, the organism causing infection can often be predicted. See Tables 30–5 and 30–6.

B. “Best Guess”

Select an empiric regimen that is likely to be effective against the suspected pathogens.

C. Laboratory Control

Specimens for laboratory examination should be obtained before institution of therapy to determine susceptibility.

D. Clinical Response

Based on clinical response and other data, the laboratory reports are evaluated and then the desirability of changing the regimen is considered. If the specimen was obtained from a normally sterile site (eg, blood, cerebrospinal fluid, pleural fluid, joint fluid), the recovery of a microorganism in significant amounts is meaningful even if the organism recovered is different from the clinically suspected agent, and this may force a change in treatment. Isolation of unexpected microorganisms from the respiratory tract, gastrointestinal tract, or surface lesions (sites that have a complex flora) may represent colonization or contamination, and cultures must be critically evaluated before medications are abandoned that were judiciously selected on a “best guess” basis.

E. Drug Susceptibility Tests

Some microorganisms are predictably inhibited by certain medications; if such organisms are isolated, they need not be tested for drug susceptibility. For example, all group A hemolytic streptococci are inhibited by penicillin. Other organisms (eg, enteric gram-negative rods) are variably susceptible and generally require susceptibility testing whenever they are isolated. Organisms that once had predictable susceptibility patterns are now associated with resistance and require testing. Examples include the pneumococci, which may be resistant to multiple medications (including penicillin, macrolides, and TMP-SMZ); the enterococci, which may be resistant to penicillin, aminoglycosides, and vancomycin; and ESBL producing- E. coli resistant to third-generation cephalosporins and fluoroquinolones.

When culture and susceptibility results have been finalized, clinicians must use the most narrow-spectrum agent and the shortest duration possible to decrease the selection pressure for antibacterial resistance.

Antimicrobial drug susceptibility tests may be performed on solid media as disk diffusion tests, in broth, in tubes, in wells of microdilution plates, or as E-tests (strips with increasing concentration of antibiotic). The latter three methods yield results expressed as MIC (minimal inhibitory concentration). In most infections, the MIC is the appropriate in vitro test to guide selection of an antibacterial agent. When there appear to be marked discrepancies between susceptibility testing and clinical response, the following possibilities must be considered:

1. Selection of an inappropriate medication, medication dosage, or route of administration.
2. Failure to drain a collection of pus or to remove a foreign body.
3. Failure of a poorly diffusing drug to reach the site of infection (eg, central nervous system) or to reach intracellular phagocytosed bacteria.
4. Superinfection in the course of prolonged chemotherapy.
5. Emergence of drug resistance in the original pathogen or superinfection with a new more resistant organism.
6. Participation of two or more microorganisms in the infectious process, of which only one was originally detected and used for medication selection.
7. Inadequate host defenses, including immunodeficiencies and diabetes mellitus.
8. Noninfectious causes, including drug fever, malignancy, and autoimmune disease.

F. Promptness of Response

Response depends on a number of factors, including the patient (immunocompromised patients respond slower than immunocompetent patients), the site of infection (deep-seated infections such as osteomyelitis and endocarditis respond more slowly than superficial infections such as cystitis or cellulitis), the pathogen (virulent organisms such as S. aureus respond more slowly than viridans streptococci; mycobacterial and fungal infections respond slower than bacterial infections), and the duration of illness (in general, the longer the symptoms are present, the longer it takes to respond). Thus, depending on the clinical situation, persistent fever and leukocytosis several days after initiation of therapy may not indicate improper choice of antibiotics but may be due to the natural history of the disease being treated. In most infections, either a bacteriostatic or a bactericidal agent can be used. In some infections (eg, infective endocarditis and meningitis), a bactericidal agent should be used. When potentially toxic medications (eg, aminoglycosides, flucytosine) are used, serum levels of the medication are measured to minimize toxicity and ensure appropriate dosage. In patients with altered renal or hepatic clearance of medications, the dosage or frequency of administration must be adjusted; it is best to measure levels in older adults, in morbibly obese patients, or in those with altered kidney function when possible and adjust therapy accordingly.

G. Duration of Antimicrobial Therapy

Generally, effective antimicrobial treatment results in reversal of the clinical and laboratory parameters of active infection and marked clinical improvement. However, varying periods of treatment may be required for cure. Key factors include (1) the type of infecting organism (bacterial infections generally can be cured more rapidly than fungal or mycobacterial ones), (2) the location of the process (eg, endocarditis and osteomyelitis require prolonged therapy), and (3) the immunocompetence of the patient.
Table 30–5. Examples of initial antimicrobial therapy for acutely ill, hospitalized adults pending identification of causative organism (in alphabetical order).

<sup>1</sup>Amoxicillin-clavulanate is available as a combination of amoxicillin, 250 mg, 500 mg, or 875 mg, plus 125 mg of clavulanic acid. Augmentin XR is a combination of amoxicillin 1 g and clavulanic acid 62.5 mg.

<sup>2</sup>TMP-SMZ is a fixed combination of 1 part trimethoprim and 5 parts sulfamethoxazole. Single-strength tablets: 80 mg TMP, 400 mg SMZ; double-strength tablets: 160 mg TMP, 800 mg SMZ.

<sup>3</sup>The diagnosis should be confirmed by culture before therapy. *Salmonella* gastroenteritis does not require therapy. For susceptible *Shigella* isolates, give ciprofloxacin, 500 mg orally twice daily for 5 days. For *Campylobacter* infection, give azithromycin, 1 g orally once daily, or ciprofloxacin, 500 mg orally twice daily for 5 days. For *E. histolytica* infection, give metronidazole, 750 mg orally three times daily for 5–10 days, followed by diiodohydroxyquinoline (not available in United States), 650 mg orally three times daily for 3 weeks.

<sup>4</sup>Fluoroquinolones with activity against *S. pneumoniae,* including penicillin-resistant isolates, include gemifloxacin (not available in United States) (320 mg orally once daily), levofloxacin (500–750 mg orally once daily), and moxifloxacin (400 mg orally once daily). Use fluoroquinolones as drug of choice if recent antibiotic use within 3 months or comorbidities present.

<sup>5</sup>Fluoroquinolones and dosages include ciprofloxacin, 500 mg orally twice daily; ofloxacin, 400 mg orally twice daily; levofloxacin, 500 mg orally daily.

<sup>6</sup>Test of cure recommended if ceftriaxone is not used.

CA-MRSA, community-acquired methicillin-resistant *Staphylococcus aureus*; MRSA, methicillin-resistant *S. aureus*; MSSA, methicillin-sensitive *S. aureus*; TMP-SMZ, trimethoprim-sulfamethoxazole.

### H. Adverse Reactions and Toxicity

These include hypersensitivity reactions, direct toxicity, superinfection by drug-resistant microorganisms, and drug interactions. If the infection is life-threatening and treatment cannot be stopped, the reactions are managed symptomatically or another medication is chosen that does not cross-react with the offending one (Table 30–4). If the infection is less serious, it may be possible to stop all antimicrobials and monitor the patient closely.

### I. Route of Administration

Intravenous therapy is preferred for acutely ill patients with serious infections (eg, endocarditis, meningitis, sepsis, severe pneumonia) when dependable levels of antibiotics are required for successful therapy. Certain medications (eg, doxycycline, fluconazole, voriconazole, rifampin, metronidazole, TMP-SMZ, and fluoroquinolones) are so well absorbed that they generally can be administered orally in seriously ill—but not hemodynamically unstable—patients.

Food does not significantly influence the bioavailability of most oral antimicrobial agents. However, the tetracyclines (particularly tetracycline) and the quinolones chelate multivalent cations resulting in decreased oral bioavailability. Posaconazole suspension should always be administered with food.

A major complication of intravenous antibiotic therapy is infection due to the manipulation of the intravenous catheter. Peripheral catheters are changed every 48–72 hours.
to decrease the likelihood of catheter-associated infection, and antimicrobial-coated central venous catheters (minocycline and rifampin, chlorhexidine and sulfadiazine) have been associated with a decreased incidence of these infections. Most of these infections present with local signs of infection (erythema, tenderness) at the insertion site. In a patient with fever who is receiving intravenous therapy, the catheter must always be considered a potential source. Small-gauge (20–23F) peripherally inserted silicone or polyurethane catheters (Per Q Cath, A-Cath, Ven-A-Cath, and others) are associated with a low infection rate and can be maintained for 3–6 months without replacement. Such catheters are ideal for long-term outpatient antibiotic therapy.

J. Cost of Antibiotics

The cost of these agents can be substantial. In addition to acquisition costs and monitoring costs (drug levels, liver biochemical tests, electrolytes, etc), the cost of treating adverse reactions, the cost of treatment failure and super-infection, and the costs associated with drug administration must be considered.

HYPERSENSITIVITY

Penicillin Allergy

All penicillins are cross-sensitizing and cross-reacting. Skin tests using penicilloyl-polylysine and undegraded penicillin can identify most individuals with IgE-mediated reactions (hives, bronchospasm). In those patients with positive reaction to skin tests, the incidence of subsequent immediate severe reactions associated with penicillin administration is high. A history of a penicillin reaction in the past is often not reliable. Only a small proportion (less than 5%) of patients with a stated history of penicillin allergy experience an adverse reaction when challenged with the medication. The decision to administer penicillin or related medications (other beta-lactams) to patients with an allergic history depends on the severity of the reported reaction, the severity of the infection being treated, and the availability of alternative medications. For patients with a history of severe reaction (anaphylaxis), alternative medications should be used. In the rare situations where there is a strong indication for using penicillin (eg, syphilis in pregnancy) in allergic patients, desensitization can be performed. If the reaction is mild (nonurticarial rash), the patient may be rechallenged with penicillin or may be given another beta-lactam antibiotic.

Allergic reactions include anaphylaxis, serum sickness (urticaria, fever, joint swelling, angioedema 7–12 days after exposure), skin rashes, fever, interstitial nephritis, eosinophilia, hemolytic anemia, other hematologic disturbances, and vasculitis. The incidence of hypersensitivity to penicillin is estimated to be 1–5% among adults in the United States. Life-threatening anaphylactic reactions are very rare (0.05%). Ampicillin produces maculopapular skin rashes more frequently than other penicillins, but many ampicillin (and other beta-lactam) rashes are not allergic in origin. The nonallergic ampicillin rash usually occurs after 3–4 days of therapy, is maculopapular, is more common in patients with coexisting viral illness (especially Epstein-Barr infection), and resolves with continued therapy. The maculopapular rash may or may not reappear with rechallenge. Beta-lactams can induce nephritis with primary tubular lesions associated with anti-basement membrane antibodies.

If the intradermal test described below is negative, desensitization is not necessary, and a full dose of the penicillin may be given. If the test is positive, alternative medications should be strongly considered. If that is not feasible, desensitization is necessary.

Patients with a history of allergy to penicillin are also at an increased risk for having a reaction to cephalosporins or carbapenems. A common approach to these patients is to assess the severity of the reaction. If an IgE-mediated reaction to penicillin can be excluded by history, a cephalosporin can be administered. When the history justifies concern about an immediate-type reaction, penicillin skin testing should be performed. If the test is negative, the cephalosporin or carbapenem can be given. If the test is positive, there is a 5–10% chance of cross-reactivity with cephalosporins, and the decision whether to use cephalosporins depends on the availability of alternative agents and the severity of the infection. While carbapenems historically have been considered highly cross-reactive with penicillins, the cross-reactivity appears to be minimal (1%).

IMMUNIZATION AGAINST INFECTIOUS DISEASES

RECOMMENDED IMMUNIZATION FOR ADULTS

Immunization is one of the most important tools (along with sanitation) used to prevent morbidity and mortality from infectious diseases. In general, the administration of most vaccinations induces a durable antibody response (active immunity). In contrast, passive immunization
occurs when preformed antibodies are given (eg, immune globulin from pooled serum), resulting in temporary protection which is a less durable response. The two variants of active immunization are live attenuated vaccines (which are believed to result in an immunologic response more like natural infection), and inactivated or killed vaccines.

The schedule of vaccinations varies based on the risk of the disease being prevented by vaccination, whether a vaccine has been given previously, the immune status of the patient (probability of responding to vaccine) and safety of the vaccine (live versus killed product, as well as implications for the fetus in pregnant women). Recommendations for healthy adults as well as special populations based on medical conditions are summarized in Table 30–7, which can be accessed online at https://www.cdc.gov/vaccines/schedules.

1. Healthy Adults
Vaccination recommendations are made by the Advisory Committee on Immunization Practices (ACIP) of the US Centers for Disease Control and Prevention (Table 30–7).

2. Pregnant Women
Given the uncertainty of risks to the fetus, vaccination during pregnancy is generally avoided with the following exceptions: tetanus (transfer of maternal antibodies across the placenta is important to prevent neonatal tetanus), diphtheria, and influenza. Live vaccines are avoided during pregnancy.

Influenza can be a serious infection if acquired in pregnancy, and all pregnant women should be offered influenza (inactivated) vaccination. The live attenuated (intrasatal) influenza vaccine is not recommended during pregnancy.

3. HIV-Infected Adults
HIV-infected patients have impaired cellular and B cell responses. Inactivated or killed vaccinations can generally be given without any consequence, but the recipient may not be able to mount an adequate antibody response. Live or attenuated vaccines are generally avoided with some exceptions (ie, in patients with CD4+ T lymphocytes greater than 200 cells/ml). Guidelines for vaccinating HIV-infected patients have been issued jointly by the Centers for Disease Control and Prevention, the US National Institutes of Health, and the HIV Medical Association of the Infectious Diseases Society of America. Timing of vaccination is important to optimize response. If possible, vaccination should be given early in the course of HIV disease or following immune reconstitution.

4. Hematopoietic Cell Transplant Recipients
Hematopoietic cell transplant (HCT) recipients have varying rates of immune reconstitution following transplantation, depending on (1) the type of chemotherapy or radiotherapy used pretransplant (in autologous HCT), (2) the preparative regimen used for the transplant, (3) whether graft-versus-host disease is present, and (4) the type of immunosuppression used posttransplantation (in allogeneic HCT). Vaccines may not work immediately in the posttransplant period. B cells may take 3–12 months to return to normal posttransplant, and naïve T cells that can respond to new antigens appear only 6–12 months posttransplant. B cells of posttransplant patients treated with rituximab may take up to 6 months to fully recover after the last dose of the medication. Vaccines are therefore administered 6–12 months following transplantation with a minimum of 1 month between doses to maximize the probability of response.

5. Solid Organ Transplant Recipients
Solid organ transplant recipients demonstrate a broad spectrum of immunosuppression, depending on the reason for and type of organ transplantation and the nature of the immunosuppression (including T-cell-depleting agents during treatment of organ rejection). These factors affect the propensity for infection posttransplantation and the ability to develop antibody responses to vaccination. In many cases, the time between placing a patient on a transplant list and undergoing the transplantation takes months or years. Providers should take this opportunity to ensure that indicated vaccines are given during this pretransplant period to optimize antibody responses. If this is not possible, most experts give vaccines 3–6 months following transplantation. Live vaccines are contraindicated in the posttransplant period.

RECOMMENDED IMMUNIZATIONS FOR TRAVELERS
Individuals traveling to other countries frequently require immunizations in addition to those routinely recommended and may benefit from chemoprophylaxis against various diseases. Vaccinations against yellow fever and meningococcus are the only ones required by certain countries. These and other travel-specific vaccines are listed at http://wwwnc.cdc.gov/travel/destinations/list.

Various vaccines can be given simultaneously at different sites. Some, such as cholera, plague, and typhoid vaccine, cause significant discomfort and are best given at different times. In general, live attenuated vaccines (measles, mumps, rubella, yellow fever, and oral typhoid vaccine) should not be given to immunosuppressed individuals or household members of immunosuppressed people or to pregnant women. Immunoglobulin should not be given for 3 months before or at least 2 weeks after live virus vaccines, because it may attenuate the antibody response.

Chemoprophylaxis of malaria is discussed in Chapter 35.

VACCINE SAFETY
Most vaccines are safe to administer. In general, it is recommended that the use of live vaccines be avoided in immunocompromised patients, including pregnant women. Vaccines are generally not contraindicated in the following situations: mild, acute illness with low-grade

</table>

1. Precaution for LAIV does not apply to alcoholism. 2. See notes for influenza, hepatitis B, measles, mumps, and rubella, and varicella vaccinations. 3. Hematopoietic stem cell transplant.

(continued)
Haemophilus influenzae type b vaccination
Special situations
- Anatomical or functional asplenia (including sickle cell disease): 1 dose Hib if previously did not receive Hib; if elective splenectomy, 1 dose Hib, preferably at least 14 days before splenectomy
- Hematopoietic stem cell transplant (HSCT): 3-dose series Hib 4 weeks apart starting 6–12 months after successful transplant, regardless of Hib vaccination history

Hepatitis A vaccination
Routine vaccination
- Not at risk but want protection from hepatitis A (identification of risk factor not required): 2-dose series HepA (Havrix 6–12 months apart or Vaqta 6–18 months apart [minimum interval: 6 months]) or 3-dose series HepA–HepB (Twinrix at 0, 1, 6 months [minimum intervals: 4 weeks between doses 1 and 2, 5 months between doses 2 and 3])

Special situations
- At risk for hepatitis A virus infection: 2-dose series HepA or 3-dose series HepA–HepB as above
  - Chronic liver disease
  - Clotting factor disorders
  - Men who have sex with men
  - Injection or non-injection drug use
  - Homelessness
  - Work with hepatitis A virus in research laboratory or nonhuman primates with hepatitis A virus infection
  - Travel in countries with high or intermediate endemic hepatitis A
  - Close personal contact with international adoptee (e.g., household, regular babysitting) in first 60 days after arrival from country with high or intermediate endemic hepatitis A (administer dose 1 as soon as adoption is planned, at least 2 weeks before adoptee's arrival)

Hepatitis B vaccination
Routine vaccination
- Not at risk but want protection from hepatitis B (identification of risk factor not required): 2- or 3-dose series HepB (2-dose series Heplisav-B at least 4 weeks apart [2-dose series HepB only applies when 2 doses of Heplisav-B are used at least 4 weeks apart] or 3-dose series Engerix-B or Recombivax HB at 0, 1, 6 months [minimum intervals: 4 weeks between doses 1 and 2, 8 weeks between doses 2 and 3, 16 weeks between doses 1 and 3]) or 3-dose series HepA–HepB (Twinrix at 0, 1, 6 months [minimum intervals: 4 weeks between doses 1 and 2, 5 months between doses 2 and 3])

Special situations
- At risk for hepatitis B virus infection: 2-dose (Heplisav-B) or 3-dose (Engerix-B, Recombivax HB) series HepB, or 3-dose series HepA–HepB as above
  - Hepatitis C virus infection
  - Chronic liver disease (e.g., cirrhosis, fatty liver disease, alcoholic liver disease, autoimmune hepatitis, alanine aminotransferase [ALT] or aspartate aminotransferase [AST] level greater than twice upper limit of normal)
  - HIV infection
  - Sexual exposure risk (e.g., sex partners of hepatitis B surface antigen (HBsAg)-positive persons; sexually active persons not in mutually monogamous relationships, persons seeking evaluation or treatment for a sexually transmitted infection, men who have sex with men)
  - Current or recent injection drug use
  - Percutaneous or mucosal risk for exposure to blood (e.g., household contacts of HBsAg-positive persons; residents and staff of facilities for developmentally disabled persons; health care and public safety personnel with reasonably anticipated risk for exposure to blood or blood-contaminated body fluids; hemodialysis, peritoneal dialysis, home dialysis, and predialysis patients; persons with diabetes mellitus age younger than 60 years and, at discretion of treating clinician, those age 60 years or older)
  - Incarcerated persons
  - Travel in countries with high or intermediate endemic hepatitis B

Human papillomavirus vaccination
Routine vaccination
- Females through age 26 years and males through age 21 years: 2- or 3-dose series HPV vaccine depending on age at initial vaccination; males age 22 through 26 years may be vaccinated based on individual clinical decision (HPV vaccination routinely recommended at age 11–12 years)
- Age 15 years or older at initial vaccination: 3-dose series HPV vaccine at 0, 1–2, 6 months (minimum intervals: 4 weeks between doses 1 and 2, 12 weeks between doses 2 and 3, 5 months between doses 1 and 3; repeat dose if administered too soon)
• Age 9 through 14 years at initial vaccination and received 1 dose, or 2 doses less than 5 months apart: 1 dose HPV vaccine
• Age 9 through 14 years at initial vaccination and received 2 doses at least 5 months apart: HPV vaccination complete, no additional dose needed
• If completed valid vaccination series with any HPV vaccine, no additional doses needed

Special situations
• Immunocompromising conditions (including HIV infection) through age 26 years: 3-dose series HPV vaccine at 0, 1–2, 6 months as above
• Men who have sex with men and transgender persons through age 26 years: 2- or 3-dose series HPV vaccine depending on age at initial vaccination as above
• Pregnancy through age 26 years: HPV vaccination not recommended until after pregnancy; no intervention needed if vaccinated while pregnant; pregnancy testing not needed before vaccination

Influenza vaccination
Routine vaccination
• Persons age 6 months or older: 1 dose IIV, RIV, or LAIV appropriate for age and health status annually
• For additional guidance, see www.cdc.gov/flu/professionals/index.htm

Special situations
• Egg allergy, hives only: 1 dose IIV, RIV, or LAIV appropriate for age and health status annually
• Egg allergy more severe than hives (e.g., angioedema, respiratory distress): 1 dose IIV, RIV, or LAIV appropriate for age and health status annually in medical setting under supervision of health care provider who can recognize and manage severe allergic conditions
• Immunocompromising conditions (including HIV infection), anatomical or functional asplenia, pregnant women, close contacts and caregivers of severely immunocompromised persons in protected environment, use of influenza antiviral medications in previous 48 hours, with cerebrospinal fluid leak or cochlear implant: 1 dose IIV or RIV annually (LAIV not recommended)

Measles, mumps, and rubella vaccination
Routine vaccination
• No evidence of immunity to measles, mumps, or rubella: 1 dose MMR
  - Evidence of immunity: Born before 1957 (except health care personnel [see below]), documentation of receipt of MMR, laboratory evidence of immunity or disease (diagnosis of disease without laboratory confirmation is not evidence of immunity)

Special situations
• Pregnancy with no evidence of immunity to rubella: MMR contraindicated during pregnancy; after pregnancy (before discharge from health care facility), 1 dose MMR
• Non-pregnant women of childbearing age with no evidence of immunity to rubella: 1 dose MMR
• HIV infection with CD4 count ≥200 cells/μL for at least 6 months and no evidence of immunity to measles, mumps, or rubella: 2-dose series MMR at least 4 weeks apart; MMR contraindicated in HIV infection with CD4 count <200 cells/μL
• Severe immunocompromising conditions: MMR contraindicated
• Students in postsecondary educational institutions, international travelers, and household or close personal contacts of immunocompromised persons with no evidence of immunity to measles, mumps, or rubella: 1 dose MMR if previously received 1 dose MMR, or 2-dose series MMR at least 4 weeks apart if previously did not receive any MMR
• Health care personnel born in 1957 or later with no evidence of immunity to measles, mumps, or rubella: 1 dose MMR for rubella; if born before 1957, consider 2-dose series MMR at least 4 weeks apart for measles or mumps, or 1 dose MMR for rubella

Meningococcal vaccination
Special situations for MenACWY
• Anatomical or functional asplenia (including sickle cell disease), HIV infection, persistent complement component deficiency, eculizumab use: 2-dose series MenACWY (Menactra, Menveo) at least 8 weeks apart and revaccinate every 5 years if risk remains
• Travel in countries with hyperendemic or epidemic meningococcal disease, microbiologists routinely exposed to Neisseria meningitidis: 1 dose MenACWY and revaccinate every 5 years if risk remains
• First-year college students who live in residential housing (if not previously vaccinated at age 16 years or older) and military recruits: 1 dose MenACWY

Special situations for MenB
• Anatomical or functional asplenia (including sickle cell disease), persistent complement component deficiency, eculizumab use, microbiologists routinely exposed to Neisseria meningitidis: 2-dose series MenB-4C (Bexsero) at least 1 month apart, or 3-dose series MenB-FHbp (Trumenba) at 0, 1–2, 6 months (if dose 2 was administered at least 6 months after dose 1, dose 3 not needed); MenB-4C and MenB-FHbp are not interchangeable (use same product for all doses in series)
• Pregnancy: Delay MenB until after pregnancy unless at increased risk and vaccination benefit outweighs potential risks
• Healthy adolescents and young adults age 16 through 23 years (age 16 through 18 years preferred) not at increased risk for meningococcal disease: Based on individual clinical decision, may receive 2-dose series MenB-4C at least 1 month apart, or 2-dose series MenB-FHbp at 0, 6 months (if dose 2 was administered less than 6 months after dose 1, administer dose 3 at least 4 months after dose 2); MenB-4C and MenB-FHbp are not interchangeable (use same product for all doses in series)
Table 30–7. Recommended adult immunization schedule—United States, 2019. (continued)

**Pneumococcal vaccination**

**Routine vaccination**
- Age 65 years or older (immunocompetent): 1 dose PCV13 if previously did not receive PCV13, followed by 1 dose PPSV23 at least 1 year after PCV13 and at least 5 years after last dose PPSV23.  
  - Previously received PPSV23 but not PCV13 at age 65 years or older: 1 dose PCV13 at least 1 year after PPSV23.  
  - When both PCV13 and PPSV23 are indicated, administer PCV13 first (PCV13 and PPSV23 should not be administered during same visit).

**Special situations**
- Age 19 through 64 years with chronic medical conditions (chronic heart [excluding hypertension], lung, or liver disease; diabetes), alcoholism, or cigarette smoking: 1 dose PPSV23
- Age 19 years or older with immunocompromising conditions (congenital or acquired immunodeficiency [including B- and T-lymphocyte deficiency, complement deficiencies, phagocytic disorders, HIV infection], chronic renal failure, nephrotic syndrome, leukemia, lymphoma, Hodgkin disease, generalized malignancy, laryngeal immunosuppression [e.g., drug or radiation therapy], solid organ transplant, multiple myeloma) or anatomical or functional asplenia (including sickle cell disease and other hemoglobinopathies): 1 dose PCV13 followed by 1 dose PPSV23 at least 8 weeks later, then another dose PPSV23 at least 5 years after previous PPSV23, at age 65 years or older, administer 1 dose PPSV23 at least 5 years after most recent PPSV23 (note: only 1 dose PPSV23 recommended at age 65 years or older).
- Age 19 years or older with cerebrospinal fluid leak or cochlear implant: 1 dose PCV13 followed by 1 dose PPSV23 at least 8 weeks later; at age 65 years or older, administer another dose PPSV23 at least 5 years after PPSV23 (note: only 1 dose PPSV23 recommended at age 65 years or older).

**Tetanus, diphtheria, and pertussis vaccination**

**Routine vaccination**
- Previously did not receive Tdap at or after age 11 years: 1 dose Tdap, then Td booster every 10 years

**Special situations**
- Previously did not receive primary vaccination series for tetanus, diphtheria, and pertussis: 1 dose Tdap followed by 1 dose Td at least 4 weeks after Tdap, and another dose Td 6–12 months after last Td (Tdap can be substituted for any Td dose, but preferred as first dose), Td booster every 10 years thereafter.
- Pregnancy: 1 dose Tdap during each pregnancy, preferably in early part of gestational weeks 27–36.
- For information on use of Tdap or Td as tetanus prophylaxis in wound management, see www.cdc.gov/mmwr/volumes/67/rr/rr6702a1.htm.

**Varicella vaccination**

**Routine vaccination**
- No evidence of immunity to varicella: 2-dose series VAR 4–8 weeks apart if previously did not receive varicella-containing vaccine (VAR or MMRV [measles-mumps-rubella-varicella vaccine] for children), if previously received 1 dose varicella-containing vaccine: 1 dose VAR at least 4 weeks after first dose.
  - Evidence of immunity: US-born before 1980 (except for pregnant women and health care personnel [see below]), documentation of 2 doses varicella-containing vaccine at least 4 weeks apart, diagnosis or verification of history of varicella or herpes zoster by a health care provider, laboratory evidence of immunity or disease.

**Special situations**
- Pregnancy with no evidence of immunity to varicella: VAR contraindicated during pregnancy; after pregnancy (before discharge from health care facility), 1 dose VAR if previously received 1 dose varicella-containing vaccine, or dose 1 of 2-dose series VAR (dose 2: 4–8 weeks later) if previously did not receive any varicella-containing vaccine, regardless of whether US-born before 1980.
- Health care personnel with no evidence of immunity to varicella: 1 dose VAR if previously received 1 dose varicella-containing vaccine, or dose 2 of 2-dose series VAR 4–8 weeks apart if previously did not receive any varicella-containing vaccine, regardless of whether US-born before 1980.
- HIV infection with CD4 count ≥200 cells/μL with no evidence of immunity: Consider 2-dose series VAR 3 months apart based on individual clinical decision; VAR contraindicated in HIV infection with CD4 count <200 cells/μL.
- Severe immunocompromising conditions: VAR contraindicated.

**Zoster vaccination**

**Routine vaccination**
- Age 50 years or older: 2-dose series RZV 2–6 months apart (minimum interval: 4 weeks; repeat dose if administered too soon) regardless of previous herpes zoster or previously received ZVL (administer RZV at least 2 months after ZVL).
- Age 60 years or older: 2-dose series RZV 2–6 months apart (minimum interval: 4 weeks; repeat dose if administered too soon) or 1 dose ZVL if not previously vaccinated (if previously received ZVL, administer RZV at least 2 months after ZVL; RZV preferred over ZVL).

**Special situations**
- Pregnancy: ZVL contraindicated; consider delaying RZV until after pregnancy if RZV is otherwise indicated.
- Severe immunocompromising conditions (including HIV infection with CD4 count <200 cells/μL): ZVL contraindicated; recommended use of RZV under review.
### Table 30–8. Adverse effects and contraindications to commonly used vaccines in adults (listed in alphabetical order).

<table>
<thead>
<tr>
<th>Vaccine</th>
<th>Adverse Effects</th>
<th>Contraindications¹</th>
</tr>
</thead>
<tbody>
<tr>
<td>Haemophilus influenzae Type b (Hib)</td>
<td>Minimal Consist mainly of pain at the injection site</td>
<td>Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component.</td>
</tr>
<tr>
<td>Hepatitis A</td>
<td>Minimal Consist mainly of pain at the injection site</td>
<td>Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component.</td>
</tr>
<tr>
<td>Hepatitis B</td>
<td>Minimal Consist mainly of pain at the injection site</td>
<td>Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component.</td>
</tr>
<tr>
<td>Human papillomavirus</td>
<td>Minimal Consist mainly of mild to moderate localized pain, erythema, swelling, Systemic reactions, mainly fever, seen in 4% of recipients</td>
<td>Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component.</td>
</tr>
<tr>
<td>Influenza (intramuscular inactivated and intranasal live attenuated vaccines)</td>
<td>Intramuscular, inactivated vaccine: Local reactions (erythema and tenderness) at the site of injection are common, but fevers, chills, and malaise (which last in any case only 2–3 days) are rare. <strong>Either inactivated or live attenuated vaccine:</strong> A potential association between Guillain-Barré syndrome (3000–6000 cases per year in the United States, usually following respiratory infections) and vaccination with intramuscular, inactivated influenza vaccine has been reported (possibly, 1–2 persons per million persons vaccinated), but this rate is lower than the risk of the syndrome developing after influenza itself (given that approximately 750 persons per million adults are hospitalized annually with influenza, and many more cases remain as outpatients).</td>
<td>Contraindication to both inactivated and live attenuated vaccine: History of Guillain-Barré syndrome, especially within 6 weeks of receiving a previous influenza vaccine. Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component, including egg protein.² Intranasal, live attenuated vaccine (FluMist) should not be used in: • People 50 years of age and over • Immunosuppressed individuals and those on immunosuppressive therapy • Household members of immunosuppressed individuals • Health care workers, or others with close contact with immunosuppressed persons • Presence of reactive airway disease (eg, asthma) or chronic underlying metabolic (eg, kidney), pulmonary, or heart diseases (use intramuscular inactivated vaccine) • Pregnancy³ It is recommended that salicylates should be avoided for 6 weeks following vaccination (to prevent Reye syndrome).</td>
</tr>
<tr>
<td>Measles, mumps, and rubella (MMR)⁴</td>
<td>Fever will develop in about 5–15% of unimmunized individuals, and a mild rash will develop in about 5% 5–12 days after vaccination. Fever and rash are self-limited, lasting only 2–3 days. Local swelling and induration are particularly common in individuals previously vaccinated with inactivated vaccine.</td>
<td>Pregnancy⁴ Known severe immunodeficiency (eg, from hematologic and solid cancers, receipt of chemotherapy, congenital immunodeficiency, long-term immunosuppressive therapy (eg, &gt; 2 weeks of prednisone 20 mg daily or higher), other disease- or therapy-related immune suppression, or patients with HIV infection who are severely immunocompromised. May be used in asymptomatic HIV-infected individuals whose CD4 count is &gt; 200/mcL. Severe allergic reaction (eg, anaphylaxis) to a previous dose or to a vaccine component (eg, neomycin or to related agents such as streptomycin).</td>
</tr>
<tr>
<td>Meningococcal, oligosaccharide conjugate; (MCV4 or MenACWY) [Menactra, Menevo]; meningococcal polysaccharide conjugate MPSV4 [Menomune]); meningococcal group B, recombinant (MenB [Bexsero, Trumenba])</td>
<td>Minor reactions (fever, redness, swelling, erythema, pain) occur slightly more commonly with MCV4. Major reactions are rare. A potential association between Guillain-Barré syndrome (3000–6000 cases per year in the United States, usually following respiratory infections) and vaccination with MCV4 has been reported, but current recommendations favor continued use of MCV4, since the benefits of preventing the serious consequences of meningococcal infection outweigh the theoretical risk of Guillain-Barré syndrome.</td>
<td>Any severe allergic reaction (eg, anaphylaxis) to a previous dose or to a vaccine component (eg, persons with history of adverse reaction to diphtheria toxoid should not receive meningococcal oligosaccharide conjugate and polysaccharide conjugate vaccines since the protein conjugate used in them is diphtheria toxoid).</td>
</tr>
</tbody>
</table>

(continued)
Table 30–8. Adverse effects and contraindications to commonly used vaccines in adults (listed in alphabetical order). (continued)

<table>
<thead>
<tr>
<th>Vaccine</th>
<th>Adverse Effects</th>
<th>Contraindications&lt;sup&gt;1&lt;/sup&gt;</th>
</tr>
</thead>
<tbody>
<tr>
<td>Pneumococcal conjugate (PCV13 [Prevnar]); Pneumococcal polysaccharide (PPSV23) [Pneumovax])</td>
<td>Mild local reactions (erythema and tenderness) occur in up to 50% of recipients, but systemic reactions are uncommon. Similarly, revaccination at least 5 years after initial vaccination is associated with mild self-limited local but not systemic reactions.</td>
<td>Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component (eg, for PCV13 to any vaccine containing diphtheria toxoid).</td>
</tr>
<tr>
<td>Tetanus, diphtheria, and pertussis (DTP, Tdap); tetanus, diphtheria (Td)</td>
<td>Minimal Consist mainly of pain at the injection site</td>
<td>Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component. For pertussis-containing vaccines: any history of unexplained encephalopathy (eg, coma, decreased level of consciousness, or prolonged seizures) within 7 days of administration of a previous dose of Tdap or diphtheria and tetanus toxoids and pertussis (DTP) or diphtheria and tetanus toxoids and acellular pertussis (Tdap) vaccine.</td>
</tr>
<tr>
<td>Varicella</td>
<td>Can occur as late as 4–6 weeks after vaccination. Tenderness and erythema at the injection site are seen in 25%, fever in 10–15%, and a localized maculopapular or vesicular rash in 5%; a diffuse rash, usually with five or fewer vesicular lesions, develops in a smaller percentage. Spread of virus from vaccinees to susceptible individuals is possible, but the risk of such transmission even to immunocompromised patients is small, and disease, when it develops, is mild and treatable with acyclovir.</td>
<td>Known severe immunodeficiency (eg, from hematologic and solid cancers, receipt of chemotherapy, congenital immunodeficiency, long-term immunosuppressive therapy [eg, &gt; 2 weeks of prednisone 20 mg daily or higher; other immunosuppressive medications], other disease- or therapy-related immune suppression, or patients with HIV infection who are severely immunocompromised). Pregnancy. Severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component (eg, neomycin). For theoretic reasons, it is recommended that salicylates should be avoided for 6 weeks following vaccination (to prevent potential for Reye syndrome).</td>
</tr>
<tr>
<td>Zoster</td>
<td>Mild and limited to local reactions Although it is theoretically possible to transmit the virus to susceptible contacts, no such cases have been reported.</td>
<td>Known severe immunodeficiency (eg, from hematologic and solid cancers, receipt of chemotherapy, congenital immunodeficiency, long-term immunosuppressive therapy [eg, &gt; 2 weeks of prednisone 20 mg daily or higher; other immunosuppressive medications], other disease- or therapy-related immune suppression, or patients with HIV infection who are severely immunocompromised. May be used in asymptomatic HIV-infected individuals whose CD4 count is &gt; 200/mcL). Pregnancy. Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component (eg, gelatin or neomycin).</td>
</tr>
</tbody>
</table>

<sup>2</sup>The vaccine has typically been prepared using embryonated chicken eggs. However, a new vaccine using mammalian cell culture is now FDA approved.

<sup>3</sup>The inactivated influenza vaccine can be given during any trimester.

<sup>4</sup>MMR vaccine can be safely given to patients with a history of egg allergy even when severe.

<sup>5</sup>Although vaccination of pregnant women is not recommended, with the currently available RA27/3 vaccine strain, the congenital rubella syndrome does not occur in the offspring of those inadvertently vaccinated during pregnancy or within 3 months before conception.
fevers (less than 40.5°C); concurrent antibiotic therapy; soreness or redness at the site; and family history of adverse reactions to vaccinations. Absolute contraindications to vaccines are rare (Table 30–8).

**ESSENTIALS OF DIAGNOSIS**

- Modes of transmission: sexual contact with an infected person, parenteral exposure to infected blood (transfusion or needle sharing), perinatal exposure.
- Prominent systemic complaints: sweats, diarrhea, weight loss, and wasting.
- Opportunistic infections due to diminished cellular immunity—often life-threatening.
- Aggressive cancers, particularly non-Hodgkin lymphoma.
- Neurologic manifestations, including dementia, aseptic meningitis, and neuropathy.

**General Considerations**

The Centers for Disease Control and Prevention (CDC) AIDS case definition (Table 31–1) includes opportunistic infections and malignancies that rarely occur in the absence of severe immunodeficiency (eg, *Pneumocystis* pneumonia, central nervous system lymphoma). It also classifies persons as having AIDS if they have positive HIV serology and certain infections and malignancies that can occur in immunocompetent hosts but that are more common among persons infected with HIV (pulmonary tuberculosis, invasive cervical cancer). Several nonspecific conditions, including dementia and wasting (documented weight loss)—in the presence of a positive HIV serology—are considered AIDS. The definition includes criteria for both definitive and presumptive diagnoses of certain infections and malignancies. Finally, persons with positive HIV serology who have ever had a CD4 lymphocyte count below 200 cells/mcL or a CD4 lymphocyte percentage below 14% are considered to have AIDS. Inclusion of persons with low CD4 counts as AIDS cases reflects the recognition that immunodeficiency is the defining characteristic of AIDS. The choice of a cutoff point at 200 cells/mcL is supported by several cohort studies showing that AIDS will develop within 3 years in over 80% of persons with counts below this level in the absence of effective antiretroviral therapy. The prognosis of persons with HIV/AIDS has dramatically improved due to the development of effective antiretroviral treatment. One consequence is that fewer persons with HIV ever develop an infection or malignancy or have a low enough CD4 count to classify them as having AIDS, which means that the CDC definition has become a less useful measure of the impact of HIV/AIDS in the United States. Conversely, persons in whom AIDS had been diagnosed based on a serious opportunistic infection, malignancy, or immunodeficiency may now be markedly healthier, with high CD4 counts, due to the use of antiretroviral treatment. Therefore, the Social Security Administration as well as most social service agencies focus on functional assessment for determining eligibility for benefits rather than the simple presence or absence of an AIDS-defining illness.

**Epidemiology**

The modes of transmission of HIV are similar to those of hepatitis B, in particular with respect to sexual, parenteral, and vertical transmission. Although certain sexual practices (eg, receptive anal intercourse) are significantly riskier than other sexual practices (eg, oral sex), it is difficult to quantify per-contact risks. The reason is that studies of sexual transmission of HIV show that most people at risk for HIV infection engage in a variety of sexual practices and have sex with multiple persons, only some of whom may actually be HIV infected. Thus, it is difficult to determine which practice with which person actually resulted in HIV transmission.

Nonetheless, the best available estimates indicate that the risk of HIV transmission with receptive anal intercourse is between 1:100 and 1:30, with insertive anal intercourse 1:1000, with receptive vaginal intercourse 1:1000, with insertive vaginal intercourse 1:10,000, and with receptive fellatio with ejaculation 1:1000. The per-contact risk of HIV transmission with other behaviors, including receptive fellatio without ejaculation, insertive fellatio, and cunnilingus, is not known.

A number of cofactors are known to increase the risk of HIV transmission during a given encounter, including the...

</table>
The risk of acquiring HIV infection from a needlestick with infected blood is approximately 1:300. Factors known to increase the risk of transmission include depth of penetration, hollow bore needles, visible blood on the needle, and advanced stage of disease in the source. The risk of HIV transmission from a mucosal splash with infected blood is unknown but is assumed to be significantly lower.

The risk of acquiring HIV infection from illicit drug use with sharing of needles from an HIV-infected source is estimated to be 1:150. Use of clean needles markedly decreases the chance of HIV transmission, but does not eliminate it if other drug paraphernalia are shared (eg, cookers).

When blood transfusion from an HIV-infected donor occurs, the risk of transmission is 95%. Fortunately, since 1985, blood donor screening using the HIV enzyme-linked immunosorbent assay (ELISA) has been universally practiced in the United States. Also, persons who have recently engaged in unsafe behaviors (eg, sex with a person at risk for HIV, injection drug use) are not allowed to donate. This essentially eliminates donations from persons who are HIV infected but have not yet developed antibodies (ie, persons in the “window” period). HIV antigen and viral load testing have been added to the screening of blood to further lower the chance of HIV transmission. With these precautions, the chance of HIV transmission with receipt of blood transfusion in the United States is about 1:1,000,000. Between 13% and 40% of children born to HIV-infected mothers contract HIV infection when the mother has not received treatment or when the child has not received perinatal HIV prophylaxis. The risk is higher with vaginal than with cesarean delivery, higher among mothers with high viral loads, and higher among those who breastfeed their children. The combination of prenatal HIV testing and counseling, antiretroviral treatment for infected mothers during pregnancy and for the infant immediately after birth, scheduled cesarean delivery when the mother has a viral load of greater than 1000 copies/mL, and avoidance of breastfeeding has reduced the rate of perinatal transmission of HIV to less than 2% in the United States and Europe.

HIV has not been shown to be transmitted by respiratory droplet spread, by vectors such as mosquitoes, or by casual nonsexual contact. Saliva, sweat, stool, and tears are not considered infectious fluids.

Since the epidemic began in the early 1980s, a total of 1,232,346 Americans have been diagnosed with AIDS. There are an estimated 1.1 million adults and adolescents in the United States living with HIV, 15% of whom are undiagnosed. Young people (age 13 to 24) are the most likely to not know they are infected (51%). In 2016, 39,782 Americans were newly diagnosed with HIV infection. Gay and bisexual men accounted for most of the new diagnoses (67%), and among them, black/African-American men accounted for more new diagnoses (10,223) than Latinos (7425) or whites (7390). Between 2011 and 2015, new HIV diagnoses decreased by 10% among white gay and bisexual males, but increased 4% among African-American gay and bisexual males, and 14% among Latino gay and bisexual men. Heterosexual contacts accounted for 24% (9578) of new HIV diagnoses, women accounted for 19% (7529) and injection drug users for 9% (3425) of new HIV diagnoses, including gay and bisexual men who inject drugs. In 2016, African Americans and Latinos were disproportionately hard hit by the epidemic. Though representing 12% of the US population, African Americans accounted for 44% of new HIV diagnoses (17,528 cases). Latinos, who represent about 18% of the US population, accounted for 25% of new HIV diagnoses (9766 cases).

In general, the progression of HIV-related illness is similar in men and women. However, there are some important differences. Women are at risk for gynecologic complications of HIV, including recurrent candidal vaginitis, pelvic inflammatory disease, and cervical dysplasia. Violence directed against women, pregnancy, and frequent occurrence of drug use and poverty all complicate the treatment of HIV-infected women.

Worldwide there are an estimated 36.9 million persons infected with HIV, with heterosexual spread being the most common mode of transmission for men and women. The reason for the greater risk for transmission with heterosexual intercourse in Africa and Asia than in the United States may relate to cofactors such as general health status, the presence of genital ulcers, relative lack of male circumcision, the number of sexual partners, and different HIV serotypes. It is estimated that in 2016, 19.5 million persons infected with HIV were receiving treatment (53%), up from 17.1 million in 2015.

Pathophysiology

Clinically, the syndromes caused by HIV infection are usually explicable by one of three known mechanisms: immunodeficiency, autoimmunity, and allergic and hypersensitivity reactions.

A. Immunodeficiency

Immunodeficiency is a direct result of the effects of HIV upon immune cells as well as the indirect impact of a generalized state of inflammation and immune activation due to chronic viral infection. A spectrum of infections and neoplasms is seen, as in other congenital or acquired immunodeficiency states. Two remarkable features of HIV immunodeficiency are the low incidence of certain
infections such as listeriosis and aspergillosis and the frequent occurrence of certain neoplasms such as lymphoma or Kaposi sarcoma. This latter complication has been seen primarily in men who have sex with men (MSM) or in bisexual men, and its incidence steadily declined through the first 15 years of the epidemic. A herpesvirus (KSHV or HHV-8) is the cause of Kaposi sarcoma.

B. Autoimmunity/Allergic and Hypersensitivity Reactions

Autoimmunity can occur as a result of disordered cellular immune function or B lymphocyte dysfunction. Examples of both lymphocytic infiltration of organs (eg, lymphocytic interstitial pneumonitis) and autoantibody production (eg, immunologic thrombocytopenia) occur. These phenomena may be the only clinically apparent disease or may coexist with obvious immunodeficiency. Moreover, HIV-infected individuals appear to have higher rates of allergic reactions to unknown allergens as seen with eosinophilic pustular folliculitis ("itchy red bump syndrome") as well as increased rates of hypersensitivity reactions to medications (for example, the fever and sunburn-like rash seen with trimethoprim-sulfamethoxazole reactions).

Clinical Findings

The complications of HIV-related infections and neoplasms affect virtually every organ. The general approach to the HIV-infected person with symptoms is to evaluate the organ systems involved, aiming to diagnose treatable conditions rapidly. As can be seen in Figure 31–1, the CD4 lymphocyte count result enables the clinician to focus on the diagnoses most likely to be seen at each stage of immunodeficiency. Certain infections may occur at any CD4 count, while others rarely occur unless the CD4 lymphocyte count has dropped below a certain level. For example, a patient with a CD4 count of 600 cells/μL, cough, and fever may have a bacterial pneumonia but would be very unlikely to have Pneumocystis pneumonia.

A. Symptoms and Signs

Many individuals with HIV infection remain asymptomatic for years even without antiretroviral treatment, with a mean time of approximately 10 years between infection and development of AIDS. When symptoms occur, they may be remarkably protean and nonspecific. Since virtually all the findings may be seen with other diseases, a combination of complaints is more suggestive of HIV infection than any one symptom.

Physical examination may be entirely normal. Abnormal findings range from completely nonspecific to highly specific for HIV infection. Those that are specific for HIV infection include hairy leukoplakia of the tongue, disseminated Kaposi sarcoma, and cutaneous bacillary angiomatosis. Generalized lymphadenopathy is common early in infection.

The specific presentations and management of the various complications of HIV infection are discussed under the Complications section below.

![Figure 31–1.](image-url) Relationship of CD4 count to development of opportunistic infections. MAC, *Mycobacterium avium* complex; CMV, cytomegalovirus; CNS, central nervous system.
These tests measure the amount of actively replicating HIV virus. Correlate with disease progression and to guide therapy decisions (Table 31–2). As counts decrease, the risk of serious opportunistic infection over the subsequent 3–5 years increases (Figure 31–1). There are many limitations to using the CD4 count, including diurnal variation, depression with intercurrent illness, and intra-laboratory and interlaboratory variability. Therefore, the trend is more important than a single determination. The frequency of performance of counts depends on the patient’s health status and whether or not they are receiving antiretroviral treatment. All patients regardless of CD4 count should be offered antiretroviral treatment; CD4 counts should be monitored every 3–6 months in patients taking antiretroviral treatment consistently. Initiation of *Pneumocystis jirovecii* prophylactic therapy is recommended when the CD4 count drops below 200 cells/mcL, and initiation of *Mycobacterium avium* prophylaxis is recommended when the CD4 count drops below 75–100 cells/mcL. Some studies suggest that the percentage of CD4 lymphocytes is a more reliable indicator of prognosis than the absolute counts because the percentage does not depend on calculating a manual differential. While the CD4 count measures immune dysfunction, it does not provide a measure of how actively HIV is replicating in the body. HIV viral load tests assess the level of viral replication and provide useful prognostic information that is independent of the information provided by CD4 counts.

### Table 31–2. Laboratory findings with HIV infection.

<table>
<thead>
<tr>
<th>Test</th>
<th>Significance</th>
</tr>
</thead>
<tbody>
<tr>
<td>HIV enzyme-linked immunosorbent assay (ELISA)</td>
<td>Screening test for HIV infection. Of ELISA tests 50% are positive within 22 days after HIV transmission; 95% are positive within 6 weeks after transmission. Sensitivity greater than 99.9%; to avoid false-positive results, repeatedly reactive results must be confirmed with Western blot.</td>
</tr>
<tr>
<td>Western blot</td>
<td>Confirmatory test for HIV. Specificity when combined with ELISA greater than 99.99%. Indeterminate results with early HIV infection, HIV-2 infection, influenza vaccine, autoimmune disease, pregnancy, and recent tetanus toxoid administration.</td>
</tr>
<tr>
<td>HIV rapid antibody test</td>
<td>Screening test for HIV. Produces results in 10–20 minutes. Can be performed by personnel with limited training. Positive results must be confirmed with standard HIV tests (ELISA and Western blot).</td>
</tr>
<tr>
<td>Complete blood count</td>
<td>Anemia, neutropenia, and thrombocytopenia common with advanced HIV infection.</td>
</tr>
<tr>
<td>Absolute CD4 lymphocyte count</td>
<td>Most widely used predictor of HIV progression. Risk of progression to an AIDS opportunistic infection or malignancy is high with CD4 less than 200 cells/mcL in the absence of treatment.</td>
</tr>
<tr>
<td>CD4 lymphocyte percentage</td>
<td>Percentage may be more reliable than the CD4 count. Risk of progression to an AIDS opportunistic infection or malignancy is high with percentage less than 14% in the absence of treatment.</td>
</tr>
<tr>
<td>HIV viral load tests</td>
<td>These tests measure the amount of actively replicating HIV virus. Correlate with disease progression and response to antiretroviral medications. Best tests available for diagnosis of acute HIV infection (prior to seroconversion); however, caution is warranted when the test result shows low-level viremia (ie, less than 500 copies/mL) as this may represent a false-positive test.</td>
</tr>
</tbody>
</table>
**Differential Diagnosis**

HIV infection may mimic a variety of other medical illnesses. Specific differential diagnosis depends on the mode of presentation. In patients presenting with constitutional symptoms such as weight loss and fevers, differential considerations include cancer, chronic infections such as tuberculosis and endocarditis, and endocrinologic diseases such as hyperthyroidism. When pulmonary processes dominate the presentation, acute and chronic lung infections must be considered as well as other causes of diffuse interstitial pulmonary infiltrates. When neurologic disease is the mode of presentation, conditions that cause mental status changes or neuropsychopathy—e.g., alcoholism, liver disease, kidney dysfunction, thyroid disease, and vitamin deficiency—should be considered. If a patient presents with headache and a cerebrospinal fluid pleocytosis, other causes of chronic meningitis enter the differential. When diarrhea is a prominent complaint, infectious enterocolitis, antibiotic-associated colitis, inflammatory bowel disease, and malabsorptive syndromes must be considered.

**Complications**

**A. Systemic Complaints**

Fever, night sweats, and weight loss are common symptoms in HIV-infected patients and may occur without a complicating opportunistic infection. Patients with persistent fever and no localizing symptoms should nonetheless be carefully examined, and evaluated with a chest radiograph (Pneumocystis pneumonia can present without respiratory symptoms), bacterial blood cultures if the fever is greater than 38.5°C, serum cryptococcal antigen, and mycobacterial cultures of the blood. Sinus CT scans should be considered to evaluate occult sinusitis. If these studies are normal, patients should be observed closely. Antipyretics are useful to prevent dehydration.

**B. Management**—Several strategies have been developed to slow AIDS wasting. In the long term, nothing is as effective as antiretroviral treatment, since it treats the underlying HIV infection. In the short term, effective fever control decreases the metabolic rate and may slow the pace of weight loss, as does treating the underlying opportunistic infection. Food supplementation with high-calorie drinks may enable patients with not much appetite to maintain their intake. Selected patients with otherwise good functional status and weight loss due to unrelenting nausea, vomiting, or diarrhea may benefit from total parenteral nutrition (TPN). It should be noted, however, that TPN is more likely to increase fat stores than to reverse the muscle wasting process.

Two pharmacologic approaches for increasing appetite and weight gain are the progestational agent megestrol acetate liquid suspension (400–800 mg orally daily in divided doses) and the antiemetic agent dronabinol (2.5–5 mg orally three times a day), but neither of these agents increases lean body mass. Side effects from megestrol acetate are rare, but thromboembolic phenomena, edema, nausea, vomiting, and rash have been reported. Euphoria, dizziness, paranoia, and somnolence and even nausea and vomiting have been reported in 3–10% of patients using dronabinol. Dronabinol contains only one of the active ingredients in marijuana, and many patients report better relief of nausea and improvement of appetite with medical cannabis (administered via smoking, vaporization, essential oils, or cooked in food). In the United States, 33 states have legalized medical marijuana, and 10 states and the District of Columbia have legalized recreational (nonmedical) use. However, the use and sale of marijuana are still illegal under federal law.

Two regimens that have resulted in increases in lean body mass are growth hormone and anabolic steroids. Growth hormone at a dose of 0.1 mg/kg/day (up to 6 mg) subcutaneously for 12 weeks has resulted in modest increases in lean body mass. Treatment with growth hormone can cost as much as $10,000 per month. Anabolic steroids also increase lean body mass among HIV-infected patients. They seem to work best for patients who are able to do weight training. The most commonly used regimens are testosterone enanthate or testosterone cypionate (100–200 mg intramuscularly every 2–4 weeks). Testosterone transdermal system (apply 5 mg system each evening) and testosterone gel (1%; apply a 5-g packet [50 mg testosterone] to clean, dry skin daily) are also available. The anabolic steroid oxandrolone (20 mg orally in two divided doses) has also been found to increase lean body mass.

Exacerbating the decrease in caloric intake, many AIDS patients have an increased metabolic rate. This increased rate has been shown to exist even among asymptomatic HIV-infected persons, but it accelerates with disease progression and secondary infection. AIDS patients with secondary infections also have decreased protein synthesis, which makes maintaining muscle mass difficult.

1. **Weight loss and wasting syndrome**—Weight loss is a particularly distressing complication of long-standing HIV infection. Patients typically have disproportionate loss of muscle mass, with maintenance or less substantial loss of fat stores. The mechanism of HIV-related weight loss is not completely understood but appears to be multifactorial.

**A. Presentation**—AIDS patients frequently suffer from anorexia, nausea, and vomiting, all of which contribute to weight loss by decreasing caloric intake. In some cases, these symptoms are secondary to a specific infection, such as viral hepatitis. In other cases, however, evaluation of the symptoms yields no specific pathogen, and it is assumed to be due to a primary effect of HIV. Malabsorption also plays a role in decreased caloric intake. Patients may suffer diarrhea from infections with bacterial, viral, or parasitic agents.

**References**

2. Nausea—Nausea leading to weight loss is sometimes due to esophageal candidiasis and nausea should be empirically treated with an oral antifungal agent. Patients with weight loss due to nausea of unclear origin may benefit from use of antiemetics prior to meals (prochlorperazine, 10 mg three times daily; metoclopramide, 10 mg three times daily; or ondansetron, 8 mg three times daily). Dronabinol (5 mg three times daily) or medical cannabis can also be used to treat nausea. Depression and adrenal insufficiency are two potentially treatable causes of weight loss.

B. Pulmonary Disease

1. Pneumocystis pneumonia—(See also Chapter 36.) P jiroveci pneumonia is the most common opportunistic infection associated with AIDS. Pneumocystis pneumonia may be difficult to diagnose because the symptoms—fever, cough, and shortness of breath—are nonspecific. Furthermore, the severity of symptoms ranges from fever and no respiratory symptoms through mild cough or dyspnea to frank respiratory distress.

Hypoxemia may be severe, with a PO2 less than 60 mm Hg. The cornerstone of diagnosis is the chest radiograph. Diffuse or perihilar infiltrates are most characteristic, but only two-thirds of patients with Pneumocystis pneumonia have this finding. Normal chest radiographs are seen in 5–10% of patients with Pneumocystis pneumonia, while the remainder have atypical infiltrates. Apical infiltrates are commonly seen among patients with Pneumocystis pneumonia who have been receiving aerosolized pentamidine prophylaxis. Large pleural effusions are uncommon with Pneumocystis pneumonia; their presence suggests bacterial pneumonia, other infections such as tuberculosis, or pleural Kaposi sarcoma.

Definitive diagnosis can be obtained in 50–80% of cases by Wright-Giemsa stain or direct fluorescence antibody (DFA) test of induced sputum. Sputum induction is performed by having patients inhale an aerosolized solution of 3% saline produced by an ultrasonic nebulizer. Patients should not eat or drink for at least 8 hours and should not use toothpaste or mouthwash prior to the procedure since they can interfere with test interpretation. The next step for patients with negative sputum examinations is bronchoalveolar lavage. This technique establishes the diagnosis in over 95% of cases.

In patients with symptoms suggestive of Pneumocystis pneumonia but with negative or atypical chest radiographs and negative sputum examinations, other diagnostic tests may provide additional information in deciding whether to proceed to bronchoalveolar lavage. Elevation of serum lactate dehydrogenase occurs in 95% of cases of Pneumocystis pneumonia, but the specificity of this finding is at best 75%. A serum beta-glucan test is a more sensitive and specific test for Pneumocystis pneumonia compared with serum lactate dehydrogenase and may avoid more invasive tests when used in the appropriate clinical setting. Either a normal diffusing capacity of carbon monoxide (DLCO) or a high-resolution CT scan of the chest that demonstrates no interstitial lung disease makes the diagnosis of Pneumocystis pneumonia very unlikely. In addition, a CD4 count greater than 250 cells/mcL within 2 months prior to evaluation of respiratory symptoms makes a diagnosis of Pneumocystis pneumonia unlikely; only 1–5% of cases occur above this CD4 count level (Figure 31–1). This is true even if the patient previously had a CD4 count lower than 200 cells/mcL but has had an increase with antiretroviral treatment.

Pneumothoraces can be seen in HIV-infected patients with a history of Pneumocystis pneumonia.

Trimethoprim-sulfamethoxazole is the preferred treatment of Pneumocystis pneumonia (Table 31–3). In addition to specific anti-Pneumocystis treatment, corticosteroid therapy has been shown to improve the course of patients with moderate to severe P jiroveci pneumonia (PaO2 less than 70 mm Hg on room air or alveolar-arterial O2 gradient greater or equal to 35 mm Hg) when administered within 72 hours of the start of anti-Pneumocystis treatment. It should be started as early as possible after initiation of treatment, using prednisone 40 mg orally twice daily for days 1–5, 40 mg daily for days 6–10, and 20 mg daily for days 11–21 (for patients who cannot take oral medication, intravenous methylprednisolone can be substituted at 75% of the dose). The mechanism of action is presumed to be a decrease in alveolar inflammation.

2. Other infectious pulmonary diseases—

A. Presentation—Other infectious causes of pulmonary disease in AIDS patients include bacterial, mycobacterial, and viral pneumonias. Community-acquired pneumonia is the most common cause of pulmonary disease in HIV-infected persons. An increased incidence of pneumococcal pneumonia with sepsis and Haemophilus influenzae pneumonia has been reported. Pseudomonas aeruginosa is an important respiratory pathogen in advanced disease and, more rarely, pneumonia from Rhodococcus equi infection can occur. The incidence of infection with Mycobacterium tuberculosis has markedly increased in metropolitan areas because of HIV infection as well as homelessness.
Table 31–3. Treatment of AIDS-related opportunistic infections and malignancies.¹

²List of complications is not exhaustive.

³Prior to use of primaquine or dapsone, check glucose-6-phosphate dehydrogenase (G6PD) level in black patients and those of Mediterranean origin.

EPOCH, etoposide, prednisolone, vincristine (Oncovin), cyclophosphamide, doxorubicin (hydroxydaunomycin), G-CSF, granulocyte-colony stimulating factor (filgrastim).

---

2List of complications is not exhaustive.

3Prior to use of primaquine or dapsone, check glucose-6-phosphate dehydrogenase (G6PD) level in black patients and those of Mediterranean origin.

EPOCH, etoposide, prednisolone, vincristine (Oncovin), cyclophosphamide, doxorubicin (hydroxydaunomycin), G-CSF, granulocyte-colony stimulating factor (filgrastim).
Tuberculosis occurs in an estimated 4% of persons in the United States who have AIDS. Patients with active tuberculosis and CD4 counts above 350 cells/mcL are likely to present with upper lobe and hilar and paratracheal adenopathy findings similar to persons uninfected with HIV. With advanced immunodeficiency, lower lobe, middle lobe, interstitial and miliary infiltrates are more common, along with mediastinal adenopathy and extrapulmonary involvement. Although a purified protein derivative (PPD) test or an interferon gamma release assay (IGRA, including the QuantiFERON and T-SPOT tests) should be performed on all HIV-infected persons in whom a diagnosis of tuberculosis is being considered, the lower the CD4 cell count, the greater the likelihood of falsely negative PPD or IGRA test results or of indeterminate IGRA test results. Because “anergy” skin test panels do not accurately classify those patients who are infected with tuberculosis but unreactive to the PPD, they are not recommended.

B. MANAGEMENT—Treatment of HIV-infected persons with active tuberculosis is similar to treatment of HIV-uninfected tubercular individuals. However, rifampin should not be given to patients receiving a boosted protease inhibitor (PI) regimen. In these cases, rifabutin may be substituted, but it may require dosing modifications depending on the antiretroviral regimen. Multidrug-resistant tuberculosis has been a major problem in several metropolitan areas of the developed world, and reports from South Africa of “extremely resistant” tuberculosis in AIDS patients are a growing global concern. Noncompliance with prescribed antituberculous medications is a major risk factor. Several of the reported outbreaks appear to implicate nosocomial spread. The emergence of medication resistance makes it essential that antibiotic sensitivities be performed on all positive cultures. Medication therapy should be individualized. Patients with multidrug-resistant \textit{M} tuberculosis infection should receive at least three medications to which their organism is sensitive. Atypical mycobacteria can cause pulmonary disease in AIDS patients with or without preexisting lung disease and responds variably to treatment. Making a distinction between \textit{M} tuberculosis and atypical mycobacteria requires culture of sputum specimens. If culture of the sputum produces acid-fast bacilli, definitive identification may take several weeks using traditional techniques. DNA probes allow for presumptive identification usually within days of a positive culture. While awaiting definitive diagnosis, clinicians should err on the side of treating patients as if they have \textit{M} tuberculosis infection. In cases in which the risk of atypical mycobacteria is very high (eg, a person without risk for tuberculosis exposure with a CD4 count under 50 cells/mcL—see Figure 31–1), clinicians may wait for definitive diagnosis if the person is smear-negative for acid-fast bacilli, clinically stable, and not living in a communal setting. Isolation of cytomegalovirus (CMV) from bronchoalveolar lavage fluid occurs commonly in AIDS patients but does not establish a definitive diagnosis. Diagnosis of CMV pneumonia requires biopsy; response to treatment is poor. Histoplasmosis, coccidioidomycosis, and cryptococcal disease as well as more common respiratory viral infections should also be considered in the differential diagnosis of unexplained pulmonary infiltrates.

3. Noninfectious pulmonary diseases—

A. PRESENTATION—Noninfectious causes of lung disease include Kaposi sarcoma, non-Hodgkin lymphoma, interstitial pneumonitis, and increasingly, in the current antiretroviral treatment era, lung cancer. In patients with known Kaposi sarcoma, pulmonary involvement complicates the course in approximately one-third of cases. However, pulmonary involvement is rarely the presenting manifestation of Kaposi sarcoma. Non-Hodgkin lymphoma may involve the lung as the sole site of disease, but more commonly involves other organs as well, especially the brain, liver, and gastrointestinal tract. Both of these processes may show nodular or diffuse parenchymal involvement, pleural effusions, and mediastinal adenopathy on chest radiographs.

Nonspecific interstitial pneumonitis may mimic \textit{Pneumocystis} pneumonia. Lymphocytic interstitial pneumonitis seen in lung biopsies has a variable clinical course. Typically, these patients present with several months of mild cough and dyspnea; chest radiographs show interstitial infiltrates. Many patients with this entity undergo transbronchial biopsies in an attempt to diagnose \textit{Pneumocystis} pneumonia. Instead, the tissue shows interstitial inflammation ranging from an intense lymphocytic infiltration (consistent with lymphoid interstitial pneumonitis) to a mild mononuclear inflammation.

B. MANAGEMENT—Corticosteroids may be helpful in some cases refractory to antiretroviral treatment.

4. Sinusitis—

A. Presentation—Chronic sinusitis can be a frustrating problem for HIV-infected patients. Symptoms include sinus congestion and discharge, headache, and fever. Some patients may have radiographic evidence of sinus disease on sinus CT scan in the absence of significant symptoms.

B. Management—HIV-infected patients with purulent drainage should be treated for possible H influenzae with amoxicillin-potassium clavulanate (500 mg orally three times a day) (see Chapter 8). A 7-day course of pneumatic-ethedrine 60 mg twice daily may be helpful in decreasing congestion. Prolonged treatment (3–6 weeks) with an antibiotic and guaifenesin (600 mg orally twice daily) is sometimes necessary. For patients not responding to amoxicillin-potassium clavulanate, levofloxacin may be tried (400 mg orally daily). In patients with advanced immunodeficiency, Pseudomonas infections should be suspected, especially if there is not a response to first-line antibiotics. Some patients may require referral to an otolaryngologist for sinus drainage and culture for possible fungal infection (Aspergillus, Histoplasma capsulatum).

2. Central Nervous System Lymphoma—Primary non-Hodgkin lymphoma is the second most common CNS space-occupying lesion in HIV-infected patients. Symptoms are similar to those with toxoplasmosis. While imaging techniques cannot distinguish these two diseases with certainty, lymphoma more often is solitary. Other less common lesions should be suspected if there is preceding bacteremia, positive tuberculin test, fungemia, or injection drug use. These include bacterial abscesses, cryptococcomas, tuberculomas, and Nocardia lesions.

Stereotactic brain biopsy should be strongly considered if lesions are solitary or do not respond to toxoplasmosis treatment, especially if they are easily accessible. Diagnosis of lymphoma is important because many patients benefit from treatment (radiation therapy). Although a positive polymerase chain reaction (PCR) assay of cerebrospinal fluid for Epstein–Barr virus DNA is consistent with a diagnosis of lymphoma, the sensitivity and specificity of the test are not high enough to obviate the need for a brain biopsy.

1. Toxoplasmosis—Toxoplasmosis is the most common CNS space-occupying lesion in HIV-infected patients. Headache, focal neurologic deficits, seizures, or altered mental status may be presenting symptoms. The diagnosis is usually made presumptively based on the characteristic appearance of cerebral imaging studies in an individual known to be seropositive for Toxoplasma. Typically, toxoplasmosis appears as multiple contrast-enhancing lesions on CT scan. Lesions tend to be peripheral, with a predilection for the basal ganglia.

Single lesions are atypical of toxoplasmosis. When a single lesion has been detected by CT scanning, MRI scanning may reveal multiple lesions because of its greater sensitivity. If a patient has a single lesion on MRI and is neurologically stable, clinicians may pursue a 2-week empiric trial of toxoplasmosis therapy. A repeat scan should be performed at 2 weeks. If the lesion has not diminished in size, biopsy of the lesion should be performed. A positive Toxoplasma serologic test does not confirm the diagnosis because many HIV-infected patients have detectable titers without having active disease. Conversely, less than 3% of patients with toxoplasmosis have negative titers. Therefore, negative Toxoplasma titers in an HIV-infected patient with a space-occupying lesion should be a cause for aggressively pursuing an alternative diagnosis. The preferred treatment of toxoplasmosis is with pyrimethamine and sulfadiazine (Table 31–3). If pyrimethamine is not available, patients can be treated with trimethoprim-sulfamethoxazole.

3. HIV-associated dementia and neurocognitive disorders—Patients with HIV-associated dementia typically have difficulty with cognitive tasks (eg, memory, attention), exhibit diminished motor function, and have emotional or behavioral problems. Patients may first notice a deterioration in their handwriting. The manifestations of dementia may wax and wane, with persons exhibiting periods of lucidity and confusion over the course of a day. The diagnosis of HIV-associated dementia is one of exclusion based on a brain imaging study and on spinal fluid analysis that excludes other pathogens. Neuropsychiatric testing is helpful in distinguishing patients with dementia from those with depression. Many patients improve with effective antiretroviral treatment. However, slowly progressive neurocognitive deficits may still develop in patients taking antiretroviral treatment as they age.

Metabolic abnormalities may also cause changes in mental status: hypoglycemia, hyponatremia, hypoxia, and drug overdose are important considerations in this population. Other less common infectious causes of encephalopathy include progressive multifocal leukoencephalopathy (discussed below), CMV, syphilis, and herpes simplex encephalitis.

4. Cryptococcal meningitis—Cryptococcal meningitis typically presents with fever and headache. Less than 20% of patients have meningismus. Diagnosis is based on a positive latex agglutination test of serum that detects cryptococcal antigen (or “CRAG”) or positive culture of spinal fluid for Cryptococcus. Seventy to 90% of patients with cryptococcal meningitis have a positive serum CRAG. Thus, a negative serum CRAG test makes a diagnosis of cryptococcal meningitis unlikely and can be useful in the initial evaluation of a patient with headache, fever, and normal mental status. The preferred treatment is liposomal amphotericin with flucytosine (Table 31–3).

5. Meningococcal meningitis—HIV-infected persons are at increased risk for meningococcal disease. Treatment is the same as in uninfected persons. Therefore, the Advisory Committee on Immunization Practices recommends the meningococcal conjugate vaccine (serogroups A, C, W, and Y) for all HIV-infected persons aged 2 months or older.

6. HIV meningitis and HIV myelopathy—HIV meningitis, characterized by lymphocytic pleocytosis of the spinal fluid with negative culture, is common early in HIV infection. Spinal cord function may also be impaired in HIV-infected individuals. HIV myelopathy presents with leg weakness and incontinence. Spastic paraparesis and sensory ataxia are seen on neurologic examination. Myelopathy is usually a late manifestation of HIV disease, and most patients will have concomitant HIV encephalopathy. Pathologic evaluation of the spinal cord reveals vacuolation of white matter. Because HIV myelopathy is a diagnosis of exclusion, symptoms suggestive of myelopathy should be evaluated by lumbar puncture to rule out CMV polyradiculopathy (described below) and an MRI or CT scan to exclude epidural lymphoma.

7. Progressive multifocal leukoencephalopathy (PML)—PML is a viral infection of the white matter of the brain seen in patients with very advanced HIV infection. It typically results in focal neurologic deficits such as aphasia, hemiparesis, and cortical blindness. Imaging studies are strongly suggestive of the diagnosis if they show nonenhancing white matter lesions without mass effect. Extensive lesions may be difficult to differentiate from the changes caused by HIV. Several patients have stabilized or improved after the institution of effective antiretroviral treatment, and due to wide use of antiretroviral treatment, PML is now rarely seen.

D. Peripheral Nervous System

A. Presentation—Peripheral nervous system syndromes include inflammatory polyneuropathies, sensory neuropathies, and mononeuropathies.

An inflammatory demyelinating polyneuropathy similar to Guillain-Barré syndrome occurs in HIV-infected patients, usually prior to frank immunodeficiency. The syndrome in many cases improves with plasmapheresis, supporting an autoimmune basis of the disease. CMV can cause an ascending polyradiculopathy characterized by lower extremity weakness and a neutrophilic pleocytosis on spinal fluid analysis with a negative bacterial culture. Transverse myelitis can be seen with herpes zoster or CMV.

Peripheral neuropathy is common among HIV-infected persons. Patients typically complain of numbness, tingling, and pain in the lower extremities. Symptoms are disproportionate to findings on gross sensory and motor evaluation. Beyond HIV infection itself, the most common cause is prior antiretroviral treatment with stavudine or didanosine. Although not used commonly in Western countries, stavudine is still being used in resource-limited settings through national antiretroviral treatment programs. Caution should be used when administering these agents to patients with a history of peripheral neuropathy. Unfortunately, medication-induced neuropathy is not always reversed when the offending agent is discontinued. Patients with advanced disease may also develop peripheral neuropathy even if they have never taken antiretroviral treatment. Evaluation should rule out other causes of sensory neuropathy such as alcoholism, thyroid disease, vitamin B₁₂ deficiency, and syphilis.

B. Management—Treatment of peripheral neuropathy is aimed at symptomatic relief. Patients should be initially treated with gabapentin (start at 300 mg at bedtime and increase to 300–900 mg orally three times a day) or other co-analgesics for neuropathic pain (see Chapter 5). Opioid analgesics should be avoided because the condition tends to be chronic and patients are likely to become dependent on these agents without significant improvement in their well-being.

E. Rheumatologic and Bone Manifestations

Arthritis, involving single or multiple joints, with or without effusion, has been commonly noted in HIV-infected patients. Involvement of large joints is most common. Although the cause of HIV-related arthritis is unknown, most patients will respond to nonsteroidal anti-inflammatory medications. Patients with a sizable effusion, especially if the joint is warm or erythematous, should have the joint aspirated, followed by culture of the fluid to rule out suppurrative arthritis as well as fungal and mycobacterial disease.

Several rheumatologic syndromes, including reactive arthritis, psoriatic arthritis, sicca syndrome, and systemic lupus erythematosus, have been reported in HIV-infected patients (see Chapter 20). However, it is unclear if the prevalence is greater than in the general population. Cases of avascular necrosis of the femoral heads have been reported sporadically, generally in the setting of advanced disease with long-standing infection and in patients receiving long-term antiretroviral treatment. The etiology is not clear but is probably multifactorial in nature.

Osteoporosis and osteopenia appear to be more common in HIV-infected patients with chronic infection and perhaps associated with long-term use of antiretroviral treatment. Vitamin D deficiency appears to be quite common among HIV-infected populations and monitoring vitamin D levels and replacement therapy for detected deficiency are recommended. Bone mineral density scans for postmenopausal women and for men over the age of 50 is also recommended.

H. Oral Lesions

A. Presentation—The presence of oral candidiasis or hairy leukoplakia is significant for several reasons. First, these lesions are highly suggestive of HIV infection in patients who have no other obvious cause of immunodeficiency. Second, several studies have indicated that patients with candidiasis have a high rate of progression to AIDS even with statistical adjustment for CD4 count.

Hairy leukoplakia is caused by the Epstein-Barr virus. The lesion is not usually troubling to patients and sometimes regresses spontaneously. Hairy leukoplakia is commonly seen as a white lesion on the lateral aspect of the tongue. It may be flat or slightly raised, and has vertical parallel lines with fine or thick (“hairy”) projections (Figure 8–6). Oral candidiasis can be bothersome to patients, many of whom report an unpleasant taste or mouth dryness. The two most common forms of oral candidiasis seen are pseudomembranous (removable white plaques) (Figure 31–2A) and erythematous (red friable plaques) (Figure 31–2B).

B. Management—Treatment of oral candidiasis is with topical agents such as clotrimazole 10-mg troches (one troche four or five times a day). Patients with candidiasis who do not respond to topical antifungals can be treated with fluconazole (50–100 mg orally once a day for 3–7 days).

Angular cheilitis—fissures at the sides of the mouth—is usually due to Candida as well (Figure 31–2B) and can be treated topically with ketoconazole cream (2%) twice a day.

Gingival disease is common in HIV-infected patients and is thought to be due to an overgrowth of microorganisms. It usually responds to professional dental cleaning and chlorhexidine rinses. A particularly aggressive gingivitis or periodontitis will develop in some HIV-infected patients; these patients should be given antibiotics that cover anaerobic oral flora (eg, metronidazole, 250 mg four times a day for 4 or 5 days) and referred to oral surgeons with experience with these entities.

Aphthous ulcers (Figure 31–3) are painful and may interfere with eating. They can be treated with fluocinonide (0.05% ointment mixed 1:1 with plain Orabase and applied six times a day to the ulcer). For lesions that are difficult to reach, patients should use dexamethasone swishes (0.5 mg in 5 mL elixir three times a day). The pain of the ulcers can be relieved with use of an anesthetic spray (10% lidocaine). Other lesions seen in the mouths of HIV-infected patients include Kaposi sarcoma (usually on the hard palate) and warts.

I. Gastrointestinal Manifestations

1. Candidal esophagitis—(See also Chapter 15.) Esophageal candidiasis is a common AIDS complication. In a patient with characteristic symptoms, empiric antifungal treatment is begun with fluconazole (100–200 mg orally daily for 14–21 days). Improvement in symptoms should be apparent within 1–2 days of antifungal treatment. If there is no improvement, further evaluation to identify other causes of esophagitis (herpes simplex, CMV) is recommended.

2. Hepatic disease—

A. Presentation—Autopsy studies have demonstrated that the liver is a frequent site of infections and neoplasms in HIV-infected patients. However, many of these infections are not clinically symptomatic. Mild elevations of alkaline phosphatase and aminotransferases are often noted on routine chemistry panels. Mycobacterial disease, CMV, hepatitis B virus, hepatitis C virus, and lymphoma cause liver disease and can present with varying degrees of nausea, vomiting, right upper quadrant abdominal pain, and jaundice. Sulfonamides, imidazole medications, antituberculous medications, pentamidine, clarithromycin, and didanosine have also been associated with hepatitis. All nucleoside reverse transcriptase inhibitors cause lactic acidosis, which can be fatal. Lactic acidosis, however, occurs most commonly when didanosine is used with stavudine; this combination is no longer recommended in antiretroviral treatment regimens. HIV-infected patients with chronic hepatitis may have more rapid progression of liver disease because of the concomitant immunodeficiency or hepatoxicity of antiretroviral treatment. Percutaneous liver biopsy may be helpful in diagnosing liver disease, but some common causes of liver disease (eg, M avium complex, lymphoma) can be determined by less invasive measures (eg, blood culture, biopsy of a more accessible site).

b. Management—With patients living longer as a result of advances in antiretroviral treatment, advanced liver disease and hepatic failure due to chronic active hepatitis B and/or C are increasing causes of morbidity and mortality. HIV-infected individuals who are coinfected with hepatitis B should be treated with antiretroviral regimens that include medications with activity against both viruses (tenofovir disoproxil fumarate [TDF] or tenofovir alafenamide [TAF], lamivudine, or emtricitabine). Entecavir may be used if HIV viral load is suppressed; otherwise, its use can lead to lamivudine/emtricitabine-resistant HIV. It is important to be extremely cautious about discontinuing these medications in coinfected patients as sudden discontinuation could lead to a fatal flare of hepatitis B infection.

Hepatitis C is more virulent in persons with HIV and should be treated using the new HCV direct-acting antivirals (Table 16–6). Prior to treatment, the patient’s HCV viral load and HCV genotype should be determined. Depending on the genotype and the proposed treatment regimen, HCV resistance testing is recommended. For example, HCV resistance testing is recommended for patients with genotype 1a (the most common hepatitis C genotype in the United States) who are being considered for treatment with elbasvir/grazoprevir because substitutions in certain amino acid positions confer resistance. Because the appropriate treatment regimen depends on genotype, resistance profile, whether the patient is treatment naïve or not, as well as whether or not the patient has cirrhosis (and, if so, whether it is compensated or decompensated), clinicians should check the guidelines of the AASLD/IDSA (see website in references below) to see the recommended regimens (see also Tables 16–6 and 16–7). Costs of the different regimens vary by purchaser, and many clinicians choose the least expensive of the recommended regimens.

Although the recommended regimens are the same for HIV-infected patients, potential drug interactions with antiretroviral treatment may complicate treatment. Clinicians should check the guidelines of the AASLD/IDSA and US Department of Health and Human Services or the guidelines of the University of Liverpool (see references below) to determine interactions between proposed hepatitis C regimen and HIV regimen.
Liver transplants have been performed successfully in HIV-infected patients. This strategy is most likely to be successful in persons who have CD4 counts greater than 100 cells/mL and nondetectable viral loads.

University of Liverpool. HEP drug interactions. https://www.hep-druginteractions.org

3. Biliary disease—Cholecystitis presents with manifestations similar to those seen in immunocompetent hosts, but is more likely to be acalculous. Sclerosing cholangitis and papillary stenosis have also been reported in HIV-infected patients. Typically, the syndrome presents with severe nausea, vomiting, and right upper quadrant pain. Liver enzymes generally show alkaline phosphatase elevations disproportionate to elevation of the aminotransferases. Although dilated ducts can be seen on ultrasound, the diagnosis is made by endoscopic retrograde cholangiopancreatography, which reveals intraluminal irregularities of the proximal intrahepatic ducts with “pruning” of the terminal ductal branches. Stenosis of the distal common bile duct at the papilla is commonly seen. CMV, Cryptosporidium, and microsporidia are thought to play inciting roles in this syndrome, but these conditions are rarely seen unless the patient is suffering with very advanced HIV-related immunodeficiency.

4. Enterocolitis—

A. Presentation—Enterocolitis is a common problem in HIV-infected individuals. Organisms known to cause enterocolitis include bacteria (Campylobacter, Salmonella, Shigella), viruses (CMV, adenovirus), and protozoans (Cryptosporidium, Entamoeba histolytica, Giardia, Isospora, microsporidia). HIV itself may cause enterocolitis. Several of the organisms causing enterocolitis in HIV-infected individuals also cause diarrhea in immunocompetent persons. However, HIV-infected patients tend to have more severe and more chronic symptoms, including high fevers and severe abdominal pain that can mimic acute abdominal catastrophes. Bacteremia and concomitant biliary involvement are also more common with enterocolitis in HIV-infected patients. Relapses of enterocolitis following adequate therapy have been reported with both Salmonella and Shigella infections.

Because of the wide range of agents known to cause enterocolitis, a stool culture and multiple stool examinations for ova and parasites (including modified acid-fast staining for Cryptosporidium) should be performed. Those patients who have Cryptosporidium in one stool with improvement in symptoms in less than 1 month should not be considered to have AIDS, as Cryptosporidium is a cause of self-limited diarrhea in HIV-negative persons. More commonly, HIV-infected patients with Cryptosporidium infection have persistent enterocolitis with profuse watery diarrhea.

b. Management—To date, no consistently effective treatments have been developed for Cryptosporidium infection. The most effective treatment of cryptosporidiosis is to improve immune function through the use of effective antiretroviral treatment. The diarrhea can be treated symptomatically with diphenoxylate with atropine (one or two tablets orally three or four times a day). Those who do not respond may be given paragorec with bismuth (5–10 mL orally three or four times a day). Octreotide in escalating doses (starting at 0.05 mg subcutaneously every 8 hours for 48 hours) has been found to ameliorate symptoms in approximately 40% of patients with cryptosporidiosis or idiopathic HIV-associated diarrhea, although the benefit is often short-lived.

Patients with a negative stool examination and persistent symptoms should be evaluated with colonoscopy and biopsy. Patients whose symptoms last longer than 1 month with no identified cause of diarrhea are considered to have a presumptive diagnosis of AIDS enteropathy. Patients may respond to institution of effective antiretroviral treatment. Upper endoscopy with small bowel biopsy is not recommended as a routine part of the evaluation.

5. Other disorders—Two other important gastrointestinal abnormalities in HIV-infected patients are gastropathy and malabsorption. It has been documented that some HIV-infected patients do not produce normal levels of stomach acid and therefore are unable to absorb medications that require an acid medium. This decreased acid production may explain, in part, the susceptibility of HIV-infected patients to Campylobacter, Salmonella, and Shigella, all of which are sensitive to acid concentration. There is no evidence that Helicobacter pylori is more common in HIV-infected persons. A malabsorption syndrome occurs commonly in AIDS patients. It can be due to infection of the small bowel with M avium complex, Cryptosporidium, or microsporidia.

J. Endocrinologic Manifestations

Hypogonadism is probably the most common endocrinologic abnormality in HIV-infected men. The adrenal gland is also a commonly afflicted endocrine gland in patients with AIDS. Abnormalities demonstrated on autopsy include infection (especially with CMV and M avium complex), infiltration with Kaposi sarcoma, and injury from hemorrhage and presumed autoimmunity. The prevalence of clinically significant adrenal insufficiency is low. Patients...
K. Skin Manifestations

The skin manifestations that commonly develop in HIV-infected patients can be grouped into viral, bacterial, fungal, neoplastic, and nonspecific dermatitides.

1. Viral dermatitides—

a. Herpes simplex infections—These infections occur more frequently, tend to be more severe, and are more likely to disseminate in AIDS patients than in immunocompetent persons. Because of the risk of progressive local disease, all herpes simplex attacks should be treated for 5–10 days with acyclovir (400 mg orally three times a day), famciclovir (500 mg orally twice daily), or valacyclovir (500 mg orally twice daily) (Table 31–3). To avoid the complications of attacks, many clinicians recommend suppressive therapy for HIV-infected patients with a history of recurrent herpes. Options for suppressive therapy include acyclovir (400 mg orally twice daily), famciclovir (250 mg orally twice daily), and valacyclovir (500 mg orally daily). Long-term suppressive herpes prophylaxis with acyclovir does not reduce HIV transmission between heterosexual men and women from developing countries.

b. Herpes zoster—This is a common manifestation of HIV infection (Figure 31–4). Patients with herpes zoster infections should be treated for 7–10 days with famciclovir (500 mg orally three times a day) or valacyclovir (500 mg three times a day). Acyclovir can also be used, but it requires very frequent dosing (800 mg orally four or five times per day for 7 days). Vesicular lesions should be cultured if there is any question about their origin, since herpes simplex responds to much lower doses of acyclovir. Disseminated zoster and cases with ocular involvement should be treated with intravenous (10 mg/kg every 8 hours for 7–10 days) rather than oral acyclovir. The recombinant zoster vaccine (Shingrix, two doses administered 2–6 months apart) can be given to HIV-infected patients. Because it is not a live virus like the previous zoster vaccine (Zostavax), it is not contraindicated in patients with immune deficiency but, based on other vaccines, HIV-infected patients are likely to develop more robust immune response to the vaccine when their CD4 count is greater than 200/mcL. The long-term benefit of Shingrix in preventing shingles in HIV-infected persons has yet to be established.

2. Herpesvaricella—This is a common manifestation of herpes varicella-zoster virus and occurs in the setting of dermatitis or other dermatologic conditions. These infections are treated with topical liquid nitrogen.

2. Bacterial dermatitides—

A. Staphylococcal infection—Staphylococcus is the most common bacterial cause of skin disease in HIV-infected patients; it usually presents as folliculitis, superficial abscesses (furuncles), or bullous impetigo. These lesions should be treated aggressively since sepsis can occur. Folliculitis is initially treated with topical clindamycin or mupirocin, and patients may benefit from regular washing with an antibacterial soap such as chlorhexidine. Intranasal mupirocin has been used successfully for staphylococcal decolonization in other settings. In HIV-infected patients with recurrent staphylococcal infections, weekly intranasal mupirocin should be considered in addition to topical care and systemic antibiotics. Abscesses often require incision and drainage. Patients may need antibiotic therapy as well. Due to high frequency of methicillin-resistant Staphylococcus aureus (MRSA) skin infections in HIV-infected populations, lesions should be cultured prior to initiating empiric antistaphylococcal therapy. Recommendations for empiric therapy are either (1) trimethoprim-sulfamethoxazole (one double-strength tablet orally twice daily) with or without clindamycin (500 mg orally three times daily); or (2) doxycycline (100 mg orally twice daily) with close follow-up.

B. Bacillary angiomatosis—It is caused by two closely related organisms: Bartonella henselae and Bartonella quintana. The epidemiology of these infections suggests zoonotic transmission from fleas of infected domestic cats. The most common manifestation is raised, reddish, highly vascular skin lesions (Figure 31–5) that can mimic the vascular skin lesions of Kaposi sarcoma. Fever is a common manifestation of this infection; involvement of bone, lymph nodes, and liver has also been reported. The infection responds to antibiotics. Patients may need antistaphylococcal as well. Due to high frequency of methicillin-resistant Staphylococcus aureus (MRSA) skin infections in HIV-infected populations, lesions should be cultured prior to initiating empiric antistaphylococcal therapy. Recommendations for empiric therapy are either (1) trimethoprim-sulfamethoxazole (one double-strength tablet orally twice daily) with or without clindamycin (500 mg orally three times daily); or (2) doxycycline (100 mg orally twice daily) with close follow-up.

3. Fungal rashes—

A. Rashes due to dermatophytes and Candida—Most fungal rashes afflicting AIDS patients are due to dermatophytes and Candida. While particularly common in the inguinal region, they may occur anywhere on the body. Fungal rashes generally respond well to topical clotrimazole (1% cream twice a day) or ketoconazole (2% cream twice a day).

B. Seborrheic dermatitis—This is more common in HIV-infected patients. Scrapings of seborrhea have revealed Malassezia furfur (Pityrosporum ovale), implying that the seborrhea is caused by this fungus. Consistent with the isolation of this fungus is the clinical finding that seborrhea responds well to topical clotrimazole (1% cream) as well as hydrocortisone (1% cream).

4. Neoplastic dermatitides—See Chapter 6 and the Kaposi sarcoma section below.

5. Nonspecific dermatitides—

A. Xerosis—This condition presents in HIV-infected patients with severe pruritus. The patient may have no rash, or nonspecific excoriations from scratching. Treatment is with emollients (eg, absorption base cream) and antipruritic lotions (eg, camphor 9.5% and menthol 0.5%).

B. Psoriasis—Psoriasis can be very severe in HIV-infected patients. Phototherapy and etretinate (0.25–9.75 mg/kg/day orally in divided doses) may be used for recalcitrant cases in consultation with a dermatologist.
L. HIV-Related Malignancies

Four cancers are currently included in the CDC classification of AIDS: Kaposi sarcoma, non-Hodgkin lymphoma, primary lymphoma of the brain, and invasive cervical carcinoma. Epidemiologic studies have shown that between 1973 and 1987, among single men in San Francisco, the risk of Kaposi sarcoma increased more than 3000-fold and the risk of non-Hodgkin lymphoma more than 10-fold. The increase in incidence of malignancies is probably a function of impaired cell-mediated immunity. In the current treatment era, cancers not classified as AIDS-related, such as lung cancer, are being increasingly diagnosed in aging HIV-infected individuals despite optimal antiretroviral treatment. Cohort studies suggest that HIV-infected adults are at increased risk for any cancers compared to age-matched uninfected populations. Mortality secondary to malignancies represents an increasing cause of death in HIV-infected populations.

1. Kaposi sarcoma—

A. Presentation—Lesions may appear anywhere; careful examination of the eyelids, conjunctiva, pinnae, palate, and toe webs is mandatory to locate potentially occult lesions. In light-skinned individuals, Kaposi lesions usually appear as purplish, nonblanching lesions that can be papular or nodular (Figure 31–6). In dark-skinned individuals, the lesions may appear browner. In the mouth, lesions are most often palatal papules, though exophytic lesions of the tongue and gingivae may also be seen. Kaposi lesions may be confused with other vascular lesions such as angiomata and pyogenic granulomas. Kaposi sarcoma lesions can occur shortly after initiating antiretroviral treatment, especially in patients starting antiretroviral treatment who have advanced immunodeficiency. In this situation, Kaposi sarcoma is likely to be an immune reconstitution reaction (see Inflammatory Reactions below). Kaposi sarcoma can also cause visceral disease (eg, gastrointestinal, pulmonary).

B. Management—Patients with mild to moderate forms of Kaposi sarcoma do not require specific treatment as the lesions usually resolve with effective antiretroviral treatment. However, it should be noted that the lesions may flare when antiretroviral treatment is first initiated—probably as a result of an immune reconstitution process. Advanced disease is treated with combination chemotherapy (Table 31–3).

2. Non-Hodgkin lymphoma—

A. Presentation—Non-Hodgkin lymphomas in HIV-infected persons tend to be very aggressive. These malignancies are usually of B cell origin and characterized as diffuse large-cell tumors. Over 70% of the malignancies are extranodal.

B. Management—The prognosis of patients with systemic non-Hodgkin lymphoma depends primarily on the degree of immunodeficiency at the time of diagnosis. Patients with high CD4 counts do markedly better than those diagnosed at a late stage of illness. Patients with primary central nervous system lymphoma are treated with radiation. Response
to treatment is good, but prior to the availability of antiretroviral treatment, most patients died within a few months after diagnosis due to their underlying disease. Systemic disease is treated with combination chemotherapy (eg, EPOCH [etoposide, prednisolone, vincristine, cyclophosphamide, doxorubicin]) with rituximab. Granulocyte colony-stimulating factor (G-CSF; filgrastim) is used to maintain white blood counts.

3. Hodgkin disease—Although Hodgkin disease is not included as part of the CDC definition of AIDS, studies have found that HIV infection is associated with a fivefold increase in the incidence of Hodgkin disease. HIV-infected persons with Hodgkin disease are more likely to have mixed cellularity and lymphocyte depletion subtypes of Hodgkin disease and to seek medical attention at an advanced stage of disease.

4. Anal dysplasia and squamous cell carcinoma—These lesions have been strongly correlated with previous infection by human papillomavirus (HPV) and have been noted in HIV-infected men and women. Although many of the infected MSM report a history of anal warts or have visible warts, a significant percentage have silent papillomavirus infection. Cytologic (using Papanicolaou smears) and papillomavirus DNA studies can easily be performed on specimens obtained by anal swab. Because of the risk of progression from dysplasia to cancer in immunocompromised patients, some experts suggest that annual anal swabs for cytologic examination should be done in all HIV-infected persons. An anal Papanicolaou smear is performed by rotating a moistened Dacron swab about 2 cm into the anal canal. The swab is immediately inserted into a cytology bottle. However, there is no evidence that screening for anal cancer with Papanicolaou smears decreases the incidence of invasive cancer.

HPV also appears to play a causative role in cervical dysplasia and neoplasia. The incidence and clinical course of cervical disease in HIV-infected women are discussed below.

M. Gynecologic Manifestations

Vaginal candidiasis, cervical dysplasia and neoplasia, and pelvic inflammatory disease are more common in HIV-infected women than in uninfected women. These manifestations also tend to be more severe when they occur in association with HIV infection. Therefore, HIV-infected women need frequent gynecologic care. Vaginal candidiasis may be treated with topical agents or a single dose of oral fluconazole (150 mg) (see Chapter 36). Recurrent vaginal candidiasis should be treated with fluconazole (100–200 mg) for at least 7 days.

The incidence of cervical dysplasia in HIV-infected women is 40%. Because of this finding, recommended screening for HIV-infected women is more extensive than for uninfected women (see Chapter 18). For women younger than age 30 years, a Papanicolaou smear should be performed within a year of the onset of sexual activity, but no later than age 21 years. If normal, Papanicolaou smears should be performed yearly. After three negative examinations, screening should be done every 3 years. HPV DNA testing of the cervical specimen is not recommended for women younger than age 30 years.

For women age 30 and older, screening should continue beyond age 65 unlike the general population. There are two accepted screening protocols, one using cytology alone, the other using cytology with HPV DNA cotesting. A Papanicolaou smear is done when HIV is diagnosed and every 12 months thereafter and after three negative examinations, ongoing screening should be performed every 3 years. Alternatively, a Papanicolaou smear with cotesting for HPV DNA can be performed when HIV is diagnosed or starting when patients are age 30 years old. If Papanicolaou is normal and HPV test is negative, then the next screening should be in 3 years.

The management of abnormal Papanicolaou tests and positive HPV tests is the same in infected women as in uninfected women. Treatment should follow the consensus guidelines in the references below.

While pelvic inflammatory disease appears to be more common in HIV-infected women, the bacteriology of this condition appears to be the same as among HIV-uninfected women. HIV-infected women with pelvic inflammatory
disease should be treated with the same regimen as uninfected women (see Chapter 18).

N. Coronary Artery Disease
HIV-infected persons are at higher risk for coronary artery disease than age- and sex-matched controls. Part of this increase in coronary artery disease is due to changes in lipids caused by antiretroviral agents (see Treatment section on Antiretroviral Therapy below), especially stavudine and several of the PIs. However, some of the risk appears to be due to HIV infection, independent of its therapy. It is important that clinicians pay close attention to this issue because myocardial infarctions tend to present at a younger age in HIV-infected individuals than in HIV-uninfected individuals. HIV-infected patients with symptoms of coronary artery disease such as chest pain or dyspnea should be rapidly evaluated. Clinicians should aggressively treat conditions that result in increased risk of heart disease, especially smoking, hypertension, hyperlipidemia, obesity, diabetes mellitus, and sedentary lifestyle.

O. Inflammatory Reactions (Immune Reconstitution Inflammatory Syndromes)
With initiation of antiretroviral treatment, some patients experience inflammatory reactions that appear to be associated with immune reconstitution as a rapid increase in CD4 count. These inflammatory reactions may present with generalized signs of fevers, sweats, and malaise or with or without more localized manifestations that usually represent unusual presentations of opportunistic infections. For example, vitreitis has developed in patients with CMV retinitis after they have been treated with antiretroviral treatment.

*M. avium* can present as focal even suppurative lymphadenitis or granulomatous masses in patients receiving antiretroviral treatment. Tuberculosis may paradoxically worsen with new or evolving pulmonary infiltrates and lymphadenopathy. PML and cryptococcal meningitis may also behave atypically. Clinicians should be alert to these syndromes, which are most often seen in patients who have initiated antiretroviral treatment in the setting of advanced disease and who show rapid increases in CD4 counts with treatment. The diagnosis of immune reconstitution inflammatory syndrome (IRIS) is one of exclusion and can be made only after recurrence or new opportunistic infection has been ruled out as the cause of the clinical deterioration. Management of IRIS is conservative and supportive with use of corticosteroids only for severe reactions. Most authorities recommend that antiretroviral treatment be continued unless the IRIS reaction is life-threatening.

Prevention
A. Primary Prevention
Until vaccination is a reality, prevention of HIV infection will depend on HIV testing and counseling, including precautions regarding sexual practices and injection drug use, initiation of antiretroviral treatment as a prevention tool for transmission to others, preexposure and postexposure use of antiretroviral treatment, perinatal management including antiretroviral treatment of the mother, screening of blood products, and infection control practices in the health care setting.

1. HIV testing and counseling—Primary care clinicians should routinely obtain a sexual history and provide risk factor assessment of their patients. Because approximately 15% of the HIV-infected persons in the United States do not know they are infected, the US Preventive Services Task Force recommends that clinicians screen for HIV infection in adolescents and adults ages 15 to 65 years. Younger adolescents and older adults who are at increased risk should also be screened. Clinicians should review the risk factors for HIV infection with the patient and discuss safer sex and safer needle use as well as the meaning of a positive test. Although the CDC recommends “opt-out” testing in medical settings, some states require specific written consent. For persons whose test results are positive, it is critically important that they be connected to ongoing medical care. Many public health systems advocate for initiating care and treatment the same day that someone tests positive if appropriate resources are available (see C. Antiretroviral Treatment, below). Referrals for partner-notification services, social services, mental health services, and HIV-prevention services should also be provided. Prevention interventions focused on the importance of HIV-infected persons not putting others at risk have been successful.

For patients whose test results are negative, clinicians should review safer sex and needle use practices, including counseling not to exchange bodily fluids unless they are in a long-term mutually monogamous relationship with
someone who has tested HIV antibody-negative and has not engaged in unsafe sex, injection drug use, or other HIV risk behaviors for at least 6 months prior to or at any time since the negative test.

To prevent sexual transmission of HIV, only latex or polyurethane condoms should be used, along with a water-soluble lubricant. Although nonoxynol-9, a spermicide, kills HIV, it is contraindicated because in some patients it may cause genital ulcers that could facilitate HIV transmission. Patients should be counseled that condoms are not 100% effective. They should be made familiar with the use of condoms, including, specifically, the advice that condoms must be used every time, that space should be left at the tip of the condom as a receptacle for semen, that intercourse with a condom should not be attempted if the penis is only partially erect, that men should hold on to the base of the condom when withdrawing the penis to prevent slippage, and that condoms should not be reused. Although anal intercourse remains the sexual practice at highest risk for transmitting HIV, seroconversions have been documented with vaginal and oral intercourse as well. Therefore, condoms should be used when engaging in these activities. Women as well as men having sex with men should understand how to use condoms to be sure that their partners are using them correctly. Partners of HIV-infected women should use latex or polyurethane barriers such as dental dams (available at dental supply stores) to prevent direct oral contact with vaginal secretions. Several randomized trials in Africa demonstrated that male circumcision significantly reduced HIV incidence in men, but there are a number of barriers to performing widespread circumcisions among men in Africa.

Persons using injection drugs should be cautioned never to share needles or other drug paraphernalia. When sterile needles are not available, bleach does appear to inactivate HIV and should be used to clean needles.

2. Antiretroviral treatment for decreasing transmission of HIV to others—Besides preventing progression of HIV disease, effective antiretroviral treatment likely decreases the risk of HIV transmission between sexual partners. Among serodiscordant couples, stably suppressing HIV with antiretroviral treatment almost completely eliminates the risk of HIV transmission to the uninfected partner. Although HIV-negative persons in stable long-term partnerships with HIV-infected persons represent only one group of at-risk persons, theoretically increasing the use of antiretroviral treatment among the population of HIV-infected persons could decrease community-wide transmission of HIV. Despite major improvements in effectiveness and tolerability of antiretroviral treatment, only about 60% of HIV-infected persons in the United States are virally suppressed. Persons in whom the HIV virus has been “undetectable” for a prolonged period have virtually no chance of sexually transmitting HIV. Still, because of the possibility of variations in measured viral load, and not knowing whether their partners are virally suppressed, and the possibility of transmission through blood, all HIV-infected persons should practice safer sex and not share needles so as to avoid the possibility of transmitting HIV.

3. Preexposure antiretroviral treatment prophylaxis—Several large randomized double-blind placebo-controlled trials demonstrated that administering emtricitabine/TDF (Truvada) can reduce the risk of sexual transmission of HIV among uninfected individuals at high risk for infection; one study was of HIV-negative men and transgender women who have sex with men, and two studies were of heterosexual HIV-discordant couples. Preexposure tenofovir has also been shown to reduce HIV infection among injection drug users from Thailand. In addition, real-world studies of men who have sex with men, where adherence with emtricitabine/TDF has been high, have found preexposure prophylaxis (PrEP) to be highly effective in preventing HIV infection. Emtricitabine/TAF (Descovy) is under study for PrEP, but is not currently recommended because of questions of whether it has as good penetration into genital fluids.

Who should be prescribed PrEP is not a simple question. PrEP is best thought of as one “option” for HIV prevention, rather than as the only option. Whether it is the “best” option depends on three things: (1) the likelihood that a person will have HIV-infected partners or use the needles of infected persons, (2) whether there is a better option available to prevent HIV, and (3) the patient’s ability to take a daily medication. CDC guidelines recommend offering PrEP to persons at “substantial risk” for HIV. Risk for HIV is a combination of the likelihood of having a partner who is HIV-infected and the likelihood that the behavior (eg, type of intercourse, shared needles) transmits HIV. Men who have sex with men, and transgender male-to-females are the groups with the highest HIV seroprevalence in the United States, and they are likely to have partners who are known to be or at risk for being HIV-infected. Those who have receptive anal intercourse have the highest risk of HIV because the behavior is much more efficient at transmitting HIV than other sexual practices. Heterosexual drug users are also at high risk for HIV-infection if they do not consistently use clean needles or if they trade drugs for sex. It can be hardest to assess the risk of heterosexual non-drug users because it requires assessing the likelihood that their partners have HIV risks such as being bisexual men or using injection drugs. Factors known to increase the risk of HIV transmission and therefore make PrEP a good choice for particular groups of patients are shown in Table 31–4.
condoms even when taught to do so. In addition, condoms ever, for a variety of reasons, people do not always use other sexually transmitted diseases and pregnancy. How ing HIV? Latex or polyurethane condoms are an excellent .cdc.gov/hiv/risk/prep/index.html (Last updated November 1, 2018). PrEP checklists for providers and patients are available at https://www STD, sexually transmitted disease; TDF, tenofovir dipoxil fumarate. damage if emtricitabine/TDF is stopped. HBV-infected persons may experience HBV reactivation and liver emtricitabine/TDF is contraindicated if creatinine clearance < 60 mL/min. HBV-infected persons may experience HBV reactivation and liver damage if emtricitabine/TDF is stopped. eGFR, estimated glomerular filtration rate; HBV, hepatitis B virus; STD, sexually transmitted disease; TDF, tenofovir diproxil fumarate. PrEP checklists for providers and patients are available at https://www.cdc.gov/hiv/risk/prep/index.html (Last updated November 1, 2018).

How does PrEP compare to other options for preventing HIV? Latex or polyurethane condoms are an excellent choice for preventing sexual transmission of HIV because they are inexpensive, have no side effects, and prevent other sexually transmitted diseases and pregnancy. However, for a variety of reasons, people do not always use condoms even when taught to do so. In addition, condoms break or slip on occasion, so even persons who always use condoms may want the extra protection of PrEP if they have a known HIV-infected partner. History of sexually transmitted diseases is proof of unprotected sex and increases the likelihood that PrEP is a good option for a patient.

Finally, for PrEP to be effective, patients have to be willing to take it. Taking one pill right before sex would not be expected to offer protection because the medicine would not have adequate drug levels in the body. Maximum concentrations are achieved in various locations in the body at different treatment intervals: in blood, maximum levels are achieved after 20 days of daily dosing; in rectal tissue, after 7 days; in cervicovaginal tissue, after 20 days. Study participants who took at least 4 daily doses in a week were protected almost as well as those who took the drug every day, indicating that missed doses do not render the treatment ineffective; however, adherence to daily dosing is the safest method.

Recommendations on initial and follow-up assessments are shown in Table 31–4. Emtricitabine/TDF is contraindicated for persons with kidney disease (creatinine clearance less than 60 mL) because of the small risk of kidney toxicity with TDF. Decreases in bone mineral density have been documented in persons taking emtricitabine/TDF for PrEP at 24 weeks; whether this decrease will have clinical significance is unknown. In someone with osteoporosis or at high risk for osteoporosis, clinical judgement would be needed to assess whether the benefits of emtricitabine/TDF justified the risks of worsening bone density. If emtricitabine/TAF is found to be effective as PrEP, it would be a good alternative to emtricitabine/TDF for patients with kidney disease or osteoporosis since TAF appears to have less effect on the kidney and bone than TDF.

Substantial increases in sexually transmitted diseases have also been seen in persons taking PrEP, indicating the importance of regular follow-up in patients using PrEP. Some patients are reluctant to use insurance to cover the cost of the medication for fear of revealing that they are at risk for HIV; without insurance, the cost is high. Compassionate use programs are available from the medication manufacturer for low-income uninsured persons.

4. Postexposure prophylaxis for sexual and drug use exposures to HIV—The goal of postexposure prophylaxis is to reduce or prevent local viral replication prior to dissemination such that the infection can be aborted. Although there is no proof that administration of antiretroviral medications following a sexual or parenteral drug use exposure reduces the likelihood of infection, there is suggestive data from animal models, perinatal experience,
and a case-control study of health care workers who experienced a needle stick.

Treatment of persons who have been exposed to HIV should be within 72 hours, but sooner is better. All exposed persons should first receive HIV testing to exclude the possibility that they are already infected. If rapid tests are not available, treatment should begin pending the results of a standard HIV test.

The choice of antiretroviral agents and the duration of treatment are the same as those for exposures that occur through the occupational route; the preferred regimen is tenofovir 300 mg with emtricitabine 200 mg daily with raltegravir 400 mg twice a day. In contrast to those with occupational exposures, some individuals may present very late after exposure. Because the likelihood of success declines with length of time from HIV exposure, treatment is not recommended after more than 72 hours after exposure. In addition, because the psychosocial issues involved with postexposure prophylaxis for sexual and drug use exposures are complex, it should be offered with prevention counseling. Counseling should focus on how to prevent future exposures. Individuals with ongoing risk for HIV infection should be considered candidates for PrEP. Clinicians needing more information on postexposure prophylaxis for occupational or nonoccupational exposures should contact the National Clinicians’ Post-Exposure Prophylaxis Hotline (1-888-448-4911; http://ncce.ucsf.edu/clinician-consultation/pep-post-exposure-prophylaxis/).

5. Prevention of perinatal transmission of HIV—Prevention of perinatal transmission of HIV begins by offering HIV counseling and testing to all women who are pregnant or considering pregnancy. HIV-infected women who are pregnant should start antiretroviral treatment with at least three medications. Recommended regimens are zidovudine and lamivudine with either ritonavir-boosted lovatiranav or ritonavir-boosted azacavir. Cesarean delivery should be planned if HIV viral load is greater than 1000 copies/mL near the time of delivery. Zidovudine should be given to the infant after birth for 6 weeks. When possible, breastfeeding should be avoided.

6. Prevention of HIV transmission in health care settings—in health care settings, universal body fluid precautions should be used, including use of gloves when handling body fluids and the addition of gown, mask, and goggles for procedures that may result in splash or droplet spread, and use of specially designed needles with sheath devices to decrease the risk of needle sticks. Because transmission of tuberculosis may occur in health care settings, all patients with cough should be encouraged to wear masks. Hospitalized HIV-infected patients with cough should be placed in respiratory isolation until tuberculosis can be excluded by chest radiograph and sputum smear examination.

Epidemiologic studies show that needle sticks occur commonly among health care professionals, especially among surgeons performing invasive procedures, inexperienced hospital housestaff, and medical students. Efforts to reduce needle sticks should focus on avoiding recapping needles and use of safety needles whenever doing invasive procedures under controlled circumstances. The risk of HIV transmission from a needle stick with blood from an HIV-infected patient is about 1:300. The risk is higher with deep punctures, large inoculum, and source patients with high viral loads. The risk from mucous membrane contact is too low to quantitate.

Health care professionals who sustain needle sticks should be counseled and offered HIV testing as soon as possible. HIV testing is done to establish a negative baseline for worker’s compensation claims in case there is a subsequent conversion. Follow-up testing is usually performed at 6 weeks, 3 months, and 6 months. With the patient’s permission, their blood can be tested for HIV antibody and HIV viral load.

A case-control study by the CDC indicates that administration of zidovudine following a needle stick decreases the rate of HIV seroconversion by 79%. Therefore, providers should be offered antiretroviral treatment as soon as possible after exposure and continued for 4 weeks. The preferred regimen is TDF 300 mg with emtricitabine 200 mg (Truvada) daily with raltegravir 400 mg twice a day. Providers who have exposures to persons who are likely to have antiretroviral medication resistance (eg, persons receiving therapy who have detectable viral loads) should have their therapy individualized, using at least two medications to which the source is unlikely to be resistant. Because reports have noted hepatotoxicity due to nevirapine in this setting, this agent should be avoided. Unfortunately, there have been documented cases of seroconversion following potential parental exposure to HIV despite prompt use of zidovudine prophylaxis.
Counseling of the provider should include “safer sex” guidelines.

7. Prevention of transmission of HIV through blood or blood products—Current efforts in the United States to screen blood and blood products have lowered the risk of HIV transmission with transfusion of a unit of blood to 1:1,000,000. Use of blood and blood products should be judicious, with patients receiving the least amount necessary, and patients should be encouraged to donate their own blood prior to elective procedures.

8. HIV vaccine—Primate model data have suggested that development of a protective vaccine may be possible, but clinical trials in humans have been disappointing. Only one vaccine trial has shown any degree of efficacy. In this randomized, double-blind, placebo-controlled trial, a recombinant canarypox vector vaccine plus two booster injections of a recombinant gp120 vaccine reduced the risk of HIV among a primarily heterosexual population in Thailand, but efficacy was too low (31%) for widespread use. A mosaic HIV vaccine resulted in a strong immune response among adult humans and protection against infection with an HIV-like virus in rhesus monkeys. The vaccine is currently being studied in a phase IIB trial in sub-Saharan Africa.

B. Secondary Prevention

In the era prior to the development of effective antiretroviral treatment, cohort studies of individuals with documented dates of seroconversion demonstrate that AIDS developed within 10 years in approximately 50% of untreated seropositive persons. With currently available treatment, progression of disease has been markedly decreased. In addition to antiretroviral treatment, prophylactic regimens can prevent opportunistic infections and improve survival. Prophylaxis and early intervention prevent several infectious diseases, including tuberculosis and syphilis, which are transmissible to others. Recommendations for screening tests, vaccinations, and prophylaxis are listed in Table 31–5.

1. Tuberculosis—Because of the increased occurrence of tuberculosis among HIV-infected patients, all such individuals should undergo an intradermal PPD test or an interferon-gamma release assay (IGRA) blood test at baseline and yearly thereafter if they remain at risk of exposure (eg, incarcerated, living in congregate settings). Those with a positive PPD (defined for HIV-infected patients as greater than 5 mm of induration) or a positive IGRA assay (results that are reported as positive and not negative or indeterminate) should be clinically evaluated for active tuberculosis, including by a chest radiograph. Patients with an infiltrate in any location, especially if accompanied by mediastinal adenopathy, should have sputum sent for acid-fast staining. Patients with active tuberculosis should be treated as outlined in Chapter 9 (see Tables 9-14 and 9-15). Patients with a positive PPD or IGRA assay, a normal chest radiograph, or negative sputum sample for active tuberculosis infection are classified as having latent tuberculosis infection. Patients with latent tuberculosis infection who have not been previously treated for (active or latent) tuberculosis should receive isoniazid (300 mg orally daily or twice weekly) with pyridoxine (50 mg orally daily) for 9 months. In patients with advanced immunodeficiency, both the PPD and IGRA assay are more likely to be falsely negative or (for IGRA assay) indeterminant. Therefore, it may be worth retesting patients with initially low CD4 counts once they have received antiretroviral treatment and have immune reconstitution (CD4 count greater than or equal to 200 cells/mcL).

2. Syphilis—Because of the increased number of cases of syphilis among MSM, including those who are HIV-infected, all such men should be screened for syphilis by a rapid plasma reagin (RPR) or Venereal Disease Research Laboratories (VDRL) test every 6 months. Increases of syphilis cases among HIV-infected persons are of particular concern because these individuals are at increased risk for reactivation of syphilis and progression to tertiary syphilis despite standard treatment. Because the only widely available tests for syphilis are serologic and because HIV-infected individuals are known to have disordered antibody production, there is concern about the interpretation of these titers. This concern has been fueled by a report of an HIV-infected patient with secondary syphilis and negative syphilis serologic testing. Furthermore, HIV-infected individuals may lose fluorescent treponemal antibody absorption (FTA-ABS) reactivity after treatment for syphilis, particularly if they have low CD4 counts. Thus, in this population, a nonreactive treponemal test does not rule out a past history of syphilis. In addition, persistence of treponemes in the spinal fluid after one dose of benzathine penicillin has been demonstrated in HIV-infected patients with primary and secondary syphilis. Therefore, the CDC has recommended an aggressive diagnostic approach to HIV-infected patients with reactive RPR or VDRL tests of longer than 1 year (or unknown) duration.

¹Consider in patients age > 50 years with history of varicella immunity and T cells > 200 cells/mcL.

All such patients should have a lumbar puncture with cerebrospinal fluid cell count and cerebrospinal fluid VDRL. Those with a normal cerebrospinal fluid evaluation are treated as having late latent syphilis (benzathine penicillin G, 2.4 million units intramuscularly weekly for 3 weeks) with follow-up titers. Those with a pleocytosis or a positive cerebrospinal fluid-VDRL test are treated as having neurosyphilis (aqueous penicillin G, 2–4 million units intravenously every 4 hours, or procaine penicillin G, 2.4 million units intramuscularly daily, with probenecid, 500 mg four times daily, for 10 days) followed by weekly benzathine penicillin G 2.4 million units intramuscularly for 3 weeks. Some clinicians take a less aggressive approach to patients who have low titers (less than 1:8), a history of having been treated for syphilis, and a normal neurologic examination. Close follow-up of titers is mandatory if such a course is taken. For a more detailed discussion of this topic, see Chapter 34.

3. Immunizations—HIV-infected individuals should receive immunizations as outlined in Table 31–5. Patients without evidence of hepatitis B surface antigen or surface antibody should receive hepatitis B vaccination, using the 40-mcg formulation; the higher dose is to increase the chance of developing protective immunity. If the patient does not have immunity 1 month after the three-shot series,
then the series should be repeated. HIV-infected persons should also receive the standard inactivated vaccines such as tetanus and diphtheria boosters that would be given to uninfected persons. Most live vaccines, such as yellow fever vaccine, should be avoided. Measles vaccination, while a live virus vaccine, appears relatively safe when administered to HIV-infected individuals and should be given if the patient has never had measles or been adequately vaccinated. The new recombinant adjuvanted herpes zoster vaccine (Shingrix), two doses 2–6 months apart, is recommended for HIV-infected persons with CD4 counts greater than 200 cells/mcL. However, it is not known if it is efficacious in preventing herpes zoster in this population.

4. Other measures—A randomized study found that multivitamin supplementation decreased HIV disease progression and mortality in HIV-infected women in Africa. However, supplementation is unlikely to be as effective in well-nourished populations.

HIV-infected individuals should be counseled with regard to the importance of practicing safer sex even with other HIV-infected persons because of the possibility of contracting a sexually transmitted disease, such as gonorrhea or syphilis. There is also the possibility of transmission of a particularly virulent or a drug-resistant strain between HIV-infected persons. Substance abuse treatment should be recommended for persons who are using recreational drugs. They should be warned to avoid consuming raw meat, eggs, or shellfish to avoid infections with *Toxoplasma*, *Campylobacter*, and *Salmonella*. HIV-infected patients should wash their hands thoroughly after cleaning cat litter or should forgo this household chore to avoid possible exposure to toxoplasmosis. To reduce the likelihood of infection with *Bartonella* species, patients should avoid activities that might result in cat scratches or bites. Although the data are not conclusive, many clinicians recommend that HIV-infected persons—especially those with low CD4 counts—drink bottled water instead of tap water to prevent cryptosporidia infection.

Because of the emotional impact of HIV infection and subsequent illness, many patients will benefit from supportive counseling.

**Treatment**

Treatment for HIV infection can be broadly divided into the following categories: (1) prophylaxis for opportunistic infections, malignancies, and other complications of HIV infection; (2) treatment of opportunistic infections, malignancies, and other complications of HIV infection; and (3) treatment of the HIV infection itself with combination antiretroviral treatment.

**A. Prophylaxis for Complications of HIV Infection**

In general, decisions about prophylaxis of opportunistic infections are based on the CD4 count, recent HIV viral load, and a history of having had the infection in the past. In the era prior to antiretroviral treatment, patients who started taking prophylactic regimens were maintained on them indefinitely. However, studies have shown that in patients with robust improvements in immune function—as measured by increases in CD4 counts above the levels that are used to initiate treatment—prophylactic regimens can safely be discontinued.

Because individuals with advanced HIV infection are susceptible to a number of opportunistic pathogens, the use of agents with activity against more than one pathogen is preferable.

1. **Prophylaxis against *Pneumocystis* pneumonia**—Patients with CD4 counts below 200 cells/mcL, a CD4 lymphocyte percentage below 14%, or weight loss or oral candidiasis should be offered primary prophylaxis for *Pneumocystis* pneumonia. Patients with a history of *Pneumocystis* pneumonia should receive secondary prophylaxis until their viral load is undetectable and they have maintained a CD4 count of 200 cells/mcL or more while receiving antiretroviral treatment for longer than 3 months. Regimens for *Pneumocystis* prophylaxis are given in Table 31–6.

2. **Prophylaxis against *M avium* complex infection**—Patients whose CD4 counts fall to below 75–100 cells/mcL should be given prophylaxis against *M avium* complex infection. Clarithromycin (500 mg orally twice daily) and azithromycin (1200 mg orally weekly) have both been shown to decrease the incidence of disseminated *M avium* complex infection by approximately 75%, with a low rate of breakthrough of resistant disease. The azithromycin regimen is generally preferred based on high compliance and low cost. Prophylaxis against *M avium* complex infection may be discontinued in patients whose CD4 counts rise above 100 cells/mcL in response to antiretroviral treatment for longer than 3 months.

3. **Prophylaxis against toxoplasmosis**—Toxoplasmosis prophylaxis is desirable in patients with a positive IgG toxoplasma serology and CD4 counts below 100 cells/mcL. Trimethoprim-sulfamethoxazole (one double-strength tablet daily) offers good protection against toxoplasmosis, as does a combination of pyrimethamine, 25 mg orally once a week, plus dapsone, 50 mg orally daily, plus leucovorin, 25 mg orally once a week. A glucose-6-phosphate dehydrogenase (G6PD) level should be checked prior to dapsone therapy, and a methemoglobin level should be checked at 1 month. Prophylaxis can be discontinued when the CD4 cells have increased to greater than 200 cells/mcL for more than 3 months.

**B. Treatment of Complications of HIV Infection**

Treatment of common AIDS-related complications is detailed above and in Table 31–3. In the era prior to the use of antiretroviral treatment, patients required lifelong treatment for many infections, including CMV retinitis, toxoplasmosis, and cryptococcal meningitis. However, among patients who have a good response to antiretroviral treatment, maintenance therapy for some opportunistic infections can be terminated. For example, in consultation with

an ophthalmologist, maintenance treatment for CMV infection can be discontinued when persons receiving antiretroviral treatment have had a sustained increase in CD4 count to greater than 100 cells/mcL for at least 3–6 months. Similar results have been observed in patients with M. avium complex bacteremia, who have completed a year or more of therapy for M. avium complex and have an increase in their CD4 count to 100 cells/mcL for greater than 6 months while receiving antiretroviral treatment. Cessation of secondary prophylaxis for Pneumocystis pneumonia is described above.

Treating patients with repeated episodes of the same opportunistic infection can pose difficult therapeutic challenges. For example, patients with second or third episodes of Pneumocystis pneumonia may have developed allergic reactions to standard treatments with a prior episode. Fortunately, there are several alternatives available for the treatment of Pneumocystis infection. Trimethoprim with dapsone and primaquine with clindamycin are two combinations that often are tolerated in patients with a prior allergic reaction to trimethoprim-sulfamethoxazole and intravenous pentamidine. Patients in whom second episodes of Pneumocystis pneumonia develop while taking prophylaxis tend to have milder courses.

Adjunctive Treatments—Epoetin alfa (erythropoietin) is approved for use in HIV-infected patients with anemia, including those with anemia secondary to zidovudine use. As zidovudine is rarely used now, especially at high doses, the use of epoetin alfa has also decreased. An erythropoietin level less than 500 milli-units/mL should be demonstrated before starting therapy. The starting dose of epoetin alfa is 8000 units subcutaneously three times a week. Hypertension is the most common side effect.

Human G-CSF (filgrastim) and granulocyte-macrophage colony-stimulating factor (GM-CSF [sargramostim]) have been shown to increase the neutrophil counts of HIV-infected patients. Because of the high cost of this therapy, the dosage should be closely monitored and minimized, aiming for a neutrophil count of 1000/mcL. When the medication is used for indications other than cytotoxic chemotherapy, one or two doses at 5 mcg/kg per week subcutaneously are usually sufficient.

C. Antiretroviral Therapy

The availability of agents that in combination suppress HIV replication (Table 31–7) has had a profound impact on the natural history of HIV infection. Indeed, with the advent of effective antiretroviral treatment, the life expectancy of HIV-infected persons approaches that of uninfected persons when treatment is initiated early in the course of the disease and maintained.

The recognition that HIV damages the immune system from the beginning of infection, even when the damage is not easily measured by conventional tests, combined with the greater potency, the improved side-effect profile, and the decreased pill burden of modern HIV regimens, have led to the recommendation to start treatment for all HIV-infected persons regardless of CD4 count. The START trial demonstrated that immediate treatment is associated with a greater than 50% reduction in risk for serious illness or death, compared to delaying treatment until the CD4 count falls below 350 cells/mcL.

Rapid initiation programs have been created, where treatment can be started on the same day that patients test positive for HIV, so patients can start receiving treatment promptly and avoid being lost to follow-up. To do this, the clinic must have sufficient resources, medical and nonmedical, to help patients cope with these major events in a short time. Also, 5–20% of patients in developed countries who are treatment-naïve have a virus that is resistant to some medications; therefore, if treatment is started before the results of resistance testing are available, a nonnucleoside reverse transcriptase inhibitor (NNRTI) should not be used. Recommended regimens for initiating treatment...

¹Standard monitoring is complete blood count (CBC) and differential, basic chemistries, serum aminotransferases and total bilirubin every 3–6 months; urinalysis at baseline and annually during antiretroviral treatment; fasting glucose or hemoglobin A₁c at baseline and annually during antiretroviral treatment, and fasting lipid profile at baseline, 4–8 weeks after starting an antiretroviral treatment regimen that affects lipids, and annually for everyone over 40 years of age.

²Average wholesale price (AWP, for AB-rated generic when available) for quantity listed. Source: IBM Micromedex Red Book (electronic version). IBM Watson Health, Greenwood Village, CO, USA. Available at https://www.micromedexsolutions.com (cited April 25, 2019). AWP may not accurately represent the actual pharmacy cost because wide contractual variations exist among institutions.

Before resistance testing results are available include (1) dolutegravir/TAF or TDF/emtricitabine (or lamivudine), (2) bictegravir/TAF/emtricitabine, or (3) boosted darunavir/TAF or TDF/emtricitabine (or lamivudine). Also, patients requiring abacavir as part of their regimen, should not start treatment prior to the results of HLA-B*5701 allele testing.

Once a decision to initiate therapy has been made, several important principles should guide therapy. First, because medication resistance to antiretroviral agents develops in HIV-infected patients, a primary goal of therapy should be complete suppression of viral replication as measured by the serum viral load. Therapy that achieves undetectable viral load has been shown to provide a durable response to the therapy. To achieve this and maintain virologic control over time, combination therapy with at least three medications from at least two different classes is necessary. Partially suppressive combinations should be avoided. Similarly, if toxicity develops, it is preferable to change the offending medication rather than reduce individual doses. Exceptions to the three-drug rule from at least two different classes are emerging. A combination of dolutegravir plus lamivudine has been shown to be noninferior to dolutegravir plus TDF and emtricitabine as initial therapy in patients with HIV viral load of less than 500,000 copies/mL. In April 2019, the FDA approved Dovato, a complete, once-daily, single-tablet...
combination of dolutegravir 50 mg and lamivudine 300 mg. A second exception is the coformulation of dolutegravir and rilpivirine (Juluca); this combination is FDA approved as an alternative treatment for patients who have been successfully virally suppressed for at least 6 months, have no history of treatment failure, and are not resistant to either of the two component agents.

The presence of an acute opportunistic infection in most cases does not preclude the initiation of antiretroviral treatment. Randomized trials compared early initiation of antiretroviral treatment (within 2 weeks of starting treatment for an opportunistic infection or tuberculosis) with antiretroviral treatment that was deferred until after treatment of the opportunistic infection was completed (6 weeks after its start); results demonstrated that early initiation reduced death or AIDS progression by 50%. The reduced progression rates were related to more rapid improvements in CD4 counts in patients with advanced immunodeficiency. Furthermore, IRIS and other adverse events were no more frequent in the early antiretroviral treatment arm.

Several randomized studies have also demonstrated improved clinical outcomes in HIV/tuberculosis coinfected patients who initiate antiretroviral treatment early in the setting of active treatment for tuberculosis and whose CD4 counts are less than 50 cells/mcL. The exception to early antiretroviral treatment in the setting of active infections may be in patients with a CNS-associated infection, such as cryptococcal or tuberculosis meningitis. Several studies from low-income countries have shown high mortality rates with early antiretroviral treatment initiation in this setting.

For hospitalized patients, initiating treatment in patients with opportunistic infections requires close coordination between inpatient and outpatient clinicians to ensure that treatment is continued once patients are discharged.

D. Choosing an Antiretroviral Treatment Regimen

Although the ideal combination of medications has not yet been defined for all possible clinical situations, optimal regimens can be better understood after a review of the available agents. These medications can be grouped into five major categories: nucleoside and nucleotide reverse transcriptase inhibitors (NRTIs); nonnucleoside reverse transcriptase inhibitors (NNRTIs); protease inhibitors (PI); entry inhibitors, which include a fusion inhibitor and CCR5 antagonists; and integrase inhibitors.

1. Nucleoside and nucleotide reverse transcriptase inhibitors (NRTI)—There are currently eight NRTI agents available (counting TDF and TAF as separate agents) for use. The choice of which agent to use depends primarily on the patient’s prior treatment experience, results of resistance testing, medication side effects, other underlying conditions, and convenience of formulation. However, most clinicians use fixed-dose combinations (see Table 31–8) of either emtricitabine/TDF, emtricitabine/TAF, or abacavir/lamivudine (ABC/lamivudine), all of which can be given orally once daily. Emtricitabine is dosed at 200 mg orally twice daily or 300 mg once daily. Prior to initiation of abacavir, patients should undergo HLA-B*5701 allele testing for HLA typing. Those with the B*5701 allele should not be treated with abacavir because the likelihood of a hypersensitivity reaction developing is high; the reaction is characterized by a flu-like syndrome with rash and fever that worsens with successive doses. Unfortunately, the absence of this allele does not guarantee that the patient will avoid the hypersensitivity reaction. Individuals in whom the hypersensitivity reaction develops should not be rechallenged with this agent because subsequent hypersensitivity reactions can be fatal. Abacavir has also been associated with an increased risk of myocardial infarction in some cohort studies, generally in patients who have underlying risks for cardiovascular disease. Consequently, abacavir should not be used in such patients if effective alternative nucleoside or nucleotide analog agents exist. Abacavir is usually prescribed as a fixed-dose combination pill with lamivudine for use as a once-daily pill (Epzicom; Table 31–8).

A. Zidovudine—Zidovudine was the first approved antiretroviral medication for HIV infection. It is administered at a dose of 300 mg orally twice daily. A combination of zidovudine 300 mg and lamivudine 150 mg (Combivir) is available. Approximately 40% of patients experience subjective side effects that usually remit within 6 weeks. The common dose-limiting side effects are anemia and neutropenia, which require ongoing laboratory monitoring. Long-term use has been associated with lipoatrophy.

B. Lamivudine—Lamivudine is a safe and well-tolerated agent. The dosage is 150 mg orally twice daily or 300 mg orally once a day. The dose should be reduced in patients with chronic kidney disease. There are no significant side effects with lamivudine; it has activity against hepatitis B, though HBV resistance to it is an increasing problem.

C. Emtricitabine—Emtricitabine is dosed at 200 mg orally once daily. Emtricitabine also has activity against hepatitis B. Its dosage should be reduced in patients with chronic kidney disease.

D. Abacavir—Abacavir is dosed at 300 mg orally twice daily. Prior to initiation of abacavir, patients should undergo testing for HLA typing. Those with the B*5701 allele should not be treated with abacavir because the likelihood of a hypersensitivity reaction developing is high; the reaction is characterized by a flu-like syndrome with rash and fever that worsens with successive doses. Unfortunately, the absence of this allele does not guarantee that the patient will avoid the hypersensitivity reaction. Individuals in whom the hypersensitivity reaction develops should not be rechallenged with this agent because subsequent hypersensitivity reactions can be fatal. Abacavir has also been associated with an increased risk of myocardial infarction in some cohort studies, generally in patients who have underlying risks for cardiovascular disease. Consequently, abacavir should not be used in such patients if effective alternative nucleoside or nucleotide analog agents exist. Abacavir is usually prescribed as a fixed-dose combination pill with lamivudine for use as a once-daily pill (Epzicom; Table 31–8).

NNRTI, non-nucleoside reverse transcriptase inhibitor (eg, delavirdine, efavirenz, etravirine, nevirapine, rilpivirine); NRTI, nucleoside/nucleotide reverse transcriptase inhibitor (eg, abacavir, didanosine, emtricitabine, lamivudine, stavudine, tenofovir, zidovudine); PEP, preexposure prophylaxis; TAF, tenofovir alafenamide; TDF, tenofovir disoproxil fumarate.

Average wholesale price (AWP, for AB-rated generic when available) for quantity listed. Source: IBM Micromedex Red Book (electronic version) IBM Watson Health, Greenwood Village, CO, USA. Available at https://www.micromedexsolutions.com (cited April 25, 2019). AWP may not accurately represent the actual pharmacy cost because wide contractual variations exist among institutions.
Abacavir is also formulated with zidovudine and lamivudine in a single pill (Trizivir, one tablet orally twice daily; Table 31–8). Trizivir is not recommended as solo treatment for HIV because it is not as efficacious as combining two nucleoside/nucleotide analogs with a ritonavir-boosted PI, an NNRTI, or an integrase inhibitor.

**E. Tenofovir**—Tenofovir is the only licensed nucleotide analog. It comes in two forms: tenofovir disoproxil fumarate (TDF) and tenofovir alafenamide (TAF). TDF is available for use both in the form of a single pill at an oral dose of 300 mg once daily and as an oral fixed-dose combination pill with emtricitabine 200 mg (Truvada; Table 31–8) once daily. Several other single-tablet once-a-day complete regimens include TDF (Atripla, Complera, Stribild) (Table 31–8). Tenofovir is active against hepatitis B, including isolates that have resistance to lamivudine. TDF is associated with a clinically modest loss of kidney function, a small increased risk of acute renal injury, and increased rate of bone resorption. It should not be used in patients at risk for kidney disease or without dose adjustment in those with creatinine clearance below 60 mL/min or in those with or at risk for osteopenia/osteoporosis. For these patients, TAF is the better choice.

TAF attains higher levels in cells with a much lower plasma level. For this reason, it appears to cause less harm to kidneys and less bone resorption. It is not available as a single agent but is available in a combination tablet with emtricitabine (Descovy, Table 31–8). Single-tablet once-a-day regimens that include TAF (Genvoya and Odofsey) are also available (Table 31–8). TAF should not be used with rifamycins.

Because of concern regarding nephrotoxicity for both TDF and TAF, it is recommended that the serum creatinine be checked at baseline, at 2–8 weeks, and then every 3–6 months and that a urinalysis and urine glucose and protein be checked at baseline and monitored periodically as clinically indicated.

**F. Didanosine**—The most convenient formulation of didanosine is the enteric-coated capsule. For adults weighing at least 60 kg, the dose is one 400-mg enteric-coated capsule orally daily; for those 30–59 kg, the dose is one 250-mg enteric-coated capsule orally daily. Didanosine should be taken on an empty stomach.

Didanosine has been associated with pancreatitis. The incidence of pancreatitis with didanosine is 5–10%—of fatal pancreatitis, less than 0.4%. Patients with a history of pancreatitis, as well as those taking other medications associated with pancreatitis (including trimethoprim-sulfamethoxazole and intravenous pentamidine) are at higher risk for this complication. Other common side effects with didanosine include a dose-related, reversible, painful peripheral neuropathy, which occurs in about 15% of patients, and dry mouth. Fulminant hepatic failure and electrolyte abnormalities, including hypokalemia, hypocalcemia, and hypomagnesemia, have been reported in patients taking didanosine. Because of the side-effect profile, didanosine is rarely used today.

**2. Nonnucleoside reverse transcriptase inhibitors**—NNRTIs inhibit reverse transcriptase at a site different from that of the nucleoside and nucleotide agents described above. The major advantage of NNRTIs is that four of them (efavirenz, rilpivirine, doravirine, and nevirapine) have potencies comparable to that of PI (next section), at least for patients with viral loads under 100,000 copies/mL—with lower pill burden and fewer side effects. Unlike PI, they do not appear to cause lipodystrophy; patients with cholesterol and triglyceride elevations who are switched from a PI to an NNRTI may have improvement in their lipids. The resistance patterns of NNRTIs are distinct from those of the PI. Because these agents may cause alterations in the clearance of PIs, dose modifications may be necessary when these two classes of medications are administered concomitantly. There is a high degree of cross-resistance among the “first-generation” NNRTIs, such that resistance to one medication in this class uniformly predicts resistance to other medications. However, the “second-generation” NNRTI etravirine appears to have consistent antiviral activity in patients with prior exposure and resistance to nevirapine, efavirenz, or delavirdine. In particular, the K103N mutation does not appear to have an impact on etravirine (or rilpivirine).

There is no therapeutic reason for using more than one NNRTI at the same time.

**A. Efavirenz**—The major advantages of efavirenz are that it can be given once daily in a single dose (600 mg orally) and is available in a once-daily fixed-dose combination with TDF and emtricitabine in a single pill (Atripla; Table 31–8). The major side effects are rash and psychiatric/neurologic complaints, with patients reporting symptoms ranging from lack of concentration and strange dreams to delusions and mania. These side effects tend to wane over time, usually within a month or so; however, there are some patients who cannot tolerate these effects, especially if they persist longer than a month. Participant level data from four randomized trials of efavirenz regimens versus non-efavirenz containing regimens found increased suicidality (hazard ratio of 2.6) among those taking efavirenz. Administration of efavirenz with food, especially fatty food, may increase its serum levels and consequent neurotoxicity. Therefore, it should be taken on an empty stomach; taking before bedtime may also reduce patients’ experience of neuropsychiatric symptoms.

**B. Doravirine**—Dosed at 100 mg orally daily, this drug can be taken with or without food. Two 48-week Phase III studies showed that, in previously untreated individuals, doravirine, when used with two NRTIs resulted in similar levels of viral suppression as efavirenz plus two NRTIs or darunavir/ritonavir plus two NRTIs. It is also available as a single-pill combination with TDF and lamivudine (Delstrigo; Table 31–8). It is well tolerated. In cases of virologic failure, NNRTI cross-resistance may develop.

**C. Rilpivirine**—This medication, dosed at 25 mg once daily, is equal in efficacy to efavirenz in patients with HIV viral loads below 100,000 copies/mL. Rilpivirine should not be used in patients with baseline viral loads of 100,000 copies/mL or greater or those with CD4 counts below 200 cells/μL because of greater risk of viral failure. As is true of efavirenz, rilpivirine is available in a once-daily fixed-dose combination with TDF and emtricitabine (Complera; Table 31–8) and with TAF and emtricitabine.
Ten PIs—indinavir, nelfinavir, ritonavir, saquinavir, amprenavir, fosamprenavir, lopinavir, atazanavir, tipranavir, and darunavir—are available. PIs are potent suppressors of HIV replication and are administered as part of a combination regimen.

All of the PIs—to differing degrees—are metabolized by the cytochrome P450 system, and each can inhibit and induce various P450 isoenzymes. Therefore, medication interactions are common and difficult to predict. Clinicians should consult the product inserts before prescribing PIs with other medications. Medications such as rifampin that are known to induce the P450 system should be avoided.

The fact that the PIs are dependent on metabolism through the cytochrome P450 system has led to the use of ritonavir to boost the medication levels of saquinavir, lopinavir, indinavir, atazanavir, tipranavir, darunavir, and amprenavir, allowing use of lower doses and simpler dosing schedules of these PIs. A second boosting agent, cobicistat, is coformulated with the PI atazanavir (Evotaz) and darunavir (Prescobic). Similar to ritonavir, cobicistat also inhibits liver enzymes that metabolize other HIV medications.

In fact, guidelines recommend that all PI-containing regimens except nelfinavir use boosting if possible.

When choosing which PI to use, prior patient experience, resistance patterns, side effects, and ease of administration are the major considerations. The first three PIs to be developed—indinavir, saquinavir, and ritonavir (as single agents)—are now rarely used because of the superiority of the second generation of PIs. Amprenavir has been almost entirely replaced by its prodrug, fosamprenavir. Unfortunately, all PIs, with the exception of unboosted atazanavir, have been linked to a constellation of metabolic abnormalities, including elevated cholesterol levels, elevated triglyceride levels, insulin resistance, diabetes mellitus, and changes in body fat composition (eg, buffalo hump, abdominal obesity). The lipid abnormalities and body habitus changes are referred to as lipodystrophy. Although lipodystrophy is commonly associated with PIs, it has been seen also in HIV-infected persons who have never been treated with these agents. In particular, the lipodystrophy effects seen in patients receiving antiretroviral treatment appears to be more related to the nucleoside toxicity and in particular to the thymidine analogs ( stavudine and zidovudine).

Of the different manifestations of lipodystrophy, the dyslipidemias that occur are of particular concern because of the likelihood that increased levels of cholesterol and triglycerides will result in increased prevalence of heart disease. All patients taking PIs or NRTIs should have fasting serum cholesterol, low-density lipoprotein (LDL) cholesterol, and triglyceride levels performed every 12 months. Clinicians should assess for coronary heart disease risk (see Chapter 28) and consider initiating dietary changes or medication therapy (or both). PIs inhibit statin metabolism. Lovastatin and simvastatin should be avoided. In general, the least interaction is with pravastatin (20 mg daily orally). Atorvastatin (10 mg daily orally) or rosuvastatin (5 mg/day orally initially; maximum 10 mg/day) may also be used cautiously. Fish oil (3000 mg daily) combined with exercise and dietary counseling has been found to decrease triglyceride levels by 25%. Patients with persistently elevated fasting serum triglyceride levels of 500 mg/dL or more who do not respond to dietary intervention should be treated with gemfibrozil (600 mg twice daily prior to the morning and evening meals). PIs are associated with abnormalities in cardiac conduction, especially prolongation of the PR interval.

A. Indinavir—Indinavir is usually dosed at 800 mg twice daily in combination with 100 mg of ritonavir twice daily. Nausea and headache are common complaints with this medication. Indinavir crystals are present in the urine in approximately 40% of patients; this results in clinically
apparent nephrolithiasis in about 15% of patients receiving indinavir. Lower urinary tract symptoms and acute kidney injury also have been reported. Patients taking this medication should be instructed to drink at least 48 ounces of fluid a day to ensure adequate hydration in an attempt to limit these complications. Mild indirect hyperbilirubinemia is also commonly observed in patients taking indinavir but is not an indication for discontinuation of the medication.

**B. Saquinavir**—Saquinavir is formulated only as a hard-gel capsule (Invirase). It should be used only with ritonavir (1000 mg of hard-gel saquinavir with 100 mg of ritonavir orally twice daily). The most common side effects with saquinavir are diarrhea, nausea, dyspepsia, and abdominal pain.

**C. Ritonavir**—Use of this potent PI at full dose (600 mg orally twice daily) has been limited by its inhibition of the cytochrome P450 pathway causing a large number of drug-drug interactions and by its frequent side effects of fatigue, nausea, and paresthesia. However, it is widely used in lower dose (eg, 100 mg daily to 100 mg twice daily) as a booster of other PIs.

**D. Nelfinavir**—Nelfinavir is the only PI for which ritonavir boosting is not recommended. Unboosted nelfinavir is generally not as potent as a boosted PI regimen (eg, lopinavir/ritonavir plus ritonavir). The dose of nelfinavir is 1250 mg orally twice daily. Diarrhea is a side effect in 25% of patients taking nelfinavir, but this symptom may be controlled with over-the-counter antidiarrheal agents in most patients.

**E. Amprenavir**—Amprenavir has efficacy and side effects similar to those of other PIs. Common side effects are nausea, vomiting, diarrhea, rash, and perioral paresthesia. The dose is 1200 mg orally twice daily. The concentration of amprenavir decreases when coadministered with ethinyl estradiol; therefore, amprenavir should be used with circumspexion in the treatment of transgender persons requiring high-dose estrogen.

**F. Fosamprenavir**—Fosamprenavir is a prodrug of amprenavir. Its major advantage over using amprenavir is a much lower pill burden. For PI-naive patients, it can be dosed at 1400 mg orally twice daily (four capsules a day) or at 1400 mg orally daily (two capsules) with ritonavir 200 mg orally daily (two capsules) or at 700 mg orally with ritonavir 100 mg orally twice daily. Patients previously treated with a PI should receive 700 mg orally with ritonavir 100 mg orally twice daily. Side effects are similar to those with amprenavir—most commonly gastrointestinal distress and hyperlipidemia. As with amprenavir, the concentration of fosamprenavir decreases when coadministered with ethinyl estradiol; therefore, fosamprenavir should be used with circumspexion in the treatment of transgender persons requiring high-dose estrogen.

**G. Lopinavir/r**—Lopinavir/r is lopinavir (200 mg) coformulated with a low dose of ritonavir (50 mg) to maximize the bioavailability of lopinavir. It has been shown to be more effective than nelfinavir when used in combination with stavudine and lamivudine. The usual dose is lopinavir 400 mg with ritonavir 100 mg (two tablets) orally twice daily with food. When given along with efavirenz or nevirapine, a higher dose (600 mg/150 mg—three tablets) is usually prescribed. The most common side effect is diarrhea, and lipid abnormalities are frequent. Because of these side effects, lopinavir/r has fallen off the list of medications recommended as part of first-line treatment regimens.

**H. Atazanavir**—Atazanavir is available alone and coformulated with cobicistat (Evotaz). Atazanavir can be dosed as 400 mg (two 200-mg capsules) daily with food or it can be dosed as 300 mg in combination with 100 mg of ritonavir once daily with food. When coformulated with cobicistat, it is dosed at 300 mg atazanavir and 150-mg cobicistat. The most common side effect is mild hyperbilirubinemia that resolves with discontinuation of the medication. Nephrolithiasis and cholelithiasis have also been reported with this PI. Both tenofovir and efavirenz lower the serum concentration of atazanavir. Therefore, when either of these two medications is used with atazanavir, it should be boosted by administering ritonavir or given coformulated with cobicistat. Proton pump inhibitors are contraindicated in patients taking atazanavir because atazanavir requires an acidic pH to remain in solution.

**I. Tipranavir**—Tipranavir is the only nonpeptidic PI approved by the US Food and Drug Administration (FDA). Because of its unique structure, it is active against some strains of HIV that are resistant to other PIs. It is dosed with ritonavir (two 250-mg capsules of tipranavir with two 100-mg capsules of ritonavir orally twice daily with food). The most common side effects are nausea, vomiting, diarrhea, fatigue, and headache. Tipranavir/ritonavir has been also associated with liver damage and should be used very cautiously in patients with underlying liver disease. Reports of intracranial hemorrhage in patients taking tipranavir-containing regimens have raised additional safety concerns about this potent PI. Because it is a sulfas-containing medication, its use should be closely monitored in patients with sulfa allergy.

**J. Darunavir**—Darunavir has impressive antiviral activity in the setting of significant PI resistance and in treatment-naive patients. It is formulated by itself and coformulated with cobicistat (Prezcobix). When formulated without cobicistat it requires boosting with ritonavir. For initial treatment of HIV or for treatment-experienced patients without darunavir-related resistance mutations, daily dosing is 800 mg of darunavir with 100 mg of ritonavir or with 150 mg of cobicistat. Darunavir 800 mg is also available in a coformulated tablet with emtricitabine, TAF, and cobicistat (Symtuza, Table 31–8). It has been approved for use by the FDA and the European Commission. For patients with prior PI treatment experience or PI resistance (with mutations known to impact darunavir), darunavir should be dosed at 600 mg orally twice daily, with ritonavir, 100 mg orally twice daily. Darunavir has a safety profile similar to other PIs, such as ritonavir-boosted lopinavir, but is generally better tolerated. Like tipranavir, darunavir is a sulfas-containing...
medication, and its use should be closely monitored in patients with sulfa allergy.

4. **Entry inhibitors**

A. **Enfuvirtide**—Enfuvirtide (Fuzeon) is known as a fusion inhibitor; it blocks the entry of HIV into cells by blocking the fusion of the HIV envelope to the cell membrane. The addition of enfuvirtide to an optimized antiretroviral regimen improved CD4 counts and lowered viral loads in heavily pretreated patients with multidrug-resistant HIV. Unfortunately, resistance develops rapidly in patients receiving nonsuppressive treatment. The dose is 90 mg by subcutaneous injection twice daily; unfortunately, painful injection site reactions develop in most patients, which makes long-term use problematic.

B. **Maraviroc**—Maraviroc is a CCR5 co-receptor antagonist. Medications in this class prevent the virus from entering uninfected cells by blocking the CCR5 co-receptor. Before starting therapy, a viral tropism assay should be performed because this class of entry inhibitors is only active against "CCR5-tropic virus." This form of the HIV-1 virus tends to predominate early in infection, while so-called dual/mixed tropic virus (which utilizes either R5 or CXCR4 co-receptors) emerges later as infection progresses. Approximately 50–60% of previously treated HIV-infected patients have circulating CCR5-tropic HIV. The medication has been shown to be effective in HIV-infected persons with ongoing viral replication despite being heavily treated and who have CCR5-tropic virus. The dose of maraviroc is 150–300 mg orally twice daily, based on the other medications the patient is taking at the time—in combination with a ritonavir boosted PI, 150 mg daily of maraviroc has been used successfully. Common side effects are cough, fever, rash, musculoskeletal problems, abdominal pain, and dizziness; however, maraviroc is generally well tolerated with limited impact on serum lipids.

5. **Integrase inhibitors**—Integrase inhibitors slow HIV replication by blocking the HIV integrase enzyme needed for the virus to multiply. They are now the preferred regimens for initiating therapy because of the combination of efficacy, ease of administration, and low incidence of side effects. Four integrase inhibitors are currently available: raltegravir, elvitegravir, dolutegravir and bictegravir. A fifth agent, cabotegravir, currently in phase III testing, can be coformulated with rilpivirine in a long-acting injectable form; it may prove to be an effective two-drug antiretroviral treatment regimen for patients successfully suppressed on a three-drug regimen. Clinical trials of available integrase inhibitors reveal a consistent pattern of more rapid decline in viral load compared with more standard PI/r or NNRTI-based regimens. Integrase inhibitors are effective (when combined with other active medications) in the treatment of HIV-infected patients with documented resistance to each of the three main classes of antiretroviral medications (nucleoside analogs, PI, NNRTI). Avoid administering integrase inhibitors with antacids or other medications with divalent cations (Ca²⁺, Mg²⁺, Al³⁺, Fe³⁺) because chelation of the integrase inhibitor by the cation reduces absorption. When these medications must be taken with integrase inhibitors, consult a pharmacist to determine the best separation of times of administration.

A. **Raltegravir**—The dose of raltegravir is 400 mg orally twice daily. It has been found to be superior to efavirenz and ritonavir-boosted darunavir and ritonavir-boosted atazanavir. It is the recommended integrase inhibitor for pregnant women. Common side effects are diarrhea, nausea, and headache, but overall, it is well tolerated and has the additional advantage over PI-based regimens and efavirenz-based regimens in that it appears to have little impact on lipid profiles or glucose metabolism.

B. **Elvitegravir**—Elvitegravir is not manufactured as a single agent. It can be prescribed in a once-a-day combination pill (Stribild) that contains 125 mg of elvitegravir and 150 mg of cobicistat, a boosting agent, along with standard doses of TDF and emtricitabine (Table 31–8). Stribild has been shown to be noninferior to two preferred first-line regimens: Atripla and boosted atazanavir with emtricitabine/ TDF. The main side effect of Stribild is an increase in serum creatinine levels that has been shown to be related to the cobicistat inhibition of tubular secretion of creatinine by the kidney and is thought to be nonpathologic and reversible. However, because of this effect, Stribild is recommended in patients with estimated creatinine clearance greater than 70 mL/min. A urine analysis should be done at baseline and at initial follow-up to look for proteinuria and glycosuria, which are signs of tubulopathy. Diarrhea and rash may also occur, although overall the medication is well tolerated. Elvitegravir is also coformulated with emtricitabine and TAF along with cobicistat boosting in a single once-a-day pill (Genvoya, Table 31–8). Since TAF appears to have fewer side effects than TDF, this is likely to become the preferred elvitegravir regimen.

C. **Dolutegravir**—Dolutegravir shows excellent potency and tolerability and is dosed once a day in most circumstances. It has been shown to be superior to efavirenz and darunavir. Unlike elvitegravir, dolutegravir does not require a boosting agent and has fewer drug-drug interactions. Similar to cobicistat, it inhibits tubular secretion of creatinine by the kidney, resulting in small increases in serum creatinine levels. The standard dosage used in treatment-naïve, integrase-naïve patients is 50 mg/day. It is available combined with abacavir and lamivudine in a single once a day tablet (Triumeq, Table 31–8). In patients receiving efavirenz, fosamprenavir/ritonavir, tipranavir/ritonavir, or rifampin, the dose should be increased to 50 mg twice daily. It should also be dosed at 50 mg twice daily in integrase-experienced patients in whom integrase resistance is suspected. Indeed, when combined with other active medications, it has been shown to provide some activity in patients with integrase resistance who have not responded to prior raltegravir- or elvitegravir-containing regimens. Dolutegravir has demonstrated impressive results in clinical trials of treatment-naïve patients, in terms of effectiveness, tolerability, and high barrier to resistance, when compared with the more standard NNRTI, boosted PI, and raltegravir-containing regimens. Dolutegravir is coformulated in combination with rilpivirine (Juluca, Table 31–8) for use as a once-a-day (to be taken
with a meal) treatment for patients who are virologically suppressed (viral load less than 50 copies/mL) on a stable regimen for at least 6 months, with no history of treatment failures or resistance to either of the two agents.

**D. Bictegravir**—Bictegravir is dosed once daily, does not require boosting, and has a high barrier to resistance. It is dosed at 50 mg daily. It has been shown to be noninferior to dolutegravir. It is not available as a single agent but is marketed as a fixed-dose combination of bictegravir with emtricitabine and TAF.

**6. Ibalizumab**—A novel treatment for HIV, ibalizumab is a monoclonal antibody that blocks the entry of HIV into the CD4 cell by blocking the CD4 receptor. Given as an intravenous infusion therapy along with other oral HIV medications, it is used as rescue therapy for patients with multidrug-resistant HIV that is not controlled by other treatments.

**7. Constructing an initial regimen**—Consensus guidelines of the International Antiviral Society—USA Panel recommend starting antiretroviral treatment with one of three integrase inhibitor–containing regimens (Table 31–9). For the two regimens that use tenofovir, the TAF form is recommended due to less kidney and bone toxicity. All three regimens are available as a single once a day pill.

Studies have shown dolutegravir/abacavir/lamivudine to be superior to efavirenz/TDF/emtricitabine and have shown dolutegravir to be superior to ritonavir-boosted darunavir (both combined with either abacavir/lamivudine or TDF/emtricitabine). A network meta-analysis adjusting for NRTI backbone found that dolutegravir had superior efficacy in suppressing viral load compared with regimens containing ritonavir-boosted atazanavir, ritonavir-boosted darunavir, efavirenz, or ritonavir-boosted lopinavir. Discontinuation due to adverse events was also statistically lower in the dolutegravir regimens.

The drug combinations incorporating the integrase inhibitor raltegravir have done well in comparative studies. Among treatment-naïve patients, raltegravir in combination with TDF/emtricitabine is as effective as efavirenz/TDF/emtricitabine for daily treatment and has fewer side effects. In a 5-year follow-up to the double-blind trial, the raltegravir arm outperformed the efavirenz combination regimen largely due to better long-term tolerability. Furthermore, the CD4 response appeared better in patients treated with the raltegravir combination.

Neural tube defects have been reported in the offspring of women taking dolutegravir at conception, so the drug should be avoided in women who may become pregnant. For now, raltegravir is the integrase inhibitor recommended for women who are already pregnant. Elvitegravir/cobicistat and other drugs boosted with cobicistat should not be used during pregnancy and neither should bictegravir (because of lack of data regarding adverse effects). Recommended drugs in pregnancy include atazanavir/ritonavir, darunavir/ritonavir, efavirenz, and rilpivirine.

For patients who cannot take an integrase inhibitor, alternative regimens are recommended (Table 31–9).

Resistance testing should be performed prior to starting antiretroviral treatment. Of newly infected persons in some urban areas of the United States, 8–10% have NNRTI resistance (primarily K103N). Patients with NNRTI resistance would not be expected to respond fully to an efavirenz-based regimen. The most important determinant of treatment efficacy is adherence to the regimen. Therefore, it is vitally important that the regimen chosen be one to which the patient can easily adhere (Figure 31–7). In general, patients are more compliant with medication regimens (Table 31–9) that offer a complete regimen in one pill that needs to be taken only once or twice a day, do not require special timing with regard to meals, can be taken at the same time as other medications, do not require refrigeration or special preparation, and do not have bothersome side effects. Given the high level of effectiveness of recommended regimens, patients for whom the viral load does not fully suppress are likely noncompliant. Pharmacists and other specially trained clinicians can be very effective in helping patients improve their adherence by taking the time to understand why patients miss their medications and problem solve (eg, take medicine at same time every day, keep a supply in the car or at work in case they forget). For certain populations (eg, unstably housed individuals), specially tailored programs that include medication dispensing are needed.

**E. Monitoring Antiretroviral Treatment**

**1. Goals of monitoring antiretroviral treatment**—Monitoring of antiretroviral treatment (Figure 31–7) has two goals: evaluate for toxicity and measure efficacy using objective markers to determine whether to maintain or change regimens. Laboratory evaluation for toxicity depends on the specific medications in the combination but generally should be done approximately every 3–4 months once a patient is on a stable regimen. Patients who are intolerant of their initial regimen should be changed to one of the other initial recommended or alternative regimens in Table 31–9. The second aspect of monitoring is to measure objective markers of efficacy. The CD4 cell count and HIV viral load should be repeated 1–2 months after the initiation or change of antiretroviral regimen and every 3–6 months thereafter in clinically stable patients. With integrase regimens, approximately 80% of patients will have undetectable HIV viral load at 1 month. All patients should have undetectable viral loads by 3 months; if not, the usual problem is compliance (see next section). (Patients receiving antiretroviral treatment with undetectable viral load for 2 years and CD4 counts 300 cells/mcL or more may need CD4 testing only every 12 months.)

**2. The challenge of compliance**—In a patient who is adherent to an effective regimen, viral loads should be undetectable within 4–12 weeks. For patients in whom viral loads are not suppressed or who have viral rebound after suppression, the major question facing the clinician is whether the patient is nonadherent or has resistance to the regimen, or both. The issue is complicated because many patients report being more compliant than they really are. Patients who are having trouble adhering to their treatment should receive counseling on how to better comply with their treatment. In patients who are adherent or who have missed enough doses to make resistance possible,

1 These recommended and alternative initial regimens are drawn from Saag MS et al. Antiretroviral drugs for treatment and prevention of HIV infection in adults: 2018 recommendations of the International Antiviral Society—USA Panel. JAMA. 2018;320(4):379–96.
2 Usual medication doses are supplied when not part of a fixed-dose preparation.
TAF, tenofovir alafenamide; TDF, tenofovir disoproxil fumarate.
Repeatedly positive ELISA and Western blot confirmation of HIV

Perform HIV viral load and resistance testing and begin a recommended antiretroviral treatment regimen (Table 31–9)

Viral load detectable after 4–12 weeks of treatment or viral rebound after suppression

Assess adherence. If not adherent, initiate adherence counseling. If adherent, or if prolonged period of partial or nonadherence,

Change to alternative drug or regimen

Intolerance to regimen

Perform resistance testing and change to a regimen with three drugs to which the patient is not resistant from at least two different classes.

**Figure 31–7.** Approach to monitoring initial and subsequent antiretroviral therapy.

Resistance testing should be performed. Based on the results of resistance testing, and assessment of the patient’s ability to comply with complicated regimens or to tolerate predictable side effects, the clinician should prescribe a combination of three medications to which there is no or only minimal resistance.

Once antiretroviral treatment has been initiated, it is not advisable to stop the therapy unless there is a compelling reason (eg, toxicity, poor adherence, etc). So-called drug holidays or structured treatment interruptions have been shown to increase risk of AIDS-related complications, increase CD4 declines, and increase morbidity from non-AIDS-related complications (eg, myocardial infarctions and liver failure) and are not recommended.

**3. The challenge of medication resistance**—HIV-1 medication resistance limits the ability to fully control HIV replication and remains an important cause for antiretroviral regimen failure. Resistance has been documented for all currently available antiretrovirals including the newer classes of fusion inhibitor, CCR5 inhibitors, and integrase inhibitors. Although HIV medication resistance has been common historically, reports suggest that the degree of high-level resistance is declining in the past few years, which is likely related to better tolerated, easier to use, and more efficacious antiretroviral agents. Resistance also occurs in patients who are antiretroviral treatment-naïve, but who have been infected with a medication resistant strain—primary resistance or transmitted medication resistance. Cohort studies of antiretroviral treatment-naïve patients entering care in North America and Western Europe show that roughly 10–12% (and as high as 25%) of recently infected individuals have been infected with a medication-resistant strain of HIV-1.

In addition to being performed as part of a standard baseline, resistance testing is also recommended for patients who are receiving antiretroviral treatment and have suboptimal viral suppression (ie, viral loads greater than 200 copies/mL). Both genotypic and phenotypic tests are commercially available and in randomized controlled studies their use has been shown to result in improved short-term virologic outcomes compared to making treatment choices without resistance testing. Furthermore, multiple retrospective studies have conclusively demonstrated that resistance tests provide prognostic information about virologic response to newly initiated therapy that cannot be gleaned from standard clinical information (ie, treatment history, examination, CD4 count, and viral load tests).

Because of the complexity of resistance tests, many clinicians require expert interpretation of results. In the case of genotypic assays, results may show that the mutations that are selected for during antiretroviral treatment are medication-specific or contribute to broad cross-resistance to multiple medications within a therapeutic class. An example of a medication-specific mutation for the reverse transcriptase inhibitors would be the M184V mutation that is selected for by lamivudine or emtricitabine therapy—this mutation causes resistance only to those two medications. Conversely, the thymidine analog mutations (“TAMs”) of M41L, D67N, K70R, L210W, T215Y/F, and T219Q/K/E are selected for by either zidovudine or stavudine therapy, but cause resistance to all the medications in the class and often extend to the nucleotide inhibitor tenofovir when three or more of these TAMs are present. Further complicating the interpretation of genotypic tests is the fact that some mutations that cause resistance to one medication can actually make the virus that contains this mutation more sensitive to another medication. The M184V mutation, for example, is associated with increased sensitivity to zidovudine, stavudine, and tenofovir. The most common mutations associated with medication resistance and cross-resistance patterns for NRTIs, NNRTIs, PIs, and integrase inhibitors can be found.
at https://hivdb.stanford.edu (see specific references below). Phenotypic tests also require interpretation in that the distinction between a resistant virus and sensitive one is not fully defined for all available medications.

Both methods of resistance testing are limited by the fact that they may measure resistance in only some of the viral strains present in an individual. Resistance results may also be misleading if a patient is not taking antiretroviral medications at the time of testing because the dominant virus is likely the wild-type, even if there are resistant viruses in the body that can become dominant with the selective pressure of antivirals. Thus, resistance results do not replace a careful history of what medications a patient has taken in the past and for how long. Also, the results of resistance testing should be viewed cumulatively—ie, if resistance is reported to an agent on one test, it should be presumed to be present thereafter even if subsequent tests do not give the same result.

F. Constructing Alternative Antiretroviral Treatment Regimens

In designing second-line regimens for patients with resistance to initial therapy, the goal is to identify three medications from at least two different classes to which the virus is not resistant. Even without resistance testing, certain forms of cross-resistance between medications within a class can be assumed. For example, the resistance patterns of lopinavir/ritonavir and indinavir are overlapping, and patients with virus resistant to these agents are unlikely to respond to nefinavir or saquinavir even though they have never received treatment with these agents. Similarly, the resistance patterns of nevirapine and efavirenz are overlapping—as are the resistance patterns between raltegravir and elvitegravir.

In constructing regimens, toxicities should be nonoverlapping and agents that are either virologically antagonistic or incompatible in terms of drug-drug interactions should be avoided. For example, the combination of stavudine plus didanosine should be avoided, since there is increased risk of toxicities, in particular in pregnant women because of the increased risk of lactic acidosis, which can be fatal. Moreover, the nucleoside pair of zidovudine and stavudine should be avoided because of increased toxicity and the potential for antagonism that results from intracellular competition for phosphorylation. The combination of didanosine with tenofovir should be avoided because of observed declines in CD4 counts. Etravirine should not be used with boosted tipranavir because of drug-drug interactions. Lamivudine and emtricitabine are essentially the same medication and so are not used together.

Given the availability of new class medications and new generation medications, a combination of antiretroviral treatment can successfully treat virtually all patients—no matter how much resistance is present.

Course & Prognosis

With improvements in therapy, patients who are compliant with treatment should have near normal life spans. A population-based study conducted in Denmark found that HIV-infected persons at age 25 years without hepatitis C had a life expectancy similar to that of an uninfected 25-year-old. Unfortunately, not all HIV-infected persons have access to treatment. Studies consistently show less access to treatment for blacks, the homeless, and injection drug users. For patients whose disease progresses even though they are receiving appropriate treatment, meticulous palliative care must be provided (see Chapter 5), with attention to pain control, spiritual needs, and family (biologic and chosen) dynamics.

When to Refer

- HIV-infected patients in whom viral loads cannot be fully suppressed on one of the initial recommended regimens should be referred to specialists.
- Specialty consultation is particularly important for those patients with detectable viral loads on antiretroviral treatment; those intolerant of standard medications; those in need of systemic chemotherapy; and those with complicated opportunistic infections, particularly when invasive procedures or experimental therapies are needed.

When to Admit

Patients with opportunistic infections who are acutely ill (eg, who are febrile, who have had rapid change of mental status, or who are in respiratory distress) or who require intravenous medications.

VIRAL DISEASES

HUMAN HERPESVIRUSES

1. Herpesviruses 1 & 2

ESSENTIALS OF DIAGNOSIS

- Spectrum of illness: stomatitis, urogenital lesions, Bell palsy, encephalitis.
- Variable intervals between exposure and clinical disease, since herpes simplex virus (HSV) causes both primary (often subclinical) and reactivation disease.

General Considerations

HSV-1 and HSV-2 affect primarily the oral and genital areas, respectively. Asymptomatic shedding of either virus is common, but it is more common with HSV-2 and from genital areas, with most infected individuals shedding virus at least once a month, which may be responsible for transmission. Asymptomatic HSV-2–infected individuals shed the virus less often than those with symptomatic infection. Clinical disease typically indicates reactivation. Total and subclinical shedding of HSV-2 virus decrease after the first year of initial infection, although viral shedding continues for years thereafter.

Although HSV-2 is the most common cause of genital ulcers in the developed world, epidemiologic studies show that HSV-1 is a more common cause of both genital and oral lesions than HSV-2 in young women in the United States. Most HSV-2–infected persons in the United States are unaware that they are infected.

HSV-2 seropositivity increases the risk of HIV acquisition (it is threefold higher among persons who are HSV-2 seropositive than among those who are HSV-2 seronegative), and HSV-2 reactivates more often in advanced HIV infection. HIV replication is increased by interaction with HSV proteins. Suppression of HSV-2 decreases HIV-1 plasma levels and genital tract shedding of HIV, which can contribute to a reduction in the sexual transmission of HIV-1.

Clinical Findings

A. Symptoms and Signs

1. Mucocutaneous disease—See Chapter 6 for HSV-1 mucocutaneous disease ("herpes labialis" or "gingivostomatitis"). Digital lesions (whitlows) (Figure 32–1) are an occupational hazard in medicine and dentistry. Contact sports (eg, wrestling) are associated with outbreaks of skin infections ("herpes gladiatorum"). Vesicles form moist ulcers after several days and epithelialize over 1–2 weeks if untreated. Primary infection is usually more severe than recurrences but may be asymptomatic. Recurrences often involve fewer lesions, tend to be labial, heal faster, and are induced by stress, fever, infection, sunlight, chemotherapy (eg, fludarabine, azathioprine), or other undetermined factors.

HSV-2 lesions largely involve the genital tract, with the virus remaining latent in the presacral ganglia (see Chapter 6). Occasionally, lesions arise in the perianal region or on the buttocks and upper thighs. Dysuria, cervicitis, and urinary retention may occur in women. Urethritis may occur in men. Proctitis and extensive, ulcerating, weeping sacral lesions may be presenting symptoms in HIV-infected persons with CD4 cytopenia. Large ulcerations and atypical lesions suggest drug-resistant isolates.

2. Ocular disease—HSV can cause uveitis, keratitis, blepharitis, and keratoconjunctivitis (see Chapter 7). Lesions limited to the epithelium usually heal without affecting vision, whereas stromal involvement can cause uveitis, scarring, and eventually blindness. HSV is the second most common cause, after VZV, of acute retinal necrosis.

3. Neonatal and congenital infection—Both herpesviruses rarely infect the fetus and induce congenital malformations (organomegaly, bleeding, and central nervous system [CNS] abnormalities). The global rate of neonatal herpes is estimated to be about 10 cases per 100,000 live births. Maternal infection during the third trimester is associated with the highest risk of neonatal transmission, but about 70% of these infections are asymptomatic or unrecognized. Neonatal transmission during delivery, however, is more common than intrauterine infection. Invasive fetal monitoring and vacuum or forceps delivery increase the risk of herpesvirus transmission.
4. **CNS disease**—Traditionally, herpes simplex encephalitis is associated with HSV-1 infection and aseptic meningitis with HSV-2 infection. Both viruses, however, can cause encephalitis (and in one report, simultaneously). Encephalitis presents with nonspecific symptoms: a flu-like prodrome, followed by headache, fever, behavioral and speech disturbances, and focal or generalized seizures. The temporal lobe is often involved. Untreated disease and presentation with coma carry a high mortality. Ischemic stroke, although infrequent, can complicate the course of HSV meningitis or encephalitis. Many survivors suffer neurologic sequelae, which are observed more frequently among patients with HSV-1 infection. Both HSV-1 and HSV-2 can cause mild, nonspecific neurologic symptoms and are also associated with benign recurrent lymphocytic (Mollaret) meningitis.

5. **Disseminated infection**—Disseminated HSV infection occurs in the setting of immunosuppression, either primary or iatrogenic, or rarely with pregnancy. In disseminated disease, skin lesions are not always present. Disseminated skin lesions are a particular complication in patients with atopic eczema (eczema herpeticum) and burns. Pneumonia can occur regardless of immune status.

6. **Bell palsy**—HSV-1 is a cause of Bell palsy (facial nerve paralysis).

7. **Esophagitis and proctitis**—HSV-1 can cause esophagitis in immunocompromised patients, particularly those with AIDS. The lesions are smaller and deeper than those observed in patients with cytomegalovirus (CMV) esophagitis or with other herpesviruses known to cause esophagitis in immunocompromised persons. Proctitis occurs mainly in men who have sex with men.

8. **Erythema multiforme**—Herpes simplex viruses and certain drugs are a leading cause of erythema multiforme minor ("herpes-associated erythema multiforme") and of the more severe condition Stevens-Johnson syndrome/toxic epidermal necrolysis (see also Chapter 6).

9. **Other**—HSV is the cause of approximately 1% of cases of acute liver failure, particularly in pregnant women and immunosuppressed patients. The mortality of such rare fulminant hepatitis is nearly 75%. An HSV lower respiratory tract infection of unknown clinical significance is common in mechanically ventilated patients. Evidence suggests that this finding is usually an indicator rather than the cause of a poor clinical condition. HSV-1 pneumonia is associated with high morbidity in patients with solid tumors. HSV-1 is reported to be a cause of perinephric abscess, febrile neutropenia, chronic urticaria, and esophagitis and enteritis in systemic lupus erythematosus. HSV is also associated with *Helicobacter pylori*-negative upper gastrointestinal tract ulcers.

### B. Laboratory Findings

1. **Mucocutaneous disease**—See Chapter 6.

2. **Ocular disease**—Herpes keratitis is diagnosed by branching (dendritic) ulcers that stain with fluorescein. The extent of epithelial injury in herpes keratitis correlates well with polymerase chain reaction (PCR) positivity. Uveitis from HSV is often diagnosed clinically, although PCR assays on anterior chamber aspirated material may assist in making the diagnosis.

3. **Encephalitis and recurrent meningitis**—Cerebrospinal fluid (CSF) pleocytosis is common, with a similar increase in the number of red cells although CSF findings may be atypical in immunosuppressed patients. HSV real-time DNA PCR of the CSF is a rapid, sensitive, and specific tool for early diagnosis and can be included in a multiple rapid array panel. Viral detection by this method can be used if the clinical picture is consistent, especially if initial studies are negative. Antibodies to HSV in CSF can confirm the diagnosis but appear late in disease. Viral culture shows a sensitivity of only 10%. MRI scanning is often a useful adjunct showing increased signal in the temporal and frontal lobes. Temporal lobe seizure foci may be shown on electroencephalograms (EEGs).

4. **Esophagitis, proctitis, and other gastrointestinal disease**—Esophagitis is diagnosed by endoscopic biopsy with real-time PCR and cultures. Proctitis may be diagnosed by rectal swab for PCR, culture, or both. Complicated cases may require biopsy. Concomitant hepatitis and colitis have been reported with herpes simplex.

5. **Pneumonia**—Pneumonia is diagnosed by clinical, pathologic, and radiographic findings. The CT findings include diffuse or multifocal areas of ground-glass attenuation or consolidative changes or both and are best confirmed by using high-resolution CT techniques.

#### Treatment & Prophylaxis

Medications that inhibit replication of HSV-1 and HSV-2 include trifluridine and vidarabine (both for keratitis), acyclovir and related compounds, foscarnet, and cidofovir (Table 32–1). Agents under study include helicase-primase inhibitors (amprenavir, fosamprenavir, and pritelivirus) with promising preliminary (phase II) data.
### Table 32–1. Agents for viral infections.

Sources: Data from Drugs.com and Lexicomp Online.

1 Agents used exclusively in the management of HIV infection and AIDS are found in Chapter 31. Agents used in the management of HBV and HCV infections are found in Chapter 16.

2 Dosing varies considerably by indication and may require adjustment based on patient’s clinical state and type of viral infection. Consultation with a pharmacist is recommended.

CMV, cytomegalovirus; CNS, central nervous system; CSF, cerebrospinal fluid; HBV, hepatitis B virus; HCV, hepatitis C virus; HPV, human papillomavirus; HSV, herpes simplex virus; RSV, respiratory syncytial virus; VZV, varicella-zoster virus.
A. Mucocutaneous Disease
See Chapter 6.

B. Keratitis and Uveitis
For the treatment of acute epithelial keratitis, oral antiviral agents such as valacyclovir or famciclovir are first-line therapies (see Chapter 7). The usage of topical corticosteroids may exacerbate the infection, although systemic corticosteroids may help with selected cases of stromal infection. Long-term treatment (more than 1 year) with acyclovir at a dosage of 800 mg/day orally decreases recurrence rates of keratitis, conjunctivitis, or blepharitis due to HSV.

Uveitis is best managed with oral systemic (not topical) acyclovir, although HSV resistance among HIV-infected patients is reported because of the diversity of the HSV quasispecies often present.

C. Neonatal Disease
Counseling (but not serologic screening) should be offered to pregnant mothers. The use of maternal antenatal suppressive therapy with acyclovir (typically, 400 mg orally three times daily) beginning at 36 weeks’ gestation decreases the presence of detectable HSV, the rates of recurrence at delivery, and the need for cesarean delivery. Cesarean delivery is recommended for pregnant women with active genital lesions or typical prodromal symptoms.

D. Encephalitis and CNS Meningitis
Because of the need for rapid treatment to decrease mortality and neurologic sequelae, intravenous acyclovir (10 mg/kg every 8 hours for 10 days or more, adjusting for kidney disease) should be started in those patients with suspected HSV encephalitis, stopping only if another diagnosis is established. If the PCR of CSF is negative but clinical suspicion remains high, treatment should be continued for 10 days because the false-negative rate for PCR can be as high as 25% (especially in children) and acyclovir is relatively nontoxic. HSV viral load does not appear to correlate with outcome of meningitis, and it is not recommended to follow viral load over time.

Long-term neurologic sequelae of HSV encephalitis are common, and late pediatric relapse is recognized. Acyclovir resistance in a case of herpes simplex encephalitis is reported. Aseptic meningitis may also require a course of intravenous acyclovir or valacyclovir. Long-term oral prophylaxis with valacyclovir, however, does not appear to prevent recurrences of aseptic meningitis with HSV-2.

E. Disseminated Disease
Disseminated disease responds best to parenteral acyclovir when treatment is initiated early.

F. Bell Palsy
Prednisolone, 25 mg orally twice daily for 10 days started within 72 hours of onset, significantly increases the rate of recovery. Data on antiherpes antiviral agents are equivocal and therefore HSV assays are not routinely recommended; according to one study, valacyclovir (but not acyclovir), 1 g orally daily for 5 days, plus corticosteroid therapy may be beneficial if started within 7 days of symptom onset. In patients with severe or complete facial paralysis, such antiviral therapy is often administered but without proof of efficacy.

G. Esophagitis and Proctitis
Patients with esophagitis should receive either intravenous acyclovir (5–10 mg/kg every 8 hours) or oral acyclovir (400 mg five times daily) through resolution of symptoms, typically 3–5 days; however, longer treatment may be necessary for immunosuppressed patients. Maintenance therapy for AIDS patients is also with acyclovir (400 mg orally three to five times daily). Proctitis is treated with similar dosages and usually responds within 5 days.

H. Erythema Multiforme
Suppressive therapy with oral acyclovir (400 mg twice a day for 6 months) decreases the recurrence rate of HSV-associated erythema multiforme. Valacyclovir (500 mg orally twice a day) may be effective in cases unresponsive to acyclovir.

Prevention
Besides antiviral suppressive therapy (see Erythema multiforme, above and in Chapter 6), prevention also requires counseling and the use of condom barrier precautions during sexual activity. Disclosure to sexual partners of HSV-seropositive status is associated with a 50% reduction in HSV-2 acquisition. Male circumcision is associated with a lower incidence of acquiring HSV-2 infection.

Preventing spread to hospital staff and other patients from cases with mucocutaneous, disseminated, or genital disease requires isolation and usage of hand washing and gloving–gowning precautions. Staff with active lesions (eg, whitlows) should not have contact with patients. There is no approved herpes vaccine.

2. Varicella (Chickenpox) & Herpes Zoster (Shingles)

ESSENTIALS OF DIAGNOSIS

- **Varicella rash**: pruritic, centrifugal, papular changing to vesicular ("dew drops on a rose petal"), pustular, and finally crusting.
- **Zoster rash**: tingling, pain, eruption of vesicles in a dermatomal distribution, evolving to pustules and then crusting.

**General Considerations**

Varicella-zoster virus (VZV), or HHV-3, disease manifestations include chickenpox (varicella) and shingles (herpes zoster). Chickenpox generally presents during childhood; has an incubation period of 10–20 days (average 2 weeks); and is highly contagious, spreading by inhalation of infective droplets or contact with lesions.

The incidence and severity of herpes zoster ("shingles"), which affects up to 25% of persons during their lifetime, increases with age due to an age-related decline in immunity against VZV. More than half of all patients in whom herpes zoster develops are older than 60 years, and the incidence of herpes zoster reaches 10 cases per 1000 patient-years by age 80 (by which time 50% are infected with VZV). The annual incidence in the United States of 1 million cases is increasing as the population ages. Populations at increased risk for varicella-zoster–related diseases include immunosuppressed persons and persons receiving biologic agents.

**Clinical Findings**

**A. Varicella**

1. **Symptoms and signs**—Fever and malaise are mild in children and more marked in adults. The pruritic rash begins prominently on the face, scalp, and trunk, and later involves the extremities (Table 32–2). Maculopapules change within a few hours to vesicles that become pustular and eventually form crusts (Figures 32–2 and 32–3). New lesions may erupt for 1–5 days, so that different stages of

| Table 32–2. Diagnostic features of some acute exanthems. |
|-----------------|-----------------|-----------------|-----------------|-----------------|
| **Disease**     | **Prodromal Signs and Symptoms** | **Nature of Eruption** | **Other Diagnostic Features** | **Laboratory Tests** |
| Atypical measles| Same as measles. | Maculopapular centripetal rash, becoming confluent. | History of measles vaccination. | Measles antibody present in past, with titer rise during illness. |
| Chikungunya fever| 2–4 (sometimes 1–12) days, fever, headaches, abdominal complaints, myalgias, arthralgias. | Maculopapular, centrally distributed, pruritic, can be bullous with sloughing in children, occasional facial edema and petechiae. | History of mosquito bites, epidemiologic factors. | ELISA-based IgM or IgG (fourfold increase in titers); PCR and cultures are infrequently available. |
| Eczema herpeticum | None. | Vesculopustular lesions in area of eczema. | Herpes simplex virus isolated in cell culture. Multinucleate giant cells in smear of lesion. |
| Ehrlichiosis | Headache, malaise. | Rash in one-third, similar to Rocky Mountain spotted fever. | Pancytopenia, elevated liver biochemical tests. | Polymerase chain reaction, immunofluorescent antibody. |
| Enterovirus infections | 1–2 days of fever, malaise. | Maculopapular rash resembling rubella, rarely papulovesicular or petechial. | Aseptic meningitis. | Virus isolation from stool or cerebrospinal fluid; complement fixation titer rise. |
| Exanthema subitum (HHV-6, 7; roseola) | 3–4 days of high fever. | As fever falls, pink maculopapules appear on chest and trunk; fade in 1–3 days. | | White blood cell count low. |
| Infectious mononucleosis (EBV) | Fever, adenopathy, sore throat. | Maculopapular rash resembling rubella, rarely papulovesicular. | Splenomegaly, tonsillar exudate. | Atypical lymphocytes in blood smears; heterophile agglutination (Monospot test). |

1https://www.cdc.gov/smallpox/index.html

CDC, Centers for Disease Control and Prevention; EBV, Epstein-Barr virus; ELISA, enzyme-linked immunosorbent assay; EM, electron microscopy; HHV, human herpesvirus; Ig, immunoglobulin; PCR, polymerase chain reaction.

The eruption are usually present simultaneously. The crusts slough in 7–14 days. The vesicles and pustules are superficial and elliptical, with slightly serrated borders. Pitted scars are frequent. Although the disease is often mild, complications (such as secondary bacterial infection, pneumonitis, and encephalitis) occur in about 1% of cases and often lead to hospitalization.

Varicella is more severe in older patients and immunocompromised persons. In the latter, atypical presentations, including widespread dissemination in the absence of skin lesions, are often described. After the primary infection, the virus remains dormant in cranial nerve sensory ganglia and spinal dorsal root ganglia. Latent VZV will reactivate as herpes zoster in about 10–30% of persons. There is a small increased risk of Guillain-Barré syndrome for at least 2 months after an acute herpes zoster attack.

2. Laboratory findings—Diagnosis is usually made clinically, with confirmation by direct immunofluorescent antibody staining or PCR of scrapings from lesions, both of which are more sensitive than culture. Multinucleated giant cells are usually apparent on a Tzanck smear of material from the vesicle base. Leukopenia and subclinical transaminase elevation are often present, and
thrombocytopenia occasionally occurs. Although elevation of varicella IgM is occasionally used to diagnose a primary VZV infection, the assay has poor performance and is generally not recommended. The exception is that varicella antibody tested in the CSF is useful for identifying CNS involvement if VZV vasculopathy is suspected but CSF VZV DNA PCR is negative. A varicella skin test and interferon-gamma enzyme-linked immunospot (ELISPOT) can screen for VZV susceptibility.

B. Herpes Zoster

Herpes zoster ("shingles") usually occurs among adults, but cases are reported among infants and children. Shingles incidence rises markedly with age because of immunosenescence and loss of specific immunity to VZV, with rates of 8 to 12 per 1000 person-years in individuals older than 80 years. Skin lesions resemble those of chickenpox. Pain is often severe and commonly precedes the appearance of rash. Lesions follow a dermatomal distribution, with thoracic and lumbar roots being the most common. In most cases, a single unilateral dermatome is involved, but occasionally, neighboring and distant areas are involved. Lesions on the tip of the nose, inner corner of the eye, and root and side of the nose (Hutchinson sign) indicate involvement of the trigeminal nerve (herpes zoster ophthalmicus). Facial palsy and lesions of the external ear with or without tympanic membrane involvement, vertigo and tinnitus, or deafness signify geniculate ganglion involvement (Ramsay Hunt syndrome or herpes zoster oticus). Shingles is a particularly common and serious complication among immunosuppressed patients.

Complications

A. Varicella

Secondary bacterial skin superinfections, particularly with group A Streptococcus and Staphylococcus aureus, are the most common complications. Cellulitis, erysipelas, and scarlet fever are described. Bullous impetigo and necrotizing fasciitis are less often seen. Other associations with varicella include epiglottitis, necrotizing pneumonia, osteomyelitis, septic arthritis, epidural abscess, meningitis, endocarditis, pancreatitis, giant cell arteritis, inflammatory bowel disease, and purpura fulminans. Toxic shock syndrome can also develop.

Interstitial VZV pneumonia is more common in adults (especially smokers, HIV-infected patients, and pregnant women) and may result in acute respiratory distress syndrome (ARDS). After healing, numerous densely calcified lesions are seen throughout the lung fields on chest radiographs.

Historically, neurologic complications developed in about 1 in 2000 children. Cerebellar ataxia occurs at a frequency of 1-4000 in the young. A limited course and complete recovery are the rule. Encephalitis is similarly infrequent, occurs mostly in adults, and is characterized by delirium, seizures, and focal neurologic signs. The rates for both mortality and long-term neurologic sequelae are
about 10%. Ischemic strokes in the wake of acute VZV infection present at a mean of 4 months after rashes and may be due to an associated vasculitis. Multifocal encephalitis, ventriculitis, myeloradiculitis, arterial aneurysm formation, and arteritis are also described in immunosuppressed, especially HIV-infected, patients.

Clinical hepatitis is uncommon and mostly presents in the immunosuppressed patient but can be fulminant and fatal. Reye syndrome (fatty liver with encephalopathy) also complications varicella (and other viral infections, especially influenza B virus), usually in childhood, and is associated with aspirin therapy (see Influenza, below).

When contracted during the first or second trimesters of pregnancy, varicella carries a very small risk of congenital malformations, including cicatricial lesions of an extremity, growth retardation, microphthalmia, cataracts, chorioretinitis, deafness, and cerebrocortical atrophy. If varicella develops around the time of delivery, the newborn is at risk for disseminated disease.

### B. Herpes Zoster

Postherpetic neuralgia occurs in 60–70% of patients who have herpes zoster and are older than 60 years. The pain can be prolonged and debilitating. Risk factors for postherpetic neuralgia include advanced age, female sex, the presence of a prodrome, and severity of rash or pain but not family history.

Other complications include the following: (1) bacterial skin superinfections; (2) herpes zoster ophthalmicus, which occurs with involvement of the trigeminal nerve, is a sight-threatening complication (especially when it involves the iris), and is a marker for stroke over the ensuing year (Hutchinson sign is a marker of ocular involvement in the HIV-positive population); (3) rarely, unilateral ophthalmoplegia; (4) involvement of the geniculate ganglion of cranial nerve VII as well as cranial nerves V, VIII, IX, and X; (5) aseptic meningitis; (6) peripheral motor neuropathy; (7) transverse myelitis; (8) encephalitis; (9) acute cerebellitis; (10) stroke; (11) vasculopathy; (12) acute retinal necrosis; (13) progressive outer retinal necrosis (largely among HIV-infected persons); (14) temporal arteritis; and (15) sacral meningoradiculitis (Elsberg syndrome). VZV is a major cause of Bell palsy in patients who are HSV seronegative.

Diagnosis of neurologic complications requires the detection of VZV DNA in CSF or the detection of VZV DNA in tissue. Diagnosis by examination of saliva may be possible. Zoster sine herpete (pain without rash) can also be associated with most of the above complications.

#### Treatment

### A. General Measures

In general, patients with varicella should be isolated until primary lesions have crusted. The skin is kept clean. Pruritus can be relieved with antihistamines, calamine lotion, and colloidal oatmeal baths. Fever can be treated with acetaminophen (not aspirin). Fingernails can be closely cropped to avoid skin excoriation and infection.

### B. Antiviral Therapy

#### 1. Varicella—Uncomplicated disease in otherwise healthy children and adolescents does not require antiviral therapy. Acyclovir, 20 mg/kg (up to 800 mg per dose) orally four times daily for 5–7 days, should be given within the first 24 hours after the onset of varicella rash and should be considered for patients older than 12 years, secondary household contacts (disease tends to be more severe in secondary cases), patients with chronic cutaneous and cardiopulmonary diseases, and children receiving long-term therapy with salicylates (to decrease the risk of Reye syndrome). Acyclovir hastens defervescence and healing of lesions but does not impact complication rates. Experience with valacyclovir and famciclovir in these settings is scant and while these agents are often used, their use is not FDA-approved in the United States. Nonsteroidal anti-inflammatory drug (NSAID) use in varicella-infected children appears to be associated with an increase in bacterial infections.

In immunocompromised patients, in pregnant women during the third trimester, and in patients with extracutaneous disease (encephalitis, pneumonitis), antiviral therapy with high-dose acyclovir (30 mg/kg/day in three divided doses intravenously for at least 7 days) should be started once the diagnosis is suspected. Corticosteroids may be useful in the presence of pneumonia. Prolonged prophylactic acyclovir is important to prevent VZV reactivation in profoundly immunosuppressed patients.

#### 2. Herpes zoster—For uncomplicated herpes zoster, valacyclovir or famciclovir is preferable to acyclovir due to dosing convenience and higher drug levels in the body (Table 32–1). Therapy should start within the first 72 hours of the onset of the lesions and be continued for 7 days or until the lesions crust over. Amenamevir is an oral helicase-primase inhibitor given as a single dose that was approved to treat shingles in Japan in 2017 but is not yet available in the United States. Antiviral therapy reduces the duration of herpetic lesions and associated episodes of acute pain but does not in all studies decrease the risk of postherpetic neuralgia. Corticosteroids (a tapering course starting at 60 mg/day, for 2–3 weeks) are safe in immunocompetent patients and may be useful in the acute management of disease to hasten the resolution of acute lesions. Corticosteroids do not prevent the development of postherpetic neuralgia.

Intravenous acyclovir is used for extradermatomal complications of zoster. Adjunctive therapy may be considered in retinal disease (foscarnet) and acute herpetic zoster (sorivudine, a topical antiviral). In cases of prolonged or repeated acyclovir use, immunosuppressed patients may require a switch to foscarnet due to the development of acyclovir-resistant VZV infections. VZV associated with the Ramsay Hunt syndrome is more resistant to antiviral therapy.

### C. Treatment of Postherpetic Neuralgia

Once established, postherpetic neuralgia is difficult to treat, and less than half of patients achieve adequate pain relief. This condition may respond to neuropathic pain agents such as gabapentin or lidocaine patches. Tricyclic antidepressants, opioids, and capsaicin cream are also
widely used and effective. The epidural injection of corticosteroids and local anesthetics appears to modestly reduce herpetic pain at 1 month but, as with oral corticosteroids, is not effective for prevention of long-term postherpetic neuralgia. There is reported success using transcutaneous electrical nerve stimulation.

**Prognosis**

The total duration of varicella from onset of symptoms to disappearance of crusts rarely exceeds 2 weeks. Fatalities are rare except in immunosuppressed patients.

Herpes zoster resolves in 2–6 weeks. Antibodies persist longer and at higher levels than with primary varicella. Eye involvement with herpes zoster necessitates periodic future examinations.

**Prevention**

Health care workers should be screened for varicella and vaccinated if seronegative. Patients with active varicella or herpes zoster are promptly separated from seronegative patients. For patients with varicella, airborne and contact isolation is recommended, whereas for those with zoster, contact precautions are sufficient. For immunosuppressed patients with zoster, precautions should be the same as if the patient had varicella. Exposed serosusceptible patients should be placed in isolation and exposed serosusceptible employees should stay away from work for 8–21 days after exposure. Health care workers with zoster should receive antiviral agents during the first 72 hours of disease and withdraw from work until lesions are crusted. The need for postexposure prophylaxis should be assessed.

**Varicella**

1. **Vaccination**—Universal childhood vaccination against varicella is effective. The varicella vaccine is live and attenuated, safe, and over 98.1% effective when given after 13 months of age. A single antigen live attenuated vaccine (VARIVAX, VARILRIX) or a quadrivalent measles, mumps, rubella, and varicella (MMRV) vaccine (ProQuad) is available (the combination is immunogenic). The first dose of the single antigen vaccine should be administered at 12–18 months of age and the second at 4–6 years. Alternatively, the MMRV vaccine can be given as a first dose at 12–15 months of age and the second dose before elementary school entry. Aspirin should be avoided for at least 6 weeks after vaccination because of the risk of Reye syndrome. The single antigen vaccine is safe and well tolerated, but the quadrivalent MMRV vaccine is associated with a small risk of febrile seizures 5–12 days after vaccination among infants aged 12–23 months. Because of this risk, the Centers for Disease Control and Prevention (CDC) recommends using separate varicella and measles, mumps, and rubella (MMR) vaccines for the first dose in children younger than 48 months old. Rashes, when secondary to the varicella vaccine, appear 15–42 days after vaccination. Rare cases of keratitis are associated with zoster and varicella vaccines.

For serosusceptible individuals older than 13 years, two doses of varicella vaccine (single antigen) administered 4–8 weeks apart are recommended. For those who received a single dose in the past, a catch-up second dose is advised, especially in the epidemic setting (where it is effective when it can be given during the first 5 days postexposure). Household contacts of immunocompromised patients should adhere to these recommendations. Susceptible pregnant women (who should not be vaccinated with live varicella or zoster vaccines during pregnancy) need to receive the first dose of single antigen vaccine before discharge after delivery and the second dose 4–8 weeks later. The Advisory Committee on Immunization Practices (ACIP) recommends administration of the single agent varicella vaccine as two doses 3 months apart to HIV-infected children aged 12 months or older with CD4 lymphocyte percentage greater than 15% and adolescents and adults with CD4 lymphocyte counts 200 cells/μL or higher.

The vaccine may also be given to patients with impaired humoral immunity, to patients receiving corticosteroids, to pediatric oncology patients receiving chemotherapy, and to patients with juvenile rheumatoid arthritis who receive methotrexate. Patients receiving high doses of corticosteroids for over 2 weeks may be vaccinated a month after discontinuation of the therapy. Patients with leukemia, lymphoma, or other malignancies whose disease is in remission and who have not undergone chemotherapy for at least 3 months may be vaccinated. Kidney and liver transplant patients should be vaccinated if they are susceptible to varicella.

The incidence of varicella in the United States is significantly reduced with the varicella vaccine. Although uncommon, the varicella vaccine, like any of the live varicella-zoster vaccines, has the potential to reactivate and cause clinical disease. It is thought that vaccination against varicella provides less protection against future zoster than does natural varicella infection. The incidence of varicella-associated group A streptococcal infection and varicella neurologic complications are both diminished with the advent of varicella vaccination.

The FDA no longer maintains a registry for exposed pregnant women because of the low rate of such incidents and the general safety of varicella vaccines. Incidents can be reported to Merck (877-888-4231) or through the Vaccine Adverse Events Registry System Vaccine (https://vaers.hhs.gov/index).

2. **Postexposure**—Postexposure vaccination is recommended for unvaccinated persons without other evidence of immunity. Varicella-zoster immune globulin available in the United States only as VariZIG should be considered for susceptible exposed patients (for up to 10 days after exposure but as soon as feasible) who cannot receive the vaccine, including immunosuppressed patients, neonates from mothers with varicella around the time of delivery, exposed premature infants born from serosusceptible mothers at greater than 28 weeks of gestation, neonates born at less than 28 weeks of gestation regardless of maternal serostatus, and nonimmune pregnant women. No controlled studies have evaluated the use of acyclovir in this setting. VariZIG is given by intramuscular injection in a dosage of 125 international units/10 kg, to a maximum of 625 international units with a weight-based (2-kg cutoff) minimum dose of 62.5 or 125 international units, with a repeat identical dose in 3 weeks if a high-risk patient remains exposed. VariZIG has no place in
therapy of established disease; however, it reduces severity of varicella in high-risk children or adults (ie, those with impaired immunity, pregnant women, and infants exposed peripartum) if given within 4 days of exposure. Varicella vaccination should be delayed at least 5 months after VariZIG administration. If VariZIG is not available, standard pooled intravenous immunoglobulin (IVIG) (400 mg/kg given in one dose) can be given. Acyclovir (40–80 mg/kg) for 5 days or the varicella vaccine (if not contraindicated) can also be given as postexposure prophylaxis within 3 days of exposure. Either of these options offers an efficacy of 70–85% compared to 90% efficacy for VariZIG.

Further information may be obtained by calling the Centers for Disease Control and Prevention’s Immunization Information Hotline (800-232-2522).

B. Herpes Zoster

Shingrix, HZ/su (GlaxoSmithKline Biologics), an adjuvanted recombinant subunit vaccine, was approved in 2017 by the FDA for VZV and is recommended for individuals 50 years of age and older. Unlike the older live attenuated VZV vaccine (ZOSTAVAX, see below), Shingrix is particularly effective in reducing the incidence of herpes zoster infection and postherpetic neuralgia in adults 70 years of age and older; immunosenscencence to the vaccine does not appear to occur in older patients. It can also be used in immunosuppressed patients. Two doses of the vaccine given 2 months apart had 97% efficacy in preventing herpes zoster. Shingrix also appears to be safe in HIV-infected persons with CD4 counts above 50 cells/mcL, recipients of autologous stem cell transplants, and adults with autoimmune disease taking immunosuppressive therapy.

The older live attenuated VZV vaccine, ZOSTAVAX (19,400 plaque forming units [pfu] of Oka/Merck strain) contains at least 14 times the concentration of varicella virus found in VARIVAX. It is recommended for persons 60 years and older because it reduces the incidence of herpes zoster by 33–55% in the first 3 years after vaccination and reduces the incidence of postherpetic neuralgia by 55–67%. The efficacy of ZOSTAVAX wanes over time, from 69% in the first year after vaccination to 45% by the third year.

Even if the person has had a prior episode of herpes zoster, either of the two zoster vaccines has efficacy and can be administered. No specific recommendations exist regarding how long to wait between a zoster outbreak and administering the vaccine; the CDC recommends waiting at least until the outbreak has resolved. The attenuated VZV vaccine is safe, but only moderately immunogenic among HIV-infected persons with a CD4 count of at least 200 cells/mcL. Decreased efficacy occurs in patients older than 70, and this vaccine should not be given to immunosuppressed persons. Nonetheless, hematologic oncology patients taking anti-CD20 monoclonal antibodies may be successfully vaccinated. An increased risk of herpes zoster during a 6-week interval following vaccination is reported among patients taking immunosuppressant medications. This vaccine provides protection for about 3 years.

Concurrent administration of the adjuvanted recombinant subunit vaccine or the live attenuated VZV vaccine with pneumococcal vaccine is safe. If a varicella vaccine is mistakenly administered to an adult instead of a live attenuated zoster vaccine, the dose should be considered invalid and the patient should be administered a dose of zoster vaccine at the same visit. The zoster vaccine cannot be used in children in place of varicella vaccine; if the vaccine is accidentally given to a child, the event should be reported to the CDC.

3. Epstein-Barr Virus & Infectious Mononucleosis

ESSENTIALS OF DIAGNOSIS

- Malaise, fever, and (exudative) sore throat.
- Palatal petechiae, lymphadenopathy, splenomegaly, and, occasionally, a maculopapular rash.
- Positive heterophile agglutination test (Monospot).
- Atypical large lymphocytes in blood smear; lymphocytosis.
- Complications: hepatitis, myocarditis, neuropathy, encephalitis, airway obstruction from adenitis, hemolytic anemia, thrombocytopenia.

General Considerations

Epstein-Barr virus (EBV, or human herpes virus-4 [HHV-4]) is one of the most ubiquitous human viruses, infecting more than 95% of the adult population worldwide and persisting for the lifetime of the host. Infectious mononucleosis is a common manifestation of EBV and may occur at any age. In the United States the incidence of EBV infection is declining although prevalence of EBV remains high for those aged 12–19 years. In the developing world, infectious mononucleosis occurs at younger ages and tends to be less symptomatic. Rare cases in older adults occur usually without the full symptomatology. EBV is largely transmitted by saliva but can also be recovered from genital secretions. Saliva may remain infectious during convalescence, for 6 months or longer after symptom onset. The incubation period lasts several weeks (30–50 days). Patients with immunodeficiency...
disorders are at risk for the full spectrum of EBV-associated disorders.

**Clinical Findings**

**A. Symptoms and Signs**

Fever, sore throat, fatigue, malaise, anorexia, and myalgia typically occur in the early phase of the illness. Physical findings include lymphadenopathy (discrete, nonsuppurative, slightly painful, especially along the posterior cervical chain), transient bilateral upper lid edema (Hoagland sign), and splenomegaly (in up to 50% of patients and sometimes massive). A maculopapular or occasionally petechial rash occurs in less than 15% of patients unless ampicillin is given (in which case rash was thought to occur in more than 90% of patients; however, recent data indicates that the incidence of drug hypersensitivity is much lower than previously reported). Conjunctival hemorrhage, exudative pharyngitis, uvular edema, tonsillitis, or gingivitis may occur and soft palatal petechiae may be noted. Complications of acute disease are more common among older adults.

Other manifestations include hepatitis, interstitial pneumonitis (sometimes with pleural involvement), cholestasis, gastritis, kidney disease (mostly interstitial nephritis), epiglottitis, and nervous system involvement in 1–5% (mononeuropathies and occasionally aseptic meningitis, encephalitis, cerebellitis, peripheral and optic neuritis, transverse myelitis, or Guillain-Barré syndrome). Vaginal ulcers are rare but may be present. Airway obstruction from lymph node enlargement can occur.

**B. Laboratory Findings**

An initial phase of granulocytopenia is followed within 1 week by lymphocytic leukocytosis (greater than 50% of all leukocytes) with atypical lymphocytes (larger than normal mature lymphocytes, staining more darkly, and showing vacuolated, foamy cytoplasm and dark nuclear chromatin) comprising more than 10% of the leukocyte count. Hemolytic anemia, with antibodies, occurs occasionally as does thrombocytopenia (at times marked and life-threatening).

Diagnosis is made based on characteristic manifestations and serologic evidence of infection (the heterophile sheep cell agglutination [HA] antibody tests or the correlated mononucleosis spot test [Monospot]). These tests usually become positive within 4 weeks after onset of illness and are specific but often not sensitive in early illness. Heterophile antibodies may be absent in young children and in as many as 20% of adults. During acute illness, there is a rise and fall in immunoglobulin M (IgM) antibody to EB virus capsid antigen (VCA) and a rise in immunoglobulin G (IgG) antibody to VCA, which persists for life. Antibodies (IgG) to EBV nuclear antigen (EBNA) appear after 4 weeks of onset and also persist. Absence of IgG and IgM VCA or the presence of IgG EBNA should make one reconsider the diagnosis of acute EBV infection.

PCR for EBV DNA is useful in the evaluation of malignancies associated with EBV. For instance, detection of EBV DNA in CSF shows a sensitivity of 90% and specificity of nearly 100% for the diagnosis of primary CNS lymphoma in patients with AIDS.

**Differential Diagnosis**

CMV infection, toxoplasmosis, acute HIV infection, secondary syphilis, HHV-6 infection, rubella, and drug hypersensitivity reactions may be indistinguishable from infectious mononucleosis due to EBV, but exudative pharyngitis is usually absent and the heterophile antibody tests are negative. With acute HIV infection, rash and mucocutaneous ulceration are common but atypical lymphocytosis is much less common. Heterophile-negative infectious mononucleosis with nonsignificant lymphocytosis (especially if rash or mucocutaneous ulcers are present) should prompt investigation for acute HIV infection. CMV, toxoplasmosis and, on occasion, EBV can cause heterophile-negative infectious mononucleosis with atypical lymphocytosis. Mycoplasma infection may also present as pharyngitis, though lower respiratory symptoms usually predominate. A hypersensitivity syndrome induced by carbamazepine or phenytoin may mimic infectious mononucleosis.

The differential diagnosis of acute exudative pharyngitis includes gonococcal and streptococcal infections, and infections with adenovirus and herpes simplex. Head and neck soft tissue infections (pharyngeal and tonsillar abscesses) may occasionally be mistaken as the lymphadenopathy of mononucleosis.

**Complications**

Secondary bacterial pharyngitis can occur and is often streptococcal. Splenic rupture (0.5–1%) is a rare but dramatic complication, and a history of preceding trauma can be elicited in 50% of the cases. Acalcular cholecytitis, fulminant hepatitis with massive necrosis, pericarditis and myocarditis are also infrequent complications.

**Treatment**

**A. General Measures**

Over 95% of patients with acute EBV-associated infectious mononucleosis recover without specific antiviral therapy. Treatment is symptomatic with NSAIDs or acetaminophen and warm saline throat irrigations or gargles three or four times daily. Acyclovir decreases viral shedding but shows no clinical benefit. Corticosteroid therapy, although widespread, is not recommended in uncomplicated cases; its use is reserved for impending airway obstruction from enlarged lymph nodes, hemolytic anemia, and severe thrombocytopenia. The value of corticosteroid therapy in impending splenic rupture, pericarditis, myocarditis, and nervous system involvement is less well established. If a throat culture grows beta-hemolytic streptococci, a 10-day course of penicillin or azithromycin is indicated. Ampicillin and amoxicillin are avoided because of the frequent association with rash, although one recent study indicates that the incidence of drug hypersensitivity is much lower than previously reported.

EBV infections in solid organ transplant recipients are difficult to prevent and treat, although recent data suggest possible utility of pretransplant rituximab for high-risk transplant recipients. The role of antiviral prophylaxis for preventing posttransplantation EBV infection and sequelae, including posttransplant lymphoproliferative disorders
(PTLD) in patients who are donor organ EBV-positive and recipient negative (the main risk factor for both early PTLD [less than 1 year posttransplantation] and late PTLD [more than 1 year]). One recent retrospective study indicated that prophylaxis with acyclovir, valacyclovir, ganciclovir, or valganciclovir delayed primary EBV infection at 100 days posttransplant. A decreased incidence of late-onset PTLD and EBV-related neoplasias in treated patients was also noted. Finally, new therapies are being developed to protect hematopoietic stem cell transplant recipients from many viruses, including EBV.

B. Treatment of Complications

Hepatitis, myocarditis, and encephalitis are treated symptomatically. Rupture of the spleen requires splenectomy and is most often caused by deep palpation of the spleen or vigorous activity. Patients should avoid contact or collision sports for at least 4 weeks to decrease the risk of splenic rupture (even if splenomegaly is not detected by physical examination, which can be insensitive).

Prognosis & Prevention

In uncomplicated cases, fever disappears in 10 days and lymphadenopathy and splenomegaly in 4 weeks. The debility sometimes lingers for 2–3 months.

Death is uncommon and is usually due to splenic rupture, hypersplenic phenomena (severe hemolytic anemia, thrombocytopenic purpura), or encephalitis.

4. Other EBV-Associated Syndromes

EBV viral antigens are found in more than 90% of patients with endemic (African) Burkitt lymphoma and nasopharyngeal carcinoma (among whom quantified EBV DNA can be used to follow disease). Risk factors for Burkitt lymphoma include a history of malaria (which may decrease resistance to EBV infection) while risk factors for nasopharyngeal carcinoma include long-term heavy cigarette smoking and seropositive EBV serologies (VCA and deoxyribonuclease [DNase]). VCA-IgA in peripheral blood is a sensitive and specific predictor for nasopharyngeal carcinoma in an endemic area.

Among Hodgkin lymphoma patients, EBV seropositivity is common when the disease is found in the developing world or is associated with HIV infection, when pathologic specimens show mixed cellularity, and when patients are younger than 10 years or older than 45 years at onset of the lymphoma. The EBV-seropositive have a worse prognosis for early stages of Hodgkin lymphoma.

Chronic EBV infection is associated with aberrant cellular immunity (a low frequency of EBV-specific CD8+ T cells), an X-linked lymphoproliferative syndrome (Duncan disease), lymphomatoid granulomatosis, and a fatal T-cell lymphoproliferative disorder in children.

EBV is an important trigger for hemophagocytic lymphohistiocytosis among immunodeficient patients and causes B-cell lymphomas (such as primary CNS lymphoma in HIV-infected individuals), natural killer/T-cell lymphoma, and posttransplant lymphoproliferative disorders. CD30 and EBV viral loads are prognostic markers for EBV-associated lymphoproliferative disease. PTLD are commonly associated with EBV, especially in children. EBV-naive patients who receive a donor organ from an EBV-infected donor are at the highest risk for the development of PTLD. EBV serostatus, however, is not associated with overall survival among patients with PTLD. Decreasing the iatrogenic immunosuppression given to prevent graft rejection is the initial step in managing such patients, while rituximab (CD20 monoclonal antibody) is effective in treating more than two-thirds of cases. Oral muco-cutaneous ulcerative disease in the HIV-infected may be due to EBV.

Age is a major determinant of the type of tumor associated with EBV. T and NK cell lymphoma caused by chronic active EBV infections are more frequent in childhood while peripheral T-cell lymphomas and diffuse large B-cell lymphomas are more common in older patients due to waning immunity. EBV is also associated with leiomyomas in children with AIDS and with nasal T-cell lymphomas.

When to Admit

Presence of severe complications of EBV disease including the following:

- Acute meningitis, encephalitis, or Guillain-Barré syndrome.
- Severe thrombocytopenia; significant hemolysis.
- Potential splenic rupture.
- Airway obstruction from severe adenitis.
- Pericarditis.
- Abdominal findings mimicking an acute abdomen.

General Considerations

Most cytomegalovirus (CMV) infections are asymptomatic. After primary infection, the virus remains latent in most body cells. Seroprevalence in adults of Western developed countries is about 60–80% but is higher in developing countries. The virus can be isolated from various tissues under nonpathogenic conditions. Transmission occurs through sexual contact, breastfeeding, blood products, or transplantation; it may also occur person-to-person (eg, day care centers) or be congenital. Serious disease occurs primarily in immunocompromised persons, including those with inflammatory bowel disease.

There are three recognizable clinical syndromes: (1) perinatal disease and CMV inclusion disease, (2) diseases in immunocompetent persons, and (3) diseases in immunocompromised persons. Congenital CMV infection is the most common congenital infection in developed countries (about 0.6% of live births, with higher rates in underdeveloped areas and among lower socioeconomic groups). Transmission is much higher from mothers with primary disease than those with reactivation (40% vs 0.2–1.8%). About 10% of infected newborns will be symptomatic with CMV inclusion disease.

In immunocompetent persons, acute CMV infection is the most common cause of the mononucleosis-like syndrome with negative heterophile antibodies. In critically ill immunocompetent adults, CMV reactivation is associated with prolonged hospitalization and death. CMV appears to be involved in the malignant manifestations of glioblastoma multiforme.

In immunocompromised persons, solid organ and bone marrow transplant recipients are at highest risk for a year after allograft transplantation (but especially during the first 100 days afterward) and in particular when graft-versus-host disease is present or when the donor is CMV seropositive and the recipient is seronegative. Depending on the serostatus of the donor and recipient, disease may present as primary infection or reactivation. The risk of CMV disease is proportionate to the degree of immunosuppression and manifestations may differ by the cause. CMV may contribute to transplanted organ dysfunction, which often mimics organ rejection. CMV retinitis may develop after solid organ or bone marrow transplantation. CMV disease in HIV-infected patients (retinitis, serious gastrointestinal disease) occurs most prominently when the CD4 count is less than 50 cells/mcL and can be a marker for increased mortality. Antiretroviral therapy (ART) reduces the frequency of retinitis and may reverse active disease. Patients with immune recovery with CD4 cell count greater than 100 cells/mcL show decreased mortality. CMV retinitis associated with intravitreal delivery of corticosteroids (injections or implants) or systemic anti-TNF antibodies is also described. Occasionally, CMV retinitis presents in immunocompetent persons. Serious gastrointestinal CMV disease also occurs after organ transplantation, cancer chemotherapy, or corticosteroid therapy. CMV may exist alongside other pathogens, such as Cryptosporidium, in up to 15% of patients with AIDS cholangiopathy. CMV pneumonitis occurs in transplant recipients (mainly bone marrow and lung) with a mortality rate up to 60–80%, and less often in AIDS patients. CMV pneumonitis in hematologic malignancies (eg, lymphoma) is increasingly reported. Neurologic CMV infection in patients with advanced AIDS is usually associated with disseminated CMV infection.

Clinical Findings

A. Symptoms and Signs

1. Perinatal disease and CMV inclusion disease—CMV inclusion disease in infected newborns is characterized by hepatitis, thrombocytopenia, microcephaly, periventricular CNS calcifications, mental retardation, and motor disability. Hearing loss develops in more than 50% of infants who are symptomatic at birth. Most infected neonates are asymptomatic, but neurologic deficits may ensue later in life, including hearing loss in 15% and mental retardation in 10–20%. Perinatal infection acquired through breastfeeding or blood products typically shows a benign clinical course.

2. Disease in immunocompetent persons—Acute CMV infection is characterized by fever, malaise, myalgias, arthralgias, and splenomegaly. Exudative pharyngitis or cervical lymphadenopathies are uncommon, but cutaneous rashes (including the typical maculopapular rash after exposure to ampicillin) are common. The mean duration of symptoms is 7–8 weeks. Complications include mucosal gastrointestinal damage, encephalitis, severe hepatitis, thrombocytopenia (on occasion, refractory), the Guillain-Barré syndrome, pericarditis, and myocarditis. A mononucleosis-like syndrome due to CMV can also occur post splenectomy, often years later and associated with a protracted fever, marked lymphocytosis, and impaired anti-CMV IgM response.

3. Disease in immunocompromised persons—Distinguishing between CMV infection (with evidence of CMV replication) and CMV disease (evidence for systemic symptoms or organ invasion by pathologic diagnosis) is important. In addition to patients infected with HIV, those who have undergone transplantation (solid organ or hematopoietic stem cell) show a wide spectrum of disease including gastrointestinal (eg, acute cholecystitis), kidney, and CNS disease, as outlined above. CMV viral loads serve as an important predictor of disease presence.

A. CMV retinitis—A funduscopic examination reveals neovascular, proliferative lesions (“pizza-pie” retinopathy). Immune restoration with ART is associated with CMV vitritis and cystoid macular edema.

B. Gastrointestinal and hepatobiliary CMV—Esophagitis presents with odynophagia. Gastritis can occasionally cause bleeding, and small bowel disease may mimic inflammatory bowel disease or may present as ulceration or perforation. Colonic CMV disease causes diarrhea, hematochezia, abdominal pain, fever, and weight loss and may mimic inflammatory bowel disease. CMV hepatitis commonly complicates liver transplantation and appears to be increased in those with hepatitis B or hepatitis C viral infection.
VIRAL & RICKETTSIAL INFECTIONS

C. Respiratory CMV—CMV pneumonitis is characterized by cough, dyspnea, and relatively little sputum production. Concomitant infection with Pneumocystis jirovecii occurs among patients regardless of HIV status.

D. Neurologic CMV—Neurologic syndromes associated with CMV include polyradiculopathy, transverse myelitis, ventriculoencephalitis (suspected with ependymitis), and focal encephalitis. These manifestations are more prominent in patients with advanced AIDS in whom the encephalitis has a subacute onset.

B. Laboratory Findings

1. Mothers and newborns—Pregnant women should be tested for CMV viremia every 3 months if found to be seropositive during the first trimester. Congenital CMV disease is confirmed by presence of the virus in amniotic fluid or an IgM assay from fetal blood. Amniocentesis is less reliable before 21 weeks of gestation (due to inadequate fetal urinary development and release into the amniotic fluid), but amniocentesis is attendant with greater risk when performed after 21 weeks of gestation. PCR assays of dried blood samples from newborns, micro-enzyme-linked immunosorbent assay (ELISA), shell-vial culture, or culture of urine, saliva, or blood specimens obtained during the first 3 weeks of life are used to diagnose congenital CMV infection.

2. Immunocompetent persons—The acute mononucleosis-like syndrome is characterized by initial leukopenia; within 1 week, it is followed by absolute lymphocytosis with atypical lymphocytes. Abnormal liver biochemical tests are common in the first 2 weeks of the disease (often 2 weeks after the fever). Detection of CMV DNA, specific IgM, or a fourfold increase of specific IgG levels support the diagnosis of acute infection.

3. Immunocompromised persons—CMV retinitis is diagnosed on the basis of the characteristic ophthalmoscopic findings. In HIV-infected patients, negative CMV serologies lower the possibility of the diagnosis but do not eliminate it. Cultures alone are of little use in diagnosing AIDS-related CMV infections, since viral shedding of CMV is common. Detection of CMV by quantitative DNA PCR should be used to diagnose CNS infection since cultures are not specific for disease.

Detection of CMV by quantitative DNA PCR is also used in posttransplant patients to guide both treatment and prevention and should be interpreted in the context of clinical and pathologic findings. CMV viral loads are internationally standardized and have replaced conventional CMV antigenemia tests in many settings. The PCR is sensitive in predicting clinical disease. Serial PCR should be performed and compared using the same specimen type (ie, whole blood or plasma). To assist in the diagnosis CMV pneumonia, bronchoalveolar lavage fluid can be tested to quantify CMV viral load. Rapid shell-vial cultures detect early CMV antigens with fluorescent antibodies in 24–48 hours. Shell-vial cultures are more useful on bronchoalveolar lavage fluid than in routine blood monitoring. CMV colitis can occur in the absence of a detectable viremia.

C. Imaging

The chest radiographic findings of CMV pneumonitis are consistent with interstitial pneumonia.

D. Biopsy

Tissue confirmation is especially useful in diagnosing CMV pneumonitis and CMV gastrointestinal disease; the diagnosis of colonic CMV disease is made by mucosal biopsy showing characteristic CMV histopathologic findings of intranuclear (“owl’s eye”) and intracytoplasmic inclusions. In situations where histopathologic or immunohistochemical findings are not seen but CMV colitis is suspected, CMV DNA PCR can be used to identify additional cases.

Treatment

In immunocompetent persons, CMV infection is usually self-limited, and no specific antiviral therapy is needed. In immunocompromised persons, treatment of CMV disease is necessary. Treatment of CMV retinitis is discussed in Chapter 7. The role of ART in HIV infections in reducing the need for CMV antiviral agents is essential. Because recurrence occurs even at high CD4 cell counts, ongoing ophthalmologic surveillance is necessary. CMV disease in patients with solid organ transplants, AIDS, and invasive end-organ disease is typically treated initially with intravenous ganciclovir (recommended dose is 5 mg/kg every 12 hours, although this needs to be adjusted for kidney function) until two CMV PCRs 1 week apart are negative (usually 14–21 days). Oral valganciclovir (900 mg every 12 hours), which also needs to be adjusted for kidney function, is an acceptable alternative in patients with non–life-threatening disease.

Pneumonia due to CMV in hematopoietic stem cell transplant recipients is treated even more aggressively, with 5 mg/kg of ganciclovir intravenously every 12 hours for 21 days followed by 5 mg/kg daily for 3–4 weeks plus CMV immunoglobulin (500 mg/kg) or CMV immunoglobulin (150 mg/kg) twice per week for 2 weeks and then once weekly for an additional 4 weeks.

Reduction of immunosuppression should be attempted when possible (especially for muromonab, azathioprine, or mycophenolate mofetil). Secondary prophylaxis is typically maintained until immune restoration (with two CD4 T-cell counts greater than 100 cells/mcL present for at least 6 months in the setting of HIV infection). Prolonged prophylaxis may be necessary in other immunosuppressed patients, such as those receiving TNF inhibitors. Foscarnet and cidofovir are reserved for treatment of resistant infections. Other agents that may be useful in resistant CMV infections include CMV immunoglobulin, leflunomide, sirolimus-based therapy, artesunate, and adoptive immunotherapy. New anti-CMV drugs under development include brincidofovir and maribavir.

Prevention

A major source of CMV for pregnant women is their own young children, particularly those in childcare. These women can decrease their risk of contracting primary CMV just before pregnancy or during pregnancy by
practicing hand hygiene after changing diapers and after contact with respiratory secretions; avoiding kissing young children on the face; and avoiding sharing utensils, food, and cleansing objects that have been in contact with children's secretions.

ART is effective in preventing CMV infections in HIV-infected patients. Primary prevention is best accomplished by good hand hygiene and use of barrier methods during sexual contacts with persons who are members of high-prevalence groups (ie, men who have sex with men, injection drug users, and those who have exposure to children in child care).

The use of leukocyte-depleted blood products effectively reduces the incidence of CMV disease in patients who have undergone transplantation. Prophylactic and preemptive strategies (eg, antiviral agents only when antigen detection or PCR assays show evidence of active CMV replication) appear equally effective in preventing invasive disease and mortality after hematopoietic stem cell transplant. The appropriate management of transplant patients is based on the serostatus of the donor and the recipient. All effective anti-CMV agents can serve as prophylactic agents for CMV-seropositive transplants or for CMV-seronegative recipients of CMV-positive organ transplants, although starting CMV prophylaxis 14 days after transplant may help reduce late-onset CMV end-organ disease. The typical dose for ganciclovir prophylaxis is 450 mg orally twice daily, although a recent prospective trial in kidney transplant recipients indicated that prophylaxis with low-dose ganciclovir (450 mg/day, three times a week for 6 months) seemed to be effective. Acyclovir may also be used. Recommended duration of CMV prophylaxis in posttransplant patients and in other immunocompromised patients varies by the type of transplant. Letermovir is useful in prophylaxis against CMV infections in adult allogenic hematopoietic stem cell transplant recipients. It is given as 480 mg orally daily with dose adjustments for renal dysfunction (less than a creatinine clearance of 10 ml/min). Major side effects reported to date include cough, diarrhea, headache, nausea, stomach pain, weakness, and vomiting.

CMV immune globulin may also be useful in reducing the incidence of bronchiolitis obliterans in the bone marrow transplant population and is used in some centers as part of the prophylaxis in kidney, liver, and lung transplantation patients. CMV immune globulin as prophylaxis is not recommended in hematopoietic stem cell transplant recipients.

> **When to Refer**

- AIDS patients with retinitis, esophagitis, colitis, hepatobiliary disease, or encephalitis.
- Organ and hematopoietic stem cell transplants with suspected reactivation CMV.

> **When to Admit**

- Escalating CMV viral load at the onset of illness.
- Risk of colonic perforation.

- Evaluation of unexplained, advancing encephalopathy.
- Initiation of treatment with intravenous anti-CMV agents.

### 6. Human Herpesviruses 6, 7, & 8

**HHV-6** is a B-cell lymphotropic virus that is the principal cause of exanthema subitum (roseola infantum, sixth disease). Primary HHV-6 infection occurs most commonly in children under 2 years of age and is a major cause of infantile febrile seizures (21% in one recent series). HHV-6 is also associated with encephalitis (symptoms may include insomnia, seizures, and hallucinations), Hashimoto thyroiditis, myocarditis, and acute liver failure. Primary infection in immunocompetent adults is not common but can produce a mononucleosis-like illness. Pathologically, HHV-6 is associated with mesial temporal sclerosis, which may lead to mesial temporal lobe epilepsy. Reactivation of HHV-6 in immunocompetent adults is rare and can present as encephalitis. Imaging studies in HHV-6 encephalitis typically show lesions in the hippocampus, amygdala, and limbic structures.

Infection during pregnancy and congenital transmission is recognized. Most cases of reactivation occur in immunocompromised persons. Reactivation is associated with graft rejection, graft-versus-host disease, and bone marrow suppression in transplant patients and with encephalitis and pneumonitis in AIDS patients. In recipients of hematopoietic stem cell transplants, HHV-6 may cause fever. It is also associated with an HHV-6–induced encephalitis (diagnosed with multiplex PCR assays) that is correlated strongly with umbilical cord hematopoietic cell transplants (although HHV-6 is not associated with survival in such patients and surveillance for the virus may not be needed).

HHV-6 is on occasion also associated with drug-induced hypersensitivity syndromes. HHV-6 may cause fulminant hepatic failure and acute degeneration of chronic liver disease in children. Purpura fulminans and corneal inflammation are reported with HHV-6 infection. Two variants (A and B) of HHV-6 have been identified. HHV-6B is the predominant strain found in both normal and...
immunocompromised persons. Ganciclovir, cidofovir, and foscarnet (but not acyclovir) appear to be clinically active against HHV-6. Adoptively transferred virus-specific T cell therapy is also being developed for treatment of HHV-6 infections in hematopoietic stem cell transplant recipients.

HHV-7 is a T-cell lymphotropic virus that is associated with roseola seizures and, rarely, encephalitis, even in immunocompetent adults. Pregnant women are often infected. Infection with HHV-7 is synergistic with CMV in kidney transplant recipients.

HHV-8 (see also Chapter 31) is associated with Kaposi sarcoma, multicentric Castleman disease, and primary effusion (body cavity) lymphoma. HHV-8 infection is endemic in Africa; transmission seems to be primarily horizontal in childhood from intrafamilial contacts and continues through adulthood possibly by nonsexual routes.

MAJOR VACCINE-PREVENTABLE VIRAL INFECTIONS

1. Measles

ESSENTIALS OF DIAGNOSIS

- Exposure 7–18 days before onset of prodrome in an unvaccinated patient.
- Prodrome: fever, coryza, cough, conjunctivitis, malaise, irritability, photophobia, Koplik spots.
- Rash: brick red, maculopapular; appears 3–4 days after onset of prodrome; begins on the face and proceeds “downward and outward,” affecting the palms and soles last.
- Leukopenia.

General Considerations

Measles is a reportable acute systemic paramyxoviral infection transmitted by direct contact with infectious droplets or by airborne spread. It is highly contagious with communicability greatest during the preeruptive and catarhal stages but continues 4 days after the appearance of rash.

Measles elimination is defined as the absence of endemic measles virus transmission in an area for 12 months or longer. Measles remains a major cause internationally of mortality with nearly 90,000 estimated deaths per year.

Between 2000 and 2016, the annual incidence of measles decreased by 87%, although in recent years the global tally of cases has increased, with the World Health Organization (WHO) estimating 7 million infections for 2016, the year with most recently compiled complete data. The WHO previously considered measles eradicated in the Americas. Major outbreaks, however, continue throughout the world (countries with over 1000 suspected cases in 2019 include Bangladesh, Cameroon, Chad, China, the Democratic Republic of the Congo, Georgia, Kazakhstan, Kyrgyzstan, India, Indonesia, Japan, Madagascar, Malaysia, Myanmar, Nigeria, the Philippines, Russian, Thailand, the Ukraine, and possibly Venezuela) and in the United States.

Most measles cases in the United States are due to either travel to endemic areas or exposure to individuals who have not been vaccinated against measles. A large 2015 outbreak at a California Disney theme park developed into a multi-state outbreak involving 147 people. A 2017 outbreak in New York included 17 reported cases among unvaccinated Orthodox Jews and developed into a tristate outbreak. Additionally, 65 confirmed cases were identified in 2017 in a Somali-American community from Minnesota due to a decline in MMR vaccination coverage. The 2019 outbreak of measles includes 704 cases documented between January 1, 2019 and April 26, 2019 in 13 outbreaks occurring in 22 states with major outbreaks in California, New Jersey, New York, and Washington State. Previously, the highest number of reported measles cases was 667 in 27 states in 2014 followed by 372 in 2018. Intentional undervaccination continues to undermine measles elimination programs.

Clinical Findings

A. Symptoms and Signs

The incubation period for measles is 10–14 days. The illness starts with a prodromal phase manifested by high-grade fever (often as high as 40–40.6°C), malaise, coryza (nasal obstruction, sneezing, and sore throat resembling upper respiratory infections), persistent cough, and conjunctivitis (redness, swelling, photophobia, and discharge). These symptoms intensify over 2–4 days before onset of the rash and peak on the first day of the rash. The fever persists through the early rash (about 5–7 days) (Table 32–2).

The characteristic measles rash appears on the face and behind the ears. Initial lesions are pinhead-sized papules that coalesce to form a brick red, irregular, blotty maculopapular rash. The rash spreads to the trunk and extremities, including the palms and soles. It lasts for 3–7 days and fades in the same manner it appeared. Other findings include pharyngeal erythema, tonsillar exudate, moderate generalized lymphadenopathy and, at times, splenomegaly.

Koplik spots (small, irregular, and red with whitish center on the mucous membranes) are pathognomonic of measles (Figure 32–4). They appear about 2 days before the rash and last 1–4 days as tiny “table salt crystals” on the palatal or buccal mucosa opposite the molars.
Figure 32–4. Very small, bright red spots on the buccal mucosa indicative of Koplik spots. (Public Health Image Library, CDC)

B. Laboratory Findings

Leukopenia is usually present unless secondary bacterial complications exist. A lymphocyte count under 2000/mcL is a poor prognostic sign. Thrombocytopenia is common. Proteinuria is often observed.

Detection of IgM measles antibodies with ELISA or a fourfold rise in serum hemagglutination inhibition antibody supports the diagnosis. IgM assays can be falsely negative the first few days of infection and falsely positive in the presence of rheumatoid factor or with acute rubella, echovirus (formerly parvovirus B19), or HHV-6 infection.

Measles virus is technically difficult to culture. Real-time reverse transcriptase-PCR (RT-PCR), available from the CDC and some public health laboratories, can help establish a diagnosis promptly.

Differential Diagnosis

Measles is usually diagnosed clinically but may be mistaken for Kawasaki disease and other exanthematous infections (Table 32–2). Frequent difficulty in establishing a diagnosis suggests that measles may be more prevalent than is recognized.

Complications

A. Respiratory Tract Disease

Early in the course of the disease, bronchopneumonia or bronchiolitis due to the measles virus may occur in up to 5% of patients and result in serious respiratory difficulties. Bronchiectasis may occur in up to a quarter of nonvaccinated children. The incidence of severe respiratory disease may be increased among immunocompromised children and pregnant women.

B. Central Nervous System

Postinfectious encephalomyelitis occurs in 0.05–0.1% of cases, with higher rates occurring in adolescents. It is an acute demyelinating disease that usually starts 3–7 days after the rash. Seizures, coma, and other neurologic symptoms and signs may develop. Treatment is symptomatic and supportive. Virus isolation from the CNS is uncommon. There is an appreciable mortality (10–20%) and morbidity (33% of survivors are left with neurologic deficits).

Measles inclusion body encephalitis is another form of neurologic complication that results in neurologic deterioration and death within months of the acute illness among patients with impaired cellular immunity. Treatment is supportive, including stopping immunosuppressants when feasible. Interferon and ribavirin are variably successful.

Subacute sclerosing panencephalitis is a very rare, and fatal CNS complication that occurs 5–15 years after infection. It is characterized by progressive deterioration of motor and cognitive function leading to death. It is more common in boys of rural backgrounds who are infected with measles before 2 years of age.

C. Other Complications

Immediately following measles, secondary bacterial infection, particularly cervical adenitis, otitis media (the most common complication), and pneumonia, occurs in about 15% of patients. Keratoconjunctivitis is a serious complication that caused blindness before the widespread use of measles vaccine and vitamin A supplementation. Diarrhea and protein-losing enteropathy (prodromal rectal Koplik spots may occur) are significant complications among malnourished children, although the mortality associated with diarrhea is primarily 1 week prior to and 4 weeks after the measles rash, with no longer-term mortality shown with measles-associated diarrhea. Some data implicate the measles virus in the pathogenesis of rheumatoid arthritis.

Treatment

Treatment is symptomatic, including antipyretics and fluids as needed. Vitamin A supplementation for children reduces pediatric morbidity and measles-associated mortality. Data are less substantial for adult supplementation, although many advocate megadose vitamin A at the time of delivery in order to boost infant levels of the vitamin.

Measles virus is susceptible to ribavirin and other antivirals in vitro. Ribavirin is used in selected severe cases of pneumonia, but insufficient data prevent recommending antiviral use. Zinc has a role in the maintenance of normal immune functions, but routine zinc supplementation to children with measles is not recommended, again for lack of data.

Prognosis

It is estimated that 20.4 million deaths were prevented by use of measles vaccination. In the United States, the case fatality rate is around 2 per 1000 reported cases, with deaths principally due to respiratory and neurologic complications. Deaths in the developing world are mainly related to acute diarrhea and protein-losing enteropathy. Pregnant women with measles may be at increased risk for death. Historically famines are particularly associated with high measles mortality.

Prevention

Because measles is highly contagious, the vaccine coverage rates must exceed 95% to prevent outbreaks. Illness confers permanent immunity. One vaccine dose is about 93% effective. Two doses of vaccine are estimated to be 97% protective.
Migrants and asylum seekers are thought to be at higher risk because their antibody levels often are lower than needed for adequate protection. The CDC currently recommends that all individuals embarking on international travel assure that they have been vaccinated. Infants under 1 year of age should have a first dose with boosters at 12–15 months and at age 4–6, children 1 year or older should receive two doses separated by 28 days, and teens and adults without evidence of immunity similarly should receive two doses separated by 28 days.

Vaccine site reactions appear to differ by the manufacturer.

In the United States, based on the 2016 National Immunization Survey, 91.1% of children aged 19–35 months received one or more doses of MMR and 90.9% of adolescents aged 13–17 years received two or more doses. These data suggest considerable geographic disparity. Clustering of unvaccinated individuals increases the likelihood of an outbreak.

At 6 months of age, more than 99% of infants of vaccinated women and 95% of infants of naturally immune women lose maternal antibodies. The susceptibility to measles is 2.4-fold higher if the vaccine is given prior to 15 months (with impact of waning maternal antibody levels). Thus, in the United States, children receive their first vaccine dose at 12–15 months of age. The second dose is given at age 4–6 years, prior to school entry. For individuals born before 1957, herd immunity is assumed. All adults born after 1957, without evidence of immunity should receive at least one dose of MMR vaccine. Persons at high risk for measles exposure (teachers, health care workers, post–high school students, travelers to developing countries) should receive two vaccination doses at least 28 days apart. Immigrants and refugees should be screened when susceptible individuals are exposed to active measles cases should receive MMRV within 6 days of exposure in any high-risk setting. Patients with measles should be placed under air-borne precautions.

When to Refer

- Any suspect cases should be reported to public health authorities.
- HIV infection.
- Pregnancy.

When to Admit

- Meningitis, encephalitis, or myelitis.
- Severe pneumonia.
- Diarrhea that significantly compromises fluid or electrolyte status.

Jackson BD et al. Available studies fail to provide strong evidence of increased risk of diarrhea mortality due to measles in the period 4–26 weeks after measles rash onset. BMC Public Health. 2017 Nov 7;17(Suppl 4):783. [PMID: 29143685]

2. Mumps

Exposure 12–25 days before onset.

Painful, swollen salivary glands, usually parotid.

Frequent involvement of testes, pancreas, and meninges in unvaccinated individuals.

Mumps can occur in appropriately vaccinated persons in highly vaccinated communities.
**General Considerations**

Mumps is a paramyxoviral disease spread by respiratory droplets. Children are most commonly affected; however, in outbreaks, infection can affect patients in their second or third decades of life. Mumps can spread rapidly in congregate settings, such as colleges and schools. The incubation period is 12–25 days (average, 16–18 days). The mumps virus spreads through direct contact with respiratory secretions or saliva or infected surfaces. Transmission can also be airborne or via droplets. Up to one-third of affected individuals have subclinical infection, which is still transmissible. Despite high vaccination rates, several mumps outbreaks were reported over the past few years in an increasing number. In 2016 and 2017, mumps cases surged to about 6000/year, with the largest outbreak occurring at a college in northwest Arkansas, which involved 3000 cases. A combination of factors contributes to outbreaks, including efficacy of vaccines; waning individual immunity; and crowded conditions, which promote transmission.

**Clinical Findings**

**A. Symptoms and Signs**

Mumps is more serious in adults than in children and appears to occur more commonly in males. Parotid tenderness and overlying facial edema (Figure 32–5) are the most common physical findings and typically develop within 48 hours of the prodromal symptoms. Usually, one parotid gland enlarges before the other, but unilateral parotitis occurs in 25% of patients. The parotid duct (orifice of Stensen) may be red and swollen. Trismus may result from parotitis. The parotid glands return to normal within 1 week. Involvement of other salivary glands (submaxillary and sublingual) occurs in 10% of cases. Fever and malaise are variable but often minimal in young children. The entire course of mumps rarely exceeds 2 weeks.

The tests are the most common extra salivary disease site in adults. High fever, testicular swelling, and tenderness (unilateral in 75% of cases) denote orchitis, which usually develops 7–10 days after the onset of parotitis. In recent outbreaks in the United States, complications from mumps were rare: 3.3–10% of adolescent and adult males developed orchitis (which occurred less frequently in persons who have received two doses of vaccine). Lower abdominal pain and ovarian enlargement suggest oophoritis, which is usually unilateral and occurs in less than 1% of postpubertal women.

Other rare complications, occurring in less than 1% of cases, are meningitis, encephalitis, Guillain-Barré syndrome, hearing loss, priapism or testicular infarction from orchitis, pancreatitis, thyroiditis, keratitis, neuritis, hepatitis, myocarditis, thrombocytopenia, migratory arthralgias, and nephritis. No mumps-related deaths have occurred in the United States in recent outbreaks. A rare cause of mumps is iodine exposure in medical procedures ("iodide mumps").

Some epidemiologic studies have suggested an association between mumps and risk of type 1 diabetes mellitus. Further studies do not provide evidence of this association.

**B. Laboratory Findings**

Mild leukopenia with relative lymphocytosis may be present. Elevated serum amylase usually reflects salivary gland involvement rather than pancreatitis. Mild kidney injury is found in up to 60% of patients.

The characteristic clinical picture usually suffices for diagnosis. An elevated serum IgM is considered diagnostic. Repeat testing 2–3 weeks after the onset of symptoms is recommended if the first assay is negative because the rise in IgM may be delayed, especially in vaccinated persons. A fourfold rise in complement-fixing antibodies to mumps virus in paired serum IgG also confirms infection. Anti-mumps IgM and IgG in the CSF can confirm the diagnosis of meningitis. Nucleic acid amplification techniques, such as real-time RT-PCR, are more sensitive than viral cultures and are available from some commercial laboratories, selected state laboratories, and the CDC. Diagnostic yield is highest if collected during the first 3 days of illness. Confirmatory diagnosis of mumps is also made by isolating the virus preferably from a swab of the duct of the parotid or other affected salivary gland. The virus can also be isolated from CSF early in aseptic meningitis. Vaccinated persons may shed virus for shorter periods of time compared to those who are unvaccinated.

**Differential Diagnosis**

Swelling of the parotid gland may be due to calculi in the parotid ducts, tumors, or cysts. Other causes include sarcoidosis, cirrhosis, diabetes, bulimia, pilocarpine usage, and Sjogren syndrome. Parotitis may be produced by pyogenic organisms (eg, *S aureus*, gram-negative organisms [particularly in debilitated individuals with poor oral intake]), drug reaction (phenothiazines, propylthiouracil),
and other viruses (HIV, influenza A, parainfluenza, EBV infection, coxsackieviruses, adenoviruses, HHV-6). Swelling of the parotid gland must be differentiated from inflammation of the lymph nodes located more posteriorly and inferiorly than the parotid gland.

▶ Treatment

Treatment is symptomatic. Topical compresses may relieve parotid discomfort. Some clinicians advocate IVIG for complicated disease (eg, thrombocytopenia), although its definitive role is unproven. There is no specific treatment for orchitis.

▶ Prevention

Vaccination is the most effective way to prevent mumps.

Monovalent mumps vaccine is no longer available in the United States. Mumps vaccine is now administered as combined vaccine in MMR or MMRV vaccine. The vaccination schedule, indications, and contraindications are described in the measles section. The mumps vaccine component of the MMR is less effective than the measles and rubella components. One dose is 78% (range: 49–92%) protective. Two doses of the vaccine are 88% (range: 66–95%) effective. Rare reported complications of mumps vaccination include immune thrombocytopenic purpura and aseptic meningitis.

A 2017 study, evaluating the effect of a third dose of MMR vaccine after a mumps outbreak, showed that the attack rate was significantly lower among students who received a third dose compared with two doses, especially if the second dose was given more than 13 years prior to the outbreak. The CDC recommends a third dose of vaccine in case of an outbreak.

The patient should be isolated. For outbreak control, the most important step is to vaccinate all susceptible individuals. MMR vaccine is not effective in preventing the disease in unvaccinated patients who already have been exposed to the virus. In the healthcare setting, the following steps should be taken: implement droplet and standard precaution, isolate patients until swelling subsides (about 9 days from onset), and provide vaccination to healthcare workers with no evidence of immunity.

▶ When to Refer

Any suspect cases should be reported to public health authorities.

▶ When to Admit

- Trismus; meningitis; encephalitis; myocarditis; pancreatitis.
- Severe testicular pain; priapism.
- Severe thrombocytopenia.

3. Rubella

▶ ESSENTIALS OF DIAGNOSIS

- Exposure 14–21 days before onset.
- No prodrome in children, mild prodrome in adults; mild symptoms (fever, malaise, coryza) coincide with, or precede by up to 5 days, the eruption of rash.
- Posterior cervical and postauricular lymphadenopathy 5–10 days before rash.
- Fine maculopapular rash of 3 days’ duration; face to trunk to extremities.
- Leukopenia, thrombocytopenia.

▶ General Considerations

Rubella is a systemic disease caused by a togavirus transmitted by inhalation of infective droplets. It is moderately communicable. Infection usually confers permanent immunity. The incubation period is 14–21 days. The disease is transmissible from 1 week before the rash appears until 15 days afterward.

The last cases of endemic rubella and congenital rubella syndrome were reported in 2009 from the Americas region. Each year in the United States, fewer than 10 cases of rubella are reported, all of which are due to the arrival of infected persons from other countries. In 2015, the WHO declared the Americas region free of rubella and congenital rubella syndrome. Some European countries are facing a challenge with lower immunization coverage among refugees and migrants. Worldwide, cases are decreasing due to widespread implementation of rubella-containing vaccines; as of 2016, the vaccine was added to the national vaccine schedule in 152 of 194 (78%) countries, though it is important to note that extensive variation in the rate of national coverage exists. On the other hand, the number of cases of congenital rubella syndrome remains high, particularly in Africa and Southeast Asia. The increase in congenital rubella syndrome may be secondary to an increase in surveillance and reporting of congenital rubella cases. The WHO set a goal to eliminate rubella in at least five of the six WHO regions (all but the Western Pacific region, which includes China) by 2020, although plans for rubella control are inadequate in 42 countries, especially in Africa and the Eastern Mediterranean regions.
Clinical Findings

A. Postnatal Rubella

Rubella is a common childhood disease; the majority of the cases are asymptomatic. The clinical picture of rubella is difficult to distinguish from other viral illnesses, such as infectious mononucleosis, measles, echovirus infections, and coxsackievirus infections. Fever and malaise, usually mild, accompanied by tender suboccipital adenitis, may precede the eruption by 1 week. Early posterior cervical and postauricular lymphadenopathy is common. A fine, pink maculopapular rash appears and fades from the face, trunk, and extremities in rapid progression (2–3 days), usually lasting 1 day in each area (Table 32–2).

B. Congenital Rubella

The principal importance of rubella lies in its devastating effects on the fetus in utero causing fetal death, preterm delivery, and teratogenic effects. The severity of symptoms is directly related to the gestational age; fetal infection during the first trimester leads to congenital rubella in at least 80% of fetuses; however, an infection during the fourth month can lead to 10% risk of a single congenital defect. In the second trimester of pregnancy, deafness is the primary complication.

C. Laboratory Findings

When rubella is suspected, the diagnosis requires serologic confirmation. Diagnosis of acute rubella infection is based on elevated IgM antibody, fourfold or greater rise in IgG antibody titers, or isolation of the virus. Serosensitivity to rubella is thought to change with subsequent pregnancies, although data from Hong Kong (lower immunity) and the United Kingdom (higher immunity) differed in their findings.

IgM is detectable in 50% of persons on day 1 of the rash but in most on day 5 after rash onset. Antibody testing can be performed on sera or saliva. An isolated IgM-positive test does not necessarily imply acute infection. IgM antibodies can persist after an infection or could be false-positive due to cross-reactivity with other antigens such as EBV, CMV, erythrovirus, and rheumatoid factor. This distinction is very important to make when infection is suspected in pregnancy. High-avidity anti-rubella IgG assays can distinguish between acute rubella infections and lasts up to 3 months postinfection. After 3 months, low-avidity antibodies are replaced by high-avidity antibodies indicating remote infection.

The CDC can test for virus by RT-PCR from throat swabs, oral fluids, or nasopharyngeal secretions. The timing of sample collection is important and is best if collected within the first 3 days of an acute illness and within 3 months in case of congenital rubella syndrome. After 3 months of age, up to 50% of infants with congenital rubella syndrome will not shed the virus.

Complications

Complications of rubella are rare. Polyarticular arthritis and arthralgia occur more commonly in adult women; involve the fingers, wrists, and knees; and usually subside within 7 days but may persist for weeks. Hemorrhagic manifestations due to thrombocytopenia and vascular damage occur more commonly in children, unlike other complications. Hepatitis has been reported. Encephalitis, another rare complication, occurs more commonly in adults and has a high mortality rate.

Treatment

Rubella infection, including complications, is treated symptomatically.

Prevention

Patients with rubella should be isolated for 7 days after rash onset.

In the United States, monovalent rubella vaccine is no longer produced. Live attenuated rubella virus vaccine is primarily given as combination with the MMR vaccine or in combination with MMRV vaccine. It is recommended that the first dose be given between 12 months and 15 months. The second dose is given between age 4 and 6 years, prior to school entry. More details on scheduling, side effects, and contraindications are explained in the measles section. It is important that girls are immune to rubella prior to menarche. In the United States, about 80% of 20-year-old women are immune to rubella.

Rubella vaccine is safe and highly efficacious; a single dose of MMR vaccine is about 97% effective at preventing rubella.

The immune status of pregnant women should be evaluated because antibody titers fall in about 10% of vaccinated individuals within 12 years of vaccination. There is no evidence of adverse outcomes with MMR immunization of pregnant women, yet it is still recommended that women avoid pregnancy for at least 3 months after vaccination. Opportunities should be made available to vaccinate all women of childbearing age.

The administration of live vaccines to immunocompromised patients is controversial. In patients receiving immunosuppressive therapy as well as in patients who have undergone solid organ or bone marrow transplantation, seroconversion is higher to rubella compared with measles, mumps, and varicella. In addition, response to live attenuated vaccines may be lessened due to presence of antibodies from IVIG or other blood products. Safety is another concern when administering live attenuated vaccines to immunocompromised patients. Because MMR vaccine is contraindicated in solid organ transplant recipients, current evidence recommends that seronegative patients receive one or two doses of the MMR vaccine at least 4 weeks prior to solid organ transplantation. Patients who have undergone bone marrow transplant lose antigen-specific antibodies and should be revaccinated regardless of their vaccination history. The revised guidelines recommend MMR and varicella vaccines be given to seronegative patients without graft-versus-host disease 2 years after hematopoietic stem cell transplantation.

Prognosis

Rubella is a mild illness and rarely lasts more than 3–4 days. Congenital rubella has a high fetal mortality rate, and the associated congenital defects are largely permanent.
When to Refer
- Pregnancy.
- Meningitis/encephalitis.
- Significant vaccination reactions.
- Any suspect cases should be reported to public health authorities.

Clinical Findings

A. Symptoms and Signs
At least 95% of infections are asymptomatic. Patients who become symptomatic can present with abortive poliomyelitis, nonparalytic poliomyelitis, or paralytic poliomyelitis. Post-poliomyelitis syndrome is the constellation of symptoms that affect polio survivors and is not infectious.

1. Abortive poliomyelitis—Nonspecific symptoms of this minor illness include fever, headache, vomiting, diarrhea, constipation, and sore throat lasting 2–3 days.

2. Nonparalytic poliomyelitis—In addition to the above symptoms, signs of meningeal irritation and muscle spasm occur in the absence of frank paralysis.

3. Paralytic poliomyelitis—Characterized as a flaccid asymmetric paralysis affecting mostly the proximal muscles of the lower extremities; the febrile period is present over 2–3 days. Sensory loss is very rare. Paralytic poliomyelitis is divided into two forms, which may coexist: (1) spinal poliomyelitis involving the muscles innervated by the spinal nerves, and (2) bulbar poliomyelitis involving the muscles supplied by the cranial nerves (especially nerves IX and X) and of the respiratory and vasomotor centers. The most life-threatening aspect of bulbar poliomyelitis is respiratory paralysis. The incidence of paralytic poliomyelitis is higher when infections are acquired later in life.

4. Post-poliomyelitis syndrome—The syndrome presents with signs of chronic and new denervation. The most frequent symptoms are progressive muscle limb paresis with muscle atrophy, with fasciculations and fibrillation during rest activity. The restless leg syndrome is also reported.

B. Laboratory Findings
The virus may be recovered from throat washings (early) and stools (early and late) and PCR of washings, stool, or CSF can also facilitate diagnosis. CSF findings include the...
Differential Diagnosis

Acute inflammatory polyneuritis (Guillain-Barré syndrome), Japanese encephalitis virus infection, West Nile virus infection, and tick paralysis may resemble poliomyelitis. In Guillain-Barré syndrome (see Chapter 24), the weakness is more symmetric and ascending in most cases, but the Miller Fisher variant of Guillain-Barré is similar to bulbar poliomyelitis. Paresthesia is uncommon in poliomyelitis but common in Guillain-Barré syndrome. The CSF usually has high protein content but normal cell count in Guillain-Barré syndrome. Acute flaccid paralysis resembling polio with residual weakness are increasingly recognized with no evidence of polio infection. Enterovirus is isolated in some of these cases.

Treatment

In the acute phase of paralytic poliomyelitis, patients should be hospitalized. In cases of respiratory weakness or paralysis, intensive care is needed. Intensive physiotherapy may help recover some motor function with paralysis. Attention to psychological disorders in longstanding disease is also important.

Immune deficient individuals have prolonged excretion of poliovirus leading to virus circulation and threatening the polio eradication efforts. Pocapavir, an experimental capsid inhibitor antiviral agent, was tested in healthy adults given monovalent live oral poliovirus vaccine (OPV) type 1 and was shown to be safe and effective in reducing the duration of viral excretion in stool, but resistance emerged in 44% of treated participants in this study.

Immune modulators, such as prednisone, interferon, and IVIG, do not show any clear benefit in the treatment of post-polio myelitis syndrome.

Prognosis

The death-to-case ratio for paralytic polio ranges between 2% and 30%, depending on age. Bulbar poliomyelitis carries a mortality rate of up to 75%.

Prevention

Given the epidemiologic distribution of poliomyelitis and the continued concern about vaccine-associated disease with the trivalent live OPV, the inactive (Salk) parenteral vaccine is currently used in the United States for all four recommended doses (at ages 2 months, 4 months, 6–18 months, and at 4–6 years). Inactivated vaccine is also routinely used elsewhere in the developed world where one dose is often administered, although immunogenicity is improved with additional doses.

Because most of circulating vaccine-derived poliovirus and vaccine-associated poliomyelitis are live OPV type 2, the WHO replaced worldwide the trivalent live OPV (containing types 1, 2, and 3) with the bivalent live OPV (type 1 and 3) in 2016. The goal is to replace all live OPV with inactive parenteral vaccination to eliminate poliovirus circulation. The advantages of oral vaccination are the ease of administration, low cost, effective local gastrointestinal and circulating immunity, and herd immunity. Monovalent OPV type 2 (mOPV2) as well as the trivalent OPV are used for control in countries with vaccine-derived type 2 outbreaks.

Routine immunization of adults in the United States is no longer recommended because of the low incidence of the disease. Vaccination should be considered for adults not vaccinated within the prior decade who are exposed to poliomyelitis or who plan to travel to endemic areas and adults engaged in high-risk activities (eg, laboratory workers handling stools).

When to Refer

Any suspicious cases should be referred to public health authorities.

1. Rabies

Rabies is a viral (rhabdovirus) encephalitis transmitted by infected saliva that enters the body by an animal bite or an
open wound. Worldwide, over 17 million cases of animal bites are reported every year, and it is estimated that about 60,000 deaths annually are attributable to rabies. Rabies is endemic in over 150 countries; on the basis of interviews, it is estimated that over 40% of the world’s population lives in areas without rabies surveillance. Most cases of rabies occur in rural areas of Africa and Asia. India has the highest incidence, accounting for 36% of global deaths (http://www.who.int/rabies/epidemiology/en/). In developing countries, more than 90% of human cases and 99% of human deaths from rabies are secondary to bites from infected dogs. Rabies among travelers to rabies-endemic areas is usually associated with animal injuries (including dogs in North Africa and India, cats in the Middle East, and nonhuman primates in sub-Saharan Africa and Asia), with most travel-associated cases occurring within 10 days of arrival. Rare but related viruses are the Australian lyssavirus, transmitted by bats including one referred to as the black flying fox, and which has caused 3 deaths over the last 20 years, and the European lyssavirus, with cases from Germany and the United Kingdom.

In the United States, domestically acquired rabies cases are rare (approximately 92% of cases are associated with wildlife) but probably underreported. Reports largely from the East Coast show an increase in rabies among cats, with about 1% of tested cats showing rabies seropositivity. The annual caseload in the United States is 1–3 cases (https://www.cdc.gov/rabies/location/usa/surveillance/human_rabies.html). Surveillance for animal rabies in 2015 showed 5508 cases occurring in 49 states and Puerto Rico. Wildlife reservoirs, with each species having its own rabies variant(s), follow a unique geographic distribution in the United States: raccoons on the East Coast; skunks in the Midwest, Southwest, and California; and foxes in the Southwest and in Alaska. However, some areas have all three wildlife reservoirs (e.g., the hill country of Texas). Hawaii is the only rabies-free state to date. Most of Western Europe and much of Oceania is rabies-free.

Raccoons, bats, and skunks account for 84% of the rabid animals found in the United States; other rabid animals include foxes, cats, cattle, and dogs. Rodents and lagomorphs (e.g., rabbits) are unlikely to spread rabies because they cannot survive the disease long enough to transmit it (woodchucks and groundhogs are exceptions). Wildlife epizootics present a constant public health threat in addition to the danger of reintroducing rabies to domestic animals. Vaccination is the key to controlling rabies in small animals and preventing rabies transmission to human beings.

The virus enters the salivary glands of dogs 5–7 days before their death from rabies, thus limiting their period of infectivity. Less common routes of transmission include contamination of mucous membranes with saliva or brain tissue, aerosol transmission, and corneal transplantation. Recognized mutations in rabies virus proteins can subvert the host immune system. Transmission through solid organ and vascular segment transplantation from donors with unrecognized infection is also reported. A number of transplantation-associated cases are reported, including two clusters in the United States. Postexposure prophylaxis can be administered in these patients and may prevent development of disease.

The incubation period may range from 10 days to many years but is usually 3–7 weeks depending in part on the distance of the wound from the CNS. The virus travels in the nerves to the brain, multiplies there, and then migrates along the efferent nerves to the salivary glands. Rabies virus infection forms cytoplasmic inclusion bodies similar to Negri bodies. These Negri bodies are thought to be the sites of viral transcription and replication.

Clinical Findings

A. Symptoms and Signs

While there is usually a history of animal bite, bite marks may not be recognized. The prodromal syndrome consists of pain at the site of the bite in association with fever, malaise, headache, nausea, and vomiting. The skin is sensitive to changes of temperature, especially air currents (aerophobia). Percussion myoedema (a mounding of muscles after a light pressure stimulus) can be present and persist throughout the disease. The CNS stage begins about 10 days after the prodrome and may be either encephalitic ("furious") or paralytic ("dumb"). The encephalitic form (about 80% of the cases) produces the classic rabies manifestations of delirium alternating with periods of calm, extremely painful laryngeal spasms on attempting drinking (hydrophobia), autonomic stimulation (hypersalivation), and seizures. In the less common paralytic form, an acute ascending paralysis resembling Guillain-Barré syndrome predominates with relative sparing of higher cortical functions initially. Both forms progress relentlessly to coma, autonomic nervous system dysfunction, and death.

B. Laboratory Findings

Biting animals that appear well should be quarantined and observed for 10 days. Sick or dead animals should be tested for rabies. A wild animal, if captured, should be sacrificed and the head shipped on ice to the nearest laboratory qualified to examine the brain for evidence of rabies virus. When the animal cannot be examined, raccoons, skunks, bats, and foxes should be presumed to be rabid.

Direct fluorescent antibody testing of skin biopsy material from the posterior neck (where hair follicles are highly innervated) has a sensitivity of 60–80%.

Quantitative RT-PCR, nucleic acid sequence-based amplification, direct rapid immunohistochemical test, and viral isolation from the CSF or saliva are advocated as definitive diagnostic assays. Antibodies can be detected in the serum and the CSF. Pathologic specimens often demonstrate round or oval eosinophilic inclusion bodies (Negri bodies) in the cytoplasm of neuronal cells, but the finding is neither sensitive nor specific. MRI signs are diffuse and nonspecific.

Treatment & Prognosis

Management requires intensive care with attention to the airway, maintenance of oxygenation, and control of seizures. Universal precautions are essential. Corticosteroids
are of no use. Survival is rare, and data are insufficient to provide estimate of success.

If postexposure prophylaxis (discussed below) is given expeditiously, before clinical signs develop, it is nearly 100% successful in prevention of disease. Once the symptoms have appeared, death almost inevitably occurs after 7 days, usually from respiratory failure. Most deaths occur in persons with unrecognized disease who do not seek medical care or in individuals who do not receive postexposure prophylaxis. The very rare cases in which patients recover without intensive care are referred to as “abortive rabies.”

**Prevention**

Immunization of household dogs and cats and active immunization of persons with significant animal exposure (eg, veterinarians) are important. The most important decisions, however, concern animal bites. Animals that are frequent sources of infection to travelers are dogs, cats, and nonhuman primates.

In the developing world, education, surveillance, and animal (particularly dog) vaccination programs (at recurrent intervals) are preferred over mass destruction of dogs, which is followed typically by invasion of susceptible feral animals into urban areas. In some Western European countries, campaigns of oral vaccination of wild animals led to the elimination of rabies in wildlife.

**A. Local Treatment of Animal Bites and Scratches**

Thorough cleansing, debridement, and repeated flushing of wounds with soap and water are important. Rabies immune globulin or antiserum should be given as stated below. Wounds caused by animal bites should not be sutured.

**B. Postexposure Immunization**

The decision to treat should be based on the circumstances of the bite, including the extent and location of the wound, the biting animal, the history of prior vaccination, and the local epidemiology of rabies. Any contact or suspect contact with a bat, skunk, or raccoon is usually deemed a sufficient indication to warrant prophylaxis. Consultation with state and local health departments is recommended. Postexposure treatment including both immune globulin and vaccination should be administered as promptly as possible when indicated.

For patients who had not received rabies vaccination prior to possible exposure, the optimal form of passive immunization is human rabies immune globulin (HRIG; 20 international units/kg), administered once. As much as possible of the full dose should be infiltrated around the wound, with any remaining injected intramuscularly at a site distant from the wound. Finger spaces can be safely injected without development of a compartment syndrome. If HRIG is not available and appropriate tests for horse serum sensitivity are done, equine rabies antiserum (40 international units/kg) can be used.

**Two vaccines** are licensed and available for use in humans in the United States: a human diploid cell vaccine (HDCV; Immovax) and a purified chick embryo cell vaccine (PCEC, RabAvert). There are several postexposure prophylaxis strategies. The most commonly used one is the “abbreviated Essen” strategy, where either of the current vaccines is given as four intramuscular injections of 1 mL in the deltoid or, in small children, into the anterolateral thigh muscles on days 0, 3, 7, and 14 after exposure. (The fifth dose at 28 days after exposure is no longer recommended except among immunosuppressed patients.) The vaccine should not be given in the gluteal area due to suboptimal response. An alternative intramuscular vaccination strategy that takes only 1 week, with injections on days 0, 3, and 7 after exposure with a Vero cell vaccine (Verorab) is reportedly successful in achieving adequate neutralizing titers at days 14 and 28 in a study from Thailand; this vaccine is not currently available in the United States.

The WHO supports an intradermal vaccination strategy using Verorab and the inactivated rabies virus vaccine Rabipur (an alternative formulation of the PCEC [purified chick embryo cell]) (0.1 mL per intradermal injection) for regions of the world where vaccine is in short supply; either vaccine can be given at two sites on days 0, 3, 7, and 28.

**Rabies vaccines and HRIG should never be given in the same syringe or at the same site.** Allergic reactions to the vaccine are rare and include a report of sudden unilateral sensorineural hearing loss and immune thrombocytopenic purpura, although local reactions (pruritus, erythema, tenderness) occur in about 25% and mild systemic reactions (headaches, myalgias, nausea) in about 20% of recipients. Intradermal vaccines appear to be better tolerated than intramuscular vaccines, especially among young children. Adverse reactions to HRIG seem to be more frequent in women and rare in young children. The vaccines are commercially available or can be obtained through health departments.

In patients with history of past vaccination, the need for HRIG is eliminated (HRIG is in short supply worldwide), but postexposure vaccination is still required. The vaccine should be given 1 mL in the deltoid twice (on days 0 and 3). Neither the passive nor the active form of postexposure prophylaxis is associated with fetal abnormalities and thus pregnancy is not considered a contraindication to vaccination. Peripartum rabies transmission occurs but is rare. Neonates may also receive both forms of postexposure prophylaxis at birth.

The WHO has a program to eliminate dog-transmitted human rabies by 2030.

**C. Preexposure Immunization**

Preexposure prophylaxis with three injections of human diploid cell vaccine intramuscularly (1 mL on days 0, 7, and 21 or 28) is recommended for persons at high risk for exposure: veterinarians (who should have rabies antibody titers checked every 2 years and be boosted with 1 mL intramuscularly); animal handlers; laboratory workers; Peace Corps workers; and travelers with stays over 1 month to remote areas in endemic countries in Africa, Asia, and Latin America. An intradermal route is also available (0.1 mL on days 0, 7, and 21 over the deltoid) but not in the United States. Immunosuppressive illnesses and agents including corticosteroids as well as antimalarials—in particular chloroquine—may diminish the antibody response.
A single-dose booster at 10 years after initial immunization increases the level of antibody titers. Unfortunately, data from travel services indicate that only a small proportion of travelers with anticipated lengthy stays in rabies-impacted areas receive the vaccine as recommended.

**When to Refer**

Suspicion of rabies requires contact with public health personnel to initiate appropriate passive and active prophylaxis and observation of suspect cases.

**When to Admit**

- Respiratory, neuromuscular, or CNS dysfunction consistent with rabies.
- Patients with suspect rabies require initiation of therapy until the disease is ruled out in suspect animals, and this requires coordination of care based on likelihood of patient compliance, availability of inpatient and outpatient facilities, and response of local public health teams.

Davis BM et al. Everything you always wanted to know about rabies virus (but were afraid to ask). Annu Rev Virol. 2015 Nov;2(1):451–71. [PMID: 26958924]

**2. Arbovirus Encephalitides**

**ESSENTIALS OF DIAGNOSIS**

- Fever, malaise, stiff neck, sore throat, and vomiting, progressing to stupor, coma, and convulsions.
- Upper motor neuron lesion signs: exaggerated deep tendon reflexes, absent superficial reflexes, and spastic paralysis.
- CSF opening pressure and protein are often increased with lymphocytic pleocytosis.

**General Considerations**

The arboviruses are arthropod-borne viral pathogens carried by mosquitoes or ticks that produce clinical manifestations in humans. The *mosquito-borne pathogens* include togaviruses (causing Western, Eastern, and Venezuelan equine encephalitis), flaviviruses (causing West Nile fever, St. Louis encephalitis, Japanese encephalitis, and Murray Valley encephalitis; dengue, Zika, and yellow fever can present with encephalitis), bunyaviruses (the California serogroup of viruses, including the Jamestown Canyon [seen largely in Northern states] and the La Crosse viruses [seen in the upper Midwest and mid-Atlantic primarily]), and the alphavirus chikungunya. The *tick-borne* causes of encephalitis include the flavivirus of the Powassan encephalitis (North American Northeast and Great Lakes), tick-borne encephalitis virus (Europe and Asia), and the Colorado tick fever reovirus. Only those viruses causing primarily encephalitis in the United States are discussed here. The most commonly encountered arboviruses from 2017 in the United States are West Nile virus (2097 cases, 89% of arboviral neuroinvasive disease), Jamestown Canyon virus (75 cases), the La Crosse virus (63 cases), and Powassan virus (34 cases). Rare causes of domestic arboviruses were St. Louis encephalitis virus (11 cases) and eastern equine encephalitis virus disease (5 cases, 3 via organ transplantation).

West Nile virus is the leading cause of domestically acquired arboviral disease in the United States. West Nile virus disease is a nationally notifiable condition. Among the 2291 cases of domestic arboviral disease from 2017, cases were reported to the CDC from 48 states and the District of Columbia, 1425 (68%) were classified as neuroinvasive disease, and 32% were classified as non-neuroinvasive disease. Most cases are identified in Texas and California. Asymptomatic seroconversion is the norm and is not reported. Epidemiologic studies from the Dallas-Fort Worth area show consistency through time of the percentage of neuroinvasive disease.

Outbreaks with West Nile infection tend to occur between mid-July and early September. Climatic factors, including elevated mean temperatures and rainfall, correlate with increased West Nile infection. West Nile virus circulates between mosquitoes (mainly *Culex* species) and birds. In case of West Nile virus outbreak, infected birds develop high levels viremia that lead to substantial avian mortality and a high incidence of mosquito infection. Infected mosquitoes bite and infect people and other mammals. However, humans and other mammals are “dead end” hosts, since they do not transmit the virus on to other biting mosquitoes; only dengue and Venezuelan equine encephalitis viruses produce viremias high enough to allow continued transmission to other mosquitoes and ticks between humans and vectors. Human-to-human transmission is usually related to blood transfusion and organ transplantation. Since 2003, all blood donations in the United States are screened with nucleic acid amplification assays for West Nile virus. Eastern equine encephalitis is now also shown to be transmitted by organ transplantation.

**Clinical Findings**

**A. Symptoms and Signs**

West Nile virus infection has an incubation period of 2–14 days. The infection is symptomatic in no more than 10% of the cases; of those, about 10% progress to neuroinvasive disease, including meningitis, encephalitis, and flaccid paralysis. The case fatality rate is about 10%.

Symptoms include acute febrile illness, and a nonpruritic maculopapular rash is variably present. Meningitis is indistinguishable from other viral meningitis. West Nile virus encephalitis presents with fever and altered mental status. Other signs include tremors, seizures, cranial nerve palsies, and pathologic reflexes. Acute flaccid (poliomyelitis-like) paralysis, which is asymmetric and can involve facial and respiratory muscles, is a well-known complication and is less commonly seen with other arboviruses.
infection. West Nile virus can also present as Guillain-Barré syndrome with radiculopathy. The disease manifestations associated with West Nile virus infection are strongly age-dependent: the acute febrile syndrome and mild neurologic symptoms are more common in the young, aseptic meningitis and poliomyelitis-like syndromes are seen in middle-aged persons, and frank encephalopathy is seen more often in older adults. All forms of disease tend to be severe in immunocompromised persons in whom neuroinvasive manifestations and associated high mortality are more apt to develop. Other risk factors for development of neuroinvasive disease and increased mortality include black race, diabetes, chronic kidney disease, and hepatitis C virus infection.

Host genetic variation in the interferon response pathway is associated with both risk for symptomatic West Nile virus infection and increased likelihood of West Nile virus disease progression.

B. Laboratory Findings

The peripheral white blood cell count is usually normal. Usually a CSF lymphocytic pleocytosis is present, and polymorphonuclear cells predominate early. The diagnosis of arboviral encephalitides depends on serologic tests. For West Nile virus, an IgM capture ELISA in serum or CSF is almost always positive by the time the disease is clinically evident, and the presence of IgM in CSF indicates neuroinvasive disease. Documentation of a fourfold increase in acute/convalescent IgG titers is confirmatory for all arboviruses. Antibodies to arboviruses persist for life, and the presence of IgG in the absence of a rising titer of IgM may indicate past exposure rather than acute infection. Serologic tests are available commercially and through local and state health departments. Cross-reactivity exists among the different flaviviruses, so a plaque reduction assay may be needed to definitively distinguish between West Nile fever, St. Louis encephalitis, and others. PCR assays (available through state laboratories and the CDC) can be used to detect viral RNA in serum, CSF, or tissue early after illness onset and may be particularly useful in immunocompromised patients with abnormal antibody responses. Individuals with chronic symptoms after West Nile virus infection may show persistent kidney infection for up to 6 years with West Nile virus RNA present in urine. Blood products are best screened using nucleic acid assays. MRI of the brain may reveal leptomeningeal, basal ganglia, thalamic, or periventricular enhancement.

Differential Diagnosis

Mild forms of encephalitis must be differentiated from aseptic meningitis, lymphocytic choriomeningitis, and nonparalytic poliomyelitis.

Severe forms of arbovirus encephalitides are to be differentiated from other causes of viral encephalitis (HSV, mumps virus, poliovirus or other enteroviruses, HIV), encephalitis accompanying exanthematous diseases of childhood (measles, varicella, infectious mononucleosis, rubella), encephalitis following vaccination or infection (a demyelinating type seen after rabies, measles, pertussis vaccination), toxic encephalitis (from drugs, poisons, or bacterial toxins such as Shigella dysenteriae type 1), Reye syndrome, and severe forms of stroke, brain tumors, brain abscess, autoimmune processes such as lupus cerebritis, and intoxications. In the California Encephalitis Project, anti-N-methyl-D-aspartate receptor (anti-NMDAR) encephalitis is a more common cause of encephalitis than viral diseases, especially in the young, with 65% of cases of encephalitis due to anti-NMDAR occurring among patients 18 or younger.

Complications

Bronchial pneumonia, urinary retention and infection, prolonged weakness, and pressure injuries may occur. Renalopathy occurs in 24% of patients with a history of West Nile virus infection and is associated with increased risk in those with encephalitis. Few studies suggest that West Nile virus infection can persist in the kidneys, but in a subset of patients following West Nile virus infection, kidney infection may lead to progressive renal pathology.

Treatment

Although specific antiviral therapy is not available for most causative entities, vigorous supportive measures can be helpful. Some studies suggest improved outcomes with the use of IVIG enriched with West Nile virus antibody; however, a randomized, controlled trial of IVIG did not show a benefit.

Prognosis

Although most infections are mild or asymptomatic, the prognosis is always guarded, especially at the extremes of age. Most fatalities occur with neuroinvasive disease. Most patients with non-neuroinvasive West Nile virus disease or West Nile virus meningitis recover completely, but a syndrome of fatigue, malaise, and weakness can linger for weeks or months. Patients who recover from West Nile virus encephalitis or poliomyelitis often have residual neurologic deficits. The recovery of persons with severe neurologic compromise may take 6 months or longer. The sequelae of West Nile virus infection include a poliomyelitis-like syndrome, cognitive complaints, movement disorders, epilepsy, and depression; and they may become apparent late in the course of what appears to be a successful recovery.

Another entity, nonprimary infection, characterized by elevated serum IgG, absent serum IgM, and occasional detection of West Nile virus RNA in blood or CSF, is associated with underlying psychiatric disorders, hospitalization during times not associated with peak West Nile transmission, fever, and increased in-hospital mortality.

The long-term prognosis is generally better for Western equine than for Eastern equine or St. Louis encephalitis.

Prevention

Mosquito avoidance (repellents, protective clothing, and insecticide spraying) is effective prevention. Laboratory precautions are indicated for handling all these pathogens. No human vaccine is currently available for the arboviruses.
VIRAL & RICKETTSIAL INFECTIONS

3. Japanese Encephalitis

ESSENTIALS OF DIAGNOSIS

- Most important vaccine-preventable cause of encephalitis in the Asia-Pacific region.
- The virus is transmitted by mosquitoes, especially Culex species.
- Wide symptom spectrum; most infections asymptomatic.

General Considerations

The Japanese encephalitis virus is a flavivirus akin to those causing West Nile infection and St. Louis encephalitis. It is the most common cause of encephalitis in East Asia with over 68,000 estimated annual cases and up to 20,400 annual deaths. It is geographically contained to East Asia. Most cases occur in the summer and late fall, although in tropical and subtropical areas transmission occurs throughout the year. Major outbreaks every 2–15 years often correlate with patterns of agricultural development. The virus is transmitted by mosquitoes, especially Culex species. Areas with high endemicity tend to be warm-temperate, semitropical or tropical areas with high annual rainfalls. Wading birds (such as herons) and pigs more commonly sustain the infection as reservoirs in nature, since the viremia in humans is transient and not usually high enough to sustain transmission. In endemic countries, Japanese encephalitis is primarily a disease of children. Travelers to major urban areas for less than 1 month are at minimal risk for Japanese encephalitis. Transmission by blood transfusion is documented.

Clinical Findings

A. Symptoms and Signs

The median incubation period is 5–15 days. Most persons asymptomatically seroconvert. The 1% of patients in whom disease develops report sudden-onset headaches, nausea, and vomiting, followed by mental status changes, parkinsonian movement disorders, and in a smaller percentage, seizures, typically in children.

Japanese encephalitis most closely resembles St. Louis encephalitis and West Nile encephalitis, although epidemiologic data readily distinguish these infections in most instances. The clinical course is less severe in patients with a history of dengue virus infection.

B. Laboratory Findings and Diagnosis

The disease should be suspected in persons with symptoms of CNS infection who recently visited or who reside in an endemic area.

Common laboratory abnormalities include leukocytosis, mild anemia, and hyponatremia. CSF typically has a mild to moderate pleocytosis with a lymphocytic predominance, slightly elevated protein, and normal glucose.

Diagnosis is confirmed by finding anti-Japanese encephalitis IgM in CSF or serum using ELISA. Definitive diagnosis requires fourfold increase in virus-specific IgG confirmed by plaque reduction neutralization assay. Because of low levels of viremia in humans, RT-PCR is not recommended.

In severe disease, brain imaging reveals thalamic lesions, with the hippocampus, midbrain, basal ganglia, and cerebral cortex affected to varying degrees.

Complications

A variety of cognitive, neurologic, and psychiatric complications, including memory impairment and intellectual impairment in adults and children, are recognized to occur in as many as 50% of survivors and to persist at least 1–2 years after the acute infection. Rare reported complications include the opsoclonus myoclonus syndrome and the Kasabach-Merritt phenomenon of consumptive coagulopathy. The mortality is reportedly as high as 30%.

Treatment

Treatment is supportive, including antipyretics, analgesics, bed rest, and fluids. Corticosteroids may be needed for rare complications, such as the opsoclonus myoclonus syndrome.

Prevention

Using mosquito repellents; wearing long sleeves, long pants, and socks; and using air-conditioned facilities and bed nets are essential means of protection.

In the United States, inactivated Vero-cell culture-derived Japanese encephalitis vaccine (IXIARO) is licensed for the prevention of Japanese encephalitis in persons 2 months of age and older. Travelers who plan to spend more than 1 month in rural East Asia during Japanese encephalitis virus transmission season should receive the vaccine. Primary vaccination requires two doses administered 28 days apart, to be completed more than 1 week before travel. For adults, a booster dose is recommended in case of potential reexposure or of continued risk for infection if the primary series of the vaccine was administered over a 1 year before.
4. Tick-Borne Encephalitis

**ESSENTIALS OF DIAGNOSIS**
- Flaviviral encephalitis found in Eastern, Central, and occasionally Northern Europe and Asia.
- Transmitted via ticks or ingestion of unpasteurized milk.
- Long-term neurologic sequelae in 2–25% of cases.
- Therapy is largely supportive.
- Prevention: avoid tick exposure, pasteurize milk, and vaccinate.

**General Considerations**

Tick-borne encephalitis (TBE) is a flaviviral infection caused by TBE virus with three subtypes: European, Siberian, and Far Eastern. The principal reservoirs and vectors for TBE virus are ticks with small rodents as the amplifying host; humans are an accidental host. The vectors for most cases are *Ixodes ricinus* (European subtype) and *Ixodes persulcatus* (Siberian and Far Eastern subtype). Infection results from tick bites during outdoor activities in forested areas, predominantly in the late spring through fall. Ingestion of unpasteurized milk from viremic livestock (goats, sheep, and cattle) is also a recognized mode of transmission. Transmission by transplantation of solid organs is rarely reported leading to fatal outcomes. TBE is endemic in certain parts of Europe (reported recent foci include northeastern France and Bulgaria) and Asia (principally China but a few cases from Japan as well). The number of cases reported annually fluctuates significantly depending on surveillance, human activities, socioeconomic factors, ecology, and climate. Modeling studies from Prague suggest several superimposed cycles of variable year duration. The incubation period is 7–14 days for tick-borne exposures but only 3–4 days for milk ingestion.

**Powassan virus** is the only North American member of the tick-borne encephalitides. Its vector is several *Ixodes* species ticks. Most cases occur in older men (median age, 62; all deaths have occurred in persons over age 50), primarily from Northeast and North Central states (especially Minnesota, New York, and Wisconsin). Most reported cases are neuroinvasive with presentations including acute encephalitis and aseptic meningitis. The incubation period can range from 1 to 5 weeks, although pinpointing the date of actual exposure is often difficult.

**Clinical Findings**

**A. Symptoms and Signs**

Most cases are subclinical, and many resemble an influenza-like syndrome with 2–10 days of fever (usually with malaise, headache, and myalgias). In some cases, the disease is biphasic where the initial flu-like period is followed by a 1- to 21-day symptom-free interval followed by a second phase with fevers and neurologic symptoms (cases from Asia appear not to show this biphasic pattern). The neurologic manifestations range from febrile headache to aseptic meningitis and encephalitis with or without myelitis (preferentially of the cervical anterior horn) and spinal paralysis (usually flaccid). A myeloradiculitic form can also develop but is less common. Peripheral facial palsies, sometimes bilateral, tend to occur infrequently late in the course of infection, usually after encephalitis and usually are associated with a favorable outcome within 30–90 days. The main sequela of disease is paresis. Other cases of long-term morbidity include protracted cognitive dysfunction and persistent spinal nerve paralysis. The post-encephalitic syndrome is characterized by headache, difficulties concentrating, balance disorders, dysphasia, hearing defects, and chronic fatigue. A progressive motor neuron disease and partial continuous epilepsy are complications. Longstanding psychiatric complications are reported and include attention deficits, slowness of thought and learning impairment, depression, lability, and mutism.

Mortality in TBE is usually a consequence of brain edema or bulbar involvement.

**B. Laboratory Findings and Diagnosis**

Leukocytosis and neutrophilia are common. Abnormal CSF findings include an inconsistent pleocytosis that may persist for up to 4 months. Hyponatremia is more commonly seen than with other viral encephalitides. Neuroimaging might show hyperintense lesions in the thalamus, brainstem, and basal ganglia, and cerebral atrophy.

When neurologic symptoms develop, the TBE virus is typically no longer detectable in blood and CSF samples. Virus detection by RT-PCR in ticks from TBE patients, if available, can help with the diagnosis. TBE virus IgM and IgG are detected by ELISA when neurologic symptoms occur.
Cross-reactivity with other flaviviruses or a vaccinated state may require confirmation by detection of TBE virus-specific antibodies by plaque-reduction neutralization tests.

► Differential Diagnosis
The differential diagnosis includes other causes of aseptic meningitis, such as enteroviral infections; poliomyelitis (no longer reported from Eastern Europe); herpes simplex encephalitis; and a variety of tick-borne pathogens, including tularemia, the rickettsial diseases, babesiosis, Lyme disease, and other flaviviral infections. Coinfections are documented with *Anaplasma*, *Babesia*, and *Borrelia* infections.

► Treatment
There is no specific antiviral treatment, and therapy is largely supportive.

► Prognosis
The three subtypes of TPE have different prognoses. The European subtype is usually milder with up to 2% mortality and 30% neuroinvasive disease. The Siberian subtype is associated with 3% mortality and chronic, progressive disease. The Far Eastern subtype is usually more severe with up to 40% mortality and higher likelihood of neurologic involvement. All three subtypes are more severe among elderly adults compared with children. Coinfection with *Borrelia burgdorferi* (the agent of Lyme disease; transmitted by the same tick vector) may result in more severe disease.

► Prevention
There is no available TBE vaccine in the United States. There are four different inactivated TBE virus vaccines for adults and children licensed in Europe (two in Austria and Germany and two in Russia) and one available in China. The vaccine is safe and effective and should provide cross-protection against all three TBE virus subtypes. The initial vaccination schedule requires two to three doses given over 6 or more months with boosters every 1–5 years, the interval dependent on the vaccine and national guidelines. Breakthrough TBE in vaccinated individuals is reported, especially among recipients who are over 50 years of age and among persons who are immunosuppressed, such as those receiving anti-TNF therapy or methotrexate, indicating the need for a modified immunization strategy in such patients. Neuritis and neuropathies of peripheral nerves (plexus neuropathy—paresis of lower limb muscles, polyradiculopathy) are recognized complications of TBE vaccination.

The low popular support for the vaccine in endemic countries is responsible for limited abilities to control the disease. Other prevention recommendations include avoidance of tick exposure and pasteurization of cow and goat milk.

Yoshii K et al. Tick-borne encephalitis in Japan, Republic of Korea and China. Emerg Microbes Infect. 2017 Sep 20; 6(9):e82. [PMID: 28928417]

5. Lymphocytic Choriomeningitis

► General Considerations
The lymphocytic choriomeningitis virus is an arenavirus (related to the pathogen causing Lassa fever, discussed below) that primarily infects the CNS. Its main reservoir is the house mouse (*Mus musculus*). Other rodents (such as rats, guinea pigs, and even pet hamsters), monkeys, dogs, and swine are also potential reservoirs. The infected animal sheds lymphocytic choriomeningitis virus in nasal secretions, urine, and feces; transmission to humans probably occurs through aerosolized particles and mucosal exposure, percutaneous inoculation, direct contact, or animal bites. The disease in humans is underdiagnosed and occurs most often in autumn. The lymphocytic choriomeningitis virus is typically not spread person to person, although vertical transmission is reported, and it is considered to be an underrecognized teratogen. Rare cases related to solid organ transplantation and autopsies of infected individuals are also reported. All reported cases were donor derived. Outbreaks are uncommon, and usually occur in laboratory settings among those workers with significant rodent exposure.

The ubiquitous nature of its reservoir and the large distribution of the reported cases suggest a widespread geographic risk of lymphocytic choriomeningitis virus infection. Serologic surveys in the southern and eastern United States suggest past infection in approximately 3–5% of those tested, although later data from upstate New York showed less than 1% seroprevalence. Infection risk can be reduced by limiting contact with pet rodents and rodent trappings.

► Clinical Findings

A. Symptoms and Signs
The incubation period is 8–13 days to the appearance of systemic manifestations and 15–21 days to the appearance of meningeal symptoms. Symptoms are biphasic, with a
prodromal illness characterized by fever, chills, headache, myalgia, cough, and vomiting, occasionally with lymphadenopathy and maculopapular rash. After 3–5 days the fever subsides only to return after 2–4 days alongside the meningeal phase, characterized by headache, nausea and vomiting, lethargy, and variably present meningeal signs. Arthralgias can develop late in the course. Transverse myelitis, deafness, Guillain–Barré syndrome, and transient and permanent hydrocephalus are reported. Lymphocytic choriomeningitis virus is a well-known, albeit underrecognized, cause of congenital infection frequently complicated with obstructive hydrocephalus and chorioretinitis. In fetuses and newborns with ventriculomegaly or other abnormal neuroimaging findings, screening for congenital lymphocytic choriomeningitis may be considered; mothers are asymptomatic half the time. In over one-third of cases, rodent exposure is reported retrospectively. Occasionally, a syndrome resembling the viral hemorrhagic fevers is described in transplant recipients of infected organs and in patients with lymphoma.

B. Laboratory Findings

Leukocytosis or leukopenia and thrombocytopenia may be initially present. During the meningeal phase, CSF analysis frequently shows lymphocytic pleocytosis (total count is often 500–3000/mcL) alongside a slight increase in protein, while a low to normal glucose is seen in at least 25%. The virus may be recovered from the blood and CSF by mouse inoculation. Complement-fixing antibodies appear during or after the second week. Detection of specific IgM by ELISA is widely used. Detection of lymphocytic choriomeningitis virus by PCR is available in research settings.

Differential Diagnosis

The influenza-like prodrome and latent period may distinguish this from other aseptic meningitides, and bacterial and granulomatous meningitis. A history of exposure to mice or other potential vectors is an important diagnostic clue.

Treatment

Treatment is supportive. In several survivors of transplant-associated outbreaks, ribavirin (which is effective against other arenaviruses) has been used successfully along with decreasing immunosuppression.

Prognosis

Complications and fatalities are rare in the general population. The illness usually lasts 1–2 weeks, though convalescence may be prolonged. Lymphocytic choriomeningitis in solid organ transplant recipients is associated with a poor prognosis; of reported cases, the mortality rate is more than 80%.

Prevention

Pregnant women should be advised of the dangers to their unborn children inherent in exposure to rodents.

More than 200 cases of vCJD (bovine spongiform encephalopathy [BSE] or “mad cow disease”) were reported in the United Kingdom since the first documented cases there in the mid-1990s. It is far less common in North America, with only four cases reported in the United States (the last one in 2015) and two deaths in Canada from definite or probable vCJD. Of the US-reported cases, none are confirmed to have acquired the disease locally (two of them acquired the infection in the United Kingdom, one in Saudi Arabia, one possibly in a Middle Eastern or Eastern European country). This disease is characterized by its bovine-to-human transmission through ingestion of meat from cattle infected with BSE. There is no animal-to-animal spread of BSE, and milk and its derived products are not considered infectious. Reports of secondary transmission of vCJD due to blood transfusions from asymptomatic donors are reported in the United Kingdom. Although iCJD and vCJD are not associated with a known PrP gene mutation, a polymorphism in codon 129 is prevalent and seems to determine susceptibility and expression of clinical disease.

The overall annual incidence of prion disease worldwide is approximately 1–2/1 million person-years. In the United States, among the 4085 cases reported through September 18, 2018, to the US National Prion Disease Pathology Surveillance Center, 3656 (89.5%) were sporadic, 400 (9.8%) familial, 12 (0.3%) iatrogenic, and 4 (0.1%) vCJD. A chronic wasting disease also due to a transmissible spongiform encephalopathic agent is occurring among deer, elk, and moose and has been reported from 24 states including most of Wyoming and parts of Colorado but present in the East and South as well. Although there are no documented of transmission to humans, the CDC recommends refraining from killing bizarrely acting animals, not handling or eating roadkill, and wearing gloves when dressing wild game. Testing for the virus in game animals may be useful, but its efficacy is not established.

Clinical Findings

A. Symptoms and Signs

Both sCJD and fCJD usually present in the sixth or seventh decade of life, whereas the iCJD form tends to occur in a much younger population. Clinical features of these three forms of disease usually involve mental deterioration (dementia, behavioral changes, loss of cortical function) that is progressive over several months, as well as myoclonus and extrapyramidal (hypokinesia) and cerebellar manifestations (ataxia, dystarsia). Finally, coma ensues, usually associated with an akinetic state and less commonly decerebrate/decorticate posturing. Like iCJD, vCJD usually affects younger patients (averaging ~28 years), but the duration of disease is longer (about 1 year). The degree of organ involvement is often extensive, and the clinical symptoms are unique, mainly characterized by prominent psychiatric and sensory symptoms.

B. Laboratory Findings

CJD should be considered as a diagnosis in the proper clinical scenario, in the absence of alternative diagnoses after routine investigations. Abnormalities in CSF are subtle and rarely helpful. The detection of 14-3-3 protein in the CSF is helpful for the diagnosis of sCJD but not in vCJD and fCJD. Its sensitivity and specificity are widely variable among different studies and may be increased with use of tau protein assays. CSF detection of total PrP can differentiate CJD from atypical Alzheimer disease with 82% sensitivity and 91% specificity.

A blood-based assay and PCR in CSF may help with the diagnosis of vCJD with high specificity but 71% sensitivity. The assay as well as 14-3-3 protein assay and a “quaking induced conversion” assay are all available through the National Prion Disease Surveillance Center at Case Western University in Cleveland. Other referral laboratories with variable availability of assays include state health departments, academic centers, and the National Prion Clinics in the United Kingdom. It is also recognized that the presence of a variant with low titers ("very low peripheral prion colonization") in peripheral tissue, including frequently biopsied tonsillar tissue, may be responsible for the underrecognition of vCJD.

Probable diagnosis requires the presence of rapidly progressive dementia plus two of four clinical features (myoclonus, visual or cerebellar signs, pyramidal/extrapyramidal signs, and akinetic mutism) as well as a positive laboratory assay (typical EEG, positive 14-3-3 CSF assay with duration under 2 years) and MRI high signal in the caudate and/or putamen on diffusion-weighted imaging (DWI) or fluid-attenuated inversion recovery (FLAIR) imaging. In sCJD, the EEG typically shows a pattern of paroxysms with high voltages and slow waves, while the MRI is characteristic for bilateral areas of increased signal intensity, predominantly in the caudate and putamen. An MRI can improve early diagnosis of sCJD because clinical findings are often missed. When an experienced neuroradiologist or a prion disease expert reviews the MRI, diagnostic sensitivity of MRI for sCJD increases to 91%.

Differential Diagnosis

Autoimmune encephalitis can have a similar clinical picture. The presence of high titer autoantibodies (eg, to the NMDA receptor) in the CSF is consistent with autoimmune encephalitis.

Treatment & Prevention

There is no specific treatment for CJD. Once symptoms appear, the infection invariably leads to death. Flupirtine (an analgesic drug) is sometimes useful in slowing the associated cognitive decline but does not affect survival. Quinacrine (mepacrine) was evaluated as an oral treatment option but was not shown to improve survival for people with sCJD. Antibodies against PrP is also proposed as a therapeutic strategy. Studies are in progress to identify epitopes for vaccine development, but no promising candidates exist to date.

Iatrogenic CJD can be prevented by limiting patient exposure to potentially infectious sources as mentioned above. Prevention of vCJD relies on monitoring livestock for possible infection. The American Red Cross does not accept blood donations from persons with a family history of vCJD.
Clinical Findings

A. Symptoms and Signs

JCV causes lytic infection of oligodendrocytes in the white matter and symptoms presenting subacutely reflect the diverse areas of CNS involvement. Symptoms include altered mental status, aphasia, ataxia, hemiparesis or hemiplegia, and visual field disturbances. Seizures occur in about 18%. Involvement of cranial nerves and the cervical spine is rare.

B. Laboratory Findings

Quantitative PCR for JCV in CSF is used for diagnosis in patients with compatible clinical and radiologic findings. Persistent JCV viremia and increasing urinary JCV DNA may be predictive of PML. An anti-JCV IgG was higher 6 months before diagnosis but was not predictive of PML in a cohort of HIV-infected persons.

MRI of the brain shows multifocal areas of white matter demyelination without mass effect or, usually, contrast enhancement. These findings may not be distinguishable from IRIS. Increased uptake of methionine with concomitant decreased uptake of fluorodeoxyglucose in positron emission tomography may be helpful for diagnosis. In HIV-infected patients, a syndrome of cerebellar degeneration is described.

Treatment & Prevention

Limiting the immunosuppressed state without inducing an IRIS represents the mainstay of therapy for PML. Treatment of HIV with ART reduces the incidence of PML, improves the clinical symptoms, reverses some of the radiographic abnormalities, and improves the 1-year mortality rate, regardless of baseline CD4 count. Immune recovery can induce worsening of the clinical picture in a small number of cases. Immune reconstitution syndromes do not alter mortality but are associated with a form of PML called non-determined leukoencephalopathy associated with a chemokine polymorphism. Significant neurologic sequelae to PML infections are the rule and deficits may persist for years.

Decreasing immunosuppression in non-AIDS patients with PML (eg, multiple sclerosis or transplant patients) is also important. Cidofovir may be beneficial in non-AIDS-related cases, while corticosteroids may be useful with immune reconstitution. Because the JCV infects cells through serotonin receptors, some clinicians recommend the use of risperidone and mirtazapine. Anecdotal reports show that premature stopping of natalizumab in multiple sclerosis may itself lead to IRIS states. Plasma exchange, which theoretically reduces the plasma level of
agents associated with PML, may be useful in natalizumab-associated PML but is associated with a high risk of IRIS. In kidney transplant patients, a preinduction regimen with IVIG and rituximab and transplantation with lymphocyte-depleted cells appears to reduce the risk of PML. Similarly, titers of JC antibody are not shown to significantly increase prior to clinical onset of PML.

8. Human T-Cell Lymphotropic Virus (HTLV)

HTLV-1 and -2 are retroviruses that infect CD4 and CD8 T cells, respectively, where they persist as a lifelong latent infection. HTLV-1 currently infects approximately 20 million individuals worldwide. It is endemic to many regions in the world including southern Japan, the Caribbean, much of sub-Saharan Africa, South America, Eastern Europe, and Oceania. The Caribbean basin and southwestern Japan show the highest prevalence of infection (4–37%). Conversely, HTLV-2 is mainly found in native populations of South (1–58%), Central (8–10%), and North America (2–13%) as well as African pygmy tribes. In some areas of Africa (eg, Malawi), HTLV-2 seroprevalence is higher than HTLV-1 seroprevalence.

In the United States, studies done in blood donors show a seroprevalence of HTLV-1 of 0.005% and HTLV-2 of 0.014%, a decline since the early 1990s. The virus is transmitted horizontally (sex), vertically (intrauterine, peripartum, and prolonged breastfeeding), and parenterally (injection drug use and blood transfusion). Hence, a higher prevalence is seen among injection drug users. Coinfection with HIV-1 occurs but is often underrecognized. Transmission via organ transplant has been reported. Disease may flare when biologic agents are used for rheumatoid conditions.

Clinical Findings

A. Symptoms and Signs

HTLV-1 infection is associated with HTLV-1 adult T-cell lymphoma/leukemia (ATL) and HTLV-1 associated myelopathy/tropical spastic paraparesis (HAM/TSP). In contrast, HTLV-2 is significantly less pathogenic, with few reported cases of HAM/TSP as well as other neurological manifestations. The causative association of HTLV-1 with ATL, attributed to the virally encoded oncoprotein tax, is well established. The lifetime risk of developing ATL among seropositive persons is estimated to be 3% in women and 7% in men, with an incubation period of at least 15 years. The mean age at diagnosis of ATL is 40–50 years in Central and South America and 60 years in Japan.

ATL clinical syndromes may be classified as chronic, acute (leukemic), smoldering, or lymphomatous. A primary cutaneous tumor is also described and shows a worse prognosis compared with the smoldering type. Clinical features of ATL include diffuse lymphadenopathy, maculopapular skin lesions that may evolve into erythroderma, a bronchoalveolar disorder, organomegaly, lytic bone lesions, and hypercalcemia. Opportunistic infections, such as P jirovecii pneumonia and cryptococcal meningitis, are common.

HAM/TSP, associated with both HTLV-1 and HTLV-2, develops in 0.3–4% of seropositive individuals and is more common in women and in older individuals. A chronic inflammation of the spinal cord leads to intense and progressive motor weakness and symmetric spastic paraparesis, bilateral facial palsies, falls, nociceptive low back pain, and paraplegia with hyperreflexia. Bladder and sexual disorders (eg, dyspareunia, erectile dysfunction), sensory disturbances, and constipation are also common. Both viruses can also induce motor abnormalities, such as leg weakness, impaired tandem walk, and vibration sense, without overt HTLV-associated myelopathy.

HTLV-1 seropositivity is associated with an increased risk of tuberculosis, Strongyloides stercoralis hyperinfection, crusted scabies, and infective dermatitis. Inflammatory states associated with HTLV-1 infection include arthropathy, recurrent facial palsies, polymyositis, uveitis, and sicca, but inconsistently Sjögren syndrome, vasculitis, cryoglobulinemia, infiltrative pneumonitis, and ichthyosis. Bronchioloalveolar carcinoma is increased in frequency in the presence of HTLV-1.

HTLV-2 appears to cause a myelopathy that is milder and slower to progress than HAM. All-cause and cancer mortality are higher among HTLV-2 seropositive patients.

HTLV-1/HIV coinfection is associated both with higher CD4 counts and a higher risk of HAM.

B. Laboratory Findings

The peripheral smear can show atypical lymphoid cells with basophilic cytoplasm and convoluted nuclei (flower cells) but the diagnostic standard is evidence of clonal integration of the proviral DNA genome into tumor cell. The identification of HTLV-1 antibodies supports the diagnosis. Serum neopterin levels may indicate disease activity. An HTLV-1 provirus load in peripheral blood mononuclear cells and CSF cells and an HTLV-1 mRNA load are proposed as markers of HAM risk and progression. HTLV positivity is associated with erythrocytosis, lymphocytosis (HTLV-2), and thrombocytosis (HTLV-1).

Treatment, Prevention, & Prognosis

No vaccine or antiviral therapy currently exists for the prevention and treatment of HTLV infections. Management of ATL consists mainly of chemotherapy, with allogeneic stem cell transplantation and the use of monoclonal antibodies (anti-CCR4 and anti-CD25). A chemotherapy regimen in Japan using eight different agents shows a higher response rate than traditional biweekly CHOP (40% vs 25%). Combination therapy with interferon-alpha has been used with success. Nivolumab is being studied as a novel therapy. Prophylaxis against infections is needed in ATL because patients show a profound
immunodeficiency. Patients who are coinfected with HIV-1 and HTLV reportedly do respond to ART for HIV. HAM is treated with a variety of immune-modulating agents (including corticosteroids) without consistent results. Combination therapy with antiretrovirals does not show benefit, although several trials evaluating raltegravir alone or in combination with zidovudine are underway. Interferon-alpha may be of some efficacy. A significant response is reported with the combined regimen of prednisolone, pegylated interferon, and sodium valproate. Clinical trials also are currently underway to assess the efficacy of pentoxifylline, cyclosporine, and the retinoid tamibarotene in the treatment of HAM. Small, uncontrolled studies suggest plasmapheresis results in improvement in gait and sensory disturbance among some patients and improvement in muscle pain with pulsed methylprednisolone. In general, however, no agent is effective.

Screening of the blood supply for HTLV-1 is required in the United States. There is significant cross-reactivity between HTLV-1 and HTLV-2 by serologic studies, but PCR can distinguish the two. Improved assays to screen organ donors for HTLV-1 and -2 infections are needed, although such screening is not currently required.

**VIRAL HEMORRHAGIC FEVERS**

**1. Ebola Viral Disease (EVD)**

**ESSENTIALS OF DIAGNOSIS**

- **Early stage EVD:** a nonspecific febrile illness.
- **Later stage EVD:** severe gastrointestinal symptoms, then neurologic symptoms and hypovolemic shock.
- Hemorrhagic manifestations are late manifestations.
- Uveitis is a prominent ocular finding.
- Travel and contact history from an Ebola-affected country raise suspicion.
- Virus is detected with a real-time RT-PCR.

**General Considerations**

Genus *Ebolavirus* is a single-stranded RNA virus in the Filoviridae family. Four different species of *Ebolavirus* have been identified to cause human disease. Fruit bats are possible reservoir for *Ebolavirus*. Zoonotic transmission to humans occurs via contact with the reservoir or an infected primate. *Ebolavirus* can continue to be transmitted among humans who have direct contact with infected body fluids. To acquire EVD, the virus must enter the body via mucous membranes, nonintact skin, sexual intercourse, breastfeeding, or needlesticks. Traditional burial practices in Africa (which entail considerable contact with the corpse) and unprotected direct care of persons with EVD are associated with highest transmission risk. *Ebolavirus* has been detected in semen up to 9 months after recovery from infection.

EVD has a 2–21-day incubation period. Prior to manifestation of symptoms, *Ebolavirus* is not transmissible. Even at symptom onset, the risk of transmission is low but increases over time.

The first Ebola outbreak occurred in 1976 as a simultaneous epidemic in the Democratic Republic of Congo and South Sudan. Subsequent outbreaks were confined to the Democratic Republic of Congo, Uganda, and Sudan until March 2014 when the first Ebola case in West Africa was identified in Guinea. *Zaire ebolavirus* was the associated species. This Ebola outbreak grew to be larger than all prior Ebola outbreaks combined. The number of EVD cases spread rapidly; there were at least 10 affected countries, especially Guinea, Liberia, and Sierra Leone. Many cases and deaths in these countries occurred among healthcare workers. In the United States, 11 persons were treated for Ebola. Most were healthcare workers who were evacuated to the United States and 4 patients were diagnosed in the United States. Sierra Leone contained its last EVD outbreak to the United States and 4 patients were diagnosed in the United States. Sierra Leone contained its last EVD outbreak as of March 2016. Guinea was declared free of EVD transmission in June 2016. Liberia declared the end of its last outbreak in June 2016. The WHO reports that the West African Ebola outbreak was associated with 28,616 cases and 11,310 deaths during the approximately 2-year interval of the outbreak between March 2014 and March 2016.

Two outbreaks were reported in May and August of 2018, both in the Democratic Republic of Congo (where outbreaks also were reported in 2014 and 2017), and while the isolates from the two outbreaks were both the same species, complete genetic homogeneity between the isolates was not present. As of December 11, 2018, 505 probable and confirmed cases (and 296 deaths) were reported from 12 health zones in the two provinces of the Democratic Republic of Congo impacted with EVD, including 51 cases (and 17 deaths) among health care workers. In total, 10 outbreaks of Ebola have occurred in Africa since 1976.

**Clinical Findings**

**A. Symptoms and Signs**

At symptom onset, early-stage EVD most typically presents as a nonspecific febrile illness. Along with fever, patients tend to experience headache, weakness, dizziness, malaise, fatigue, myalgia, and arthralgia. After 3–5 days, patients...
with later stage EVD may develop abdominal pain, severe nausea, vomiting, and diarrhea accompanying the febrile illness. This stage of the illness may continue for a week during which time neurologic symptoms gain prominence. Encephalitis is commonly observed and manifested as confusion, slowed cognition, agitation, and occasional seizures. Shock develops in most patients, but hemorrhagic manifestations develop in only 1–5% of patients. Respiratory symptoms are not typical for EVD, although interstitial pneumonia and respiratory failure are reported.

### B. Laboratory Findings

During the first few days of symptoms, diagnosis may be made via several modalities, including antigen-capture ELISA, IgM ELISA, RT-PCR, or virus isolation. Blood samples obtained within the first 3 days of illness and tested by RT-PCR should be repeated if results are negative and clinical symptoms and signs persist. RNA levels peak a median of 7 days after illness onset. Later in the disease course or after recovery, IgM and IgG serologic tests may be sent. After about 10 days, IgM antibodies begin to develop, and, after approximately 2 weeks, an IgG antibody response develops. Postmortem diagnosis may be made by using immunohistochemistry, RT-PCR, or virus isolation.

Given that filoviruses infect dendritic cells and then hepatocytes and renal cortical cells, laboratory findings typically include a low platelet count (and a thrombotic thrombocytopenic purpura syndrome has been postulated with the probable cause multifactorial), leukopenia, and transaminitis (aspartate aminotransferase [AST] greater than alanine aminotransferase [ALT]). Additional observed laboratory abnormalities include hypoalbuminemia, electrolyte imbalance, and increased serum creatinine level. Elevated blood urea nitrogen, AST, and creatinine upon presentation are associated with higher mortality.

### Differential Diagnosis

The differential diagnosis varies with the stage of illness. Early-stage EVD is commonly mistaken for malaria, typhoid, and other viral illnesses. As gastrointestinal symptoms develop, health providers should also consider viral hepatitis, toxins, leptospirosis, and rickettsial diseases. In later stage EVD, bacterial, viral, and parasitic illnesses, including cholera and, in children, rotavirus infection can present with severe gastroenteritis and shock. Encephalitis must be differentiated from the confusion associated with uremia. Hemorrhagic manifestations raise suspicion for EVD but could be due to leukemia, thrombotic thrombocytopenic purpura, hemolytic-uremic syndrome, or disseminated intravascular coagulation. Travel and contact history are crucial when considering the differential diagnosis in areas where Ebola is not endemic.

### Complications

Hypovolemic shock and multiorgan failure are the most common complications of EVD. Hemorrhage can occur in late stages. Rhabdomyolysis is reported frequently and may explain many of the associated laboratory abnormalities. Coinfections with malaria or bacteria (or both) are important considerations and can occur before presentation and during treatment of EVD. The virus is known to persist in immunologically privileged sites, such as the CNS, eye, and testes; however, viral relapse is uncommon. Post-EVD musculoskeletal pain, headache, auditory symptoms, and ocular symptoms (uveitis being the most common ocular finding) may develop. EVD survivors exhibit high rates of neuropsychological long-term sequelae including depression, anxiety, and posttraumatic stress disorder.

### Treatment

Treatment is supportive. Several studies have shown that intravenous fluids can reduce the mortality rates to less than 50%. Despite the wide availability of oral rehydration salts, mortality approximates 70% in endemic areas. In these studies, the amount of intravenous fluid replacement was relatively less than what would be used in countries with developed health systems. Among patients treated in the United States or Europe, almost all received intravenous fluids, electrolyte supplementation, and empiric antibiotic therapy. Invasive or noninvasive mechanical ventilation and continuous renal replacement therapy are necessary in many cases. This increased level of care likely contributed to the decreased mortality (19%) among these patients. The use of individual air-conditioned biosecure cubicles is preferred to the burdensome protective equipment used during the 2014 West African outbreaks and allows for more time spent with patients.

There are no approved medications for the treatment of EVD, although five agents were available for compassionate use in a Congolese EVD outbreak. Administration of convalescent plasma does not result in improved survival. Several drugs have advanced to clinical trials; however, some trials were terminated due to low enrollment or lack of efficacy. The tested monoclonal antibodies were MAb114 (a first-generation agent isolated from a survivor of the 1995 outbreak in the Congo), ZMapp, and REGN-EB3. ZMapp is an antiviral monoclonal antibody combination developed against *Zaire ebolavirus*. ZMapp showed some therapeutic benefit, but many of these patients received multiple agents and were not part of randomized controlled trials. The PREVAIL II study evaluated ZMapp for treatment of EVD and found it to be safe and well tolerated but failed to establish efficacy due to low enrollment numbers. REGN-EB3 is given as a single dose, does not require freezing, and shows efficacy in nonhuman primates, including reduction in mortality.

The two antivirals utilized in a recent outbreak were the nucleotide analog remdesivir (GS-5734) and the RNA-dependent RNA polymerase inhibitor favipiravir. Mathematical models show a high likelihood of efficacy for both agents against EVD if given within 3–4 days of infection, and the efficacy of remdesivir is theoretically 100% while that of favipiravir is 60%. Both agents are effective in nonhuman primates and one study in man found favipiravir to be effective in patients with low to moderate viremia.

Aside from supportive treatment and experimental therapeutics, patients typically receive empiric antimarial agents in endemic areas and broad-spectrum antibiotics.
Prognosis

Children under 5 years of age and adults older than 40 have a high risk of death from EVD. Pregnancy is a risk factor for severe illness and death. In the 2014–2016 outbreak, the average maternal mortality was 86%. Immunosuppressed patients had shorter incubation time, rapid progression of disease, and poor outcomes. A higher baseline viral load was strong predictor of mortality. In general, poor overall medical care confers a poor prognosis. Among survivors, protective antibodies persist for at least 10 years.

Prevention

Risk reduction should focus on preventing wildlife to human transmission and reducing human to human transmission by surveillance, early detection and isolation of cases, contact tracing, containment measures (disinfection, hygiene, and sanitation), strict droplet and contact precautions in health care setting, and reduction of sexual transmission in Ebola survivors. The WHO recommends that men avoid sexual activity or use barrier protection during intercourse for 12 months from onset of symptoms or until their semen tests negative twice for Ebola virus.

The experimental recombinant vesicular stomatitis virus (rVSV)-based vaccine expressing Zaire ebolavirus (ZEOB) glycoprotein is found to be highly effective in disease prevention after 10 days from receiving the vaccine. Side effects, such fever, myalgia, chills, fatigue, headaches, and oligo-arthritis, developed in most of the persons who received the vaccine. A phase III clinical trial to evaluate the safety and immunogenicity of rVSV-ZEOB has shown promising results (most study participants have persistent antibody levels at 1 year; NCT02503202). A chimpanzee type 3 adenovirus vaccine is also under evaluation (NCT03140774). More than 12,000 persons were vaccinated with the glycoprotein vaccine in the most recent Congolese outbreak. Final efficacy data for this and the earlier Equateur outbreaks in the Democratic Republic of Congo are pending.

Risk stratification may be useful in deciding when and to whom to administer antiviral postexposure prophylaxis. A high-risk exposure is defined as penetrating sharps injury from used device or through contaminated gloves or clothing, direct contact with an infected patient (alive or deceased) or their bodily fluids with broken skin or mucous membranes such as eyes, nose, or mouth. The ZEOB vaccine was used in the setting of postexposure prophylaxis among healthcare workers and found to be effective, but the evidence is limited to case series. In addition, the vaccine designed against Zaire ebolavirus might not be effective for infection with other species. The vaccine-mediated immunity requires an average of 10 days to develop and might not be fast enough in certain cases to prevent infection.

Current studies focus on isolation of cross-reactive monoclonal antibodies across Ebola virus species. The use of different preparations of combination monoclonal antibodies (ZMapp and MIL-77E) as postexposure prophylaxis during the West African outbreak failed to show statistical significance, and the conclusion was that the benefit was modest, at best. Newer forms of monoclonal antibodies include virus-like particles (VLP), mucin-deleted glycoproteins, and bispecific binding proteins (which bind Ebola proteins as well as those of related viruses such as the Sudan virus). The use of antiviral agents in postexposure prophylaxis is another alternative that, to date, also shows no clear survival benefit. The agent brincidofovir, for example, was not studied further because of inadequate sample size in Liberia.

When to Admit

Persons living in or returning from a country with high rates of Ebola transmission should be monitored for 21 days and admitted to a health care facility when symptoms meeting the WHO case definition of a suspected EVD case develop, in accordance with the screening protocol designated by the respective country’s governmental health decision-making body.

2. Other Hemorrhagic Fevers

This diverse group of illnesses results from infection with one of several single-stranded RNA viruses (members of the families Arenaviridae, Bunyaviridae, Filoviridae, and Flaviviridae). Flaviviruses, such as the pathogens causing dengue and yellow fever, and Filoviridae, causing EVD, are discussed in separate sections.

Lassa fever is a rodent-associated disease caused by an Old-World arenavirus. Rodents shed the virus in urine and droppings and transmit the virus to humans either by direct contact with these materials, ingestion, or inhalation of aerosolized particles. Lassa fever is mostly endemic in West Africa. Other arenaviruses include the Junin virus (cause of Argentinian hemorrhagic fever) and the Lujo virus. Lujo virus was first described in 2008 in Zambia where it caused a small cluster of nosocomial infections.

The bunyaviruses include hantaviruses (discussed separately). Crimean Congo hemorrhagic fever (CCHF) is a disease transmitted from ticks and livestock. Human-to-human transmission can occur in the community or hospital setting by contact with infected body secretions.
The geographic distribution is widespread with cases reported from Africa, Asia, the Middle East, and Eastern Europe, with increased incidence recently in the East Mediterranean region. Butchers and slaughterhouse workers in southeastern Iran are at high risk for infection with the CCHF pathogen. Turkey reported the largest outbreak yet in 2002, with nearly 10,000 recorded cases.

Rift Valley fever is transmitted from livestock animals, infected mosquitoes, and flies. To date, there is no human-to-human transmission. Risk factors for acquiring Rift Valley fever include working with abortive animal tissue; slaughtering, skinning, or sheltering animals; and drinking unpasteurized milk. Rift Valley fever causes outbreaks in Africa, Madagascar, and the Arabian Peninsula.

A new bunyavirus, a phlebovirus, was identified in 2010 in central and northeastern China and was named for its symptoms: severe fever with thrombocytopenia syndrome (SFTS) virus. SFTS is transmitted by tick bite (Ixodidae family, including the newly discovered tick Haemaphysalis longicornis, which is found in Asia as well as among animals [rarely humans] in the eastern United States). It may also be transmitted between humans through direct contact with infected blood or secretions. Another virus (Heartland virus), identified in the United States, is similar to the SFTS virus. Transmission occurs via the Lone Star tick (Amblyomma americanum). The virus appears to be amplified in deer and raccoons. In the United States, most cases are reported from the Midwest and southern states.

Clinical Findings

A. Symptoms and Signs

The incubation period varies between species, ranging from 2 to 21 days. The clinical symptoms in the early phase of a viral hemorrhagic fever are indistinguishable from other viral illnesses. Due to lack of specific symptoms on presentation, viral hemorrhagic fevers are an important cause to consider in fever of unknown origin in children in endemic areas. The late phase is more specific and is characterized by organ failure, altered mental status, and hemorrhage. Exanthems and mucosal lesions can occur.

In advanced stages, significant edema, pleural effusion, and fewer hemorrhagic manifestations compared with EVD can develop in patients with Lassa fever and Lujo virus infection. Hearing loss in various degrees is the most common complication of Lassa fever infection. Mortality in pregnant patients during the third trimester and fetal mortality are very high.

CCHF has more prominent hemorrhagic manifestations. Patients have red eyes, flushed face, red throat, and petechiae that progress to severe uncontrollable bleeding. Severe headaches are common in CCHF and correlate with the severity of vascular damage, vasodilatation, and cytokine release.

Rift Valley fever disease can present with three distinct syndromes: (1) ocular disease; retinitis is the most common complication and permanent vision loss develops in 1–10% of patients; (2) meningoencephalitis occurs in less than 1% of cases; these patients have headache, coma, or seizures 1–4 weeks after initial symptoms and a low mortality but a high morbidity with neurologic deficits that can be severe; and (3) a hemorrhagic fever form in which patients present 2–4 days after illness and show evidence of severe liver impairment and later hemorrhages; the hemorrhagic state occurs in less than 1% of patients, but the case-fatality ratio of such patients reaches about 50%.

B. Laboratory Findings

Laboratory features usually include thrombocytopenia, leukopenia (although with Lassa fever leukocytosis is noted), anemia, elevated liver biochemical tests, and abnormalities consistent with disseminated intravascular coagulation.

Special care should be taken for handling clinical specimens of suspected cases. Laboratory personnel should be warned about the diagnostic suspicion, and the CDC must be contacted for guidance. The diagnosis may be made by antigen detection (by ELISA), culture of the virus (the “gold standard” for Lassa virus diagnosis), PCR, or demonstration of a fourfold rise in antibody titer. CCHF is best diagnosed with an IgM serology, although IgG ELISA or immunofluorescence and quantitative RT-PCR are nearly as effective. Isolation of the viruses in culture requires a biosafety level 4 laboratory. Serologic assays are attendant with early false-negative and late false-positive assays.

Differential Diagnosis

The differential diagnosis for hemorrhagic fever includes meningococcemia or other septicemias, Rocky Mountain spotted fever, dengue, typhoid fever, and malaria. SFTS differential diagnosis includes anaplasmosis, hemorrhagic fever with renal syndrome, or leptocephrosis. The likelihood of acquiring hemorrhagic fevers among travelers is low.

Treatment & Prevention

Patients should be placed in private rooms with standard contact and droplet precautions. Barrier precautions to prevent contamination of skin or mucous membranes should also be adopted by the caring personnel. Airborne precautions should be considered in patients with significant pulmonary involvement or undergoing procedures that stimulate cough.

Supportive care is the mainstay of therapy. There is no approved antiviral medication, but ribavirin is shown to be effective in vitro and in vivo against certain viruses (Lassa virus, CCHF, and Rift Valley fever pathogens). Early diagnosis and management can reduce mortality.

The efficacy for postexposure ribavirin in the management of Lassa fever, other arenaviruses, or CCHF remains anecdotal. The antitrypanosomal agent suramin may be effective against the Rift Valley fever virus. Sorafenib, a tyrosine kinase inhibitor approved for treatment of renal cell and hepatocellular carcinoma, has antiviral activity against Rift Valley fever virus. A combination of monoclonal antibodies that cross-react with the glycoproteins of Lassa virus have been tested in macaques with promising results.

An inactivated vaccine is available for Rift Valley fever but is not licensed and is not commercially available. There are no vaccines approved for other viruses causing viral infections.
hemorrhagic fever. A DNA vaccine against CCHF is developed and shows high humoral immune responses with significant protection in mouse models. A vaccine is also under development in Argentina for Argentinian hemorrhagic fever.

**When to Admit**

- Persons with symptoms of any hemorrhagic fever and who have been in possible endemic area should be isolated for diagnosis and symptomatic treatment.
- Isolation is particularly important because diseases due to some of these agents, such as Lassa virus, are highly transmissible to health care workers.

### Clinical Findings

**A. Symptoms and Signs**

A history of travel to a dengue-endemic area within 14 days of symptom onset is helpful in establishing a diagnosis. Most infected patients are asymptomatic. Only 20% develop symptoms ranging from mild disease (dengue fever) to severe hemorrhagic fever to fatal shock (dengue shock syndrome). In 2009, the WHO classified dengue as a viral hemorrhagic fever. Aedes mosquito is common in the southern states, outbreaks are uncommon. Most cases occur in travelers, immigrants, or inhabitants of US territories that are endemic to the dengue virus. Puerto Rico experiences periodic large outbreaks. In 2015 and 2016, an outbreak of locally acquired cases of dengue fever was reported from Hawaii where 264 dengue patients were identified with 46 (17.4%) of the cases among children; all cases were serotype 1.

The incubation period is usually 7–10 days. When the virus is introduced into susceptible populations, usually by viremic travelers from endemic countries, epidemic attack rates range from 50% to 70%.

**3. Dengue**

**Incubation period** 7–10 days.

- **Sudden onset of high fever, chills, severe myalgias and arthralgias, headache, and retroorbital pain.**

- **Severe dengue** is defined by the presence of plasma leakage, hemorrhage, or organ involvement.

- **Signs of hemorrhage** such as ecchymoses, gastrointestinal bleeding, and epistaxis appear later in the disease.

**General Considerations**

Dengue virus belongs to the genus *Flavivirus* and has four distinct serotypes that can cause infection. Infection with one serotype does not confer immunity to the other serotypes. Dengue is transmitted primarily from human to human by the bite of the *Aedes* mosquito. Healthcare-associated transmission (needlestick or mucocutaneous exposure) and vertical transmission occur rarely. WHO reports that dengue is currently endemic in 128 countries, mostly in tropical and subtropical regions with 3.9 billion persons at risk for infection. An estimated 390 million cases of dengue fever occur annually (with 96 million manifesting clinical disease including at least 500,000 with severe disease and up to 20,000 deaths). The surge of cases is associated with climatic factors, travel, and urbanization. Thus, along with malaria, dengue is one of the two most common vector-borne diseases of humans. Dengue is also the second overall cause of a febrile illness (after malaria and excluding common upper respiratory viral infections) in travelers returning from developing countries.

There are several factors that contribute to intermittent outbreaks in these regions, including the season of the year when rainfall is optimal for mosquito breeding, presence of a large population with no previous immunity to the specific serotype, and frequent contact between people and the vector.

In the United States, even though dengue is endemic in Northern Mexico and the *Aedes* mosquito is common in the southern states, outbreaks are uncommon. Most cases occur in travelers, immigrants, or inhabitants of US territories that are endemic to the dengue virus. Puerto Rico experiences periodic large outbreaks. In 2015 and 2016, an outbreak of locally acquired cases of dengue fever was reported from Hawaii where 264 dengue patients were identified with 46 (17.4%) of the cases among children; all cases were serotype 1.

The incubation period is usually 7–10 days. When the virus is introduced into susceptible populations, usually by viremic travelers from endemic countries, epidemic attack rates range from 50% to 70%.

**When to Admit**

- Persons with symptoms of any hemorrhagic fever and who have been in possible endemic area should be isolated for diagnosis and symptomatic treatment.

- Isolation is particularly important because diseases due to some of these agents, such as Lassa virus, are highly transmissible to health care workers.

**Clinical Findings**

**A. Symptoms and Signs**

A history of travel to a dengue-endemic area within 14 days of symptom onset is helpful in establishing a diagnosis. Most infected patients are asymptomatic. Only 20% develop symptoms ranging from mild disease (dengue fever) to severe hemorrhagic fever to fatal shock (dengue shock syndrome). In 2009, the WHO classified dengue as the following: dengue without warning signs; dengue with warning signs; and severe dengue.

After the incubation period, the febrile phase begins abruptly with nonspecific symptoms, high fever, chills, facial flushing, malaise, retroorbital eye pain, generalized body pain, and arthralgia. Some patients might have maculopapular rash, sore throat, and conjunctival injection. Not all patients have all symptoms or fever. Mild hemorrhagic manifestations can be seen. Most of the patients will recover, and fever is usually cleared by day 8.

A subset of patients, especially those with suboptimally controlled type 2 diabetes, may progress to severe dengue, which is defined by the presence of plasma leakage, hemorrhage, or organ involvement. Hematocrit drop may be the earliest sign and an indicator of the severity of plasma leakage. Pleural effusion and ascites can develop and may be detected by lateral decubitus chest radiograph or ultrasound before clinical detection. Increasing liver size, persistent vomiting, and severe abdominal pain are indications of plasma leakage. Signs of hemorrhage such as ecchymoses, gastrointestinal bleeding, and epistaxis appear. Severe organ involvement may develop, such as hepatitis, encephalitis, and myocarditis.
Shock develops in patients when a critical volume of plasma is lost through leakage. Decrease in the level of consciousness, hypothermia, hypoperfusion resulting in metabolic acidosis, progressive organ impairment, and disseminated intravascular coagulation leading to severe hemorrhage should raise concern for shock. Acute kidney injury in dengue largely occurs with shock syndrome and shows a high mortality.

**B. Laboratory Findings**

Leukopenia is characteristic, and elevated transaminases are found frequently in dengue fever. Thrombocytopenia, fibrinolysis, and hemococoncentration occur more often in the hemorrhagic form of the disease. In other forms of disease, especially in children, anemia is more common. The erythrocyte sedimentation rate (ESR) is often normal in most cases.

The nonspecific nature of the illness mandates laboratory verification for diagnosis, usually with IgM and IgG ELISAs after the febrile phase. Virus is recovered from the blood by PCR or detection of the specific viral protein NS1 by ELISA during the first few days of infection. Immunohistochemistry for antigen detection in tissue samples and dried blood spots can also be used. Thrombocytopenia in remote settings can be assessed with a tourniquet cuff test.

**Differential Diagnosis**

Distinguishing between dengue and other causes of febrile illness in endemic areas is difficult. Fevers due to dengue are more often associated with neutropenia and thrombocytopenia and with myalgias, arthralgias/arthritis, and lethargy among adults. Chikungunya is more apt to develop a chronic arthritis. The arboviral encephalitides require additional epidemiologic information and serologic data to make the diagnosis. Influenza and malaria are easily confused early in disease, although the rhinitis and malaise should help distinguish influenza, and the cyclicity of fevers and presence of splenomegaly should suggest malaria.

**Complications**

Usual complications include pneumonia, bone marrow failure, hepatitis, iritis, retinal hemorrhages and maculopathy, orchitis, and oophoritis. Neurologic complications (such as encephalitis, Guillain-Barré syndrome, phrenic neuropathy, subdural hematoma, cerebral vasculitis, and transverse myelitis) are less common. Acute disseminated encephalomyelitis has been linked with infection and vaccination. Bacterial superinfection can occur. Oral complications include acute gingivitis, palatal bleeding, tongue plaques, xerostomia, and rarely osteonecrosis of the jaw.

Maternal infection poses a risk of hemorrhage in both the mother and the infant if infection occurs near term. Severe dengue is a risk factor for obstetric complications, cesarean delivery, fetal distress, and maternal morbidity.

**Treatment**

There are no specific therapeutic options for the clinical management of dengue besides supportive care. Treatment entails the appropriate use of volume replacement, blood products, and vasopressors. Acetaminophen is recommended for analgesic and antipyretic treatment. NSAID usage should be minimized and preferably avoided to decrease the risk of gastritis and bleeding, particularly in patients with a predilection for hemorrhage or when there are abnormalities in platelet, liver function, or clotting factors.

Platelet counts do not usefully predict clinically significant bleeding. Platelet transfusions may be considered for severe thrombocytopenia (less than 10,000/mcL) or when there is evidence of bleeding. However, benefit in the absence of bleeding may not be observed, and harm may be caused by delay in count recovery. Monitoring vital signs and blood volume may help in anticipating the complications of dengue hemorrhagic fever or shock syndrome.

Repurposed drugs, such as chloroquine, statins, and balapiravir, are being explored for the treatment of dengue, although none has shown clear therapeutic benefit. New research is focusing on monoclonal antibodies as a therapeutic option as well as drugs including peptide agents that target structural and nonstructural proteins of dengue virus essential to its replication.

**Prognosis**

Although fatalities occur with severe disease, the estimated mortality (2.5% of severe cases) appears to be diminishing, likely due to improved recognition of the disease and wider availability of supportive treatment. Causes of death include hemorrhagic fever (seen with recurrent disease) and occasionally fulminant hepatitis. Thrombocytopenia and acute hepatitis are predictors of severe dengue and higher mortality. Acute kidney injury in dengue shock syndrome portends poor prognosis. In general, the more advanced forms of disease (hemorrhagic fever and shock) occur more often in Asia than in Americas. Comorbidities of cardiovascular disease, diabetes, stroke, pulmonary disease, kidney disease, and older age are associated with more severe dengue.

**Prevention**

Preventive measures should be encouraged, such as control of mosquitoes by screening and insect repellents including long-lasting insecticides, particularly during early morning and late afternoon exposures. Screening blood transfusions for dengue is of increasing importance, especially in endemic areas.

Dengvaxia, a recombinant, live, attenuated, tetravalent dengue vaccine (CYD-TDV), is the first vaccine to be approved and is now licensed for use by 19 regulatory authorities. Trials evaluating the efficacy of this vaccine reported overall 60% efficacy; however, efficacy was lower in younger age groups, seronegative individuals at the time of vaccination, and those infected with dengue serotype 2. The vaccine is given as a 0-, 6-, and 12-month series. Serious side effects were no more common than in placebo recipients. Vaccination is indicated for those between ages 9 and 45 years. Some investigators recommend limiting the vaccine to those who have prior exposure because of immune enhancement, and recommend community vaccination only when serosurveys document seropositivity.
levels of at least 70%. Pregnant women and immunosuppressed persons should not be vaccinated.

Lee IK et al. Diabetic patients suffering dengue are at risk for development of dengue shock syndrome/severe dengue: emphasizing the impacts of co-existing comorbidity(ies) and glycemic control on dengue severity. J Microbiol Immunol Infect. 2018 Jan 31. [Epub ahead of print] [PMID: 30146413]

4. Hantaviruses

**ESSENTIALS OF DIAGNOSIS**

- Transmitted by rodents and cause two clinical syndromes.
- Hemorrhagic fever with renal syndrome (HFRS): mild to severe illness.
- Hantavirus pulmonary syndrome (HPS): 40% mortality rate.

**General Considerations**

Hantaviruses are enveloped RNA bunyaviruses naturally hosted in rodents, moles, and shrews. Hantavirus infection in humans can cause several disease syndromes. HFRS is primarily caused by Dobrava–Belgrade virus, Puumala virus, Seoul virus, and Hantaan virus in Asia and Europe; these viruses are called Old World hantaviruses. Nephropathia epidemica is a milder form of HFRS. Puumula virus is the most prevalent pathogen and is present throughout Europe. The HPS, also known as hantavirus cardiopulmonary syndrome, is caused mainly by Sin Nombre virus and Andes virus, the New World Hantaviruses in Americas. While they share many clinical features, a specific strain is not associated with a specific syndrome and overlap is seen between the syndromes.

A total of 728 cases of hantavirus infection were reported between 1993 and January 27, 2017. A total of 33 cases were reported in 2017 and 3 cases were reported in 2018.

Aerosols of virus-contaminated rodent urine and feces are thought to be the main vehicle for transmission to humans. Person-to-person transmission is observed only with the Andes virus. Occupation is the main risk factor for transmission of all hantaviruses: animal trappers, forestry workers, laboratory personnel, farmers, and military personnel are at highest risk. Climate change appears to be impacting the incidence of hantavirus infection mainly through effects on reservoir ecology.

**Clinical Findings**

**A. Symptoms and Signs**

Vascular leakage is the hallmark of the disease for both syndromes, with kidneys being the main target with variants associated with HFRS and the lungs with variants associated with HPS.

HFRS manifests as mild, moderate, or severe illness depending on the causative strain. A 2- to 3-week incubation period is followed by a protracted clinical course, typically consisting of five distinct phases: febrile period, hypotension, oliguria, diuresis, and convalescence phase. Various degrees of renal involvement are usually seen, occasionally with frank hemorrhage. Disseminated intravascular coagulation and thromboembolic phenomena are recognized complications. Pulmonary edema is not typically seen but when present usually occurs in the final stages of disease (oliguric and diuretic phase). Encephalitis and pituitary involvement are rare findings with hantavirus infection, although a few cases are reported with Puumula virus. Patients may have persistent hematuria, proteinuria, or hypertension up to 35 months after infection. Smoking appears to exacerbate the viremia with the Puumula variant of HFRS.

The clinical course of HPS is divided into a febrile prodrome, a cardiopulmonary stage, oliguric and diuretic phase, followed by convalescence. A 14- to 17-day incubation period is followed by a prodromal phase, typically lasting 3–6 days, that is associated with myalgia; malaise; abdominal pain along with nausea, vomiting, and diarrhea; headache; chills; and fever of abrupt onset. An ensuing cardiopulmonary phase is characterized by the acute onset of pulmonary edema. In this stage, cough is generally present, abdominal pain and symptoms as above may dominate the clinical presentation, and in severe cases, significant myocardial depression occurs. Acute kidney injury and myositis may occur. Sequelae include neuropsychological impairments in some HPS survivors.

**B. Laboratory Findings**

Laboratory features include hemoconcentration and elevation in lactate dehydrogenase, serum lactate, and hepato-cellular enzymes. Early thrombocytopenia and leukocytosis (as high as 90,000 cells/ml in HPS) are seen in both HFRS and HPS. In HPS, immunoblasts (activated lymphocytes with plasmacytoid features) can be seen in blood, lungs, kidneys, bone marrow, liver, and spleen.

An indirect fluorescent assay and enzyme immunoassay are available for detection of specific IgM or low-avidity IgG virus-specific antibodies. A quantitative RT-PCR is available; however, the viremia of human hantavirus infections is short-term, and therefore, viral RNA cannot be readily detected in the blood or urine of patients unless for the more readily detected early viremia of the Andes variant.
A plaque reduction neutralization test remains a gold standard serologic assay and distinguishes between the different hantavirus species, although cross reaction between Old and New World viruses exist. This test needs to be performed in a laboratory with appropriate biosafety (level 3).

**Differential Diagnosis**

The differential diagnosis of the acute febrile syndrome seen with HFRS or early HPS includes scrub typhus, leptospirosis, and dengue. HPS requires differentiation from other respiratory infections caused by such pathogens as Legionella, Chlamydia, and Mycoplasma. Coxsackievirus infection should also be considered in the differential diagnosis.

**Treatment**

Treatment is mainly supportive. Cardiorespiratory support using vasopressors is frequently needed; extracorporeal membrane oxygenation may be required in severe cases of HPS. Intravenous ribavirin is used in HFRS (Hantaan virus) with some success in decreasing the severity of the kidney injury. Its effectiveness in HPS, however, is not established.

**Prevention**

Because infection is thought to occur by inhalation of rodent waste, prevention is aimed at eradication of rodents in houses and avoidance of exposure to rodent excreta, including forest service facilities. While inactivated vaccines have been used in the past in Korea and China, there is currently no commercially available vaccine and the WHO does not recommend preventive vaccination.

**Prognosis**

The outcome is highly variable depending on severity of disease. HPS is a more severe disease than HFRS, with a mortality rate of about 40%. In Sin Nombre virus infections, the persistence of elevated IgG titers correlates with a favorable outcome.

**General Considerations**

Yellow fever is a zoonotic flavivirus infection transmitted by Aedes mosquitoes bite. There are three types of transmission cycles: sylvatic (or jungle; humans working or travelling in the forest are bitten by infected mosquitoes), intermediate (most common type of outbreak in Africa; mosquitoes infect both monkeys and people leading to outbreaks in separate villages), and urban (seen in large epidemics; infected mosquitoes transmit the virus from person to person). Elevated temperatures and increased rainfall are major determinants of transmission.

Yellow fever occurs in 47 endemic countries in Africa and in Central and South America. Around 90% of cases reported every year occur in sub-Saharan Africa. Adults and children are equally susceptible, though attack rates are highest among adult males because of their work habits. Modeling data from Africa in 2013 estimates the annual case load is 84,000 to 170,000 annual cases with 29,000 to 60,000 deaths. The number of susceptible vaccinees worldwide is estimated to be between 394 million and 473 million.

**Clinical Findings**

**A. Symptoms and Signs**

Most persons have no illness or only mild illness. The incubation period is 3–6 days in persons in whom symptoms develop.

1. **Mild form**—Symptoms are malaise, headache, fever, retroorbital pain, nausea, vomiting, and photophobia. Relative bradycardia, conjunctival injection, and facial flushing may be present.

2. **Severe form**—Severe illness develops in about 15%. Initial symptoms are similar to the mild form, but brief fever remission lasting hours to a few days is followed by a “period of intoxication” manifested by fever and relative bradycardia (Faget sign), hypotension, jaundice, hemorrhage (gastrointestinal, nasal, oral), and delirium that may progress to coma.

**B. Laboratory Findings**

Leukopenia, elevated liver enzymes, and bilirubin can occur. Proteinuria is present and usually disappears completely with recovery. Bleeding dyscrasias with elevated prothrombin and partial thromboplastin times, decreased platelet count, and presence of fibrin-split products, can also occur.

In the early stages of the disease (up to 10 days), diagnosis is confirmed if yellow fever virus RNA is detected by RT-PCR in blood from a person with no history of recent yellow fever vaccination. PCR determinants are now available that distinguish between wild type virus and vaccine-associated strains.

In later stages, serologic diagnosis can be made by using ELISA to measure IgM 3 days after the onset of symptoms; however, yellow fever vaccine and other flaviviruses, including dengue, West Nile, and Zika viruses, may give a false-positive ELISA test result. Thus, the presence of yellow fever virus–specific IgM antibody and negative ELISA panel for other relevant flaviviruses confirm the diagnosis.
If ELISA is positive for other flaviviruses, the more specific plaque reduction neutralization assay should be done in reference laboratories, which measures the titer of the neutralizing antibodies in the serum toward the infecting virus.

### Differential Diagnosis

It may be difficult to distinguish yellow fever from other viral hepatitides, malaria, leptospirosis, louse-borne relapsing fever, dengue, and other hemorrhagic fevers on clinical evidence alone. Albuminuria is a constant feature in yellow fever patients, and its presence helps differentiate yellow fever from other viral hepatitides. Serologic confirmation is often needed.

### Treatment

No specific antiviral therapy is available. Treatment is directed toward symptomatic relief and management of complications.

### Prognosis

The mortality rate of the severe form is 20–50%, with death occurring most commonly between the sixth and the tenth days. Convalescence is prolonged, including 1–2 weeks of asthenia. Infection confers lifelong immunity to those who recover.

### Prevention

The yellow fever vaccine, which is derived from the live attenuated 17D strain (with substrains 17D-204 and 17DD similar in efficacy and side effects) and currently given as a single dose for a lifetime, is the most effective way to prevent and control disease. A single dose of vaccine in the past was considered to provide lifelong immunity. While the 10-year booster dose is no longer recommended for most people, persistent seropositivity at 8 years post vaccination is only 85%. Thus, at-risk groups with waning immunity and high probability of exposure may consider receiving a second dose of vaccine after 10 years (these groups are listed at [https://www.cdc.gov/yellowfever/healthcareproviders/vaccine-info.html](https://www.cdc.gov/yellowfever/healthcareproviders/vaccine-info.html)).

Yellow fever vaccine is recommended for persons aged over 9 months who are traveling to or living in areas at risk for yellow fever virus transmission. This vaccine should never be given to children under 6 months old due to their higher risk of developing encephalitis related to the vaccine. WHO recommends that all endemic countries should provide lifelong immunity and high probability of exposure may consider receiving a second dose of vaccine after 10 years (these groups are listed at [https://www.cdc.gov/yellowfever/healthcareproviders/vaccine-info.html](https://www.cdc.gov/yellowfever/healthcareproviders/vaccine-info.html)).

### Complications

Vaccination against yellow fever should be avoided during pregnancy as well as Guillain-Barré.

### General Considerations

Zika virus is a flavivirus, akin to the viruses that cause dengue fever, Japanese encephalitis, and West Nile infection.

The virus was noted in Africa and Asia during the 1950s–1980s, but first spread beyond those two continents during 2007 when an outbreak occurred in Yap State, Federated States of Micronesia. A large outbreak occurred in

World Health Organization. Yellow fever. [https://www.who.int/csr/disease/yellowfev](https://www.who.int/csr/disease/yellowfev)

---

OTHER SYSTEMIC VIRAL DISEASES

1. **Zika Virus**

### ESSENTIALS OF DIAGNOSIS

- Most infected persons asymptotically seroconvert.
- Clinical symptoms are akin to those of chikungunya virus infection but with less arthritis.
- Complications include microcephaly and ocular complications in infants born to mothers infected during pregnancy as well as Guillain-Barré.
- There is no effective antiviral or vaccine.
French Polynesia in 2013. A smaller outbreak occurred on Easter Island during 2014. The virus then spread to the Western hemisphere and was first noted in northeastern Brazil in 2015. Zika virus then spread rapidly throughout the Americas, including the United States and worldwide http://www.who.int/csr/disease/zika/en/. Despite distinct lineages, Zika virus exists as only one serotype. 

Aedes species mosquitoes, particularly Aedes aegypti, are primarily responsible for transmission of Zika virus. The biodistribution of the species largely determines the area of prevalence for Zika virus. Aedes species mosquitoes are found primarily in the southeastern United States, but one species Aedes albopictus (the Asian tiger mosquito known to sequester in tires) may be seen as far north as Pennsylvania and New Jersey. Rarely, a few other mosquito species including Anopheles and Culex may be competent for the Zika virus. Sexual transmission is reported from males and females to partners via vaginal, anal, or oral sex. Vertical transmission from pregnant woman to fetus is prominent. Transmission via platelet transfusion is also reported.

Since the onset of the first reported cases in the United States in 2015, the number of reported Zika cases is over 43,000, with 37,286 symptomatic cases from US territories (largely Puerto Rico) and 5728 cases from US states. The territorial cases are largely locally acquired and the US state cases are largely travel-acquired (with 231 of the 5728 US cases acquired via local transmission and 55 via sexual, bloodborne, or unknown routes). As of October 31, 2018, the US states reported 45 cases, with California (12) and New York (8) having the highest numbers. The number of annual cases is diminishing markedly in the United States with a peak in 2016 of 4897 travel-associated cases and 224 locally acquired cases (Florida, 218; Texas, 6).

Clinical Findings

A. Symptoms and Signs

The incubation period is about 10 days. Symptoms include acute onset fever, maculopapular rash that is usually pruritic, nonpurulent conjunctivitis, and arthralgias, the latter mimicking the symptoms of the chikungunya virus. Rash may outlast the fever but is not always present. Symptoms last up to 7 days. Most infections are asymptomatic. Viral infections most often confused with Zika include dengue and chikungunya virus infections.

B. Laboratory Findings and Diagnostic Studies

The CDC recommends that persons with symptoms of Zika infection be tested if they live in or have traveled recently to an area with active transmission, as well as all pregnant women who have lived in or visited affected regions.

Diagnosis is made by detecting viral RNA or neutralizing antibody, IgM 4 days or more after symptom onset or IgG after 7 days or more. The Trioplex real-time RT-PCR assay, which detects Zika virus, chikungunya virus, and dengue virus RNA, and the Zika MAC-ELISA, which detects Zika virus IgM antibodies, are available in some laboratories. The real-time RT-PCR detects the virus in blood or urine and should be performed within 2 weeks of illness onset. Matched serum and urine specimens should be tested simultaneously. Although not routinely recommended, RT-PCR can be performed on amniotic fluid, CSF, and placental tissue. A positive real-time RT-PCR test definitively makes the diagnosis of Zika virus infection and does not require additional confirmatory testing. A negative test does not exclude the presence of the virus in other tissues and does not rule out infection. Persons with negative tests should undergo further testing for Zika virus IgM antibody and other arboviral infections.

Persons being tested 14 days or more after symptom onset should be tested for IgM and neutralizing antibodies. Asymptomatic pregnant women should be tested for IgM 2 to 12 weeks, and on occasion longer, after travel to an area with Zika activity or if they have had sexual contact with a man with confirmed Zika virus infection. In areas with active Zika transmission, asymptomatic pregnant women should be tested for IgM antibody as part of routine obstetric care. RT-PCR testing is recommended for pregnant women more than 2 weeks after exposure who test positive for Zika IgM antibody. Persistent Zika virus RNA in serum has been reported in pregnancy. The Zika MAC-ELISA can be performed on serum or CSF. Neutralizing antibodies can cross-react with dengue and other flaviviruses, so samples testing positive should be sent to public health laboratories for confirmation. Pregnant women with confirmed or suspected Zika virus infection (positive IgM antibodies not yet confirmed to be due to Zika infection) may be monitored by serial ultrasounds at 3- to 4-week intervals, assessing fetal anatomy and growth. With a declining prevalence of Zika virus infection, positive antibody tests run the risk of more likely being false-positives and thus the need for the outlined assessments exists.

Complications

Two neurologic complications are of particular concern: (1) congenital microcephaly, often associated with brain calcifications and other abnormalities, first noted during the outbreak in Brazil and subsequently recognized to have occurred in French Polynesia as well; and (2) Guillain-Barré syndrome, first noted during the outbreak in French Polynesia. A Brazilian/European meta-analysis shows the rate of Guillain-Barré syndrome to be about 1.32%. Other congenital anomalies, including arthrogryposis among infected fetuses and infants, and spontaneous abortions are also observed. Rare deaths related to Zika virus infection are reported.

Ocular findings in Zika, reported in those congenitally infected, include focal macular pigment mottling, chorioretinal atrophy (especially in the macular area), congenital glaucoma with optical nerve hypoplasia, and optic disk abnormalities.

As with Ebola virus, the Zika virus can persist in semen for months; in the male reproductive tract the prostate gland and the testes are the presumed reservoirs. Persistence does not appear to occur in the female reproductive tract.

Treatment

There are no antivirals approved for treatment of Zika virus. Sofosbuvir, which is FDA-approved to treat hepatitis C, another flavivirus, shows some ability to inhibit Zika
replication and infection in vitro and in mice and appears to also be synergistic with interferon-alpha and with interferon-beta. Sofosbuvir also prevents vertical transmission in a mouse model. Aspirin and NSAIDs are avoided during illness caused by the flavivirus dengue because of its propensity to cause hemorrhage. Zika virus infections, however, do not appear to be associated with major hemorrhagic complications.

### Prevention

The most effective means is environmental control of mosquitoes and removal of areas where water is stagnant or builds up. Such measures include inspecting and moving houses; removal of old tires and debris from endemic areas of infection; and movement toward better living conditions, including air conditioning in impoverished areas. Because of the association between microcephaly and Zika virus infection during pregnancy, pregnant women are advised to avoid travel to areas where Zika virus is circulating (http://www.who.int/csr/disease/zika/information-for-travelers/en/). Guidelines for testing of pregnant women potentially exposed are available through the CDC. Infected individuals should refrain from blood donations for several months.

No approved vaccine against Zika virus exists. Over 40 vaccines are under study globally and 3 have entered clinical trials, including inactivated virus vaccines, VLP, recombinant viral vaccines, and DNA vaccines. Monoclonal antibodies appear to provide some relief.

### Clinical Findings

#### A. Symptoms and Signs

After an incubation period of 1–12 days (estimated median 3), there is abrupt onset of fever; headache; intestinal complaints, including diarrhea, vomiting, or abdominal pain; myalgias; and arthralgias/arthritis affecting small, large, and axial joints. The simultaneous involvement of more than 10 joints and the presence of tenosynovitis (especially in the wrist) are characteristic. The stooped posture of patients gives the disease its name. Joint symptoms persist for 4 months in 33% and linger for years in about 10%. A centrally distributed pigmented or pruritic maculopapular rash is reported in 10–40% of patients; it can be bullous with sloughing in children. Mucosal disease occurs in about 15%. Facial edema and localized petechiae are reported. Neurologic complications, including encephalitis, myelopathy, peripheral neuropathy, Guillain-Barré syndrome, myeloneuropathy, and myopathy, are usually found in persons younger than 5 or older than 49 years. Encephalitis occurred in 8.6 per 100,000 persons infected in La Réunion during 2005–2006 with 17% mortality and increased risk of encephalitis among those older than 65 years. Hemorrhagic fever–like presentations are unusual. Coinfection with other respiratory viruses and with dengue is common. Some of the neuropathology may be immune-mediated, and these cases are usually in those over age 20 and associated with longer latencies and better outcomes. Death is rare and usually related to underlying comorbidities.

#### B. Laboratory Findings

Diagnosis is made epidemiologically and clinically. Mild leukopenia occurs as does thrombocytopenia, which

2. Chikungunya Fever

Chikungunya ("that which bends up" in the Bantu language Kimakonde) fever is an alphavirus infection transmitted to humans by A aegypti and A albopictus and is considered a classic “arthritogenic” virus. The virus originated with two strains, one in West Africa and the other in East/Central/Southern Africa. In 2013, the first autochthonous case of chikungunya reported in the western hemisphere occurred on Saint Martin in the Caribbean, with isolates derivative of the East/Central/South Africa strains. Despite these differences, only one serotype exists.

For 2018, the CDC reports 75 travel-associated cases in 22 states and Puerto Rico (with the largest number of reports from California, New York, New Jersey, and Texas). The territory of Puerto Rico reports the only current locally acquired cases, with five cases as of October 30, 2018. Chikungunya virus prevalence is ubiquitous in endemic countries in Africa, the Americas, Asia, and Europe.

Among naive populations, attack rates are often as high as 50%. On Saint Martin, 39% of infections were asymptomatic. Vertical transmission is documented if the mother is viremic during parturition, and transmission does not appear to occur throughout pregnancy as it does with Zika virus. Infectious virus was isolated from saliva, although transmission from oral secretions is not observed among humans. Endemicity of A aegypti in the Americas and the introduction of A albopictus into Europe and the New World raise concern for further extension of the epidemic. Case reports show that chikungunya virus may coinfect patients with yellow fever virus, plasmodia, Zika virus, and dengue virus.
Leukopenia, thrombocytopenia.

Second attack of fever after remission lasting 2–3 days.

General Considerations
Colorado tick fever is a reportable biphasic, febrile illness caused by a reovirus infection transmitted by Dermacentor andersoni tick bite. About five cases occur annually, largely among men over age 40. The disease is limited to the western United States and Canada and is most prevalent during the tick season (March to November). There is a discrete history of tick bite or exposure in 90% of cases. The virus infects the marrow erythrocyte precursors. Blood transfusions can be a vehicle of transmission.

Clinical Findings
A. Symptoms and Signs
The incubation period is 3–6 days, rarely as long as 19 days. The onset is usually abrupt with a high fever. Severe myalgia, headache, photophobia, anorexia, nausea and vomiting, and generalized weakness are prominent. Physical findings are limited to an occasional faint rash. The acute symptoms resolve within a week. Remission is followed in 50% of cases by recurrent fever and a full recrudescence lasting 2–4 days. In an occasional case, there may be three bouts of fever.

The differential diagnosis includes influenza, Rocky Mountain spotted fever, numerous other viral infections, and, in the right setting, relapsing fevers.

B. Laboratory Findings
Leukopenia with a shift to the left and atypical lymphocytes occurs, reaching a nadir 5–6 days after the onset of illness. Thrombocytopenia may occur. An RT-PCR assay may be used to detect early viremia. Detection of IgM by capture ELISA or plaque reduction neutralization is possible after 2 weeks from symptom onset and is the most frequently used diagnostic tool.

Complications
Aseptic meningitis (particularly in children), encephalitis, and hemorrhagic fever occur rarely. Malaise may last weeks to months. Fatalities are very uncommon. Rarely, spontaneous abortion or multiple congenital anomalies may complicate Colorado tick fever infection acquired during pregnancy.

Treatment
No specific treatment is available. Ribavirin has shown efficacy in an animal model. Antipyretics are used,
although salicylates should be avoided due to potential bleeding with the thrombocytopenia seen in patients with Colorado tick fever.

**Prognosis**

The disease is usually self-limited and benign.

**Prevention**

Tick avoidance is the best prevention. The tick season is primarily from March to November, and the ticks mostly live at high altitudes (over 7000 feet) in sagebrush.

### COMMON VIRAL RESPIRATORY INFECTIONS

#### 1. Respiratory Syncytial Virus (RSV) & Other Paramyxoviruses

**ESSENTIALS OF DIAGNOSIS**

- RSV is a major cause of morbidity and mortality at the extremes of age (younger than 5 and older than 65).
- Treatment is largely supportive.
- No active vaccination for RSV is available.

**General Considerations**

Respiratory syncytial virus (RSV) is a paramyxovirus that causes annual outbreaks during the wintertime with usual onset of pulmonary symptoms between mid-October and early January in the continental United States (excluding Florida), Outside the United States, RSV usually peaks during wet months in areas with high annual precipitation and during cooler months in hot and dry areas. It occurs earlier in urban areas.

There are two major subtypes, A and B, and it appears that the A subtype is associated with disease severity. RSV is the leading cause of hospitalization in US children, with annual hospitalization rates of 6 per 1000 children younger than 5 years. Globally, the annual RSV hospitalization rates are 4 per 1000 children less than 5 years old, 19 among children less than 1 year old, 20 among children less than 6 months old, and 64 among premature children less than 1 year. Prematurity is a major risk factor for severe disease. Early RSV bronchiolitis in children, along with a family history of asthma, are associated with persistence of airway reactivity later in life.

RSV also causes upper and lower respiratory tract infection in adults, with the virus entering through contact with mucous membranes. RSV occurs with increasing severity in those with comorbid conditions, older adults (accounting for a rate of 4 per 1000 hospitalizations and 14,000 deaths annually), persons with severe combined immunodeficiency, and patients after lung or bone marrow transplantation (because CD8 T cells are not available for viral clearance). An interleukin-1 receptor polymorphism is shown to be associated with more severe bronchiolitis. Recurrences occur throughout life. The average incubation period is 5 days. Up to 10% of disease classified as invasive pneumococcal disease is thought to be RSV or influenza.

In immunocompromised patients, such as bone marrow transplant recipients, serious pneumonia can occur, and outbreaks with a high mortality rate (greater than 70%) are reported.

Other paramyxoviruses important in human disease include human metapneumovirus, parainfluenza virus, and Nipah virus.

**Human metapneumovirus** is a ubiquitous seasonal virus circulating during late winter to early spring. It is divided into subgroups A and B. Metapneumovirus accounted for 7.3% of childhood (younger than 16 years old) pneumonia in a Norwegian series of 3650 patients in which RSV accounted for 28.7%. Clinical presentations range from mild upper respiratory tract infections to severe lower respiratory tract infections (eg, bronchiolitis, croup, and pneumonia). Lower respiratory tract (sometimes severe) infections have been observed among immunocompromised and elderly adults, especially residents of nursing homes. In lung transplant recipients, human metapneumovirus is a common cause of respiratory illness and is thought to increase the risk of acute and chronic graft rejection. Ribavirin appears to be well tolerated in lung transplant recipients with metapneumovirus infection.

**Human parainfluenza viruses (HPIVs)** are commonly seen in children and are the most common cause of laryngotracheitis (croup). Four different serotypes are described, and they differ in their clinical presentations as well as epidemiology. HPIV-1 and HPIV-2 are responsible for croup. HPIV-3 is associated with bronchiolitis and pneumonia. HPIV-4 is a less frequently reported pathogen. Reinfections are common throughout life. HPIVs can also cause severe disease in older individuals, immunocompromised persons, and patients with chronic illnesses.

**Nipah virus** is a highly virulent paramyxovirus first described in 1999. Cases are concentrated mainly in Southeast Asia (Malaysia, Singapore, Bangladesh, and India). Fruit bats are identified as the natural host of the virus. An outbreak of 14 cases, 8 fatal, occurred in Bangladesh associated with drinking date palm sap between 2010 and 2014. Direct pig-human, cow-human, human-human, and nosocomial transmission are reported. Nipah virus causes acute encephalitis with a high fatality rate (67–92%), although respiratory symptoms are also described. Cranial nerve palsies, encephalopathy, and dystonia are among neurologic sequelae (15–32%) seen in infected individuals. Relapses occurring weeks and months after initial infection are described (3.4–7.5%).
Clinical Findings
A. Symptoms and Signs
In RSV bronchiolitis, proliferation and necrosis of bronchial epithelium develop, producing obstruction from sloughed epithelium and increased mucus secretion. Signs of infection include low-grade fever, tachypnea, and wheezes. Apnea is a common presenting symptom. Hyperinflated lungs, decreased gas exchange, and increased work of breathing are present. Pulmonary hemorrhage is reported. In children, RSV is globally the most common cause of acute lower respiratory infection and also a common cause of acute and recurrent otitis media. In patients with Down syndrome, RSV develops at a later age and is associated with more protracted hospitalizations.

B. Laboratory Findings
A rapid diagnosis of RSV infection is made by viral antigen identification of nasal washings using an ELISA or immunofluorescent assay, but PCR-based rapid tests are increasingly used. Multiplex assays in conjunction with influenza A and B tests are available commercially. RSV viral load assay values at day 3 of infection may correlate with requirement of intensive care and respiratory failure in children.

Human metapneumovirus is best diagnosed by PCR. Tests for rapid detection of viral antigens with immunofluorescence or ELISA, and PCR techniques are also widely available for detection of HPIV. Culture may also be used. ELISA (serum and CSF) and PCR (urine and respiratory secretions but not blood) are both used for Nipah virus infection diagnosis.

Treatment & Prevention
Treatment of RSV consists of supportive care, including hydration, humidification of inspired air, antibiotic therapy (to reduce other respiratory morbidity), and ventilatory support as needed. Neither bronchodilating agents nor corticosteroids have demonstrated efficacy in bronchiolitis although individual patients with significant bronchospasm or history of asthma might respond to them. Oral antiviral agents remain under study.

The use of aerosolized ribavirin or RSV-enriched IVIG, or both, can be considered in high-risk patients, such as those with a history of bone marrow transplantation, and appears to lessen mortality. The prophylactic monoclonal antibody palivizumab, while recommended for and effective in high-risk infants (premature infants less than 32 weeks’ gestational age, as well as infants with congenital heart and lung diseases and Down syndrome), is not of proven efficacy among adults with RSV.

A 2017 clinical trial studied the administration of palivizumab to preterm infants to prevent long-term sequelae; palivizumab did not suppress the onset of atopic asthma but did result in a significantly lower incidence of recurrent wheezing. Azithromycin therapy during RSV infection has been shown to reduce the probability of recurrent wheezing during the subsequent year by approximately 50%.

No RSV vaccine is currently commercially available.

Prevention in hospitals entails rapid diagnosis, hand washing contact isolation, and perhaps passive immunization. (Passive immunization is costly but is associated with improved antiviral titers in hematoLogic stem cell transplant recipients). The use of conjugated pneumococcal vaccination appears to decrease the incidence of concomitant pneumonia associated with viral infections in children in some countries. Viral shedding averages 11 days and correlates inversely with age and directly with severity of infection.

Therapeutic modalities for human metapneumovirus and parainfluenza virus infections under investigation include intravenous ribavirin administration.

2. Seasonal Influenza

Cases usually in epidemic pattern.
Onset with fever, chills, malaise, cough, coryza, and myalgias.
Aching, fever, and prostration out of proportion to catarrhal symptoms.
Leukopenia.

General Considerations
Influenza (an orthomyxovirus) is a highly contagious disease transmitted by the respiratory route in humans. Transmission occurs primarily by droplet nuclei rather than fomites or direct contact. There are three types of influenza viruses that infect humans. While type A can infect a variety of mammals (humans, swine, horses, etc) and birds, types B and C almost exclusively infect humans. Type A viruses are further divided into subtypes based on the hemagglutinin (H) and the neuraminidase (N) expressed on their surface. There are 18 subtypes of hemagglutinin and 11 subtypes of neuraminidase.

Annual epidemics usually appear in the fall or winter in temperate climates. Up to 5 million cases of severe influenza are estimated by the WHO to occur annually, with up to 0.5 million annual deaths. Influenza epidemics affect 10–20% of the global population on average each year and are typically the result of minor antigenic variations of the virus, or antigenic drift, which occur often in influenza A virus.
On the other hand, pandemics—associated with higher mortality—appear at longer and varying intervals (decades) as a consequence of major genetic reassortment of the virus (antigenic shift) or adaptation of an avian or swine virus to humans (as with the pandemic H1N1 virus of 1918). (https://www.who.int/influenza/surveillance_monitoring/updates/latest_update_GIP_surveillance/en/)

The highly pathogenic avian influenza subtypes are discussed in the next section. The novel swine-origin influenza A (pandemic H1N1) virus emerged in Mexico in 2009 and quickly spread throughout North America and the world causing a pandemic. This virus originated from triple-reassortment of North American swine, human, and avian virus lineages and Eurasian swine virus lineages and replaced the previous H1N1 seasonal virus.

### Clinical Findings

#### A. Symptoms and Signs

Type A and B seasonal influenza viruses produce clinically indistinguishable infections, whereas type C usually causes mild illness. The incubation period is 1–4 days. In unvaccinated persons, uncomplicated influenza often begins abruptly. Symptoms range widely from nearly asymptomatic to a constellation of systemic symptoms (including fever, chills, headache, malaise, and myalgias) and respiratory symptoms (including rhinorrhea, congestion, pharyngitis, hoarseness, nonproductive cough, and substernal soreness). Gastrointestinal symptoms and signs may occur, particularly among young children with influenza B virus infections. Fever lasts 1–7 days (usually 3–5). Elderly patients especially may present with lassitude and confusion, often without fever or respiratory symptoms. Signs include mild pharyngeal injection, flushed face, and conjunctival redness. Moderate enlargement of the cervical lymph nodes and tracheal tenderness may be observed. The presence of fever (higher than 38.2°C) and cough during influenza season is highly predictive of influenza infection in those older than 4 years.

#### B. Laboratory Findings

Rapid influenza diagnostic tests for detection of influenza antigens from nasal or throat swabs are widely available, highly specific, and produce fast results but have low sensitivity leading to high false-negative results. Not all commercial rapid influenza diagnostic tests can differentiate between influenza A and influenza B, and none of the available rapid influenza diagnostic tests can provide information on influenza A subtypes. Newer digital immunoassays and rapid nucleic acid amplification tests are more sensitive than traditional rapid influenza diagnostic tests; however, the sensitivity of newer PCR techniques is compromised early in the season during low prevalence periods. A nasopharyngeal swab, nasal aspirate, combined nasopharyngeal swab with oropharyngeal swab, or material from a bronchoalveolar lavage can be tested for any influenza strain. When influenza pneumonia is suspected, lower respiratory tract specimens should be collected and tested for influenza viruses by RT-PCR or the above assays.

### Differential Diagnosis

The differential diagnoses for influenza-like infections include a variety of viral respiratory infections (para influenza, RSV, atypical dengue, adenovirus, enterovirus, coronavirus) or other viral infections (flavivirus, CMV, EBV, acute HIV infection), as well as bacterial infections such as mycobacterial infection (atypical pneumonia), pertussis, and Legionnaire disease. Epidemiologic factors can suggest Legionnaire (elderly smokers). Chronicity of cough may suggest adenovirus, mycobacterial, or pertussis infection. Leukocytosis and lymphadenopathy are more often seen with CMV and EBV. Distinguishing influenza from dengue requires attention to rhinitis (influenza) and thrombocytopenia (dengue).

### Complications

Hospitalization or ICU admission for influenza is often a consequence of diffuse viral pneumonitis with severe hypoxemia and sometimes shock. Patients with asthma, residents of nursing homes and long-term care facilities, adults aged 65 years or older, persons who are morbidly obese, and persons with underlying medical conditions (pulmonary, renal, cardiovascular, hepatic, hematologic, neurologic and neurodevelopmental conditions; and immune-deficient conditions, such as HIV, diabetes, and cirrhosis) are at high risk for complications. Infection during pregnancy increases the risk for hospitalization and may be associated with severe illness, sepsis, pneumothorax and respiratory failure, spontaneous abortion, preterm labor, and fetal distress.

Influenza causes necrosis of the respiratory epithelium, increased adherence of bacteria to infected cells, and ciliary dysfunction, which predispose to secondary bacterial infections due to pneumococci, staphylococci, or Haemophilus spp. In turn, bacterial enzymes (eg, proteases, trypsin-like compounds, and streptokinase) activate influenza viruses. Frequent complications are acute sinusitis, otitis media, purulent bronchitis, and pneumonia. Cardiovascular diseases are a complication of influenza infection, in particular among older adults, and influenza is postulated to be a significant trigger for myocardial infarction, cerebrovascular disease, and sudden death. Several studies suggest that influenza vaccination has protective effect against major adverse cardiovascular events. Neurologic complications, including seizures and encephalopathy, may occur. Encephalopathic complications of influenza are uncommon.

Reye syndrome (fatty liver with encephalopathy) is a rare and severe complication of influenza (usually B type) and other viral diseases (especially varicella), particularly in young children. It consists of rapidly progressive hepatic failure and encephalopathy, and there is a 30% mortality rate. The pathogenesis is unknown, but the syndrome is associated with aspirin use in the management of viral infections.

### Treatment

Treatment is supportive. Antiviral therapy should be considered for all persons with acute illness, in particular those at high risk for developing complications who have a suggestive...
clinical presentation or with laboratory-confirmed influenza. Clinical trials show a reduction in the duration of symptoms, hospital admissions, as well as secondary complications, such as otitis, sinusitis, or pneumonia, but not mortality when using these agents. Maximum benefit is expected with the earliest initiation of therapy. Although the benefit of antiviral therapy after 48 hours of illness is reduced, it should be initiated if the patient is hospitalized or critically ill. Benefit has been noted up to 4–5 days into illness.

The antiviral treatment of choice should be based on the susceptibility of the circulating virus. Currently, since high levels of resistance to the adamantanes (amantadine and rimantadine) persist among seasonal H1N1 and H3N2 influenza A viruses and these agents are not effective against influenza B viruses, amantadine and rimantadine are not recommended for treatment.

Three neuraminidase inhibitors are FDA approved for treatment of influenza A and B: oral oseltamivir, inhaled zanamivir, and intravenous peramivir. The CDC recommends treatment with oral oseltamivir (75 mg twice daily for 5 days) as the drug of choice for patients of any age, pregnant women, and patients who are hospitalized or have complicated infection. Absorption of oral oseltamivir is considered reliable, except in patients with impaired gastric motility or gastrointestinal bleeding.

Inhaled zanamivir (10 mg, 2 inhalations twice daily for 5 days) is indicated for uncomplicated acute influenza in patients 7 years and older, is relatively contraindicated among persons with asthma because of the risk of bronchospasm, and is not formulated for use in mechanically ventilated patients. Inhaled zanamivir lacks efficacy in pneumonia, probably due to poor bioavailability in the peripheral lungs.

Intravenous peramivir (600 mg in single dose) is used for outpatient treatment of uncomplicated infection in patients 18 years and older and is recommended when there is a concern about inadequate oral absorption of oseltamivir. The efficacy of peramivir in patients with severe illness and in patients with influenza B is not well established. Some studies demonstrated that repeated doses for up to 5 days of intravenous peramivir is safe, effective and shorten the duration of influenza illness.

Resistance to neuraminidase inhibitors (oseltamivir, zanamivir, and peramivir) can occur during or after prolonged use in immunocompromised patients, particularly in persons who have undergone hematopoietic stem cell transplant. Intravenous zanamivir is an investigational drug that could be requested for clinical use if there is a concern for oseltamivir-resistant influenza strain. Laninamivir is a long-acting inhaled neuraminidase inhibitor used for the treatment of seasonal influenza, including infection caused by oseltamivir-resistant virus. It is licensed in Japan and South Korea and is currently in phase III clinical trials in the United States.

Baloxavir (a selective inhibitor of influenza cap-dependent endonuclease that is given as a single oral dose) was approved by the FDA in 2018 for treatment of uncomplicated influenza A and B infections. Baloxavir is given as 40 mg or 80 mg orally once daily depending on weight (the higher dose for persons 80 kg or more) and should be given within the first 48 hours of infection. Its side effects include diarrhea and bronchitis, and to date, its effects in patients older than 65 years or younger than 12 years are not established. Baloxavir’s unique mechanism of action will likely make it useful as part of multidrug therapy for resistant disease. For complicated disease, especially in immunosuppressed patients, the combination of oseltamivir, amantadine, and ribavirin appears to produce faster viral clearance but no definite clinical improvement.

The first class of organosilanes have potent antiviral activity against influenza A viruses that are resistant to amantadine and oseltamivir. Dapivirine, an FDA-approved HIV nonnucleoside reverse transcriptase inhibitor, has broad-spectrum antiviral against multiple strains of influenza A and B viruses. Iminosugars are also under study. Updated advice is available at http://www.cdc.gov/flu/index.htm.

Prognosis

The duration of the uncomplicated illness is 1–7 days, and the prognosis is excellent in healthy, nonelderly adults. Hospitalization typically occurs in those with underlying medical disease, at the extremes of age, and in pregnant women. Most fatalities are due to bacterial pneumonia although exacerbations of other disease processes, in particular cardiac diseases, occur. Pneumonia resulting from influenza has a high mortality rate among pregnant women and persons with a history of rheumatic heart disease. Mortality among adults hospitalized with influenza ranges from 4% to 8%, although higher mortality (greater than 10–15%) may be seen during pandemics and among immunocompromised individuals. At least 64% of pneumonia and influenza deaths occurred among elderly persons in the United States, who comprised only 15% of the population.

If the fever recurs or persists for more than 4 days with productive cough and white cell count over 10,000/mcl, secondary bacterial infection should be suspected. Pneumococcal pneumonia is the most common secondary infection, and staphylococcal pneumonia is the most serious. Major complications include viral myocarditis and viral encephalitis.

Prevention

Annual administration of influenza vaccine is the most effective measure for preventing influenza and its complications. Seasonal influenza vaccines can reduce influenza hospitalizations by an estimated 61%. Vaccination of healthcare workers is associated with decreased mortality among hospitalized patients and those in long-term care facilities. Vaccination prevents influenza illness among pregnant women and their infants during the first months of life.

The ACIP and the American College of Obstetricians and Gynecologists’ Committee recommend annual influenza vaccination for all persons over 6 months of age with no contraindications. Vaccination is emphasized for high-risk groups and their contacts and caregivers.

Several Cochrane database analyses have analyzed the efficacy of the influenza vaccines in select populations.
The studied groups include patients with COPD (a documented reduction in exacerbations with inactivated vaccine), the elderly (where vaccination shows some efficacy), adults with cancer (weak evidence, some lower mortality and influenza-related outcomes), healthy adults (established efficacy with inactivated vaccine, but only modest effects in pregnant women and newborns), and healthy children (where both live and inactivated vaccines lower the rate of influenza infections).

Other reviews establish the efficacy and safety of influenza vaccination in patients with rheumatoid arthritis, asthma, or myasthenia gravis, and elderly nursing home patients. The obese have an impaired response to the influenza vaccine.

Multiple influenza vaccine products are licensed in the United States and available from different manufacturers. These include inactivated influenza vaccines (standard- or high-dose, trivalent [IIV3] or quadrivalent [IIV4], adjuvanted or unadjuvanted), recombinant vaccines (trivalent [RIV3] or quadrivalent [RIV4]), and live attenuated influenza vaccine (LAIV4). All trivalent vaccines contain antigens from one strain each of influenza A (H1N1), influenza A (H3N2), and influenza B. Quadrivalent vaccines include an additional influenza B strain. The CDC does not endorse one influenza vaccine product over another, although each influenza vaccine product has different age indications and contraindications. The CDC publishes its annual influenza recommendations in the late summer (www.cdc.gov/mmwr).

LAIV4 use, not recommended by the CDC for the last two seasons due to concerns about its effectiveness against influenza viruses in prior years, is currently considered an acceptable option for groups in whom it is indicated. The efficacy of including the fourth A/Slovenian strain is as yet unknown.

Adults over the age of 18 years, including pregnant women, can receive any influenza vaccine, with few exceptions. Patients 65 years or older should receive a high-dose trivalent inactivated influenza vaccine containing four times more hemagglutinin than standard dose, or Fluad, a trivalent inactivated vaccine that contains an adjuvant (MF59), which enhances the immune response to the vaccine. Fluzone intradermal inactivated quadrivalent vaccine is equally immunogenic and safe but more expensive than the intramuscular vaccine and is not recommended for persons older than 65 years. Adults older than 65 years can use any IIV or RIV intramuscular vaccine; in a large randomized trial, high-dose IIV3 showed superior efficacy over standard-dose IIV3 and may provide better protection. Some data suggest intradermal vaccination is more effective than intramuscular vaccination in the elderly. The herpes zoster vaccine can be safely coadministered with the seasonal influenza vaccines in patients over 50 years of age, with similar immunogenicity.

For patients with cancer, chemotherapeutic regimens containing rituximab show persistent perturbations of B-cell and Ig synthesis, and these modifications decrease humoral responses to the influenza vaccine. Adjuvanted vaccine is efficacious but has resulted in brief disease exacerbation in persons with psoriatic arthritis taking TNF-alpha inhibitors.

Vaccination is contraindicated for persons with a history of severe allergic reaction to influenza. Precautions should be taken if patients report a history of Guillain-Barré syndrome 6 weeks following an influenza vaccine and if patients have a moderate to severe acute illness with or without fever until clinical improvement. Persons with a history of egg allergy with hives only may receive any recommended influenza vaccine. Those with more severe allergic reactions to eggs may receive any recommended vaccine under close observation in a health care facility under the supervision of a provider with experience treating severe allergic reactions. Only the recombinant vaccine is completely egg-free.

Additional vaccine information can be found at http://www.cdc.gov/flu/professionals/vaccination/index.htm.

When antiviral chemoprophylaxis is used, it prevents 70–90% of influenza infections. Chemoprophylaxis is not routinely recommended and is not recommended prior to exposure to prevent development of resistance. Chemoprophylaxis may be considered for persons at increased risk for complications from infection who are exposed to an infected patient within 2 weeks of vaccination, for persons unlikely to respond to vaccination because of immunosuppression after exposure to an infected person, for persons for whom vaccination is contraindicated and who are at high risk for complications after exposure to an infected person, and for prevention of infection in residents of institutions during an outbreak. Alternatively, a person can be monitored closely, and antiviral therapy initiated at the first onset of symptoms after exposure. Initiation of chemoprophylaxis is not recommended more than 48 hours after exposure. Patients taking chemoprophylaxis should seek urgent medical care if an influenza-like illness develops.

Chemoprophylaxis against influenza A and B is accomplished with daily administration of the neuraminidase inhibitors oseltamivir (75 mg/day, oral) or zanamivir (10 mg/day, inhaled) to continue through 7 days after last known exposure. For outbreak control in long-term care facilities and hospitals, a minimum of 2 weeks is recommended, including in vaccinated persons if the seasonal vaccine is not well matched to the circulating strain, to continue until 1 week after identification of the last known case. Zanamivir should not be given as chemoprophylaxis to asthmatic persons, nursing home residents, or children younger than 5 years.

Breakthrough infections with influenza occur with neuraminidase inhibitors (in a study with zanamivir) and with vaccination. The efficacy of chemoprophylaxis is proven for individuals and households but not community settings.

Hand hygiene and surgical facemasks appear to prevent household transmission of influenza virus isolates when implemented within 36 hours of recognition of symptoms in an index patient. Such nonpharmaceutical interventions assist in mitigating the spread of pandemic and interpandemic influenza to nonvaccinated persons. In one study, patients with seasonal H1N1 influenza infection were infectious from 1 day before to about 7 days following illness onset. Children and immunosuppressed persons exhibit prolonged viral shedding and may be infectious longer. Winter school breaks during periods of high
influenza transmission appear to decrease rates of visits to primary care practitioners for influenza illness among children and adults.

The data are not currently sufficient to modify statin usage for influenza vaccination. There may be, however, some impaired effectiveness against the H3N2 influenza A component of vaccines from the immunomodulatory effects of statins.

Any hospital patient in whom the infection is suspected should be isolated in an individual room with standard and droplet precautions. CDC guidelines recommend the equivalent of N95 masks for aerosol generating procedures (eg, bronchoscopy, elective intubation, suctioning, administering nebulized medications). For such procedures, an airborne infection isolation room can be used, with air exhausted directly outside or recirculated after filtration by a high efficiency particulate air (HEPA) filter. Strict adherence to hand hygiene with soap and water or an alcohol-based hand sanitizer and immediate removal of gloves and other equipment after contact with respiratory secretions is essential. Precautions should be maintained until 7 days from symptom onset or until 24 hours after symptom resolution, whichever is longer. Postexposure prophylaxis or close monitoring and early treatment should be considered for close contacts of patients who are at high risk for complications of influenza and may be considered for healthcare personnel, public health workers, or first responders who experienced a recognized, unprotected close contact exposure to a person with influenza virus infection during that person’s infectious period.

A regimen of dose sparing vaccination (to 3.5 mcg) is advocated by some providers to address the extreme shortage of influenza vaccine, particularly in developing world countries, with adequate vaccination against all components except H3N2, where there is reduced seroconversion.

**When to Admit**

- Limited availability of supporting services.
- Pneumonia or decreased oxygen saturation.
- Changes in mental status.
- Consider with pregnancy.

3. Avian Influenza

**ESSENTIALS OF DIAGNOSIS**

- Most human cases occur after exposure to infected poultry.
- Clinically indistinguishable from seasonal influenza.
- Epidemiologic factors assist in diagnosis.
- Rapid antigen assays confirm diagnosis but do not distinguish avian from seasonal influenza.

**General Considerations**

Zoonotic influenza viruses are distinct from human seasonal influenza viruses and do not easily transmit between humans. In addition, a number of viral genetic changes are required for adaptation to humans. For avian influenza viruses, birds are the natural hosts. Around the world and in North America, avian influenza A outbreaks occur in poultry from time to time (including a 2016 outbreak in Dubois County, Indiana, with avian but no human cases), and the virus has become endemic in poultry in some countries, mostly in Southeast Asia and Egypt. Occasionally, avian influenza viruses may infect humans or other mammals, including domestic cats and dogs. Illness in
Humans ranges from mild disease to rapid progressive severe disease and death depending on the subtype.

The primary risk factor for human infection is direct or indirect exposure to infected live or dead poultry or contaminated environments, such as live bird markets. Slaughtering and handling carcasses of infected poultry are also risk factors.

The emergence of H5, H7, and H9 avian influenza virus subtypes in humans raises concern that the virus may undergo genetic reassortment or mutations in some of the genes and develop greater human-to-human transmissibility with the potential to produce a global pandemic. All fatal avian influenza virus infections acquire their internal gene segments from H9N2 viruses, the most widespread avian influenza subtype.

Human infections with H5N1 viruses have been reported to WHO from 16 countries, the first report in the Americas was in Canada in 2014, and approximately 60% of the cases have died. Infection with H7N9 avian influenza virus was first reported in China in 2013. Since then, many cases have been reported around the world with an average case fatality rate of 40%. Infections with other H7 avian influenza viruses (H7N2, H7N3, and H7N7) have occurred sporadically around the world. Rare human cases of influenza H9N2 are also reported.

**Clinical Findings**

**A. Symptoms and Signs**

Distinguishing avian influenza from regular influenza is difficult. History of exposure to dead or ill birds or live poultry markets in the prior 10 days, recent travel to Southeast Asia or Egypt, or contact with known cases should be investigated. Patients infected by H5N1 or H7N9 avian influenza A viruses have an aggressive clinical course. The symptoms and signs include fever followed by lower respiratory symptoms (cough, dyspnea). Upper respiratory tract symptoms are less common. Gastrointestinal symptoms are reported more frequently in H5N1 infections. Conjunctivitis is reported in influenza H7 infections. Other systems can also be involved leading to neurologic manifestations (encephalopathy, seizure) and liver impairment. Prolonged febrile states and generalized malaise are common. Respiratory failure, multiorgan dysfunction, and septic shock are the usual cause of death. Bacterial superinfections are reported.

For human infections with H7N7 and N9B2 avian influenza virus infections, most cases have been mild with a few cases hospitalized and very few reports of deaths resulting from infection.

**B. Laboratory Findings**

Current commercial rapid antigen tests are not optimally sensitive or specific for detection of H5N1 influenza and should not be the definitive test for influenza. More sensitive RT-PCR assays are available through many hospitals and state health departments. Diagnostic yield can be improved by early collection of samples, preferably within 7 days of illness onset. Throat swabs or lower respiratory specimens (such as tracheal aspirate or bronchoalveolar lavage fluid) may provide higher yield of detection than nasal swabs. When highly pathogenic strains, such as H5N1 influenza virus infections, are suspected, extreme care in the handling of these samples must be observed during preliminary testing. Positive samples must then be forwarded to the appropriate public health authorities for further investigation (eg, culture) in laboratories with the adequate level of biosafety (level 3).

**Treatment**

Persons with severe illness and confirmed and probable cases with mild disease should receive treatment as soon as possible. The current first-line recommendation is to use the neuraminidase inhibitor oseltamivir, 75 mg orally twice daily for 5 days administered within 48 hours from onset of illness. Longer courses of therapy (eg, 10 days) should be considered in hospitalized patients with severe illness and persistent viral shedding. Data are lacking for use of inhaled zanamivir or peramivir for severe avian influenza. Overall oseltamivir, by modeling, is associated with a 49% reduction in mortality from H5N1 avian influenza virus infections. As with seasonal influenza, enteric oseltamivir is well absorbed in critically ill persons without gastric stasis, known malabsorption, or gastrointestinal bleeding. Daily intravenous peramivir (600 mg, reduced to 200 mg for kidney dysfunction) for a minimum of 5 days and a maximum of 10 or more days (depending on severity of illness) or zanamivir (10 mg inhaled daily for 10 days) may be considered in such patients. Combination therapy with amantadine or rimantadine (in countries where H5N1 influenza virus A strains are likely to be susceptible to adamantanes) may be considered in patients with pneumonia or progressive disease. Resistance of avian H5N1 influenza strains to amantadine and rimantadine is present in most geographic areas. Resistance to neuraminidase inhibitors (oseltamivir, zanamivir, and peramivir) can occur with H5N2 and H7N9 avian–infected patients. Successful treatment with administration of convalescent plasma is reported.

**Prevention**

The most effective method of prevention is avoidance of exposure. Persons who work with poultry should practice good hand hygiene and use appropriate personal protective equipment. These workers should also be vaccinated against seasonal influenza, since this can reduce the likelihood of coinfection with avian and seasonal influenza. Persons should avoid visiting live poultry markets when able and should avoid contact with ill birds. No risk exists for acquiring avian influenza through the consumption of well-cooked poultry products. The US government bans the importation of poultry from infected areas. Culling of animals has been effective in ending outbreaks of highly pathogenic avian influenza but is difficult with H7-infected poultry because most are asymptomatic. Policies regarding closure of live poultry markets during avian epidemics are controversial. Persons with exposure should monitor themselves for 10 days after the last known exposure and should seek prompt medical attention if new fever or respiratory symptoms develop. Postexposure prophylaxis is not recommended in persons working with noninfected birds or who
used appropriate personal protective equipment while working with infected birds. For persons with exposure to infected persons, postexposure prophylaxis is recommended for household and family members and may be considered for health care personnel with close unprotected contact. Postexposure prophylaxis regimens include 75 mg of oseltamivir orally or 10 mg inhaled zanamivir twice daily for 5 or 10 days from the last known exposure, depending on the length of the exposure. Careful surveillance for human cases and prudent stockpiling of medications with establishment of an infrastructure for dissemination are essential modalities of control. Nonpharmacologic means of control include masks, social distancing, quarantine, travel limitations, and infrastructure development, particularly for emergency departments.

Current vaccines do not provide cross-protection against strains of the H5, H7, and H9 influenza viruses. The United States government has prepandemic stockpiles of adjuvanted H5N1 vaccines and H7N9 vaccines that are not available to the public. The highly diverse genetic nature and the rapid evolution of the avian influenza viruses has resulted in the emergence of viruses that are distinct from stockpiled vaccines. New vaccine development is ongoing to generate vaccines against H7N9 and H5N1 with broadened protection against unmatched strains. Some of these vaccines are under study in preclinical and clinical trials; however, no vaccines are currently commercially available for humans.

Because the potential for pandemic influenza for many of the new reassortment viruses is not fully known, continued surveillance is essential, and stockpiling of vaccines, adjuvant, and medications (oseltamivir and zanamivir) is warranted at the public health level.

**General Considerations**

Middle East respiratory syndrome (MERS) is a syndrome associated with a coronavirus similar to the cause of severe acute respiratory syndrome (SARS). Patients with MERS have had a history of residence or travel in the Middle East, in particular Saudi Arabia, or contact with such patients. The virus is probably transmitted through direct or indirect contact of mucous membranes with infectious respiratory droplets. The virus is shed in stool, but the role of fecal-oral transmission is unknown. The earliest cases were identified in 2012 in the Kingdom of Saudi Arabia, and 75% of all cases have occurred there. Additional cases have occurred throughout the Middle East, Africa, and Europe, with a reported death rate of 36% (http://www.who.int/emergencies/mers-cov/en/). So-called super-spreaders are often responsible for propagating the pathogen in the early stages of an outbreak.

Person-to-person transmission can occur within families; hospital-associated cases comprise 25% of cases. The median incubation period is 5 days (range, 2–14) with the mean age of 50 (range 9 months to 99 years) and 65% occurring among men. Over 90% of patients have an underlying medical condition, including diabetes mellitus (68%), hypertension (34%), or chronic heart or kidney disease. Those with diabetes, kidney disease, chronic lung disease, or other immunocompromising conditions likely are at highest risk for severe disease. Camels appear to be the principal reservoir, and several studies show that contact with dromedary herds of camels is greater among cases than controls. Raw camel milk is considered a potential source. Persons who work with camels are more likely to have antibody evidence of past infection.

**Clinical Findings**

**A. Symptoms and Signs**

MERS is an acute respiratory syndrome, with the most common symptoms being fever (98%), cough (83%), and dyspnea (72%). Chills and rigors are common (87%). Gas- trointestinal symptoms may occur, with diarrhea being most common (26%), followed by nausea and abdominal pain, and may precede respiratory symptoms. Mild and asymptomatic cases are reported.

**B. Laboratory Findings and Imaging**

Hematologic findings in the largest series to date include thrombocytopenia (36%), lymphopenia (34%), and lymphocytosis (11%). Moderate elevations in lactate dehydrogenase (49%), AST (15%), and ALT (11%) are recognized. Chest radiograph abnormalities are nearly universal and include increased bronchovascular markings, patchy infiltrates or consolidations, interstitial changes, opacities...
(reticular and nodular) and pleural effusions, and total lung opacification. Ground-glass opacities and consolidation are most commonly seen. The findings mimic those of many other causes of pneumonia.

Serum serologies and RT-PCR are available through CDC (contact information below, on MMWR reference site). Highest viral loads are found in lower respiratory tract specimens, including bronchoalveolar lavage fluid, sputum, and tracheal aspirates. These samples are preferred for diagnosis. The CDC recommends sending lower respiratory tract specimens, nasopharyngeal and oropharyngeal swabs, and serum for testing. In confirmed cases, serial sample collection (perhaps every 2–4 days) from multiple sites is recommended to increase understanding of virus shedding kinetics. In cases in which symptom onset occurred more than 14 days prior and symptoms are ongoing, serum should be sent to the CDC for serologic testing and the above specimens should be sent for RT-PCR.

C. Case Definition

A patient with severe illness shows the following characteristics: fever (38°C, 100.4°F or higher) and pneumonia or ARDS (based on clinical or radiologic evidence); and either history of travel in or near the Arabian Peninsula within 14 days before symptom onset; or close contact with a symptomatic traveler in whom fever and acute respiratory illness (not necessarily pneumonia) developed within 14 days after traveling in or near the Arabian Peninsula (above); or is a member of a cluster of patients with severe acute respiratory illness (eg, fever and pneumonia requiring hospitalization) of unknown etiology in which MERS-CoV is being evaluated, in consultation with state and local health departments.

In milder illness, patients have fever and symptoms of respiratory illness (not necessarily pneumonia; eg, cough, shortness of breath) and history of having close contact with a confirmed MERS case as well as a history of being in a health care facility (as a patient, worker, or visitor) within 14 days of symptom onset in a country or territory within the Arabian Peninsula in which recent health care–associated cases of MERS have been identified.

Of note, fever may not be present in certain patients, including the very young, elderly persons, immunosuppressed individuals, or those taking certain medications.

Complications

Respiratory failure is such a common complication that in a series from Saudi Arabia, 89% of patients required intensive care and mechanical ventilation. Patients with MERS-CoV appear to advance faster to respiratory failure than do those with SARS.

Treatment

Respiratory support is essential. No vaccine or known antiviral therapy exists to combat MERS. Current therapies are adapted from SARS treatments, which include broad-spectrum antibiotics, corticosteroids, interferons, ribavirin, lopinavir-ritonavir, or mycophenolate mofetil. A small retrospective study found improved survival at 14 days with ribavirin and interferon-alpha but not at 28 days.

Prognosis

The overall mortality rate of identified cases is about 36%. Advanced age is associated with a poor prognosis.

Prevention

Isolation and quarantine of cases is authorized by CDC. Strict infection control measures are essential as well as care and management of household contacts and hospital workers engaged in the care of patients. Travelers to Saudi Arabia (including the many pilgrims to the holy sites) should practice frequent hand washing and avoid contact with those who have respiratory symptoms. Evaluation of patients with suspect symptoms within 14 days of return from Saudi Arabia is essential. Because healthcare workers engaged in procedures that involve contact with respiratory droplets are at risk, isolation of high-risk patients is essential, as are simple hygienic measures. Control measures, including quarantining in the home for high-risk exposed persons and the use of facemasks for preventing hospital-acquired infections, are important. Assisting public health authorities with case reporting and surveillance is essential.

Camel workers including slaughterhouse and market workers, veterinarians, and racing personnel should wear personal protective equipment and practice good personal hygiene, including frequent hand washing after touching animals. Family members of such personnel should not be exposed to work paraphernalia including clothing and shoes and should shower at the site of employment rather than the home. Avoid direct contact with camels (who may be asymptomatic but who can transmit the virus through nasal or ocular discharge, milk, urine, and feces). All infected animals should be kept off the market, including their meat products, and buried or destroyed.

Adenovirus Infections

General Considerations

At least 60 serotypes of adenovirus are currently described and these are members of 7 species classified A–G. About half of these subgroups produce a variety of clinical syndromes. Adenoviruses show a worldwide distribution and occur throughout the year. These infections are usually self-limited or clinically inapparent and occur most commonly among infants, young children, and military recruits. However, these infections may cause significant morbidity and mortality in immunocompromised persons, such as HIV-infected persons and COPD patients, as well as in patients who have undergone solid organ and hematopoietic stem cell transplantation or cardiac surgery or in
Clinical Findings

A. Symptoms and Signs

The incubation period is 4–9 days. Clinical syndromes of adenovirus infection, often overlapping, include the following. The common cold (see Chapter 8) is characterized by rhinitis, pharyngitis, and mild malaise without fever. Conjunctivitis is often present. Nonstreptococcal exudative pharyngitis is characterized by fever lasting 2–12 days and accompanied by malaise and myalgia. Lower respiratory tract infection may occur, including bronchiolitis, suggested by cough and rales, or pneumonia. Types 1, 2, 3, 4, and 7 commonly cause acute respiratory disease and atypical pneumonia; coinfections or serial infections are documented to occur. Infections are especially severe in Native American children. Adenovirus type 14 is increasingly reported as a cause of severe and sometimes fatal pneumonia in those with chronic lung disease but is also seen in healthy young adults and military recruit outbreaks. Viral or bacterial coinfections occur with adenovirus infection in 15–20% of cases. Pharyngoconjunctival fever is caused by fever and malaise, conjunctivitis (often unilateral), mild pharyngitis, and cervical adenitis. Epidemic keratoconjunctivitis (transmissible person-to-person, most often types 8, 19, and 37) occurs in adults and is manifest by bilateral conjunctival redness, pain, tearing, and an enlarged preauricular lymph node (multiple types may be involved in a single outbreak). Type 53 (a D adenovirus) was the cause of a 2017 outbreak in a Los Angeles County Eye Clinic. Keratitis may lead to reduced vision and blindness. Sexual transmitted genitourinary ulcers and urethritis may be caused by types 2, 8, and 37. Adenoviruses also cause acute gastroenteritis (types 40 and 41), mesenteric adenitis, acute appendicitis, thabdomyolysis, and intussusception. Rarely, they are associated with encephalitis, meningitis, acute respiratory distress syndrome (ARDS), acute flaccid paralysis, and pericarditis. Adenovirus is commonly identified in endomyocardial tissue of patients with myocarditis and dilated cardiomyopathy. Risk factors associated with severity of infection include youth, chronic underlying infections, recent transplantation, and serotypes 5 or 21.

Hepatitis (type 5 adenovirus), pneumonia, and hemorrhagic cystitis (types 11 and 34) tend to develop in infected liver, lung, or kidney transplant recipients, respectively. Disease states that may develop in hematopoietic stem cell transplant patients include hepatitis, pneumonia, diarrhea, hemorrhagic cystitis, tubulointerstitial nephritis, colitis, and encephalitis.

B. Laboratory Findings and Imaging

Antigen detection assays including direct fluorescence assay or enzyme immunoassay are rapid and show sensitivity of 40–60% compared with viral culture (considered the standard). Samples with negative rapid assays require PCR assays or viral cultures for diagnosis. Quantitative real-time rapid-cycle PCR is useful in distinguishing disease from colonization, especially in hematopoietic stem cell transplant patients. Multiplex nucleic acid amplification assays can test for multiple respiratory viruses simultaneously with increased sensitivity. Adenovirus differs from other viral and bacterial respiratory infections seen on chest CT imaging, appearing as a multifocal consolidation or ground-glass opacity without airway inflammatory findings.

Treatment & Prognosis

Treatment is symptomatic. Ribavirin or cidofovir is used in immunocompromised individuals with occasional success, although cidofovir is attendant with significant renal toxicity. Brincidofovir, the lipid-conjugated prodrug of cidofovir, has better oral bioavailability, is better tolerated, and achieves higher intracellular concentrations of active drug than cidofovir but currently is only available through compassionate use policies. A 2017 study of brincidofovir showed efficacy in controlling adenovirus in pediatric hematopoietic cell transplant patients. IVIG is also used in immunocompromised patients and can be used in combination with other therapies, but data are still limited. Reduced immunosuppression is often required. Typing of isolates is useful epidemiologically and in distinguishing transmission from endogenous reactivation. Topical steroids or tacrolimus may be used to treat adenoviral keratoconjunctivitis. Complications of adenovirus pneumonia in children include bronchiolitis obliterans. Deaths are reported on occasion.

The control of epidemic adenoviral conjunctivitis is often difficult and requires meticulous attention to hand hygiene, use of disposable gloves, sterilization of equipment (isopropyl alcohol is insufficient, recommendations are preferred), cohorting of cases, and furloughing of employees. Treatment with a combination of povidone-iodine 1.0% eyedrops and dexamethasone 0.1% eyedrops four times a day can reduce symptoms and expedite recovery.

Vaccines are not available for general use. Use of live oral vaccines containing attenuated type 4 and type 7 was reinstated in military personnel in 2013 and has been associated with significant decrease in adenoviral disease.

1. **Erythoparvovirus Infections**

Parvovirus B19, more commonly known as parvovirus B19, infects human erythroid precursor cells. It is quite widespread (by age 15 years about 50% of children have detectable IgG), and its transmission occurs through respiratory secretions and saliva, through the placenta (vertical transmission with 30–50% of pregnant women nonimmune), and through administration of blood products. The incubation period is 4–14 days. Chronic forms of the infection can occur. Bocavirus, another erythroparvovirus, is a cause of winter acute respiratory disease in children and adults.

**Clinical Findings**

**A. Symptoms and Signs**

Parvovirus B19 causes several syndromes and manifests differently in various populations.

1. **Children**—In children, an exanthematous illness (“fifth disease,” erythema infectiosum) is characterized by a fiery red “slapped cheek” appearance, circumoral pallor, and a subsequent lacy, maculopapular, evanescent rash on the trunk and limbs. Eosinophilic cellulitis (Well syndrome) is also reported with parvovirus B19, as are microvesicular eruptions and atypical rashes. Parvovirus B19 is also one of the most common causes of myocarditis in childhood.

2. **Immunocompromised patients**—A transient aplastic crisis and pure red blood cell aplasia may occur. Bone marrow aspirates reveal absence of mature erythroid precursors and characteristic giant pronormoblasts. The parvovirus B19 gene is detected in 16–19% of acute leukemia and chronic myeloid leukemia patients.

3. **Adults**—A limited nonerosive symmetric polyarthritis that mimics lupus erythematosus and rheumatoid arthritis, which may in some cases be a type II mixed cryoglobulinemia, can develop in middle-aged persons (especially women). Rashes, especially facial, are less common in adults.

Chloroquine and its derivatives exacerbate parvovirus B19–associated anemia and are linked with significantly lower hematocrit in hospital admissions in malaria endemic areas. Rare reported presentations include myocarditis with infarction, constrictive pericarditis, chronic dilated cardiomyopathy (although a 2016 analysis from the Netherlands dispute some cardiac findings), Hashimoto thyroiditis, hepatitis, pneumonitis, neutropenia, thrombocytopenia, a lupus-like syndrome, glomerulonephritis, CNS vasculitis, papular-purpuric “gloves and socks” syndrome, complications of drug hypersensitivity, and a chronic fatigue syndrome. A subclinical infection is documented among patients with sickle cell disease. Other CNS manifestations of parvovirus B19 include encephalitis, meningitis, stroke (usually in sickle cell anemia patients with aplastic crises), and peripheral neuropathy (brachial plexitis and carpal tunnel syndrome) with occasional chronic residua.

The symptoms of parvovirus B19 infection can mimic those of autoimmune states such as lupus, systemic sclerosis, antiphospholipid syndrome, or vasculitis. A more specific entity named relapsing symmetric seronegative synovitis with edema was reported in two cases to be associated serologically with parvovirus B19 infection.

In pregnancy, premature labor, hydrops fetalis, and fetal loss are reported sequelae. Pregnant women with a recent exposure or with suggestive symptoms should be tested for the disease and carefully monitored if results are positive.

A serosurvey from France suggests parvovirus B19 infection may occur more commonly in patients with schizophrenia.

**B. Laboratory Findings**

The diagnosis is clinical (Table 32–2) but may be confirmed by either an elevated titer of IgM anti-parvovirus B19 antibodies in serum or with PCR in serum or bone marrow. By the time common presenting symptoms manifest, in particular a rash or polyarthropathy in an immunocompetent patient, the viremia may have cleared but IgM antibodies are likely present. In immunocompromised patients, RT-PCR is the optimal test. Autoimmune antibodies (antiphospholipid and antineutrophil cytoplasmic antibodies) can be present and are thought to be a consequence of molecular mimicry. False-positive serologies also occur in the presence of recent IVIG and anti–B-cell therapy. Also, remnant parvovirus B19, from tissue and serum, is thought to explain some false-positive findings. Assays on marrow tissue are indicated only if a marrow is deemed necessary for other hematologic reasons.

**Treatment**

Treatment in healthy persons is symptomatic (NSAIDs are used to treat arthralgias, and transfusions are used to treat transient aplastic crises). In immunosuppressed patients including those infected with HIV, IVIG is very effective in the short-term reduction of anemia. Relapses tend to occur about 4 months after administration of IVIG. There is no reduction in encephalitic complications with IVIG. Intrauterine blood transfusion can be considered in severe fetal anemia, although such transfusions have been linked to impaired neurologic development.

**Prevention & Prognosis**

Several nosocomial outbreaks are documented. In these cases, standard containment guidelines, including hand washing after patient exposure and avoiding contact with pregnant women, are paramount.

The prognosis is generally excellent in immunocompetent individuals. In immunosuppressed patients, persistent anemia may require prolonged transfusion dependence. Remission of parvovirus B19 infection in AIDS patients may occur with ART, though the immune reconstitution inflammatory syndrome is also reported.

2. Poxvirus Infections

Among the poxviruses causing disease in humans, the following are the most clinically important: variola/vaccinia, molluscum contagiosum, orf and paravaccinia, and monkeypox.

1. Variola/vaccinia—Smallpox (variola) was a highly contagious disease associated with high mortality and disabling sequelae. Its manifestations include severe headache, acute onset of fever, prostration and a rash characterized by uniform progression from macules to papules to pustules, deep-seated vesicles or pustules. The synchronous progression in smallpox readily differentiates lesions from those of varicella (see also Chapter 6).

Complications of smallpox include bacterial superinfections (cellulitis and pneumonia), encephalitis, and keratitis with corneal ulcerations (risk factor for blindness). Effective vaccination led to its global elimination by 1979 and routine vaccination stopped in 1985. Recommendations to destroy remaining samples of this virus have not been acted upon thus far, and significant concern exists for potential misuse of these repositories in military or terrorist activities.

Smallpox should be considered, in concordance with the CDC Smallpox Response Plan (https://www.cdc.gov/smallpox/bioterrorism-response-planning/community/index.html), in any patient with fever and a characteristic rash for which other etiologies—such as herpes infections (eczema herpeticum may be differentiated from suspect smallpox by appropriate serologic stains and clinical appearance), erythema multiforme, drug reactions, or other infections—are unlikely. Patients with suspected infection should be placed in airborne and contact isolation and the official agency contacted (CDC Poxvirus and Rabies Branch help desk may be reached at 404-639-4129 and the Director’s Emergency Operation Center at 770-488-7100).

Guidelines regarding smallpox vaccination are available at https://www.cdc.gov/smallpox/vaccine-basics/index.html.

2. Molluscum contagiosum—Molluscum contagiosum is caused by a molluscipox virus that may be transmitted sexually or by other close contact. The disease is manifested by pearly, raised, umbilicated skin nodules sparing the palms and soles. Keratoconjunctivitis can occur. Most ocular lesions are typical umbilicated dome-shaped lesions, but a variety of atypical ocular lesions are reported often in immunocompetent patients, more often in females and young adults (mean age 19).

There may be an association with atopic dermatitis or eczema. Marked and persistent lesions in AIDS patients respond readily to combination ART. Treatment options include destructive therapies (curettage, cryotherapy, cantharidin, 10–15% hydrogen peroxide, and keratolytics, among others), immunomodulators (imiquimod, cimetine, and Candida antigen), and antiviral agents (topical cidofovir is effective anecdotally in refractory cases; brincidofovir, an agent under investigation for treating other viral infections, has shown some efficacy). No treatment is uniformly effective, and multiple courses of therapy are often needed. One meta-analysis recommends natural resolution of lesions if normal immunity can be restored. Cryptococcal skin lesions can mimic molluscum contagiosum.

3. Orf and paravaccinia—Orf (contagious pustular dermitis, or ecthyma contagiosa) and paravaccinia (milker’s nodules) are occupational diseases acquired by contact with sheep/goats and cattle, respectively. Household meat processing and animal slaughter have been implicated as risk factors. A new poxvirus akin to parapoxviruses was reported in 2015 in two patients from rural Tennessee and Missouri (the latter had also traveled to Tanzania). Orf is a common infection in sheep, goats, and deer. Thus, it is found worldwide, and farmers, veterinarians, and hunters are considered high-risk populations. It progresses through six clinically distinct dermatologic stages and lesions usually heal in 3–6 weeks without scarring. The use of nonporous gloves for persons handling animals is recommended, especially if the persons are immunosuppressed. Molecular tests are used to confirm clinical diagnosis. Although there is no specific treatment, Orf anecdotally responds to imiquimod. A live vaccine is available for animals.

4. Monkeypox—First identified in 1970, monkeypox is enzootic in the rain forests of equatorial Africa and presents in humans as a syndrome similar to smallpox. The incubation period is about 13 days (range, 6–28 in a recent Central African Republic outbreak) and limited person-to-person spread occurs. African mortality rates vary from 3% to 11% depending on the immune status of the patient. Secondary attack rates appear to be about 10%. Since 2016, confirmed cases of monkeypox have occurred in Central African Republic, Democratic Republic of the Congo, Liberia, Nigeria, and Sierra Leone and in captive chimpanzees in Cameroon. Risk factors identified from the Democratic Republic of Congo include being bitten by rodents, working as a hunter, and being male over 18 years of age. Confusion with smallpox and varicella occurs; however, both lymphadenopathy (seen in up to 90% of unvaccinated persons) and a febrile prodrome are prominent features in monkeypox infection. The monkeypox rash is distinguished by its deep-seated and well-circumscribed nature, lesions at the same stage of development (unlike varicella but like smallpox), and its centrifugal progression (including palms and soles). Suspected cases should be placed on standard, contact, and droplet precautions; local and state public health officials and the CDC should be notified for assistance with confirmation of the diagnosis (by electron microscopy, viral culture, ELISA, PCR, and a GeneXpert assay referred to as MPX/OPX [monkeypox/orthopox]). There are no standard or optimized guidelines for the clinical management of monkeypox. Cidofovir is effective in vitro against monkeypox, and its less toxic prodrug...
VIRUSES & GASTROENTERITIS

Viruses are responsible for at least 30–40% of cases of infectious diarrhea in the United States. These agents include rotaviruses; caliciviruses, including noroviruses such as Norwalk virus; astroviruses; enteric adenoviruses; and, less often, toroviruses, coronaviruses, picornaviruses (including the Aichi virus), and pestiviruses. Rotaviruses and noroviruses are responsible for most nonbacterial cases of gastroenteritis.

Rotaviruses are reoviruses with eight species and significant animal reservoirs. They are the leading worldwide cause of dehydrating gastroenteritis in very young children and are associated with significant morbidity and mortality. Each year, over 400,000 children die of rotavirus infection worldwide. Children aged 6 months to 2 years are the most affected, although adults are affected occasionally as well. By age 5, virtually every child has been infected with this pathogen. The diverse set of rotaviruses (classified by glycoproteins and protease-sensitive proteins [G-type and P-type antigens], which segregate independently) results in a constellation of phenotypes, although only about four of these are responsible for over 90% of disease. Rotavirus infections follow an endemic pattern, especially in the tropics and low-income countries, but they peak during the winter in temperate regions. The virus is transmitted by fecal-oral route and can be shed in feces for up to 3 weeks in severe infections. In outbreak settings (eg, day care centers), the virus is ubiquitously found in the environment, and secondary attack rates are between 16% and 30% (including household contacts). Nosocomial outbreaks are reported.

The disease is usually mild and self-limiting. A 2- to 3-day prodrome of fever and vomiting is followed by nonbloody diarrhea (up to 10–20 bowel movements per day) lasting for 1–4 days. It is thought that systemic disease occurs rarely, and unusual reported presentations include cerebellitis and pancreatitis. Patients with gastroenteritis are not routinely tested for rotavirus because the results do not alter treatment. Oral and intravenous rehydration solutions are the primary treatment options, but effective adjunctive therapies include specific probiotics (eg, Lactobacillus GG or Saccharomyces boulardii), nitazoxanide, diosmectite, or raccadotril. Adjunctive therapies such as oral odanestron shorten the median duration of diarrhea and hospitalization. Local intestinal immunity gives protection against successive infection.

Vaccines have been highly successful in reducing the global burden of rotavirus. Currently they are recommended for infants older than 6 weeks but younger than 2 years; studies are underway to assess the safety and efficacy of starting vaccination in the newborn period. Several rotavirus vaccines exist, and two are available in the United States: a live, oral, pentavalent human-bovine reassortment rotavirus vaccine (PRV, RotaTeq; to be given at 2, 4, and 6 months of age) and a live, oral attenuated monovalent human rotavirus vaccine (HRV, Rotarix; to be given at 2 and 4 months of age). The vaccines showed 85–98% efficacy against severe rotavirus gastroenteritis in trials based in the Americas and Europe. Reduced efficacy (50–64%) has been noted in studies conducted in Asia and Africa. One advantage of these vaccines is the evidence of heterotypic immunity (prevention against rotavirus strains not included in the vaccine). Accordingly, some data from the Americas suggest that rotavirus vaccination confers herd immunity to children under 1 year of age.

Vaccine coverage is inadequate in the United States for rotavirus (74.6% in the 2016 National Immunization Study), particularly among the poor. National immunization programs of over 80 countries include rotavirus vaccine, and the different rotavirus vaccines are available commercially in 100 countries.

Effectiveness of live oral rotavirus vaccines is reduced in low-resource settings.
With the control of rotavirus, noroviruses, such as Norwalk virus (one of a variety of small round viruses divided into 6 genogroups [3 causing disease in man] and at least 25 genotypes), are now the major cause of diarrhea globally. Noroviruses are a leading cause of food-borne disease in the United States (with food handlers largely responsible and associated foods most often leafy vegetables, fruits/nuts, and mollusks) and are significantly associated with military deployment as well as travel-associated and nosocomial infections.

Norovirus gastroenteritis is responsible for up to 20% of all diarrhea in both children and adults and an estimated 800 deaths annually in the United States and 200,000 deaths globally. The efficacy of the rotavirus vaccination has increased the percentage of gastroenteritis caused by norovirus. The noroviruses appear to evolve by antigenic drift (similar to influenza). While 90% of young adults show serologic evidence of past infection, no long-lasting protective immunity develops, and reinfections are common.

Outbreak environments include long-term care facilities (nursing homes in particular), restaurants, hospitals, schools, day care centers, vacation destinations (including cruise ships), and military bases. Persons at particular risk are younger individuals, older adults, those who are institutionalized, and those who are immunosuppressed. A strain that began in Australia (GI.4 Sydney) is responsible for increasing proportions of US cases. The GI.4 Sydney strain was the main cause of all cruise ship norovirus infections between 2008 and 2014. It was also the predominant cause of acute gastroenteritis in the 2016–2017 season in the United States. Although transmission is usually fecal-oral, airborne, person-to-person, and waterborne transmission are also documented. A short incubation period (24–48 hours), a short symptomatic illness (12–60 hours, but up to 5 days in hospital-associated cases), a high frequency (greater than 50%) of vomiting, and absence of bacterial pathogens in stool samples are highly predictive of norovirus gastroenteritis.

RT-PCR of stool samples is used for diagnostic and epidemiologic purposes. Several licensed multiple pathogen platform assays are available, but they are expensive and interpretation of the cause of illness in a given patient may be difficult. Treatment options are similar to rotavirus (see above) and rely mostly on oral and intravenous rehydration. Deaths are rare in the developed world, and the more common associated diseases are aspiration pneumonia, septicemia, and necrotizing enterocolitis.

Outbreak control for both rotavirus and norovirus infections include strict adherence to general hygienic measures. Despite the promise of alcohol-based sanitizers for the control of pathogen transmission, such cleansers may be relatively ineffective against the noroviruses compared with antibacterial soap and water, reinforcing the need for new hygienic agents against this prevalent group of viruses. Cohorting of sick patients, contact precautions for symptomatic hospitalized patients, exclusion from work of symptomatic staff until symptom resolution (or 48–72 hours after this for norovirus disease), and proper decontamination procedures are crucial.

**ENTEROVIRUSES THAT PRODUCE SEVERAL SYNDROMES**

The most famous enterovirus, the poliomyelitis virus, is discussed above under Major Vaccine-Preventable Viral Infections. Other clinically relevant enteroviral infections are discussed in this section.

1. **Coxsackievirus Infections**

Coxsackievirus infections cause several clinical syndromes. As with other enteroviruses, infections are most common during the summer. Two groups, A and B, are defined either serologically or by mouse bioassay. There are more than 50 serotypes.

![Clinical Findings](https://example.com/cf.png)

**A. Symptoms and Signs**

**1. Summer grippe (A and B)**—A febrile illness, principally of children, summer grippe usually lasts 1–4 days. Minor upper respiratory tract infection symptoms are often present.

**2. Herpangina (A2–6, 10; B3)**—There is sudden onset of fever, which may be as high as 40.6°C, sometimes with febrile convulsions. Other symptoms are headache, myalgia, and vomiting. The sore throat is characterized early by petechiae or papules on the soft palate that ulcerate in about 3 days and then heal. Treatment is symptomatic.

**3. Epidemic pleurodynia (Bornholm disease) (B1–5)**—Pleuritic pain is prominent. Tenderness, hyperesthesia, and muscle swelling are present over the area of diaphragmatic attachment. Other findings include headache, sore throat, malaise, nausea, and fever. Orchitis and aseptic meningitis occur in less than 10% of patients. Most patients are ill for 4–6 days.

**4. Aseptic meningitis (A and B) and other neurologic syndromes**—Fever, headache, nausea, vomiting, stiff neck, drowsiness, and CSF lymphocytosis without chemical abnormalities may occur, and pediatric clusters of group B
As with enterovirus 70, the heart failure in the neonatal period secondary to in utero myocarditis and over 20% of adult cases of myocarditis and dilated cardiomyopathy are associated with group B (especially B3) infections.

5. Acute nonspecific pericarditis (B types)—Sudden onset of anterior chest pain, often worse with inspiration and in the supine position, is typical. Fever, myalgia, headache, and pericardial friction rub appear early and these symptoms are often transient. Evidence for pericardial effusion on imaging studies is often present, and the occasional patient has a paradoxical pulse. Electrocardiographic evidence of pericarditis is often present. Relapses may occur.

6. Myocarditis (B1–5)—Heart failure in the neonatal period secondary to in utero myocarditis and over 20% of adult cases of myocarditis and dilated cardiomyopathy are associated with group B (especially B3) infections.

7. Hand, foot, and mouth disease (A5, 6, 10, 12, and 16, B5)—This disease is sometimes epidemic and is characterized by stomatitis, a vesicular rash on hands and feet, nail dystrophies, and onychomadesis (nail shedding) (Figure 32–6). Enterovirus 71 is also a causative agent of usually more severe disease. A16 disease is usually mild. A6 may be atypical but is usually self-limited. Rare fatalities are reported among surveillance programs in China.

8. Epidemic conjunctivitis—As with enterovirus 70, the A24 variant of coxsackievirus is associated with acute epidemic hemorrhagic conjunctivitis in tropical areas with outbreaks reported in southern China, Pakistan, southern Sudan, the Comoros, Uganda, Cuba, and Thailand. It is also reported as a cause of corneal endothelitis after cataract surgery.

9. Other syndromes associated with coxsackievirus infections—These include rhabdomyolysis, fulminant neonatal hepatitis (occurs rarely), pancreatitis with concomitant hepatitis and myocarditis (A4), glomerulopathy (group B infections), onychomadesis (B1), neonatal hemophagocytic lymphohistiocytosis (B1), types 1 and 2 diabetes mellitus (mainly group B infections), and thyroid disease (group B4), although definitive causality is not established. A pathogenic role in primary Sjögren syndrome and acute myocardial infarction has also been proposed for group B coxsackievirus infections. A report of confirmed infective endocarditis due to coxsackievirus B2 in a patient with a prosthetic cardiac device suggests that viral etiologies of culture-negative infective endocarditis should be considered.

B. Laboratory Findings

Routine laboratory studies show no characteristic abnormalities. Neutralizing antibodies appear during convalescence. The virus may be isolated from throat washings or stools inoculated into suckling mice. Viral culture is expensive, labor intensive, and requires several days for results. A PCR test for enterovirus RNA is available and, although it cannot identify the serotype, may be useful, particularly in cases of meningitis.

Treatment & Prognosis

Treatment is symptomatic. Except for meningitis, myocarditis, pericarditis, diabetes, and rare illnesses such as pancreatitis or poliomyelitis-like states, the syndromes caused by coxsackieviruses are benign and self-limited. Two controlled trials showed a potential clinical benefit with plecanaril for patients with entroviral meningitis although the compassionate use of this medication has stopped (clinicians can contact Schering Plough for updates). There are anecdotal reports of success with IVIG in severe disease. Vaccines against the most common etiologic agents in a given country have been developed, but simultaneous circulation of more than one virus make coxsackievirus vaccines based on a single agent relatively ineffective.
Over 30 serotypes of echoviruses are recognized and the most common serotypes for disease are types 6, 9, 11, 19, and 30. Most can cause aseptic meningitis, which may be associated with a rubelliform rash. Transmission is primarily fecoral. Hand washing is an effective control measure in outbreaks of aseptic meningitis. Outbreaks related to fecal contamination of water sources, including drinking water and swimming and bathing pools, were reported previously.

Besides meningitis, other conditions associated with echoviruses range from common respiratory diseases and epidemic diarrhea to myocarditis, a hemorrhagic obstetric syndrome, keratoconjunctivitis, severe hepatitis with coagulopathy, leukocytoclastic vasculitis, encephalitis with sepsis, interstitial pneumonitis, pleurodynia, hemophagocytic syndromes (in children with cancer), sudden deafness, encephalitis, acute flaccid paralysis (a leading cause in India), optic neuritis, uveitis, and septic shock. Echoviruses and enteroviruses are also a common cause of nonspecific exanthems.

As with other enterovirus infections, diagnosis is best established by correlation of clinical, epidemiologic, and laboratory evidence. Cytopathic effects are produced in tissue culture after recovery of virus from throat washings, blood, or CSF. An enterovirus PCR of the CSF can assist in the diagnosis and is associated with a shorter duration of hospitalization in febrile neonates. Fourfold or greater rises in antibody titer signify systemic infection.

Treatment is usually symptomatic, and the prognosis is excellent, though there are reports of mild paralysis after CNS infection. In vitro data suggest some role for amantadine or ribavirin, but clinical studies supporting these findings are not available.

From a public health standpoint, clustered illnesses, such as among travelers swimming in sewage-infested seaway, suggest point-source exposure. Prevention of fecal contamination and maintenance of pool hygiene through chlorination and pH control are important public health control measures.

3. Enteroviruses 68, 70, 71, & Related Agents
Several distinct clinical syndromes are described in association with enteroviruses.

**Enterovirus D68 (EV-D68)** is a unique enterovirus that shares epidemiologic characteristics with human rhinovirus and is typically associated with respiratory illness. Several clusters are reported from the Netherlands, Japan, the Philippines, and Thailand. An outbreak throughout the United States was reported during 2014–2015. The outbreak was also associated with cases of acute flaccid myelitis but not definitively linked thus far. The virus is implicated also in aseptic meningitis and encephalitis.

**Enterovirus 70 (EV-70),** a ubiquitous virus first identified in 1969 and responsible for abrupt bilateral eye discharge and subconjunctival hemorrhage with occasional systemic symptoms, is most commonly associated with acute hemorrhagic conjunctivitis.

**Enterovirus 71 (EV-71)** almost always occurs in the Asia-Pacific region and is associated with hand, foot, and mouth disease (HFMD), which can be severe or even fatal, herpangina as well as a form of epidemic encephalitis associated on occasion with pulmonary edema, and acute flaccid paralysis often mimicking poliomyelitis. A recombinant virus (between EV-71 and coxsackievirus A16) caused an outbreak of HFMD in Fuyang, China, in 2008. In Taiwan, 29% of EV-71 cases in children are asymptomatic. There is an association reported between gastrointestinal enterovirus infection and type 1 diabetes.

Human enteroviruses are neurotropic. They may have a role in amyotrophic lateral sclerosis. EV-D68 has been reported in a case of fatal meningitis/encephalitis. A number of nonpolio type C enteroviruses are associated with polio-like syndromes, and surveillance for these is most active in China. Enterovirus infection of the pancreas can trigger cell-mediated autoimmune destruction of beta cells resulting in diabetes. Enterovirus myocarditis can be a serious infection in neonates, complicated by cardiac dysfunction and arrhythmias.

Mortality is especially high in EV-71–associated brainstem encephalitis, which is often complicated by pulmonary edema, particularly when it occurs in children younger than 5 years. A complication is autonomic nervous system dysregulation, which may precede the pulmonary edema. Because of lower herd immunity, HFMD tends to infect the very young (under age 5) in nonendemic areas. Clinical and epidemiologic findings aided by isolation of the suspect agent from conjunctival scraping for EV-70; vesicle swabs, body secretions, or CSF for EV-71; and respiratory secretions for D68 facilitate diagnosis of these enteroviral entities. Enzyme immunoassays and complement fixation tests show good specificity but poor sensitivity (less than 80%). RT-PCR may increase the detection rate in enterovirus infections and is useful in the analysis of CSF samples among patients with meningitis and of blood samples among infants with a sepsis-like illness.

Treatment of these entities remains largely symptomatic. A study in China showed that recombinant human interferon-alpha1b in EV-71–associated hand, foot, and mouth disease was associated with decreased fever duration, healing time of typical skin or oral mucosal lesions, and EV-71 viral load. There is anecdotal success in managing myocarditis with immunoglobulins.

The major complication associated with EV-70 is the rare development of an acute neurologic illness with motor paralysis akin to poliomyelitis. Treatment of acute flaccid paralysis related to EV-71 with IVIG does not appear to improve neurologic outcomes. Attention-deficit hyperactivity occurs in about 20% with confirmed infection.

EV-D68 requires supportive care with particular attention to respiratory support. The CDC’s National Enterovirus Surveillance System should receive reports of disease at wnhix@cdc.gov.

Household contacts, especially children under 6 months of age, are at particular risk for EV-71 acquisition. A commercial disinfectant, Virkon S at 1–2% application, appears to reduce infectivity of fomites. A stage-based supportive treatment for EV-71 infections, recognizing the potential for

CMDT 2020 1451

CMDT20_Ch32_p1399-p1464.indd 1451

01/07/19 2:42 PM
Severe, intractable headaches, prostration, persisting weakness, and encephalitis should prompt a search for pathogenic viruses. General Considerations

Prodrome of headache, then chills and fever. The diagnosis is confirmed by complement fixation, virus isolation, or PCR. Macular rash appearing on days 4–7 on the trunk and extremities and diaphoresis on the palms and soles. CSF parameters include a normal count in over 90% and an abnormal protein in less than 50%. CNS infection may be associated with migration of peoples as well as with refugee camps. Because of aerosol transmissibility, R. prowazekii is considered a possible bioterrorism agent. In the United States, cases occur among the homeless, refugees, and the unhygienic, most often in the winter.

Rickettsial Diseases

Epidemic (Louse-Borne) Typhus

4. Human Parechovirus Infection (HPeV)

HPeV is 1 of 19 genotypes among a distinct genus of picorna- viruses and causes a wide variety of disease in humans, especially in infants. The pathogen mainly affects small children during the summer and early fall, although disease can also occur in older adults. Cases are reported worldwide. HPeV3 is the most commonly reported isolate in the United States. Clinical presentation is mainly driven by gastrointestinal and respiratory illness, although otitis, neonatal sepsis, fever without a detectable source, gastroenteritis, flaccid paralysis, myalgias (which may be epidemic), diffuse maculopapular rash, conjunctivitis, and palmar-plantar rashes, aseptic meningitis, intracranial hemorrhage, seizures, pericarditis, and an acute disseminated encephalitis are described in the literature.

HPeV6 typically affects individuals older than 20 years. HPeV3 is responsible for meningitis/encephalitis, neonatal sepsis (13% of late-onset neonatal sepsis [between 4 and 120 days of life] in one series was due to parechovirus) and was reported in association with necrotizing enterocolitis and hepatitis. It is the most common cause of neonatal meningitis and is the picornavirus most often found in CSF samples of CNS-related infections in very young children. CSF parameters include a normal count in over 90% and an abnormal protein in less than 50%. CNS infection may be seen with HPeV4 as well. Respiratory and gastrointestinal illnesses are seen with types HPeV4–HPeV6, HPeV10, and HPeV13–HPeV15.

Treatment is largely supportive and rapid identification of the viral antigen by PCR in stools, respiratory samples, and CSF may decrease use of unnecessary antibiotics and shorten hospital stay, although current PCR assays are not always sufficiently sensitive to exclude parechoviruses. Intravenous immunoglobulin was anecdotally successful in one case of parechovirus dilated cardiomyopathy and maternal antibodies to parechovirus type 3 are protective. Reported complications of neonatal cerebral infections include learning disabilities, epilepsy, and cerebral palsy. Because of aerosol transmissibility, parechovirus is considered a possible bioterrorism agent. In the United States, cases occur among the homeless, refugees, and the unhygienic, most often in the winter.

\(^1\) Also serve as arthropod reservoirs by maintaining rickettsiae through transovarian transmission.

\(^2\) Limited data available on exact cell involved in pathogenesis.

\(^3\) Human infection results from inhalation of dust.
R prowazekii can survive in lymphoid and adipose (in endothelial reservoirs) tissues after primary infection, and years later, produce recrudescence of disease (Brill-Zinsser disease) without exposure to infected lice. This phenomenon can serve as a point source for future outbreaks.

An extrahuman reservoir of R prowazekii in the United States is flying squirrels, Glaucomys volans. Transmission to humans can occur through their ectoparasites, known as sylvatic typhus, usually causing atypical mild disease. A case of recrudescence (Brill-Zinsser) disease 11 years after disease acquired by contact with flying squirrels is reported. Foci of sylvatic typhus are found in the eastern United States and are reported to occur in Brazil, Ethiopia, and Mexico.

► Clinical Findings

A. Symptoms and Signs

Prodromal malaise, cough, headache, backache, arthralgia, myalgia, and chest pain begin after an incubation period of 10–14 days, followed by an abrupt onset of chills, high fever, and prostration, with flu-like symptoms progressing to delirium and stupor. The headache is severe, and the fever is prolonged (Table 32–2).

Other findings consist of conjunctivitis, mild vitritis, retinal lesions, optic neuritis, and hearing loss from neuropathy of the eighth cranial nerve, abdominal pain, and often splenomegaly. Flushed faces and macular rash (that may become confluent) appear; the rash appears first in the axillae and then over the trunk, spreading to the extremities on the fifth or sixth day of illness but sparing the palms of hands and soles of feet. In severely ill patients, the rash becomes hemorrhagic, and hypotension becomes marked. Pneumonia, thromboses, vasculitis with major vessel obstruction and gangrene, circulatory collapse, myocarditis, uremia, and seizure may occur. Improvement begins 13–16 days after onset with a rapid drop of fever and typically a spontaneous recovery.

Brill-Zinsser disease has a more gradual onset than primary R prowazekii infection; fever and rash are of shorter duration, and the disease is milder.

B. Laboratory Findings

The white blood cell count is variable. Thrombocytopenia, elevated liver enzymes, proteinuria, and hematuria commonly occur. Serum obtained 5–12 days after onset of symptoms usually shows specific antibodies for R prowazekii antigens as demonstrated by complement fixation, microagglutination, or immunofluorescence. In primary rickettsial infection, early antibodies are IgM; in recrudescence (Brill-Zinsser disease), early antibodies are predominantly IgG. A PCR test exists, but its availability is limited.

C. Imaging

Radiographs of the chest may show patchy consolidation.

Differential Diagnosis

The prodromal symptoms and the early febrile stage lack enough specificity to permit diagnosis in nonepidemic situations. The rash is sufficiently distinctive for diagnosis, but it may be absent in up to 50% of cases or may be difficult to observe in dark-skinned persons. A variety of other acute febrile diseases should be considered, including typhoid fever, meningococcemia, and measles.

► Treatment

Treatment consists of doxycycline 100 mg orally twice daily for 7–10 days or for at least 3 days after the fever subsides. A single dose of 200 mg of doxycycline may be effective; however, some patients may relapse. Chloramphenicol is considered less effective than doxycycline, but it is still the drug of choice in pregnancy.

► Prognosis

The prognosis depends greatly on the patient’s age and immune status. The mortality rate is 10% in the second and third decades but in the past, it reached 60% in the sixth decade. Brill-Zinsser disease is rarely fatal.

► Prevention

Prevention consists of louse control with insecticides, particularly by applying chemicals to clothing or treating it with heat, and frequent bathing.

A deloused and bathed typhus patient is not infectious. The disease is not transmitted from person to person. Patients are infectious from the lice during the febrile period and perhaps 2–3 days after the fever returns to normal.

No vaccine is available for the prevention of R prowazekii infection.

Ulutasdemir N et al. The epidemic typhus and trench fever are risk for public health due to increased migration in southeast of Turkey. Acta Trop. 2018 Feb;178:115–8. [PMID: 29126839]

2. Endemic (Murine) Typhus

Rickettsia typhi, a ubiquitous pathogen recognized on all continents, is transmitted from rat to rat through the rat flea (Table 32–3). Serosurveys of animals show high prevalence of antibodies to R typhi in opossums, followed by dogs and cats. Humans usually acquire the infection in an urban or suburban setting when bitten by an infected flea. Rare human cases in the developed world occur in travelers, usually to Southeast Asia, Africa, or the Mediterranean area, although other pockets of infection are also known to occur in the Andes and the Yucatán. In the United States, the related Rickettsia felis cases (now a spotted fever rickettsia, discussed below) are mainly reported from Texas and southern California.

► Clinical Findings

A. Symptoms and Signs

The presentation is nonspecific, including fever, headache, myalgia, and chills. Relative bradycardia is reported. Maculopapular rash occurs in around 50% of cases; it is concentrated on the trunk, mostly sparing the palms and soles, and fades rapidly.
The illness may be associated with maternal death, miscarriage, preterm birth, and low birth weight if acquired early during pregnancy.

### B. Laboratory Findings

Serologic confirmation may be necessary for differentiation, with complement-fixing or immunofluorescent antibodies detectable within 15 days after onset, with specific R typhi antigens. A fourfold rise in serum antibody titers between the acute and the convalescent phase is diagnostic. It is important to note that R typhi antigens frequently cross-react with those of R prowazekii. The PCR can distinguish between these two infections depending on the sample type, the timing of sample collection, bacterial load, and severity of disease. During the first week of illness, PCR is the most sensitive test if samples are taken before doxycycline administration.

#### Differential Diagnosis

The most common entity in the differential diagnosis is Rocky Mountain spotted fever, usually occurring after rural exposure and with a different rash (centripetal versus centrifugal for epidemic or endemic typhus).

#### Complications

The most common complication is pulmonary, in the form of pneumonia, followed by pleural effusion and respiratory failure. Other complications include neurologic (peripheral facial paralysis, meningitis, ataxia, seizures), acute kidney injury, and multiorgan failure. Rare complications include ocular findings, disseminated intravascular coagulation, and hemophagocytosis syndrome. Anemia, thrombocytopenia, leukopenia, hyponatremia, and elevated levels of liver enzymes commonly occur.

#### Treatment

Doxycycline 100 mg orally twice daily for 7–10 days (or until the patient is afebrile for 48 hours) is the drug of choice, except during pregnancy. Ciprofloxacin (500–750 mg orally twice a day) and ampicillin (500 mg orally three times a day) are reportedly successful in pregnant women. Azithromycin is frequently used but is not associated with improved fetal outcomes.

#### Prevention

Preventive measures are directed at control of rats and ectoparasites (rat fleas) with insecticides, rat poisons, and rat-proofing of buildings.

#### Prognosis

Endemic typhus is usually a self-limited disease. A large case series from Texas reported a fatality rate of 0.4%.

### 3. Scrub Typhus (Tsutsugamushi Fever)

#### General Considerations

Scrub typhus is caused by Orientia tsutsugamushi, which is a parasite of rodents and is transmitted by larval trombiculid mites (chiggers). Multiple strains exist and are associated with geographic areas. The disease is endemic in Korea; China; Taiwan; Japan; Pakistan; India (where it is reported to be the leading cause of acute febrile illness in central India); Thailand (where scrub typhus is also the leading cause of acute undifferentiated fever); Malaysia; Vietnam; Laos; and Queensland, Australia (Table 32–3), which form an area known as the “tsutsugamushi triangle.” Scrub typhus is a cause of acute febrile illness in India and China and is a recognized cause of fever of unknown origin. Cases are also reported in the Middle East, Kenya, and South America. Transmission is often more common at higher altitudes. The mites live on vegetation (grass and brush) but complete their maturation cycle by biting humans who encounter infested vegetation. Risk factors in China include female sex, age between 60 and 69 years, and farming. Therefore, the disease is more common in rural areas, but urban cases have also been described. Vertical transmission occurs, and blood transfusions may transmit the pathogen as well. Rare occupational transmission via inhalation is documented among laboratory workers. Cases among travelers to endemic areas are increasingly recognized.

#### Clinical Findings

**A. Symptoms and Signs**

After a 1- to 3-week incubation period, malaise, chills, severe headache, and backache develop. At the site of the bite, a papule evolves into a flat black eschar (the groin and the abdomen being the most common sites followed by the chest and axilla), which is a helpful finding for diagnosis but was only described in 19% of patients in a South Korean series of scrub typhus. The regional lymph nodes are commonly

#### Complications

Other complications include neurologic (peripheral facial paralysis, meningismus, ataxia, seizures), acute kidney injury, and multiorgan failure. Rare complications include ocular findings, disseminated intravascular coagulation, and hemophagocytosis syndrome. Anemia, thrombocytopenia, leukopenia, hyponatremia, and elevated levels of liver enzymes commonly occur.

#### ESSENTIALS OF DIAGNOSIS

- Exposure to mites in endemic South and East Asia, the western Pacific (including Korea), and Australia.
- Black eschar at site of the bite, with regional and generalized lymphadenopathy.
- High fever, relative bradycardia, headache, myalgia, and a short-lived macular rash.
- Frequent pneumonitis, encephalitis, and myocarditis.

enlarged and tender, and sometimes a more generalized adenopathy occurs. Fever rises gradually during the first week of infection, and the rash is usually macular and primarily on the trunk area. The rash can be fleeting or more severe, peaking at 8 days but lasting up to 21 days after onset of infection. Relative bradycardia, defined as an increase in heart rate of fewer than 10 beats/min for a 1-degree Celsius increase in temperature, frequently accompanies scrub typhus infection. The occurrence of relative bradycardia has no effect on clinical outcome. Gastrointestinal symptoms, including nausea, vomiting, and diarrhea, occur in nearly two-thirds of patients and correspond to the presence of superficial mucosal hemorrhage, multiple erosions, or ulcers in the gastrointestinal tract. Acute kidney injury and other renal abnormalities are frequently present.

Severe complications, such as pneumonitis, myocarditis, encephalitis or aseptic meningitis, peritonitis, granulomatous hepatitis, hemophagocytic syndrome, immune thrombocytopenia, disseminated intravascular coagulation, cerebrovascular hemorrhage or infarction, cranial nerve palsies, parkinsonian symptoms, ARDS, or hemophagocytosis, may develop during the second or third week. An attack confers prolonged immunity against homologous strains and transient immunity against heterologous strains. Heterologous strains produce mild disease if infection occurs within a year after the first episode.

B. Laboratory Findings

Thrombocytopenia and elevation of liver enzymes, bilirubin, and creatinine are common. Indirect immunofluorescent assay and indirect immunoperoxidase assays are the gold standard for scrub typhus diagnosis. These tests are expensive and have limited availability. An ELISA detecting *Orientia* specific antibodies in serum is available. PCR (from the eschar or blood) is the most sensitive diagnostic test but remains positive even after initiation of treatment. Culture of the organism from blood obtained in the first few days of illness is another diagnostic modality but requires a specialized biological safety level 3 laboratory. It is suggested to combine IgM detection by ELISA and conventional PCR to improve the diagnosis of scrub typhus.

Differential Diagnosis

Leptospirosis, typhoid, dengue, malaria, Q fever, hemorrhagic fevers, tuberculosis meningitis, and other rickettsial infections should be considered. The headache may mimic trigeminal neuralgia. Scrub typhus is a recognized cause of obscure tropical fevers, especially in children. The presence of an eschar, lymphocytosis, and elevated C-reactive protein (CRP) helped distinguish scrub typhus from dengue in a Northern Thai study.

Treatment & Prognosis

Without treatment, fever subsides spontaneously after 2 weeks, but the mortality rate may be 10–30%. The treatment of choice is doxycycline (100 mg orally twice daily) or minocycline (100 mg intravenously twice daily) until there is evidence of clinical improvement for at least 3 days after the fever subsides. Shorter duration of therapy is associated with relapse. Alternative therapy for pregnant women and patients with doxycycline allergy include chloramphenicol, although chloramphenicol- and tetracycline-resistant strains have been reported from Southeast Asia. Azithromycin is shown to be as effective as doxycycline with fewer side effects, but it is more expensive. Azithromycin may not prevent poor fetal outcomes in infected pregnant women. Poor prognostic factors include hypotension requiring vasopressors, ICU care, age over 60 years, absence of an eschar (making the diagnosis difficult), pregnancy, and laboratory findings such as leukocytosis or hypoalbuminemia. Most patients recover without neurologic sequelae.

Prevention

Mite control with repeated application of long-acting miticides and, less so, rodent control can make endemic areas safe. Insect repellents on clothing and skin as well as protective clothing are effective preventive measures. Although chemoprophylaxis with doxycycline has been used, the CDC does not recommend prophylaxis with antibiotics for asymptomatic travelers. No effective vaccines are available.

General Considerations

Despite its name, most cases of Rocky Mountain spotted fever (RMSF) occur outside the Rocky Mountain area. More than half of the cases are from five states: North Carolina, Tennessee, Oklahoma, Missouri, and Arkansas. RMSF is endemic in Central and South America with a small fatal familial cluster reported from Panama (Table 32–3). Native Americans are at high risk for infection. The causative agent, *R. rickettsii*, is transmitted to humans by the bite of ticks, including the Rocky Mountain wood tick, *Dermacentor andersoni*, in the western United States, and the American dog tick, *D. variabilis*, in the eastern United States. Several hours of contact between the tick and the human host are required for transmission. The brown dog tick, *Rhipicephalus sanguineus*, is a vector in eastern Arizona and responsible for many Native American cases. Epidemic RMSF, as described in Arizona and Mexico, is associated with massive local infestations of the brown dog tick in domestic dogs, which may explain why the incidence of RMSF in the three most highly affected communities in an Arizona epidemic from 2003 to 2012 was 150 times the US national average. Other hard-bodied ticks transmit the organism in the southern United States and in Central and South America and are responsible for transmitting it among rodents, dogs, porcupines, and other animals. Human cases reemerged in Mexico in 2008 after decades of quiescence (since the 1940s). In 2015, northern Mexico reported a total of 1129 RMSF cases including 188 deaths, mostly in Sonora, Mexico.

There are 25 genotypes of *R. rickettsii* in four different groups, and potential genomic-clinical correlations are underway. Several other rickettsial species cause mild, nonlethal infections in the United States, including *R. parkeri*, *R. philipi*, and *R. massiliae*. These are discussed in the “tick typhus” section.

In the United States, the estimated annual incidence of RMSF is as high as seven cases per million persons (primarily occurring from April through September), with a higher incidence among children and men. Better diagnostic capacity and improved surveillance are thought responsible for the changing epidemiology.

A Brazilian spotted fever with higher mortality than RMSF is thought to be due to a virulent strain of *R. rickettsii*. A host of spotted fever species have been identified from human patients over the last 20 years throughout the world including species from China (*Rickettsia* sp. XY99), Slovakia (*R. slovaca*), Morocco (*R. aeschlimannii*), Sicily (*R. massiliae*), China, and Egypt (*R. sibirica monolitimonae*).

Clinical Findings

A. Symptoms and Signs

RMSF can cause severe multiorgan dysfunction and fatality rates of up to 73% if left untreated, making it the most serious rickettsial disease. Two to 14 days (mean, 7 days) after the bite of an infectious tick, symptoms begin with the abrupt onset of high fever, chills, headache, nausea and vomiting, myalgias, restlessness, insomnia, and irritability. The characteristic rash (faint macules that progress to maculopapules and then petechiae) appears between days 2 and 6 of fever. It initially involves the wrists and ankles, spreading centrally to the arms, legs, and trunk over the next 2–3 days. Involvement of the palms and soles is characteristic. Facial flushing, conjunctival injection, and hard palate lesions (Figure 32–7) may occur. In about 10% of cases, however, no rash or only a minimal rash is seen. Cough and pneumonitis may develop, and delirium, lethargy, seizures, stupor, and coma may also appear in more severe cases. Splenomegaly, hepatomegaly, jaundice, myocarditis (which may mimic an acute coronary syndrome), adrenal hemorrhage, polyarticular arthritis, or uremia is occasionally present. ARDS and necrotizing vasculitis, when present, are of greatest concern.

A group of four cases of RMSF in pregnant women from Sonora, Mexico, in 2015–2016, three of whom sustained spontaneous abortions, is a reminder of the grave risk of this infection for pregnant women and their fetuses.

B. Laboratory Findings

Thrombocytopenia, hyponatremia, elevated aminotransferases, and hyperbilirubinemia are common. CSF may show hypoglycorrhachia and mild pleocytosis. Disseminated intravascular coagulation is observed in severe cases. Diagnosis during the acute phase of the illness can be made by immunohistologic or PCR demonstration of *R. rickettsii* in skin biopsy specimens (or cutaneous swabs of eschars or skin lesions). Performing such studies as soon as skin lesions become apparent and before antibiotics commence maximizes sensitivity.

Serologic studies confirm the diagnosis, but most patients do not mount an antibody response until the second week of illness. The indirect fluorescent antibody test is most commonly used.

Differential Diagnosis

The diagnosis is challenging because early symptoms resemble those of many other infections. The classic triad of fever, rash, and tick bite is rarely recognized, with up to 40% of patients not recalling a tick bite. Moreover, the rash...
may be confused with that of measles, typhoid, and ehrlichiosis, or—most importantly—meningococcemia. Blood cultures and examination of CSF establish the latter. Coinfections may mask the diagnosis. Some spotted fever rickettsioses may also mimic RMSF but will not be detected by routine serologic testing for RMSF.

Treatment & Prognosis

Treatment with doxycycline at similar doses and duration as for epidemic typhus (100 mg orally twice daily for 4–10 days) is recommended. Similarly, chloramphenicol (50–100 mg/kg/day in four divided doses, orally or intravenously for 4–10 days) is the preferred alternative during pregnancy. Patients usually defervesce within 48–72 hours, and therapy should be continued for at least 3 days after defervescence occurs.

The reported mortality rate for treated patients in the United States is about 3–5%. The following features are associated with increased mortality: (1) infection in older adults or Native Americans; (2) the presence of atypical clinical features (absence of headache, no history of tick attachment, gastrointestinal symptoms) and underlying chronic diseases; and (3) a delay in initiation of appropriate antibiotic therapy. The usual cause of death is pneumonitis with respiratory or cardiac failure. A fulminant form of RMSF can be seen in patients with glucose-6-phosphate dehydrogenase deficiency. Sequelae may include seizures, encephalopathy, peripheral neuropathy, paraparesis, bowel and bladder incontinence, cerebellar and vestibular dysfunction, hearing loss, and motor deficits.

Unfavorable prognostic factors for mortality from a 2017 Brazilian series of spotted fever cases included male sex, shock, seizures, and hypotension, and unfavorable prognostic factors were urban exposure, recognition of a tick, and lymphadenopathy. Recent Mexican cases were more severe among children under 10 years of age and among the very poor.

Prevention

Protective clothing, tick-repellent chemicals, and the removal of ticks at frequent intervals are helpful measures. The effectiveness of aggressive campaigns to decrease ticks in the community is under investigation in Native American communities with high RMSF attack rates. Prophylactic therapy after a tick bite is not recommended.

2. Tick Typhus (Rickettsial Fever)

The term “tick typhus” denotes a variety of spotted rickettsial fevers, often named by their geographic location (eg, Mediterranean spotted fever, Queensland tick typhus, Oriental spotted fever, African tick bite fever, Siberian tick typhus, North Asian tick typhus) or by morphology (eg, boutonneuse fever). These illnesses are caused by various rickettsial organisms (eg, R africae, R australis, R conori, R japonica, R massiliae, R parkeri, R sibirica, and R 364D) and are transmitted by various tick species. Lymphangitis-associated rickettsiosis (LAR), caused by R sibirica mongolitimonae, was first described in 1996 and has been reported in Europe only thus far, including a small outbreak in Spain (Table 32–3). Dogs and wild animals, usually rodents and even reptiles, may serve as reservoirs for rickettsial fevers. Travel is a risk factor for disease, particularly among elderly ecotourists. In a series of 280 international travelers with rickettsial disease, the most common cause was spotted fever rickettsiosis (231 cases, 82.5% of the total) followed by scrub typhus (16, 5.7%).

Tick-borne rickettsioses are the main source of rickettsial infections in Europe and cause a syndrome similar to that seen in Mediterranean spotted fever. Newer recognized species include R helvetica, R monacensis, R massiliae, and R aeschlimannii. Another described syndrome is tick-borne lymphadenopathy/Dermacenter-borne-necrosis-erythema-lymphadenopathy/scalp eschar neck lymphadenopathy associated with R slovaca, Candidatus R rioja, and R raoultii and characterized by tick bite, eschar on the scalp, and cervical lymphadenopathy.

The pathogens usually produce an eschar or black spot (tâche noire) at the site of the tick bite that may be useful in diagnosis, though spotless boutonneuse fever occurs. Symptoms include fever, headache, myalgias, and rash. Painful lymphadenopathy or lymphangitis may also occur. Rarely, papulovesicular lesions may resemble rickettsial-pox. Endothelial injury produces perivascular edema and dermal necrosis. Regional adenopathy, disseminated lesions, kidney disease, splenic rupture, and focal hepatic necrosis are observed. Neurologic manifestations, including encephalitis, internuclear ophthalmoplegia, coronary involvement, and the hemophagocytic syndrome, are rare.

The diagnosis is clinical, with serologic or PCR (culture can be used but is less sensitive than either) of the bulky coat of blood, or an eschar if one is available, used for confirmation. Treatment should be started upon clinical suspicion since delayed therapy is the usual cause of increased morbidity. Oral treatment with doxycycline (100 mg twice daily) or chloramphenicol (50–75 mg/kg/day in four divided doses) for 7–10 days is indicated. Caution is advised with the use of ciprofloxacin because it is associated with a poor outcome and increases the severity of disease in Mediterranean spotted fever. The combination of azithromycin and rifampin is effective and safe in pregnancy. Prevention entails protective clothing, repellents, and inspection for and removal of ticks.

Formerly classified as an endemic or murine typhus, the cat-flea typhus, caused by R felis is more properly classified as a spotted fever. The causative agent has been linked to the cat flea and opossum exposure. While the diseases appear to be ubiquitous, most cases in the United States (southern Texas and California, and possibly Hawaii) occur in the spring and summer. Treatment is the same as for other rickettsial fevers.
Cases of non-rickettsiae-associated spotted fever tend to have a better prognosis than due those due to *R. rickettsiae* infection. Treatment for non-rickettsiae-associated spotted fever as well as *R. rickettsiae* infection is with tetracycline, and there is some laboratory evidence that these organisms may be less responsive to macrolides.

**Rickettsialpox**

Rickettsialpox is an acute, self-limiting, febrile illness caused by *Rickettsia akari*, a parasite of mice, transmitted by the mite *Liponyssoides sanguineus* (Table 32–3). Because rickettsialpox has features of both the typhus group and of the spotted fever group of rickettsia, it falls into its own “transitional” category. *R akari* infections are reported globally. Seroprevalence studies among injection drug users in Baltimore show seropositivity as high as 16%. In New York, its association with poverty is very strong. The illness has also been found in farming communities. Crowded conditions and mouse-infested housing allow transmission of the pathogen to humans. The classic triad of fever, rash, and eschar is found in 99% of cases. The primary lesion is a painless red papule that appears at variable times but on the average a week after a mite bite. The lesion often vesiculates and forms a black eschar.

The onset of symptoms—chills, fever, headache, photophobia, and disseminated aches and pains—is sudden. The fever may be followed by a widespread papular eruption 2–4 days later, with an average of 30–40 lesions that spare the palms and soles. The interval from vesiculation to crust formation is about 10 days. Early lesions may resemble those of chickenpox (typically vesicular versus papulovesicular in rickettsialpox). Pathologic findings include dermal edema, subepidermal vesicles, and at times a lymphocytic vasculitis.

Transient leukopenia and thrombocytopenia and acute hepatitis can occur. A fourfold rise in serum antibody titers to rickettsial antigen, detected by complement fixation or indirect fluorescent assays, is diagnostic and available through the CDC. Conjugated anti-rickettsial globulin can identify antigen in punch biopsies of skin lesions. PCR detection of rickettsial DNA in fresh tissue also appears of value. *R akari* can also be isolated from eschar biopsy specimens.

Treatment consists of oral doxycycline (100 mg twice daily) for 2–5 days or until defervescence. The disease is usually mild and self-limited without treatment, but occasionally, severe symptoms may require hospitalization. Control requires the elimination of mice from human habitations and insecticide applications.

**General Considerations**

Human ehrlichiosis and anaplasmosis are endemic in the United States.

*Ehrlichia chaffeensis* (Table 32–3), the most common species infecting humans, is seen primarily in the south-central United States (especially Arkansas, Missouri, Oklahoma, and New York). *Ehrlichia ewingii* causes human granulocytic ehrlichiosis similar to anaplasmosis and constitutes almost 10% of ehrlichiosis cases; most cases in the United States are reported from the Midwest and Southeast. A new species of *Ehrlichia* isolated in 2009 is referred to as *Ehrlichia muris eauclairensis* and is seen in the upper Midwestern United States. Human granulocytic anaplasmosis is caused by *Anaplasma phagocytophilum*; most cases in the United States are reported from New England, New York, Minnesota, and Wisconsin. Anaplasmosis is being reported from Asia, South Korea, Mongolia, China (where a new species is identified, *Anaplasma capra*), and Northern Europe.

In North America, the major tick-borne rickettsial disease vectors for these pathogens are (1) the Lone Star tick (*Amblyomma americanum*), which is the vector for *E. chaffeensis* and *E. ewingii*; (2) the black-legged tick (*Ixodes scapularis*), which is a vector for *B. burgdorferi* (Lyme disease), *Babesia microti* (babesiosis), and *A. phagocytophilum* (anaplasmosis); and (3) the western black-legged tick (*Ixodes pacificus*), which is a vector for *A. phagocytophilum* along the Pacific coast of the United States. Vectors for European and Asian cases are not reported to date. The principal reservoirs for human monocytic ehrlichiosis and human granulocytic anaplasmosis are the white tail deer and the white-footed mouse, respectively. Other mammals are implicated as well. Transfusion-transmitted anaplasmosis has been reported.

CDC reports indicate that the incidences of human monocytic ehrlichiosis, granulocytic ehrlichiosis and, in particular, anaplasmosis are increasing; cases are reportable...
to local and state health departments. Because more than one agent may coexist in the same area, cases of human ehrlichiosis and anaplasmosis may be reported as “human ehrlichiosis/anaplasmosis undetermined” in the absence of species identification.

Neorickettsia sennetsu is a related rickettsial pathogen that causes rare infection in Southeast Asia among populations who consume raw fish.

The case fatality rate is 1% with *E chaffeensis* infections and 0.3% among cases of human anaplasmosis. Contrary to earlier reports, most recent cases of *E ewingii* infection have occurred among immunocompetent patients. No deaths have been reported from either *E ewingii* or *E muris eauclairensis*.

**Clinical Findings**

A. Symptoms and Signs

Clinical disease of human monocytic ehrlichiosis ranges from mild to life-threatening. Typically, after a 1- to 2-week incubation period and a prodrome consisting of malaise, rigitors, and nausea, high fever and headache develop. A pleomorphic rash may occur. Presentation in immunosuppressed patients (including transplant patients) and older patients tends to be more severe. Rare serious sequelae include acute respiratory failure and ARDS; neurologic complications, the most common being meningoencephalitis and aseptic meningitis; acute kidney disease (which may mimic thrombotic thrombocytopenic purpura); hemophagocytic syndrome; and multiorgan failure.

The clinical manifestations of human granulocytic ehrlichiosis and anaplasmosis are similar to those seen with human monocytic ehrlichiosis. Rash, however, is infrequent. If a rash is present, coinfection with other tick-borne diseases or an alternative diagnosis should be suspected. Persistent fever and malaise are reported to occur for 2 or more years. Reported complications of anaplasmosis include leukopenia, thrombocytopenia, and cerebral infarction.

Coinfection with anaplasmosis and Lyme disease or babesiosis may occur, but the clinical manifestations (including fever and cytopenias) are more severe with anaplasmosis than with Lyme disease. A spirochete, *Borrelia miyamotoi*, may mimic anaplasmosis in its clinical manifestations.

B. Laboratory Findings

Diagnosis can be made by the history of tick exposure followed by a characteristic clinical presentation. Leukopenia, absolute lymphopenia, thrombocytopenia, and transaminitis occur often. Thrombocytopenia occurs more often than leukopenia in human granulocytic ehrlichiosis. Examination of peripheral blood with Giemsa stain may reveal characteristic intraleukocytic vacuoles (morulae) in up to 20% of patients. An indirect fluorescent antibody assay is available through the CDC and requires acute and convalescent sera. A PCR assay can be helpful for making the diagnosis early in the disease course. PCR assay is most sensitive in the first week of illness and can be used as a confirmatory test.

**Treatment & Prevention**

Treatment for human ehrlichiosis and anaplasmosis is with doxycycline, 100 mg twice daily (orally or intravenously) for 10–14 days or until 3 days of defervescence. Rifampin is an alternative in pregnant women. Treatment should not be withheld while awaiting confirmatory serology when suspicion is high. Lack of clinical improvement and defervescence 48 hours after doxycycline initiation suggests an alternate diagnosis. Some patients may continue to have headache, weakness, and malaise for weeks despite adequate treatment. Tick control is the essence of prevention.

2. Q Fever (Coxiella burnetti Infection)

**ESSENTIALS OF DIAGNOSIS**

- Exposure to sheep, goats, cattle, or their products; some infections are laboratory acquired.
- Acute or chronic febrile illness: headache, cough, prostration, and abdominal pain.
- Pneumonitis, hepatitis, or encephalopathy; less often, endocarditis, vascular infections, or chronic fatigue syndrome.
- A common cause of culture-negative endocarditis.

**General Considerations**

Q fever, a reportable and significantly underestimated disease in the United States, is caused by the gram-negative intracellular coccobacillus *C burnetti*. *Coxiella* infections occur globally, mostly in cattle, sheep, and goats, in which they cause mild or subclinical disease (Table 32–3). In these animals, reactivation of the infection occurs during pregnancy and causes abortions or low birth weight offspring. *Coxiella* is resistant to heat and drying and remains infective in the environment for months.

Human infection occurs via inhalation of aerosolized bacteria (in dust or droplets) from feces, urine, milk, or products of conception of infected animals. Ingestion and skin penetration are other recognized routes of transmission. A major outbreak in the Netherlands during 2007–2010 was thought to be due inhalation of aborted cattle products of conception associated with changes in breeding practices. There is a known occupational risk for animal handlers, slaughterhouse workers, veterinarians, laboratory workers, and other workers exposed to animal products. In the United States, over 60% of cases do not report an exposure to potentially infectious animals, but cases are more than twice as likely as non-cases to report drinking raw milk.
Human-to-human transmission does not seem to occur, but maternal-fetal infection can occur and infection after liver transplant is reported.

Clinical Findings

A. Symptoms and Signs

Asymptomatic infection is common. For the remaining cases, a febrile illness develops after an incubation period of 2–3 weeks, usually accompanied by headache, relative bradycardia, prostration, and muscle pains. The clinical course may be acute, chronic (duration 6 months or longer), or relapsing. Pneumonia and granulomatous hepatitis are the predominant manifestations in the acute form (and these may vary in incidence geographically), whereas other less common manifestations include skin rashes (maculopapular or purpuric), fever of unknown origin, myocarditis, pericarditis, aortic aneurysms, aseptic meningitis, encephalitis, orchitis, iliopecto abscess, spondylodiscitis, tenosynovitis, granulomatous osteomyelitis (more often seen in children), and regional (mediastinal) or diffuse lymphadenopathies.

It has been recommended that the term “chronic Q fever” be abandoned to avoid confusion and be replaced with “persistent focalized infections.” The most common presentation in patients with persistent focalized infections is culture-negative endocarditis. Risk factors for endocarditis are the immunocompromised state, presence of preexisting valvular conditions, male sex, and age above 40 years. Valvular prosthesis (mechanical or bioprosthesis) represents the most important risk factor. In series of post-cardiac surgery patients with culture-negative endocarditis, Q fever is often the most common cause (about 40% of cases).

The clinical manifestations of endocarditis are nonspecific with fever, night sweats, and weight loss. Rarely, urticaria, edema, erythema nodosum, and arthralgias are reported. Sudden cardiac insufficiency, stroke, or other embolic and myotic aneurysms can also develop. Vascular infections, particularly of the aorta (causing mycotic aneurysms) and of graft prostheses, are the second most common presentation and are associated with a high mortality (25%). A post–Q fever chronic fatigue syndrome (1 year after acute infection with chronic symptoms) is controversial and of unknown pathophysiology. Cognitive behavioral therapy is effective in reducing fatigue severity in patients with Q fever fatigue syndrome; long-term treatment with doxycycline has not been shown to be effective.

New infection or reactivation of Q fever can occur in pregnant women and is associated with spontaneous abortions, intrauterine growth retardation, intrauterine fetal death, and premature delivery. C. burnetii infection during the first trimester can cause oligohydramnios.

B. Laboratory Findings

Laboratory examination during the acute phase may show elevated liver biochemical tests and occasional leukocytosis. Patients with acute Q fever usually produce antibodies to C. burnetii phase II antigen (phase II antigens are formed in vitro from deleted avirulent mutants and are empirically more commonly seen in acute disease, whereas phase I antigens, seen in nature and laboratory infections, are found in the IgG form in chronic disease). A fourfold rise between acute and convalescent sera by indirect immunofluorescence is diagnostic of the infection. Real-time PCR for C. burnetii DNA is helpful only in early diagnosis of Q fever. C. burnetii DNA becomes undetectable in serum as serologic responses develop. The positive predictive value of antibodies to phase II antigens in acute disease is at most 65%, and considerable intertest variability exists with phase 2 antigens. Diagnostic tests combining PCR with ELISA (Immuno-PCR) improve the sensitivity and specificity during the first 2 weeks after the onset of symptoms.

While persistent infection can be diagnosed based on serologic tests done at 3- and 6-month intervals (with an IgG titer against phase I antigen of 1:1600 or greater), the sensitivity of such serologies is often low, and the diagnosis of Q fever is often made clinically. An automated epifluorescence assay has greater than 95% sensitivity for the detection of phase I antigens in persistent infection. C. burnetii-specific interferon-gamma, interferon-gamma/IL-2 ratio has a sensitivity of 79% and a specificity and 97% for the diagnosis of persistent infection.

Diagnosis of Q fever endocarditis is often made at the time of valve replacement with PCR of tissue samples. C. burnetii may also be isolated from affected valves using the shell-vial technique.

C. Imaging

Radiographs of the chest can show patchy pulmonary infiltrates. All patients with acute Q fever should be screened for underlying valvular disease with echocardiography. Initial imaging and follow-up with serial 18-FDG PET/CT scan may be helpful in identifying chronic infection and monitoring treatment response.

Differential Diagnosis

Viral, mycoplasma, and bacterial pneumonias; viral hepatitis; brucellosis; Legionnaire disease; murine or scrub typhus; Kawasaki disease; tuberculosis; psittacosis; and other animal-borne diseases can have similar clinical presentations to Q fever. Q fever should be considered in cases of unexplained fevers with negative blood cultures in association with embolic or cardiac disease. Cases of Q fever can mimic autoimmune disease. Coinfection with typhus and leptospirosis is reported.

Treatment & Prognosis

Doxycycline is the most effective drug against C. burnetii; there are rare reports of doxycycline resistance. Isolates remain susceptible to levofloxacin, moxifloxacin, and to a lesser extent ciprofloxacin. No resistance to sulfamethoxazole–trimethoprim is reported to date.

For acute infection, treatment with doxycycline (100 mg orally twice daily) for 14 days or at least 3 full days after defervescence is recommended. Even in untreated patients, the mortality rate is usually low, except when endocarditis develops.

There are no clear guidelines on the treatment of persistent C. burnetii infections. To date, there is no antibiotic that has bactericidal effect against C. burnetii. Most experts
Elevated ESR and CRP levels.

Clinical Findings

Fever, conjunctivitis, oral mucosal changes, rash, may take trimethoprim-sulfamethoxazole as an alternative.

In addition, patients undergoing routine valve surgery should have routine Q fever serologies in endemic countries and appropriate treatment if tests are positive for Q fever.

All infected pregnant women should be given long-term trimethoprim-sulfamethoxazole (320/1600 mg orally for the duration of pregnancy, but not beyond 32 weeks’ gestation) to prevent the obstetric complications.

In retrospective studies, an increased risk of diffuse B-cell lymphoma and follicular lymphoma was found in patients with Q fever compared with the general population. Patients with persistent focalized infections were at higher risk for lymphadenitis and progression to lymphoma.

Prevention

Prevention is based on detection of the infection in livestock, with reduction of contact with infected and parturient animals; and effective pasteurization of milk. A whole-cell Q fever vaccine is available in Australia for persons with high-risk exposures, although there are reports of vaccine failure more than 15 days after vaccination.

The organism is highly transmissible to laboratory workers and culture techniques require a biosafety level 3 setting. *C. burnetii* is a category B bioterrorism agent. In the setting of a bioterrorist attack, postexposure prophylaxis with doxycycline 100 mg orally twice a day for 5–7 days should be administered within 8–12 days of exposure. Pregnant women may take trimethoprim-sulfamethoxazole as an alternative.

**KAWASAKI DISEASE**

**ESSENTIALS OF DIAGNOSIS**

- Fever, conjunctivitis, oral mucosal changes, rash, cervical lymphadenopathy, peripheral extremity changes.
- Elevated ESR and CRP levels.
- Risk for coronary arteritis and aneurysms.

**General Considerations**

Kawasaki disease is a worldwide multisystem disease. It is also known as the “mucocutaneous lymph node syndrome.” It occurs mainly in children between the ages of 3 months and 5 years but can occur occasionally in adults as well. Kawasaki disease occurs most often in Asians or native Pacific Islanders. Its incidence in Japan is twice that of the United States, and it occurs among siblings at twice the incidence of cases and at higher rates among parents of cases. These findings plus the known seasonality (higher incidence in winter and early spring) and occasional epidemic pattern of cases point to the inadequate current understanding of the etiology of this disease.

It is an acute, self-limiting, mucocutaneous vasculitis characterized by the infiltration of vessel walls with mononuclear cells and later by IgA secreting plasma cells that can result in the destruction of the tunica media and aneurysm formation. The cause of Kawasaki disease remains unknown. Epidemiologic studies show an increased risk with advanced maternal age, mother of foreign birth, maternal group B *Streptococcus* colonization, and early infancy hospitalization for a bacterial illness. Genetic factors are considered to play an important role in the pathogenesis of the disease. Ongoing analyses identify many gene polymorphisms, which significantly correlate with Kawasaki disease susceptibility (at least 23 to disease, and 10 to the presence of coronary aneurysms).

**Clinical Findings**

A clinical diagnosis of classic or “complete” Kawasaki disease requires the presence of at least 5 days of fever, usually high-grade (over 39°C to 40°C) and four of the following five criteria: (1) bilateral nonexudative conjunctivitis (begins shortly after the onset of fever), (2) oral changes (erythema and cracking of lips, strawberry tongue, and erythema of oral and pharyngeal mucosa; ulcers and pharyngeal exudates are not consistent with Kawasaki disease), (3) peripheral extremity changes (erythema and edema of the hands and feet in the acute phase, and/or periungual desquamation within 2 to 3 weeks after the onset of fever), (4) polymorphous rash, and (5) cervical lymphadenopathy (larger than 1.5 cm diameter, usually unilateral; least common of the clinical features). The revised case definition allows the diagnosis on day 4 in the presence of more than four principal clinical criteria, particularly when redness and swelling of the hands and feet are present.
A diagnosis of atypical or “incomplete” Kawasaki disease could be diagnosed in patients with unexplained fever and fewer than four principal criteria if accompanied by compatible laboratory or findings of aneurysms detected by echocardiography or angiography. Laboratory findings in the acute phase typically include leukocytosis with neutrophilic predominance, anemia, and an elevated ESR and CRP. High platelet counts are characteristic but occur in the second week. N-terminal moiet of B-type natriuretic peptide (NT-proBNP), likely indicative of myocardial involvement, may be elevated in some patients with Kawasaki disease.

Major complications include arteritis and aneurysms of the coronary vessels. The arteritis begins 6–8 days after the onset of disease, occurs in about 25% of untreated patients, and occasionally causes myocardial infarction. Coronary complications are more common among patients older than 6 years or younger than 1 year of age; males; and those unresponsive to IVIG, who received a smaller dose of IVIG, or did not receive treatment within 10 days of symptom onset. While myocarditis can be found in all patients with Kawasaki disease on histologic specimens and is prominent during the acute stage, only a small percentage of patients are clinically symptomatic.

Cardiac complications include left ventricular dysfunction, which usually normalizes promptly with IVIG therapy, and mitral regurgitation, which occurs early and does not appear to persist. Noninvasive diagnosis of coronary complications can be made with CT coronary angiography (the most sensitive test), magnetic resonance angiography, or transthoracic echocardiography (advocated for early screening). Kawasaki shock syndrome is a complication, with an estimated incidence of 7%, possibly caused by decrease in peripheral vascular resistance, myocarditis with or without myocardial ischemia, and capillary leakage.

The multisystemic findings of Kawasaki disease show it to be a systemic disease that affects medium-sized arteries of multiple organs, including elevations in serum transaminases, interstitial pneumonitis, abdominal pain, vomiting, diarrhea, gallbladder hydrops, pancreatitis, lymphadenopathy, hypalbuminemia, arrhythmias, aseptic meningitis, acute encephalopathy with biphasic seizures and late reduced diffusion, retinal and choroidal detachment, pulmonary complications (effusions, empyema, pneumothorax), hemophagocytic lymphohistiocytosis syndrome, and pyuria. CSF pleocytosis with a mononuclear cell predominance, normal glucose levels, and protein levels is seen in one-third of children who undergo lumbar puncture.

Other diseases with similar presentation that should be considered include measles in unimmunized children as well as other viral infections, such as adenovirus, scarlet fever, and toxic shock syndrome; rickettsial infections; or leptospirosis and drug hypersensitivity reactions.

▶ Treatment & Prevention

All patients meeting the diagnostic criteria for Kawasaki disease (complete and incomplete), including patients with recurrent Kawasaki disease, should be treated as soon as the diagnosis is suspected to reduce inflammation and arterial damage.

A single dose of IVIG should be given in the first 10 days of the illness. Patients in whom the diagnosis was made later than the tenth day may still benefit from IVIG treatment if they have elevated inflammatory markers (ESR or CRP), with persistent fever or have coronary artery aneurysms. When IVIG treatment is not given, coronary artery aneurysms occur in 20% of children. Even when treated with IVIG within the first 10 days of illness, coronary artery aneurysms still develop in 5% of patients. Rare cases of aseptic meningitis are reported with IVIG. Coombs-positive hemolytic anemia, especially in individuals with AB blood type and anaphylactic reactions to immunoglobulins with selective IgA deficiency are other complications associated with IVIG administration.

Although aspirin does not lower the frequency of development of coronary abnormalities, it has important anti-inflammatory activity and antiplatelet activity. Concomitant aspirin with IVIG should be started at 80–100 mg/kg/day orally (divided into four doses and not exceeding 4 g/day) until the patient is afebrile for 48 hours and then reduced to 3–5 mg/kg/day until markers of acute inflammation normalize. Since ibuprofen antagonizes the irreversible platelet inhibition induced by aspirin, it should be avoided when aspirin is given.

The use of corticosteroids for children with Kawasaki disease is controversial. According to the most recent published guidelines by the American Heart Association, single-dose pulse methylprednisolone should not be used routinely for patients with Kawasaki disease. A course of corticosteroid therapy with tapering over 2–3 weeks could be considered in addition to IVIG and aspirin for patients at high-risk for not responding to IVIG.

Resistant Kawasaki disease, defined as having recrudescent or persistent fever at least 36 hours after the end of the first IVIG infusion when no other source of fever is found, develops in about 10–20% of patients. The Egami score is a predictor used in Japan to help determine who will respond to IVIG, although the scoring system has been shown to have lower utility in US cases. The presence of coronary artery abnormalities on the initial echocardiogram and their presence before day 5 of fever predict nonresponse to IVIG in one Israeli study.

Options for refractory cases include a second dose of IVIG, high-dose pulse corticosteroids over 3 days with or without a subsequent oral taper course, longer oral tapering course of corticosteroids over 2–3 weeks together with IVIG and aspirin, infliximab, the anti-inflammatory interleukin 1 receptor antagonist anakinra, low-dose methotrexate, and cyclosporine. Immunomodulatory monoclonal antibody therapy and cytotoxic agents, or (rarely) plasma exchange should be considered only in highly refractory cases in which other therapy has failed.

The most common serious complication in the acute phase is thrombotic occlusion of a coronary artery aneurysm leading to myocardial infarction or sudden death. An echocardiogram is recommended within 1–2 weeks and 4–6 weeks after treatment for uncomplicated patients. More frequent imaging is recommended for patients with significant and evolving coronary artery abnormalities. Anticoagulation with warfarin or low-molecular-weight
Heparin is indicated, along with aspirin, in patients with rapidly expanding coronary artery aneurysms. Aspirin, a second antiplatelet agent, and anticoagulation with warfarin, low-molecular-weight heparin, or direct-acting oral anticoagulants (which need further study in this population) may be considered for patients with large or giant aneurysms (at least 8 mm) (which correlate with delay in diagnosis) and a recent history of coronary artery thrombosis. If myocardial infarction occurs, therapy with thrombolitics, percutaneous coronary intervention, coronary artery bypass grafts, and even cardiac transplantation should be considered. Manifestations of coronary artery aneurysms can occur as late as in the third or fourth decade of life with a study showing a prevalence of 5% coronary sequelae from Kawasaki disease among young adults evaluated with angiography. Calcified coronary aneurysms on CT scans are less likely to regress.

**Prognosis**

The reported recurrence rate is 3% in one study from Japan. The highest risk of recurrence occurs in the first 2 years after the first episode. The mortality peaks between 15 and 45 days after the onset of fever, at the time of coronary artery vasculitis, thrombocytosis, and a hypercoagulable state.

Over the long-term, the risk for clinical cardiac events in patients with no coronary artery abnormalities is similar to the general population. For patients in whom coronary artery abnormalities developed, the risk for cardiac complications, such as thrombosis, stenosis, myocardial infarction, and death, ranges between 1% and 48%. Follow-up is especially needed among the subset of patients with neutropenia who have been treated with IVIG. The administration of IVIG is shown to improve left ventricular function. The AHA recommends risk stratification based on the assessment of coronary luminal dimensions by echocardiogram, under cardiologic supervision. The frequency of clinical follow-up, diagnostic testing, reproductive counseling, indications for medical therapy (beta-blockers, statins), and thromboprophylaxis (aspirin and anticoagulation) depends on the individual's risk assessment.

**When to Refer**

All cases of Kawasaki disease merit referral to specialists.

INFECTIONS CAUSED BY GRAM-POSITIVE BACTERIA

STREPTOCOCCAL INFECTIONS

1. Pharyngitis

ESSENTIALS OF DIAGNOSIS

- Abrupt onset of sore throat, fever, malaise, nausea.
- Throat red and edematous, with or without exudate; cervical nodes tender.
- Diagnosis confirmed by culture of throat.

General Considerations

Group A beta-hemolytic streptococci (Streptococcus pyogenes) are the most common bacterial cause of pharyngitis. Transmission occurs by droplets of infected secretions. Group A streptococci producing erythrogenic toxin may cause scarlet fever in susceptible persons.

Clinical Findings

A. Symptoms and Signs

“Strep throat” is characterized by a sudden onset of fever, sore throat, pain on swallowing, tender cervical adenopathy, malaise, and nausea. The pharynx, soft palate, and tonsils are red and edematous. There may be a purulent exudate. The Centor clinical criteria for the diagnosis of streptococcal pharyngitis are temperature greater than 38°C, tender anterior cervical adenopathy, lack of a cough, and pharyngotonsillar exudate.

The rash of scarlet fever (also called scarletina) is diffusely erythematous and resembles a sunburn, and superimposed fine red papules give the skin a sandpaper consistency; it is most intense in the groin and axillae. It blanches on pressure, may become petechial, and fades in 2–5 days, leaving a fine desquamation. The face is flushed, with circumoral pallor, and the tongue is coated with enlarged red papillae (strawberry tongue).

B. Laboratory Findings

Leukocytosis with neutrophil predominance is common. Throat culture onto a single blood agar plate has a sensitivity of 80–90%. Rapid diagnostic tests based on detection of streptococcal antigen are slightly less sensitive than culture. Clinical criteria, such as the Centor criteria, are useful for identifying patients in whom a rapid antigen test or throat culture is indicated. Patients who meet two or more of these criteria merit further testing. When three of the four are present, laboratory sensitivity of rapid antigen testing exceeds 90%. When only one criterion is present, streptococcal pharyngitis is unlikely. In high-prevalence settings or if clinical suspicion for streptococcal pharyngitis is high, a negative antigen test or culture should be confirmed by a follow-up culture.

Complications

Suppurative complications include sinusitis, otitis media, mastoiditis, peritonsillar abscess, and cervical lymphadenitis. Nonsuppurative complications are rheumatic fever and glomerulonephritis. Rheumatic fever may follow recurrent episodes of pharyngitis beginning 1–4 weeks after the onset of symptoms. Glomerulonephritis follows a single infection with a nephritogenic strain of streptococcus group A (eg, types 4, 12, 2, 49, and 60), more commonly on the skin than in the throat, and begins 1–3 weeks after the onset of the infection. These complications are more common in children.

Differential Diagnosis

Streptococcal sore throat resembles (and cannot be reliably distinguished clinically from) pharyngitis caused by viruses such as adenoviruses, Epstein-Barr virus, or other bacteria such as Fusobacterium necrophorum and Arcanobacterium haemolyticum (which also may cause a rash). Pharyngitis and lymphadenopathy are common findings in acute HIV
infection. Generalized lymphadenopathy, splenomegaly, atypical lymphocytosis, and a positive serologic test distinguish mononucleosis from streptococcal pharyngitis. Diphtheria is characterized by a pseudomembrane; oropharyngeal candidiasis shows white patches of exudate and less erythema; and necrotizing ulcerative gingivostomatitis (Vincent fusospirochetal gingivitis or stomatitis) presents with shallow ulcers in the mouth. Neisseria gonorrhoeae, Chlamydia trachomatis, and primary herpes simplex virus should be considered in those with risk factors. Retropharyngeal abscess or bacterial epiglottitis should be considered when odynophagia and difficulty in handling secretions are present and when the severity of symptoms is disproportionate to findings on examination of the pharynx. F. necrophorum causes pharyngitis at a similar rate as group A beta-hemolytic streptococci in adolescents and young adults. F. necrophorum pharyngitis is associated with Lemierre syndrome, suppurrative thrombophlebitis of the internal jugular vein, bacteremia, and metastatic infections. Early recognition and treatment of this syndrome is important.

**Treatment**

Antimicrobial therapy has a modest effect on resolution of symptoms and primarily is administered for prevention of complications. Antibiotic therapy can be safely delayed until the diagnosis is established on the basis of a positive antigen test or culture. Empiric therapy usually is not a cost-effective approach to the management of most adults with pharyngitis because the prevalence of streptococcal pharyngitis is likely to be no more than 10–20% in typical clinical settings. The positive predictive value of clinical criteria is low. Since macrolides are not reliable against F. necrophorum infection, adolescents or young adults with pharyngitis and unconfirmed streptococcal infection should be given penicillin or amoxicillin preferentially at the doses listed below. If the pharyngitis does not resolve quickly, symptoms worsen, or unilateral neck swelling develops, clinicians should consider suppurative complications such as peritonsillar abscess and Lemierre syndrome.

**A. Benzathine Penicillin G**

Benzathine penicillin G, 1.2 million units intramuscularly as a single dose, is optimal therapy.

**B. Penicillin VK**

Penicillin VK, 250 mg orally four times daily or 500 mg orally twice daily for 10 days, is effective.

**C. Amoxicillin**

Amoxicillin, 1000 mg orally once daily or 500 mg orally twice daily for 10 days, is another option.

**D. Cephalosporins**

Cephalaxin, 500 mg orally twice daily for 10 days, cefdinir, 300 mg orally twice daily for 5–10 days or 600 mg orally once daily for 10 days, cefadroxil, 1000 mg orally once daily for 10 days, and cefpodoxime, 100 mg orally twice daily for 5–10 days, should be reserved for penicillin-allergic patients who do not have immediate-type hypersensitivity.

**E. Macrolides**

Erythromycin, 500 mg orally four times a day, or azithromycin, 500 mg orally once daily for 5 days, is an alternative for the penicillin-allergic patient. Macrolides are less effective than penicillins and are considered second-line agents. Macrolide-resistant strains almost always are susceptible to clindamycin, a suitable alternative to penicillins; a 10-day course of 300 mg orally three times daily is effective.

**Prevention of Recurrent Rheumatic Fever**

Effectively controlling rheumatic fever depends on identification and treatment of primary streptococcal infection and secondary prevention of recurrences. Patients who have had rheumatic fever should be treated with a continuous course of antimicrobial prophylaxis for at least 5 years. Effective regimens are erythromycin, 250 mg orally twice daily, or penicillin G, 500 mg orally daily.

**When to Refer**

Patients with peritonsillar or retropharyngeal abscess should be referred to an otolaryngologist.

**When to Admit**

- Odynophagia resulting in dehydration.
- Suspected or known epiglottitis.

2. **Streptococcal Skin Infections**

Group A beta-hemolytic streptococci are not normal skin flora. Streptococcal skin infections result from colonization of normal skin by contact with other infected individuals or by preceding streptococcal respiratory infection.

**Clinical Findings**

**A. Symptoms and Signs**

**Erysipelas** is a painful superficial cellulitis that frequently involves the face. It is well demarcated from the surrounding normal skin. It affects skin with impaired lymphatic drainage, such as edematous lower extremities or wounds (Figure 33–1).

**Impetigo** is a focal, vesicular, pustular lesion with a thick, amber-colored crust with a “stuck-on” appearance (see Chapter 6).
B. Laboratory Findings

Cultures obtained from a wound or pustule are likely to grow group A streptococci. Blood cultures are occasionally positive.

Treatment

Parenteral antibiotics are indicated for patients with facial erysipelas or evidence of systemic infection. Penicillin, 2 million units intravenously every 4 hours, is the drug of choice. However, staphylococcal infections may at times be difficult to differentiate from streptococcal infections. In practice, initial therapy for patients with risk factors for Staphylococcus aureus (eg, injection drug use, diabetes mellitus, wound infection) should cover this organism. Either nafcillin, 1–2 g every 4–6 hours intravenously, or cefazolin, 1 g intravenously or intramuscularly every 8 hours, is a reasonable choice. In the patient at risk for methicillin-resistant S aureus infection or with a serious penicillin allergy (ie, anaphylaxis), vancomycin, 1 g intravenously every 12 hours, or daptomycin, 4 mg/kg intravenously daily, should be used (Table 33–1).

Patients who do not require parenteral therapy may be treated with amoxicillin, 500 mg three times daily or 875 mg twice daily for 7–10 days. A first-generation oral cephalosporin, eg, cephalaxin, 500 mg four times daily, or clindamycin, 300 mg orally three times daily, is an alternative to amoxicillin. In patients with recurrent cellulitis of the leg, maintenance therapy (for at least 1 year) with penicillin, 250 mg orally twice daily, may reduce relapses.

3. Other Group A Streptococcal Infections

Arthritis, pneumonia, empyema, endocarditis, and necrotizing fasciitis are relatively uncommon infections that may be caused by group A streptococci. Toxic shock–like syndrome also occurs.

Table 33–1. Empiric treatment of common skin and soft tissue infections (SSTIs).

</table>

1Antibiotic therapy should be given in addition to incision and drainage for purulent skin and soft tissue infections if the patient has any of the following: severe or extensive disease, symptoms and signs of systemic illness, purulent cellulitis/wound infection, comorbidities and extremes of age, abscess in area difficult to drain or on face/hand, associated septic phlebitis, or lack of response to incision and drainage alone.

2Regimens with activity against methicillin-resistant *S aureus*. Other regimens approved by the FDA for treatment of complicated skin and soft tissue infections include tigecycline 100 mg intravenously once followed by 50 mg intravenously twice a day, cefaroline 600 mg twice a day for 7–14 days, dalbavancin 1 g intravenously on day 1 and then 500 mg intravenously on day 8, oritavancin as a single intravenous dose of 1200 mg, and telavancin 10 mg/kg intravenously once daily for 7–14 days.
Arthritis generally occurs in association with cellulitis. In addition to intravenous therapy with penicillin G, 2 million units every 4 hours (or cefazolin or vancomycin in doses recommended above for penicillin-allergic patients), frequent percutaneous needle aspiration should be performed to remove joint effusions. Open surgical drainage may be necessary in many cases.

Pneumonia and empyema often are characterized by extensive tissue destruction and an aggressive, rapidly progressive clinical course associated with significant morbidity and mortality. High-dose penicillin and chest tube drainage are indicated for treatment of empyema. Vancomycin is an acceptable substitute in penicillin-allergic patients.

Group A streptococci can cause endocarditis in rare instances. Endocarditis should be treated with 4 million units of penicillin G intravenously every 4 hours for 4–6 weeks. Vancomycin, 1 g intravenously every 12 hours, is recommended for persons allergic to penicillin.

Necrotizing fasciitis is a rapidly spreading infection involving the fascia of deep muscle. The clinical findings at presentation may be those of severe cellulitis, but the presence of systemic toxicity and severe pain, which may be followed by anesthesia of the involved area due to destruction of nerves as infection advances through the fascial planes, is a clue to the diagnosis. Surgical exploration is mandatory when the diagnosis is suspected. Early and extensive debridement is essential for survival.

Any streptococcal infection—and necrotizing fasciitis in particular—can be associated with streptococcal toxic shock syndrome, typified by invasion of skin or soft tissues, acute respiratory distress syndrome, and kidney failure. Persons who are very young, older adults, and those with underlying medical conditions are at particularly high risk for invasive disease. Bacteremia occurs in most cases. Skin rash and desquamation may not be present. Mortality rates can be up to 80%. The syndrome is due to elaboration of pyrogenic erythrogenin causing shock syndrome, which also causes scarlet fever, a superantigen that stimulates massive release of inflammatory cytokines believed to mediate the shock. A beta-lactam, such as penicillin, remains the drug of choice for treatment of serious streptococcal infections, but clindamycin, which is a potent inhibitor of toxin production, should also be administered at a dose of 600 mg every 8 hours intravenously for invasive disease, especially in the presence of shock. Intravenous immune globulin can be considered for streptococcal toxic shock syndrome for possible therapeutic benefit from specific antibody to streptococcal exotoxins in immune globulin preparations. Many dosing regimens have been used, including 0.5 g/kg once daily for 5–6 days or a single dose of 2 g/kg with a repeat dose at 48 hours if the patient remains unstable.

Outbreaks of invasive disease have been associated with colonization by invasive clones that can be transmitted to close contacts who, though asymptomatic, may be a reservoir for disease. Tracing contacts of patients with invasive disease is controversial.

**ENTEROCOCCAL INFECTIONS**

Two species, Enterococcus faecalis and Enterococcus faecium, are responsible for most human enterococcal infections. Enterococci cause wound infections, urinary tract infections, bacteremia, and endocarditis. Infections caused by penicillin-susceptible strains should be treated with ampicillin 2 g every 4 hours or penicillin 3–4 million units every 4 hours; if the patient is penicillin-allergic, vancomycin 15 mg/kg every 12 hours intravenously can be given. If the patient has endocarditis or meningitis, gentamicin 1 mg/kg every 8 hours intravenously should be added to the regimen for a duration of 2–3 weeks in order to achieve the bactericidal activity that is required to cure these infections.
BACTERIAL & CHLAMYDIAL INFECTIONS

In cases of endocarditis, ceftriaxone 2 g every 12 hours may be given instead of gentamicin in combination with the ampicillin.

Resistance to vancomycin, penicillin, and gentamicin is common among enterococcal isolates, especially *E faecium*; it is essential to determine antimicrobial susceptibility of isolates. Infection control measures that may be indicated to limit their spread include isolation, barrier precautions, and avoidance of overuse of vancomycin and gentamicin. Consultation with an infectious diseases specialist is strongly advised when treating infections caused by resistant strains of enterococci. Quinupristin/dalfopristin and linezolid are approved by the FDA for treatment of infections caused by vancomycin-resistant strains of enterococci. Daptomycin, tigecycline, tedizolid, and oritavancin are not approved by the FDA for the treatment for vancomycin-resistant strains of enterococci, although they are frequently active in vitro.

Quinupristin/dalfopristin is not active against strains of *E faecalis* and should be used only for infections caused by *E faecium*. The dose is 7.5 mg/kg intravenously every 8–12 hours. Phlebitis and irritation at the infusion site (often requiring a central line) and an arthralgia-myalgia syndrome are relatively common side effects. Linezolid, an oxazolidinone, is active against both *E faecalis* and *E faecium*. The dose is 600 mg twice daily, and both intravenous and oral preparations are available. Its two principal side effects are thrombocytopenia and bone marrow suppression; however, peripheral neuropathy, optic neuritis, and lactic acidosis have been observed with prolonged use (typically greater than 6 weeks) due to mitochondrial toxicity. Emergence of resistance has occurred during therapy with both quinupristin/dalfopristin and linezolid.

Pneumococcus is the most common cause of community-acquired pyogenic bacterial pneumonia. Alcoholism, asthma, HIV infection, sickle cell disease, splenectomy, and hematologic disorders are predisposing factors. Mortality rates remain high in cases of advanced age, multilobar disease, hypoxemia, extrapulmonary complications, and bacteremia.

### General Considerations

Pneumococcal pneumonia is the most common cause of community-acquired pyogenic bacterial pneumonia. Alcoholism, asthma, HIV infection, sickle cell disease, splenectomy, and hematologic disorders are predisposing factors. Mortality rates remain high in cases of advanced age, multilobar disease, hypoxemia, extrapulmonary complications, and bacteremia.

### Clinical Findings

#### A. Symptoms and Signs

Presenting symptoms and signs include high fever, productive cough, occasional hemoptysis, and pleuritic chest pain. Rigors may occur initially but are uncommon later in the course. Bronchial breath sounds are an early sign.

#### B. Laboratory Findings

Pneumococcal pneumonia classically is a lobar pneumonia with radiographic findings of consolidation and occasionally effusion. However, differentiating it from other pneumonias is not possible radiographically or clinically because of significant overlap in presentations. Diagnosis requires isolation of the organism in culture, although the Gram stain appearance of sputum can be suggestive. Sputum and blood cultures, positive in 60% and 25% of cases of pneumococcal pneumonia respectively, should be obtained prior to initiation of antimicrobial therapy in patients who are admitted to the hospital. A good-quality sputum sample (less than 10 epithelial cells and greater than 25 polymorphonuclear leukocytes per high-power field) shows gram-positive diplococci in 80–90% of cases. A rapid urinary antigen test for *Streptococcus pneumoniae*, with sensitivity of 70–80% and specificity greater than 95%, can assist with early diagnosis.

### Complications

Parapneumonic (sympathetic) effusion is common and may cause recurrence or persistence of fever. These sterile fluid accumulations need no specific therapy. Empyema occurs in 5% or less of cases and is differentiated from sympathetic effusion by the presence of organisms on Gram-stained fluid or positive pleural fluid cultures.

Pneumococcal pericarditis is a rare complication that can cause tamponade. Pneumococcal arthritis also is uncommon. Pneumococcal endocarditis usually involves the aortic valve and often occurs in association with meningitis and pneumonia (sometimes referred to as Austrian or Osler triad). Early heart failure and multiple embolic events are typical.

### Treatment

#### A. Specific Measures

Initial antimicrobial therapy for pneumonia is empiric (see Table 9–9) pending isolation and identification of the causative agent. Once *S pneumoniae* is identified as the infecting pathogen, any of several antimicrobial agents may be
used depending on the clinical setting, community patterns of penicillin resistance, and susceptibility of the particular isolate. Uncomplicated pneumococcal pneumonia (ie, arterial \(\mathrm{PO}_2\) greater than 60 mm Hg, no coexisting medical problems, and single-lobe disease without signs of extrapulmonary infection) caused by penicillin-susceptible strains of pneumococcus may be treated on an outpatient basis with amoxicillin, 750 mg orally twice daily for 7–10 days. Cephalosporins including cefpodoxime, 200 mg orally twice daily, and cefdinir, 300 mg twice daily, may also be used. For penicillin-allergic patients, alternatives are azithromycin, one 500-mg dose orally on the first day and 250 mg for the next 4 days; clarithromycin, 500 mg orally twice daily for 10 days; doxycycline, 100 mg orally twice daily for 10 days; levofloxacin, 750 mg orally for 5 days; or moxifloxacin, 400 mg orally for 7–14 days. Patients should be monitored for clinical response (eg, less cough, defervescence within 2–3 days) because pneumococci have become increasingly resistant to penicillin and the second-line agents.

Parenteral therapy is generally recommended for the hospitalized patient at least until there has been clinical improvement. Aqueous penicillin G, 2 million units intravenously every 4 hours, or ceftriaxone, 1 g intravenously every 24 hours, is effective for strains that are penicillin-susceptible (ie, strains for which the minimum inhibitory concentration [MIC] of penicillin is 2 mcg/mL or less for non-CNS specimens). For serious penicillin allergy or infection caused by a highly penicillin-resistant strain, vancomycin, 1 g intravenously every 12 hours, is effective. Alternatively, a respiratory fluoroquinolone (eg, levofloxacin, 750 mg) can be used. The total duration of therapy is not well defined but 5 days is appropriate for patients who have an uncomplicated infection and demonstrate a good clinical response. Corticosteroid use remains controversial in community-acquired pneumonia and should not be administered routinely.

**B. Treatment of Complications**

Pleural effusions developing after initiation of antimicrobial therapy usually are sterile, and thoracentesis need not be performed if the patient is otherwise improving. Thoracentesis is indicated for an effusion present prior to initiation of therapy and in the patient who has not responded to antibiotics after 3–4 days. Chest tube drainage may be required if pneumococci are identified by culture or Gram stain, especially if aspiration of the fluid is difficult.

Echocardiography should be done if pericardial effusion is suspected. Patients with pericardial effusion who are responding to antibiotic therapy and have no signs of tamponade may be monitored and treated with indomethacin, 50 mg orally three times daily, for pain. In patients with increasing effusion, unsatisfactory clinical response, or evidence of tamponade, pericardiocentesis will determine whether the pericardial space is infected. Infected fluid must be drained either percutaneously (by tube placement or needle aspiration), by placement of a pericardial window, or by pericardectomy. Pericardectomy eventually may be required to prevent or treat constrictive pericarditis.

Endocarditis should be treated for 4 weeks with 3–4 million units of penicillin G every 4 hours intravenously; ceftriaxone, 2 g once daily intravenously; or vancomycin, 15 mg/kg every 12 hours intravenously. Mild heart failure due to valvular regurgitation may respond to medical therapy, but moderate to severe heart failure is an indication for prosthetic valve implantation, as are systemic emboli or large friable vegetations as determined by echocardiography.

**C. Penicillin-Resistant Pneumococci**

Resistance breakpoints for parenterally administered penicillin and high-dose oral amoxicillin (2 g twice daily) are as follows: susceptible, penicillin MIC of 2 mcg/mL or less; intermediate, MIC of 4 mcg/mL; resistant, MIC of 8 mcg/mL or more. Note, however, that these breakpoints do not apply to orally administered penicillin, which are the same as for use of penicillin in treatment of meningitis. In cases of pneumococcal pneumonia where the isolate has a penicillin MIC greater than 2 mcg/mL, cephalexin or meningitis. There has been no change to the penicillin susceptibility breakpoint for pneumococcal isolates causing meningitis, nor any change in treatment recommendations.

**Prevention**

See Chapter 30 for discussion of pneumococcal vaccines. All patients should have screening for smoking cessation.

**When to Refer**

- All patients with suspected pneumococcal endocarditis or meningitis to an infectious disease specialist.
- Extensive disease.
- Seriously ill patient with pneumonia, particularly in the setting of comorbid conditions (eg, liver disease).
- Progression of pneumonia or failure to improve on antibiotics.

**When to Admit**

- All patients in whom pneumococcal endocarditis or meningitis is suspected or documented should be admitted for observation and empiric therapy.
- All patients with pneumococcal pneumonia that is multilobar or associated with significant hypoxemia.
- Failure of outpatient pneumonia therapy, including inability to maintain oral intake and medications.
- Exacerbations of underlying disease (eg, heart failure) by pneumonia that would benefit from hospitalization.
2. Pneumococcal Meningitis

**ESSENTIALS OF DIAGNOSIS**

- Fever, headache, altered mental status.
- Meningismus.
- Gram-positive diplococci on Gram stain of cerebrospinal fluid.

**General Considerations**

*S. pneumoniae* is the most common cause of meningitis in adults. Head trauma with cerebrospinal fluid leaks, sinusitis, and pneumonia may precede it.

**Clinical Findings**

**A. Symptoms and Signs**

The onset is rapid, with fever, headache, meningismus, and altered mentation. Pneumonia may be present. Compared with meningitis caused by the meningococcus, pneumococcal meningitis lacks a rash. Obtundation, focal neurologic deficits, and cranial nerve palsies are more prominent features and may lead to long-term sequelae.

**B. Laboratory Findings**

The cerebrospinal fluid typically has greater than 1000 white blood cells per microliter, over 60% of which are polymorphonuclear leukocytes; the glucose concentration is less than 40 mg/dL (2.22 mmol/L), or less than 50% of the simultaneous serum concentration; and the protein usually exceeds 150 mg/dL (1500 mg/L) (see Chapter 30).

Not all cases of meningitis will have these typical findings, and alterations in cerebrospinal fluid cell counts and chemistries may be surprisingly minimal, overlapping with those of aseptic meningitis.

Gram stain of cerebrospinal fluid shows gram-positive cocci in 80–90% of cases, and in untreated cases, blood or cerebrospinal fluid cultures are almost always positive.

**Treatment**

Antibiotics should be given as soon as the diagnosis is suspected. If lumbar puncture must be delayed (eg, while awaiting results of an imaging study to exclude a mass lesion), the patient should be treated empirically for presumed meningitis with intravenous ceftriaxone, 2 g, plus vancomycin, 15 mg/kg, plus dexamethasone, 0.15 mg/kg administered concomitantly after blood cultures (positive in 50% of cases) have been obtained. Once susceptibility to penicillin has been confirmed, penicillin, 24 million units intravenously daily in six divided doses, or ceftriaxone, 2 g every 12 hours intravenously, is continued for 10–14 days in documented cases.

The best therapy for penicillin-resistant strains is not known. Penicillin-resistant strains (MIC greater than 0.06 mcg/mL) are often cross-resistant to the third-generation cephalosporins as well as other antibiotics. Susceptibility testing is essential to proper management of this infection.

If the MIC of ceftriaxone or cefotaxime is 0.5 mcg/mL or less, single-drug therapy with either of these cephalosporins is likely to be effective; when the MIC is 1 mcg/mL or more, treatment with a combination of ceftriaxone, 2 g intravenously every 12 hours, plus vancomycin, 30 mg/kg/day intravenously in two or three divided doses, is recommended. If a patient with a penicillin-resistant organism is slow to respond clinically, repeat lumbar puncture may be indicated to assess bacteriologic response.

Dexamethasone administered with antibiotic to adults has been associated with a 60% reduction in mortality and a 50% reduction in unfavorable outcomes. It is recommended that dexamethasone be given immediately prior to or concomitantly with the first dose of appropriate antibiotic and continued in those with pneumococcal disease every 6 hours thereafter for a total of 4 days. The effect of dexamethasone on outcome of meningitis caused by penicillin-resistant organisms is not known.

**STAPHYLOCOCCUS AUREUS INFECTIONS**

1. Skin & Soft Tissue Infections

**ESSENTIALS OF DIAGNOSIS**

- Localized erythema with induration and purulent drainage.
- Abscess formation.
- Folliculitis commonly observed.
- Gram stain of pus shows gram-positive cocci in clusters; cultures usually positive.

**General Considerations**

Approximately one-quarter of people are asymptomatic nasal carriers of *S. aureus*, which is spread by direct contact. Carriage often precedes infection, which occurs as a...
Clinical Findings

A. Symptoms and Signs

*S. aureus* skin infections may begin around one or more hair follicles, causing folliculitis; may become localized to form boils (or furuncles); or may spread to adjacent skin and deeper subcutaneous tissue (ie, a carbuncle) (Figure 33–2). Deep abscesses involving muscle or fascia may occur, often in association with a deep wound or other inoculation or injection. Necrotizing fasciitis, a rare form of *S. aureus* skin and soft tissues infection, has been reported with community strains of methicillin-resistant *S. aureus*.

B. Laboratory Findings

Cultures of the wound or abscess material will almost always yield the organism. In patients with systemic signs of infection, blood cultures should be obtained because of potential bacteremia, endocarditis, osteomyelitis, or metastatic seeding of other sites. Patients who are bacteremic should have blood cultures taken early during therapy to exclude persistent bacteremia, an indicator of severe or complicated infection.

Treatment

Proper drainage of abscess fluid or other focal infections is the mainstay of therapy. Incision and drainage alone is highly effective for the treatment of most uncomplicated cutaneous abscesses. A small benefit can be obtained from the addition of antimicrobials following incision and drainage. In areas where methicillin resistance among community *S. aureus* isolates is high, recommended oral antimicrobials agents include clindamycin, 300 mg three times daily; trimethoprim-sulfamethoxazole, given in two divided doses based on 5–10 mg/kg/day of the trimethoprim component; or doxycycline or minocycline, 100 mg twice daily. When the risk of methicillin resistance is low or methicillin susceptibility has been confirmed by testing of the isolate, consider dicloxacillin or cephalaxin, 500 mg four times a day (see Table 33–1). Seven days of treatment are sufficient in most cases.

For complicated infections with extensive cutaneous or deep tissue involvement or fever, initial parenteral therapy is often indicated. When methicillin resistance rates are high (above 10%), empiric therapy with vancomycin, 1 g intravenously every 12 hours, is a drug of choice. Cefazolin 1 g intravenously or intramuscularly or a penicillinase-resistant penicillin such as nafcillin or oxacillin in a dosage of 1.5 g every 6 hours intravenously is preferred for infections caused by methicillin-susceptible isolates. Total duration of therapy for soft tissue infections depends on clinical response and effectiveness of drainage/debridement. Courses of 7 days with early transition to oral therapy are effective in many cases.

Linezolid is FDA approved for treatment of skin and skin-structure infections as well as hospital-acquired pneumonia caused by methicillin-resistant strains of *S. aureus* and clinically is as effective as vancomycin for these indications. The dose is 600 mg orally or intravenously twice a day for 10–14 days. Its considerable cost makes it an unattractive choice for most routine outpatient infections, and its safety in treatment courses lasting longer than 2–3 weeks is not well characterized. Tedizolid (an oxazolidinone, like linezolid) is also approved for treating skin and soft tissue infection at a dose of 200 mg orally once daily for 6 days. Other drugs FDA approved for treating skin and soft tissue infections include daptomycin, 4 mg/kg intravenously once daily for 7–14 days; tigecycline (a glycylcycline class antimicrobial), 100 mg intravenously once followed by 50 mg intravenously twice a day for 5–14 days; cefaroline (a novel cephalosporin with activity against methicillin-resistant *S. aureus*), 600 mg twice a day for 7–14 days; dalbavancin (a lipoglycopeptide), a single intravenous dose of 1500 mg; oritavancin (a lipoglycopeptide), a single intravenous dose of 1200 mg; telavancin (a lipoglycopeptide), 10 mg/kg intravenously once daily for 7–14 days; and delafloxacin, 450 mg orally or 300 intravenously twice daily for 5–14 days. Telavancin is also approved for the treatment of hospital-acquired *S. aureus* pneumonia but has been associated with nephrotoxicity.
2. Osteomyelitis

\textit{S. aureus} causes approximately 60\% of all cases of osteomyelitis. Osteomyelitis may be caused by direct inoculation, eg, from an open fracture or as a result of surgery; by extension from a contiguous focus of infection or open wound; or by hematogenous spread. Long bones and vertebral are the usual sites. Epidural abscess is a common complication of vertebral osteomyelitis and should be suspected if fever and severe back or neck pain are accompanied by radicular pain or symptoms and signs indicative of spinal cord compression (eg, incontinence, extremity weakness, pathologic extremity reflexes).

\subsection*{Clinical Findings}

\textbf{A. Symptoms and Signs}

The infection may be acute, with abrupt development of local symptoms and systemic toxicity, or indolent, with insidious onset of vague pain over the site of infection, progressing to local tenderness and constitutional symptoms (fever, malaise, anorexia, night sweats). Fever is absent in one-third or more of cases. Back pain is often the only symptom in vertebral osteomyelitis and may be associated with an epidural abscess and spinal cord compression. Draining sinus tracts occur in chronic infections or infections of foreign body implants.

\textbf{B. Laboratory Findings}

The diagnosis is established by isolation of \textit{S. aureus} from the blood, bone, or a contiguous focus of a patient with symptoms and signs of focal bone infection. Blood culture will be positive in approximately 60\% of untreated cases. Bone biopsy and culture are indicated if blood cultures are sterile. Inflammatory markers (C-reactive protein, erythrocyte sedimentation rate) are typically elevated.

\textbf{C. Imaging}

Bone scan and gallium scan, each with a sensitivity of approximately 95\% and a specificity of 60–70\%, are useful in identifying or confirming the site of bone infection. Plain bone films early in the course of infection are often normal but will become abnormal in most cases even with effective therapy. Spinal infection (unlike malignancy) traverses the disk space to involve the contiguous vertebral body. CT is more sensitive than plain films and helps localize associated abscesses. MRI is slightly less sensitive than bone scan, but has a specificity of 90\%. It is indicated when epidural abscess is suspected in association with vertebral osteomyelitis. \textsuperscript{18}F-FDG-PET/CT may be useful in diagnosis of vertebral osteomyelitis as well as the detection of other metastatic sites of infection.

\subsection*{Treatment}

Prolonged therapy is required to cure staphylococcal osteomyelitis. Durations of 4–6 weeks or longer are recommended. Intravenous therapy is preferred, particularly during the acute phase of the infection for patients with systemic toxicity. Cefazolin, 2 g every 8 hours, or alternatively, nafcillin or oxacillin, 9–12 g/day in six divided doses, are the drugs of choice for infection with methicillin-sensitive isolates. Patients with infections due to methicillin-resistant strains of \textit{S. aureus} who have severe penicillin allergies should be treated with vancomycin, 30 mg/kg/day intravenously divided in two or three doses. Doses should be adjusted to achieve a vancomycin trough level of 15–20 mcg/mL. In patients with \textit{S. aureus} isolates susceptible to a fluoroquinolone and rifampin, that combination has been shown to be effective if given for 4 weeks following 2 weeks of induction therapy with an intravenous agent as above. Consultation with an infectious diseases specialist is recommended. The role of newer agents, such as dapptomycin or linezolid, remains to be defined.

Surgical treatment is often indicated under the following circumstances: (1) staphylococcal osteomyelitis with associated epidural abscess and spinal cord compression, (2) other abscesses (psoas, paraspinal), (3) extensive disease, or (4) recurrent or persistent infection despite standard medical therapy. Follow-up imaging may not be needed in patients who demonstrate improvement in symptoms and normalization of inflammatory markers.

Bernard L et al; Duration of Treatment for Spondylodiscitis (DTS) study group. Antibiotic treatment for 6 weeks versus 12 weeks in patients with pyogenic vertebral osteomyelitis: an open-label, non-inferiority, randomised, controlled trial. Lancet. 2015 Mar 7;385(9971):875–82. [PMID: 25468170]

3. Staphylococcal Bacteremia

\textit{S. aureus} readily invades the bloodstream and infects sites distant from the primary site of infection. Whenever \textit{S. aureus} is recovered from blood cultures, the possibility of endocarditis, osteomyelitis, or other metastatic deep infection must be considered. Bacteremia that persists for more than 48–96 hours after initiation of therapy is strongly predictive of worse outcome and complicated infection. Given the relatively high risk of infective endocarditis in patients with \textit{S. aureus} bacteremia, transthoracic echocardiography is recommended for most patients as a sensitive and cost-effective method for excluding underlying endocarditis. However, transthoracic echocardiography may be sufficient in select patients considered to be at low risk for endocarditis, namely those who meet all the following criteria: (1) no permanent intracardiac device, (2) sterile follow-up blood cultures within 4 days after the initial set, (3) no hemodialysis dependence, (4) nosocomial acquisition of \textit{S. aureus} bacteremia, and (5) no clinical signs of infective endocarditis or secondary foci of infection.

Empiric therapy of staphylococcal bacteremia should be with vancomycin, 15–20 mg/kg/dose intravenously.
every 8–12 hours, or daptomycin 6 mg/kg/day intravenously until results of susceptibility tests are known. If the 
*S. aureus* isolate is methicillin-susceptible, treatment should be narrowed to cefazolin, 2 g every 8 hours, or
nafcillin or oxacillin, 2 g intravenously every 4 hours. Cefazolin is as effective as nafcillin or oxacillin and has
been associated with fewer adverse events during treatment. In patients with methicillin-resistant *S. aureus*, treatment
should be with vancomycin, 15–20 mg/kg/dose intravenously every 8–12 hours. Maintaining a vancomycin
trough concentration of 15–20 mcg/mL may improve outcomes and is recommended. Daptomycin 6 mg/kg/day
is also an FDA-approved option as long as the patient does not require treatment for concomitant *S. aureus*
pneumonia. The addition of rifampicin to standard antimicrobial therapy has not been shown to be beneficial in the absence of indwelling prosthetic material and is associated with more adverse events. Duration of therapy for *S. aureus* bacteremia is 4–6 weeks of antibiotic therapy but a subset of patients with uncomplicated infection may be able to be treated for 14 days. A patient with uncomplicated bacteremia must meet all the following criteria: (1) infective endocarditis has been excluded, (2) no implanted prostheses are present, (3) follow-up blood cultures drawn 2–4 days after the initial set are sterile, (4) the patient defervesces within 72 hours of initiation of effective antibiotic therapy, and (5) no evidence of metastatic infection is present on examination. When present at the time of diagnosis, central venous catheters should be removed. Vancomycin treatment failures are relatively common, particularly for complicated bacteremia and among infections involving foreign bodies. Improved outcomes have been demonstrated when consultation is obtained with an infectious diseases specialist and should be considered in all cases of *S. aureus* bacteremia.

### 4. Toxic Shock Syndrome

*S. aureus* produces toxins that cause three important entities: "scalded skin syndrome" in children, toxic shock syndrome in adults, and enterotoxin food poisoning. Toxic shock syndrome is characterized by abrupt onset of high fever, vomiting, and watery diarrhea. Sore throat, myalgias, and headache are common. Hypotension with kidney and heart failure is associated with a poor outcome. A diffuse macular erythematous rash and nonpurulent conjunctivitis are common, and desquamation, especially of palms and soles, is typical during recovery (Figure 33–3). Fatality rates may be as high as 15%. Although originally associated with tampon use, any focus (eg, nasopharynx, bone, vagina, rectum, abscess, or wound) harboring a toxin-producing *S. aureus* strain can cause toxic shock syndrome. Classically, blood cultures are negative because symptoms are due to the effects of the toxin and not systemic infection. Other entities associated with toxic shock include invasive group A streptococcal infection and certain *Clostridium* species (eg, *C. perfringens*).

Important aspects of treatment include rapid rehydration, targeted antimicrobials (antistaphylococcal therapy when *S. aureus* is implicated), management of kidney or heart failure, and addressing sources of toxin, eg, removal of tampon or drainage of abscess. Intravenous clindamycin, 900 mg every 8 hours, is often added to inhibit toxin production. Intravenous immune globulin may be considered, although there are limited data compared with streptococcus toxic shock syndrome.

## 5. Infections Caused by Coagulase-Negative *Staphylococci*

Coagulase-negative staphylococci are an important cause of infections of intravascular and prosthetic devices and of wound infection following cardiothoracic surgery. These organisms infrequently cause infections such as osteomyelitis and endocarditis in the absence of a prosthesis. Most human infections are caused by *Staphylococcus epidermidis*, *S. haemolyticus*, *S. hominis*, *S. warnerii*, *S. saprophyticus*, *S. saccharolyticus*, and *S. cohnii*. These common hospital-acquired pathogens are less virulent than *S. aureus*, and infections caused by them tend to be more indolent.

Because coagulase-negative staphylococci are normal inhabitants of human skin, it is difficult to distinguish infection from contamination, the latter perhaps accounting for three-fourths of blood culture isolates. Infection is more likely if the patient has a foreign body (eg, sternal wires, prosthetic joint, prosthetic cardiac valve, pacemaker, intracranial pressure monitor, cerebrospinal fluid shunt, peritoneal dialysis catheter) or an intravascular device in place. Purulent or serosanguineous drainage, erythema, pain, or tenderness at the site of the foreign body or device
Clinical Findings

Gas in the tissue by palpation or radiograph.

Gram-positive rods in culture or smear of exudate.

General Considerations

Gas gangrene or clostridial myonecrosis is produced by any one of several clostridia (Clostridium perfringens, C. ramosum, C. bifermentans, C. histolyticum, C. novyi, etc). Trauma and injection drug use are common predisposing conditions. Toxins produced in devitalized tissues under anaerobic conditions result in shock, hemolysis, and myonecrosis.

Clinical Findings

A. Symptoms and Signs

The onset is usually sudden, with rapidly increasing pain in the affected area, hypotension, and tachycardia. Fever is present, but is not proportionate to the severity of the infection. In the last stages of the disease, severe prostration, stupor, delirium, and coma occur.

The wound becomes swollen, and the surrounding skin is pale. There is a foul-smelling brown, blood-tinged serous discharge. As the disease advances, the surrounding tissue changes from pale to dusky and finally becomes discolored, with coalescent, red, fluid-filled vesicles. Gas may be palpable in the tissues.

B. Laboratory Findings

Gas gangrene is a clinical diagnosis, and empiric therapy is indicated if the diagnosis is suspected. Radiographic studies may show gas within the soft tissues, but this finding is not sensitive nor specific. The smear shows absence of neutrophils and the presence of gram-positive rods. Anaerobic culture confirms the diagnosis.

Differential Diagnosis

Other bacteria can produce gas in infected tissue, eg, enteric gram-negative organisms, or anaerobes.

Treatment

Adequate surgical debridement and exposure of infected areas are essential, with radical surgical excision often necessary. Penicillin, 2 million units every 3 hours intravenously, is an effective adjunct. Clindamycin may decrease the production of bacterial toxin, and some experts recommend the addition of clindamycin, 600–900 mg every 8 hours intravenously, to penicillin. Hyperbaric oxygen therapy has been used empirically, but must be used in conjunction with administration of an appropriate antibiotic and surgical debridement.

Suggests infection. Joint instability and pain are signs of prosthetic joint infection. Fever, a new murmur, instability of the prosthesis, or signs of systemic embolization are evidence of prosthetic valve endocarditis.

Infection is also more likely if the same strain is consistently isolated from two or more blood cultures (particularly if samples were obtained at different times) and from the foreign body site. Contamination is more likely when a single blood culture is positive or if more than one strain is isolated from blood cultures. The antimicrobial susceptibility pattern and speciation are used to determine whether one or more strains have been isolated.

Whenever possible, the intravascular device or foreign body suspected of being infected should be removed. However, removal and replacement of some devices (eg, prosthetic joint, prosthetic valve, cerebrospinal fluid shunt) can be a difficult or risky procedure, and it may sometimes be preferable to treat with antibiotics alone with the understanding that the probability of cure is reduced and that surgical management may eventually be necessary.

Coagulase-negative staphylococci are commonly resistant to beta-lactams and multiple other antibiotics. For patients with normal kidney function, vancomycin, 1 g intravenously every 12 hours, is the treatment of choice until susceptibility to penicillinase-resistant penicillins or other agents has been confirmed. Duration of therapy has not been established for relatively uncomplicated infections, such as those secondary to intravenous devices, which may be eliminated by simply removing the device. Infection involving bone or a prosthetic valve should be treated for 6 weeks. A combination regimen of vancomycin plus rifampin, 300 mg orally twice daily, plus gentamicin, 1 mg/kg intravenously every 8 hours, is recommended for treatment of prosthetic valve endocarditis caused by methicillin-resistant strains.

Clostridial Diseases

1. Clostridial Myonecrosis (Gas Gangrene)

- Sudden onset of pain and edema in an area of wound contamination.
- Prostration and systemic toxicity.
- Brown to blood-tinged watery exudate, with skin discoloration of surrounding area.

Bacteri & Chlamydial Infections

Gas gangrene or clostridial myonecrosis is produced by any one of several clostridia (Clostridium perfringens, C. ramosum, C. bifermentans, C. histolyticum, C. novyi, etc). Trauma and injection drug use are common predisposing conditions. Toxins produced in devitalized tissues under anaerobic conditions result in shock, hemolysis, and myonecrosis.
2. Tetanus

ESSENTIALS OF DIAGNOSIS

- History of wound and possible contamination.
- Jaw muscle stiffness (“lock jaw”), then spasms (trismus).
- Stiffness of the neck and other muscles, dysphagia, irritability, hyperreflexia.
- Finally, painful convulsions precipitated by minimal stimuli.

General Considerations

Tetanus is caused by the neurotoxin tetanospasmin, elaborated by *C. tetani*. Spores of this organism are ubiquitous in soil and may germinate when introduced into a wound. Tetanospasmin interferes with neurotransmission at spinal synapses of inhibitory neurons. As a result, minor stimuli result in uncontrolled spasms, and reflexes are exaggerated. The incubation period is 5 days to 15 weeks, with the average being 8–12 days.

Most cases occur in unvaccinated individuals. Persons at risk are older adults, migrant workers, newborns, and injection drug users. While puncture wounds are particularly prone to causing tetanus, any wound, including bites or decubiti, may become colonized and infected by *C. tetani.*

Clinical Findings

A. Symptoms and Signs

The first symptom may be pain and tingling at the site of inoculation, followed by spasticity of the muscles nearby. Stiffness of the jaw, neck stiffness, dysphagia, and irritability are other early signs. Hyperreflexia develops later, with spasms of the jaw muscles (trismus) or facial muscles and rigidity and spasm of the muscles of the abdomen, neck, and back. Painful tonic convulsions precipitated by minor stimuli are common. Spasms of the glottis and respiratory muscles may cause acute asphyxia. The patient is awake and alert throughout the illness. The sensory examination is normal. The temperature is normal or only slightly elevated.

B. Laboratory Findings

The diagnosis of tetanus is made clinically.

Differential Diagnosis

Tetanus must be differentiated from various acute central nervous system (CNS) infections such as meningitis. Trismus may occasionally develop with the use of phenothiazines. Strychnine poisoning should also be considered.

Complications

Airway obstruction is common. Urinary retention and constipation may result from spasm of the sphincters. Respiratory arrest and cardiac failure are late, life-threatening events.

Prevention

Tetanus is preventable by active immunization (see Table 30–7). For primary immunization of adults, Td (tetanus and diphtheria toxoids vaccine) is administered as two doses 4–6 weeks apart, with a third dose 6–12 months later. For one of the three doses, Tdap (tetanus toxoid, reduced-dose diphtheria toxoid, acellular pertussis vaccine) should be substituted for Td. Booster Td doses are given every 10 years or at the time of major injury if it occurs more than 5 years after a dose; a single dose of Tdap is preferred to Td for wound management if the patient has not been previously vaccinated with Tdap. Women should receive Tdap with each pregnancy, preferably between 27 and 36 weeks, with immunization at 27–30 weeks associated with the highest antibody concentrations.

Passive immunization should be used in nonimmunized individuals and those whose immunization status is uncertain whenever a wound is contaminated or likely to have devitalized tissue; tetanus immune globulin, 250 units, is given intramuscularly. Active immunization with tetanus toxoid vaccine is started concurrently. Table 33–2 provides a guide to prophylactic management.

Treatment

A. Specific Measures

Human tetanus immune globulin, 500 units, should be administered intramuscularly within the first 24 hours of presentation. Whether intrathecal administration has any additional benefit is controversial. An unblinded, randomized trial comparing intramuscular tetanus immune globulin to intramuscular plus intrathecal tetanus immune globulin found clinical benefit in the intrathecal group. However, the exact immunoglobulin preparation was not specified and the total dose was 4000 units. Tetanus does not produce natural immunity, and a full course of immunization with tetanus toxoid should be administered once the patient has recovered.

B. General Measures

Debridement of wounds should be undertaken if implicated as the source. Metronidazole, 7.5 mg/kg administered intravenously or orally every 6 hours (maximum 4 g daily), is preferred and should be administered to all patients. Penicillin, 20 million units intravenously daily in divided doses, is an alternative. Minimal stimuli can provoke spasms, so the patient should be placed at bed rest and monitored under the quietest conditions possible. Sedation, paralysis with curare-like agents, and mechanical
ventilation are often necessary. Enteral nutritional support should be given early.

**Prognosis**

High mortality rates are associated with a short incubation period, early onset of convulsions, and delay in treatment. Contaminated lesions about the head and face are more dangerous than wounds on other parts of the body.

**Botulism**

**ESSENTIALS OF DIAGNOSIS**

- Recent ingestion of home-canned or smoked foods; recovery of toxin in serum or food.
- Injection drug use.
- Diplopia, dry mouth, dysphagia, dysphonia, and muscle weakness progressing to respiratory paralysis.
- Pupils are fixed and dilated in most cases.

**General Considerations**

Botulism is a paralytic disease caused by botulinum toxin, which is produced by *Clostridium botulinum*, a ubiquitous, strictly anaerobic, spore-forming bacillus found in soil. Four toxin types—A, B, E, and F—cause human disease. Botulinum toxin is extremely potent and is classified by the CDC as a high-priority agent because of its potential for use as an agent of bioterrorism. Naturally occurring botulism exists in three forms: food-borne botulism, infant botulism, or wound botulism. Food-borne botulism is caused by ingestion of preformed toxin present in canned, smoked, or vacuum-packed foods such as home-canned vegetables, smoked meats, and vacuum-packed fish. Commercial foods have been associated with outbreaks of botulism. Infant botulism (associated with ingestion of honey) and wound botulism (often occurs in association with injection drug use) result from organisms present in the gut or wound that secrete toxin.

**Clinical Findings**

**A. Symptoms and Signs**

Twelve to 36 hours after ingestion of the toxin, visual disturbances appear, particularly diplopia and loss of accommodation. Ptosis, cranial nerve palsies with impairment of extraocular muscles, and fixed dilated pupils are characteristic signs. The sensory examination is normal. Other symptoms are dry mouth, dysphagia, and dysphonia. Nausea and vomiting may be present, particularly with type E toxin. The sensorium remains clear and the temperature normal. Paralysis progressing to respiratory failure and death may occur unless mechanical assistance is provided.

**B. Laboratory Findings**

Toxin in foods and patients’ serum can be demonstrated by mouse inoculation and identified with specific antiserum.

**Differential Diagnosis**

Because the clinical presentation of botulism is so distinctive and the differential diagnosis limited, botulism once considered is not easily confused with other diseases. Cranial nerve involvement may be seen with vertebrobasilar insufficiency, the C. Miller Fisher variant of Guillain-Barré syndrome, myasthenia gravis, or any basilar meningitis (infectious or carcinomatous). Intestinal obstruction or other types of food poisoning are considered when nausea and vomiting are present.

**Treatment**

If botulism is suspected, the practitioner should contact the state health authorities or the CDC for advice and help.
with procurement of equine serum heptavalent botulism antitoxin and for assistance in obtaining assays for toxin in serum, stool, or food. Skin testing is recommended to exclude hypersensitivity to the antitoxin preparation. Antitoxin should be administered as early as possible, ideally within 24 hours of the onset of symptoms or signs, to arrest progression of disease; its administration should not be delayed for laboratory confirmation of the diagnosis. Respiratory failure is managed with intubation and mechanical ventilation. Parenteral fluids or alimentation should be given while swallowing difficulty persists. The removal of unabsorbed toxin from the gut may be attempted. Any remnants of suspected foods should be assayed for toxin. Persons who might have eaten the suspected food must be located and observed.

ANTHRAX

Clinical Findings

A. Symptoms and Signs

1. Cutaneous anthrax—This occurs within 2 weeks after exposure to spores; there is no latency period for cutaneous disease as there is with inhalational anthrax. The initial lesion is an erythematous papule, often on an exposed area of skin that vesiculates and then ulcerates and undergoes necrosis, ultimately progressing to a purple to black eschar. The eschar typically is painless; pain indicates secondary bacterial infection. The surrounding area is edematous and vesicular but not purulent. Regional adenopathy, fever, malaise, headache, and nausea and vomiting may be present. The infection is self-limited in most cases, but hematogenous spread with sepsis or meningitis may occur.

2. Inhalational anthrax—Illness occurs in two stages, beginning on average 10 days after exposure, but may have a latent onset 6 weeks after exposure. Nonspecific viral-like symptoms such as fever, malaise, headache, dyspnea, cough, and congestion of the nose, throat, and larynx are characteristic of the initial stage. Anterior chest pain is an early symptom of mediastinitis. Within hours to a few days, progression to the fulminant stage of infection occurs in which symptoms or signs of overwhelming sepsis predominate. Delirium, obtundation, or findings of meningeal irritation suggest an accompanying hemorrhagic meningitis.

3. Gastrointestinal anthrax—Fever, diffuse abdominal pain, rebound abdominal tenderness, vomiting, constipation, and diarrhea occur 2–5 days after ingestion of food products contaminated with anthrax spores. The primary lesion is ulcerative, producing emesis that may be blood-tinged or coffee-grounds and stool that may be blood-tinged or melenic. Bowel perforation can occur. The oropharyngeal form of the disease is characterized by local lymphadenopathy, cervical edema, dysphagia, and upper respiratory tract obstruction.

B. Laboratory Findings

Laboratory findings are nonspecific. The white blood cell count initially may be normal or modestly elevated, with polymorphonuclear predominance and an increase in immature forms. Pleural fluid from patients with inhalational anthrax is typically hemorrhagic with few white cells. Cerebrospinal fluid from meningitis cases is also hemorrhagic. Gram stain of pleural fluid, cerebrospinal fluid, unspun blood, blood culture, or fluid from a cutaneous lesion may show the characteristic boxcar-shaped encapsulated rods in chains.

The diagnosis is established by isolation of the organism from culture of the skin lesion (or fluid expressed from it), blood, or pleural fluid—or cerebrospinal fluid in cases of meningitis. In the absence of prior antimicrobial therapy, cultures are invariably positive. Cultures obtained after initiation of antimicrobial therapy may be negative. If anthrax is suspected on clinical or epidemiologic grounds, immunohistochemical tests (eg, to detect capsular antigen), polymerase chain reaction assays, and serologic tests (useful for documenting past cutaneous infection) are available through the CDC and should be used to establish

| Epidemiologic setting: exposure to animals or animal hides or potential exposure from bioterrorism. |
| A painless cutaneous black eschar on exposed skin, with marked surrounding edema and vesicles. |
| Nonspecific flu-like symptoms that rapidly progress to extreme dyspnea and shock; mediastinal widening and pleural effusions on chest radiograph. |

General Considerations

Naturally occurring anthrax is a disease of sheep, cattle, horses, goats, and swine. *Bacillus anthracis* is a gram-positive spore-forming aerobic rod. Spores—not vegetative bacteria—are the infectious forms of the organism. These are transmitted to humans from contact with contaminated animals, animal products, or animal hides, or from soil by inoculation of broken skin or mucous membranes; by inhalation of aerosolized spores; or, rarely, by ingestion resulting in cutaneous, inhalational, or gastrointestinal forms of anthrax, respectively. Inhalation of aerosolized spores that were deliberately placed in the mail as an act of bioterrorism occurred in the United States in 2001. Spores germinate into vegetative bacteria that multiply locally in cutaneous and gastrointestinal anthrax but may also disseminate to cause systemic infection. Inhaled spores are ingested by pulmonary macrophages and carried via lymphatics to regional lymph nodes, where they germinate. The bacteria rapidly multiply within the lymphatics, causing a hemorrhagic lymphadenitis. Invasion of the bloodstream leads to overwhelming sepsis, killing the host.
Differential Diagnosis

Cutaneous anthrax, despite its characteristic appearance, can be confused with a variety of other also uncommon or rare conditions such as ecthyma gangrenosum, rat-bite fever, ulceroglandular tularemia, plague, glanders, rickettsialpox, orf (parapoxvirus infection), or cutaneous mycobacterial infection. Inhalational anthrax must be differentiated from mediastinitis due to other bacterial causes, fibrous mediastinitis due to histoplasmosis, coccidiodomycosis, atypical or viral pneumonia, silicosis, sarcoidosis, and other causes of mediastinal widening (eg, superior vena cava syndrome or aortic aneurysm or dissection). Gastrointestinal anthrax shares clinical features with a variety of common intra-abdominal disorders, including bowel obstruction, perforated viscus, peritonitis, gastroenteritis, and peptic ulcer disease.

Treatment

Strains of *B anthracis* (including the strain isolated in the bioterrorism cases) are susceptible in vitro to penicillin, amoxicillin, chloramphenicol, clindamycin, imipenem, doxycycline, ciprofloxacin (as well as other fluoroquinolones), macrolides, rifampin, and vancomycin. *B anthracis* may express beta-lactamases that confer resistance to cephalosporins and penicillins. For this reason, penicillin or amoxicillin is not recommended for use as a single agent in treatment of disseminated disease. Based on results of animal experiments and because of concern for engineered drug resistance in strains of *B anthracis* used in bioterrorism, ciprofloxacin is considered the drug of choice for treatment and for prophylaxis following exposure to anthrax spores. Other fluoroquinolones with activity against gram-positive bacteria (eg, levofloxacin, moxifloxacin) are likely to be just as effective as ciprofloxacin. Doxycycline is an alternative first-line agent. Combination therapy with at least one additional agent is recommended for inhalational or disseminated disease and in cutaneous infection involving the face, head, and neck or associated with extensive local edema or systemic signs of infection, eg, fever, tachycardia, and elevated white blood cell count. Single-drug therapy is recommended for prophylaxis following exposure to spores.

The required duration of therapy is poorly defined. In naturally occurring disease, treatment for 7–10 days for cutaneous disease and for at least 2 weeks following clinical response for disseminated, inhalational, or gastrointestinal infection have been standard recommendations. Because of concern about relapse from latent spores acquired by inhalation of aerosol in bioterrorism-associated cases, the initial recommendation was treatment for 60 days.

Several monoclonal antibodies are FDA approved as adjunctive treatments for inhalation anthrax. Raxibacumab is a human monoclonal antibody directed against the protective antigen component of lethal toxin and is used for treatment of inhalation anthrax in combination with recommended antibacterial treatments. Obiltoxaximab is another toxin-targeting monoclonal antibody and is given in combination with antibacterial drugs. A vaccine is also available for postexposure prophylaxis (and preexposure prophylaxis). This vaccine is administered at 0, 2, and 4 weeks postexposure combined with antimicrobial therapy.

Prevention

In 2001, the CDC offered one of two options for postal workers receiving prophylaxis for exposure to contaminated mail: (1) antibiotics for 100 days (fearing that even with 60 days of treatment late relapses might occur) or (2) vaccination with an investigative agent (three doses administered over a 1-month period) in conjunction with 40 days of antibiotic administration to cover the time required for a protective antibody response to develop. Insufficient information exists to favor one recommendation over the other.

An FDA-approved vaccine is available for persons at high risk for exposure to anthrax spores. The vaccine is cell-free antigen prepared from an attenuated strain of *B anthracis*. Multiple injections over 18 months and an annual booster dose are required to achieve and maintain protection. Existing supplies have been reserved for vaccination of military personnel. Raxibacumab and obiltoxaximab are approved for prevention of inhalation anthrax when other treatments are not available or appropriate.

Prognosis

The prognosis in cutaneous infection is excellent. Death is unlikely if the infection has remained localized, and lesions heal without complications in most cases. By contrast, the reported mortality rate for gastrointestinal and inhalational infections is up to 85%. Yet, the experience with bioterrorism-associated inhalational cases in which six of eleven victims survived suggests a somewhat better outcome with modern supportive care and antibiotics provided that treatment is initiated before the patient has progressed to the fulminant stage of disease. No cases of anthrax have occurred among the several thousand individuals receiving antimicrobial prophylaxis following exposure to spores.
DIPHTHERIA

**ESSENTIALS OF DIAGNOSIS**

- Tenacious gray membrane at portal of entry in pharynx.
- Sore throat, nasal discharge, hoarseness, fever.
- Myocarditis, neuropathy.
- Culture confirms the diagnosis.

**General Considerations**

Diphtheria is an acute infection caused by *Corynebacterium diphtheriae* that usually attacks the respiratory tract but may involve any mucous membrane or skin wound. The organism is spread chiefly by respiratory secretions. Exotoxin produced by the organism is responsible for myocarditis and neuropathy.

**Clinical Findings**

**A. Symptoms and Signs**

Nasal, laryngeal, pharyngeal, and cutaneous forms of diphtheria occur. Nasal infection produces few symptoms other than a nasal discharge. Laryngeal infection may lead to upper airway and bronchial obstruction. In pharyngeal diphtheria, the most common form, a tenacious gray membrane covers the tonsils and pharynx. Mild sore throat, fever, and malaise are followed by toxemia and prostration. Myocarditis and neuropathy are the most common and most serious complications. Myocarditis causes cardiac arrhythmias, heart block, and heart failure. The neuropathy usually involves the cranial nerves first, producing diplopia, slurred speech, and difficulty in swallowing.

**B. Laboratory Findings**

The diagnosis is made clinically but can be confirmed by culture of the organism.

**Differential Diagnosis**

Diphtheria must be differentiated from streptococcal pharyngitis, infectious mononucleosis, adenovirus or herpes simplex infection, Vincent angina, pharyngitis due to *Arcanobacterium haemolyticum*, and candidiasis. A presumptive diagnosis of diphtheria should be made on clinical grounds without waiting for laboratory verification, since emergency treatment is needed.

**Prevention**

Active immunization with diphtheria toxoid is part of routine childhood immunization with appropriate booster injections. The immunization schedule for adults is the same as for tetanus (see Table 30–7). Women should receive Tdap with each pregnancy, preferably between 27 and 36 weeks. Susceptible persons exposed to diphtheria should receive a booster dose of diphtheria toxoid (or a complete series if previously unimmunized), as well as a course of penicillin or erythromycin.

**Treatment**

Removal of membrane by direct laryngoscopy or bronchoscopy may be necessary to prevent or alleviate airway obstruction. Antitoxin, which is prepared from horse serum, must be given in all cases when diphtheria is suspected. For mild early pharyngeal or laryngeal disease, the dose is 20,000–40,000 units; for moderate nasopharyngeal disease, 40,000–60,000 units; for severe, extensive, or late (3 days or more) disease, 80,000–100,000 units. Diphtheria equine antitoxin can be obtained from the CDC.

Either penicillin, 250 mg orally four times daily, or erythromycin, 500 mg orally four times daily, for 14 days is effective therapy, although erythromycin is slightly more effective in eliminating the carrier state. Azithromycin or clarithromycin is probably as effective as erythromycin. The patient should be isolated until three consecutive cultures at the completion of therapy have documented elimination of the organism from the oropharynx. Contacts to a case should receive erythromycin, 500 mg orally four times daily for 7 days, to eradicate carriage.

**Listeria monocytogenes** is a facultative, motile, gram-positive rod that is capable of invading several cell types and causes intracellular infection. Most cases of infection caused by *L. monocytogenes* are sporadic, but outbreaks have been traced to eating contaminated food, including unpasteurized dairy

**ESSENTIALS OF DIAGNOSIS**

- Ingestion of contaminated food product.
- Undifferentiated fever in a pregnant woman in her third trimester.
- Altered mental status and fever in an elderly or immunocompromised patient.
- Obtain blood and cerebrospinal fluid cultures to confirm the diagnosis.

**General Considerations**

*Listeria monocytogenes* is a facultative, motile, gram-positive rod that is capable of invading several cell types and causes intracellular infection. Most cases of infection caused by *L. monocytogenes* are sporadic, but outbreaks have been traced to eating contaminated food, including unpasteurized dairy
products, hot dogs, delicatessen meats, cantaloupes, and ricotta cheese. Outbreaks have been associated with significant morbidity and mortality in infected persons.

**Clinical Findings**

Five types of infection are recognized:

1. **Infection during pregnancy**, usually in the last trimester, is a mild febrile illness without an apparent primary focus and may resolve without specific therapy. However, approximately one in five pregnancies complicated by listeriosis result in spontaneous abortion or stillbirth and surviving infants are at risk for clinical neonatal listeriosis.

2. **Granulomatosis infantisepticum** is a neonatal infection acquired in utero, characterized by disseminated abscesses, granulomas, and a high mortality rate.

3. **Bacteremia** with or without sepsis syndrome is an infection of neonates or immunocompromised adults. The presentation is of a febrile illness without a recognized source.

4. **Meningitis** caused by *L. monocytogenes* affects infants under 2 months of age as well as older adults, ranking third after pneumococcus and meningococcus as common causes of bacterial meningitis. Cerebrospinal fluid shows a *neutrophilic* pleocytosis. Adults with meningitis are often immunocompromised, and cases have been associated with HIV infection and therapy with tumor necrosis factor (TNF) inhibitors such as infliximab.

5. **Focal infections**, including adenitis, brain abscess, endocarditis, osteomyelitis, and arthritis, occur rarely.

**Prevention**

At-risk patients (e.g., pregnant women) should avoid unpasteurized milk products. Smoked seafoods, cold cuts, hot dogs, and meat spreads also carry risk. Thoroughly cook animal source food and wash raw vegetables.

**Treatment**

Ampicillin, 8–12 g/day intravenously in four to six divided doses (the higher dose for meningitis), is considered the treatment of choice. Gentamicin, 5 mg/kg/day intravenously once or in divided doses, is synergistic with ampicillin against *L. monocytogenes* in vitro and in animal models, and the use of combination therapy may be considered during the first few days of treatment to enhance eradication of organisms. In patients with penicillin allergies, trimethoprim-sulfamethoxazole has excellent intracellular and cerebrospinal fluid penetration and is considered an appropriate alternative. The dose is 10–20 mg/kg/day intravenously of the trimethoprim component. Mortality and morbidity rates still are high. Therapy should be administered for at least 2–3 weeks. Longer durations—between 3 and 6 weeks—have been recommended for treatment of meningitis, especially in immunocompromised persons.

**INFECTIVE ENDOCARDITIS**

**ESSENTIALS OF DIAGNOSIS**

- Fever.
- Preexisting organic heart lesion.
- Positive blood cultures.
- Evidence of vegetation on echocardiography.
- Evidence of systemic emboli.

**General Considerations**

Endocarditis is a bacterial or fungal infection of the valvular or endocardial surface of the heart. The clinical presentation depends on the infecting organism and the valve or valves that are infected. More virulent organisms—*S. aureus* in particular—tend to produce a more rapidly progressive and destructive infection. Endocarditis caused by more virulent organisms often presents as an acute febrile illness and is complicated by early embolization, acute valvular regurgitation, and myocardial abscess formation. Viridans strains of streptococci, enterococci, other bacteria, yeasts, and fungi tend to cause a more subacute picture.

Predisposing valvular abnormalities include rheumatic involvement of any valve, bicuspid aortic valves, calcific or sclerotic aortic valves, hypertrophic subaortic stenosis, mitral valve prolapse, and a variety of congenital disorders such as ventricular septal defect, tetralogy of Fallot, coarctation of the aorta, or patent ductus arteriosus. Rheumatic disease is no longer the major predisposing factor in developed countries. Regurgitation lesions are more susceptible than stenotic ones.

The initiating event in native valve endocarditis is colonization of the valve by bacteria or yeast that gain access to the bloodstream. Transient bacteremia is common during dental, upper respiratory, urologic, and lower gastrointestinal diagnostic and surgical procedures. It is less common during upper gastrointestinal and gynecologic procedures. Intravascular devices are increasingly implicated as a portal of access of microorganisms into the bloodstream. A large proportion of cases of *S. aureus* endocarditis are attributable to health care–associated bacteria.

**Native valve endocarditis** is usually caused by *S. aureus*, viridans streptococci, enterococci, or HACEK organisms (an acronym for *Haemophilus aphrophilus* [now *Aggregatibacter aphrophilus*], *Actinobacillus actinomycetemcomitans* [now *Aggregatibacter actinomycetemcomitans*], *Cardiobacterium hominis*, *Eikenella corrrodens*, and *Kingella species*). Streptococcal species formerly accounted for the majority of native valve endocarditis cases; *S. aureus* is now the leading cause. Gram-negative organisms and fungi account for a small percentage.
Clinical Findings

A. Symptoms and Signs

Virtually all patients have fever at some point in the illness, although it may be very low grade (less than 38°C) in elderly individuals and in patients with heart failure or kidney failure. Rarely, there may be no fever at all.

The duration of illness typically is a few days to a few weeks. Nonspecific symptoms are common. The initial symptoms and signs of endocarditis may be caused by direct arterial, valvular, or cardiac damage. Although a changing regurgitant murmur is significant diagnostically, it is the exception rather than the rule. Symptoms also may occur as a result of embolization, metastatic infection or immunologically mediated phenomena. These include cough; dyspnea; arthralgias or arthritis; diarrhea; and abdominal, back, or flank pain.

The characteristic peripheral lesions—petechiae (on the palate or conjunctiva or beneath the fingernails), subungual ("splinter") hemorrhages (Figure 33–4), Osler nodes (painful, violaceous raised lesions of the fingers, toes, or feet) (Figure 33–5), Janeway lesions (painless erythematous lesions of the palms or soles), and Roth spots (exudative lesions in the retina)—occur in about 25% of patients. Strokes and major systemic embolic events are present in about 25% of patients and tend to occur before or within the first week of antimicrobial therapy. Hematuria and proteinuria may result from emboli or immunologically mediated glomerulonephritis, which can cause kidney dysfunction.

B. Imaging

Chest radiograph may show evidence for the underlying cardiac abnormality and, in right-sided endocarditis, pulmonary infiltrates. The electrocardiogram is nondiagnostic, but new conduction abnormalities suggest myocardial abscess formation. Echocardiography is useful in identifying vegetations and other characteristic features suspicious for endocarditis and may provide adjunctive information about the specific valve or valves that are infected. The sensitivity of transthoracic echocardiography is between 55% and 65%; it cannot reliably rule out endocarditis but may confirm a clinical suspicion. Transesophageal echocardiography is 90% sensitive in detecting vegetations and is particularly useful for identifying valve ring abscesses as well as prosthetic valve endocarditis.

C. Diagnostic Studies

1. Blood cultures—Three sets of blood cultures are recommended before starting antibiotics to maximize microbiologic diagnosis. To maximize the yield of blood cultures, adequate volume is important. Each culture bottle should be filled with 10 mL of blood since half of adults have less than 1 colony forming unit of bacteria per mL blood. The yield of bacteria may be up to 5% higher for every additional milliliter collected. Optimal yield is with two or three sets of cultures from different sites. There is no difference in yield if blood is collected simultaneously or several hours apart.

   Approximately 5% of cases will be culture-negative, usually attributable to administration of antimicrobials prior to cultures. If antimicrobial therapy has been administered prior to obtaining cultures and the patient is clinically stable, it is reasonable to withhold antimicrobial therapy for 2–3 days so that appropriate cultures can be obtained. Culture-negative endocarditis may also be due to organisms that require special media for growth (eg, Legionella, Bartonella, Abiotrophia species, formerly referred to as nutritionally deficient streptococci), organisms that do not grow on artificial media (Treponema whippelii, or pathogens of Q fever or psittacosis), or those that may require prolonged incubation (eg, Brucella, anaerobes, HACEK organisms). Bartonella quintana is an important cause of culture-negative endocarditis.

2. Modified Duke criteria—The Modified Duke criteria are useful for the diagnosis of endocarditis. Major criteria

In injection drug users, S. aureus accounts for over 60% of all endocarditis cases and for 80–90% of cases in which the tricuspid valve is infected. Enterococci and streptococci comprise the balance in about equal proportions. Gram-negative aerobic bacilli, fungi, and unusual organisms may cause endocarditis in injection drug users.

The microbiology of prosthetic valve endocarditis also is distinctive. Early infections (ie, those occurring within 2 months after valve implantation) are commonly caused by staphylococci—both coagulase-positive and coagulase-negative—gram-negative organisms, and fungi. In late prosthetic valve endocarditis, streptococci are commonly identified, although coagulase-negative and coagulase-positive staphylococci still cause many cases.
include (1) two positive blood cultures for a microorganism that typically causes infective endocarditis or persistent bacteremia, or a single positive blood culture for Coxiella burnetii or anti–phase 1 IgG antibody titer greater than or equal to 1:800; and (2) evidence of endocardial involvement documented by echocardiography showing definite vegetation, myocardial abscess, new partial dehiscence of a prosthetic valve, or new valvular regurgitation (increase or change in murmur is not sufficient). Minor criteria include the presence of a predisposing condition; fever of 38°C or higher; vascular phenomena, such as cutaneous hemorrhages, aneurysm, systemic emboli, or pulmonary infarction; immunologic phenomena, such as glomerulonephritis, Osler nodes, Roth spots, or rheumatoid factor; and positive blood cultures not meeting the major criteria or serologic evidence of an active infection. A definite diagnosis can be made with 80% accuracy if two major criteria, one major criterion and three minor criteria, or five minor criteria are fulfilled. A possible diagnosis of endocarditis is made if one major and one minor criterion or three minor criteria are met. If fewer criteria are found, or a sound alternative explanation for illness is identified, or the patient’s febrile illness has resolved within 4 days, endocarditis is unlikely.

**Complications**

The course of infective endocarditis is determined by the degree of damage to the heart, by the site of infection (right-sided versus left-sided, aortic versus mitral valve), by the presence of metastatic foci of infection, by the occurrence of embolization, and by immunologically mediated processes. Destruction of infected heart valves is especially common and precipitous with *S. aureus*, but can occur with any organism and can progress even after bacteriologic cure. The infection can also extend into the myocardium, resulting in abscesses leading to conduction disturbances, and involving the wall of the aorta, creating sinus of Valsalva aneurysms.

Peripheral embolization to the brain and myocardium may result in infarctions. Embolization to the spleen and kidneys is also common. Peripheral emboli may initiate metastatic infections or may become established in vessel walls, leading to mycotic aneurysms. Right-sided endocarditis, which usually involves the tricuspid valve, causes septic pulmonary emboli, occasionally with infarction and lung abscesses.

**Prevention**

The American Heart Association recommends antibiotic prophylaxis for infective endocarditis in a relatively small group of patients with predisposing congenital or valvular anomalies (Table 33–3) undergoing select dental procedures, operations involving the respiratory tract, or operations of infected skin, skin structure, or musculoskeletal

4 Prophylaxis is recommended because endothelialization of prosthetic material occurs within 6 months after procedure.
tissue (Table 33–4). Current antimicrobial recommendations are given in Table 33–5.

## Treatment

Empiric regimens for endocarditis while culture results are pending should include agents active against staphylococci, streptococci, and enterococci. Vancomycin 1 g every 12 hours intravenously plus ceftriaxone 2 g every 24 hours provides appropriate coverage pending definitive diagnosis; consultation with an infectious disease expert is strongly recommended when initiating treatment.

### A. Viridans Streptococci

For penicillin-susceptible viridans streptococcal endocarditis (ie, MIC 0.1 mcg/mL or less), penicillin G, 18 million units intravenously either continuously or in four to six equally divided doses, or ceftriaxone, 2 g intravenously once daily for 4 weeks, is recommended. The duration of therapy can be shortened to 2 weeks if gentamicin, 3 mg/kg intravenously every 24 hours, is used with penicillin or ceftriaxone. The 2-week regimen is reasonable and can be considered in patients with uncomplicated endocarditis, rapid response to therapy, and no underlying kidney disease. For the patient unable to tolerate penicillin or ceftriaxone, vancomycin, 15 mg/kg intravenously every 12 hours for 4 weeks, is given with a desired trough level of 10–15 mcg/mL. Prosthetic valve endocarditis is treated with a 6-week course of penicillin or ceftriaxone and the clinician can consider adding 2 weeks of gentamicin at the start of therapy.

Viridans streptococci relatively resistant to penicillin (ie, MIC greater than 0.12 mcg/mL but less than or equal to 0.5 mcg/mL) should be treated for 4 weeks. Penicillin G, 24 million units intravenously either continuously or in four to six equally divided doses, is combined with gentamicin, 3 mg/kg intravenously every 24 hours for the first 2 weeks. Ceftriaxone may be a reasonable alternative treatment option for isolates that are susceptible to ceftriaxone. In the patient with IgE-mediated allergy to penicillin, vancomycin alone, 15 mg/kg intravenously every 12 hours for 4 weeks, should be administered. Prosthetic valve endocarditis

2For patients undergoing respiratory tract procedures involving incision of respiratory tract mucosa to treat an established infection or a procedure on infected skin, skin structure, or musculoskeletal tissue known or suspected to be caused by S aureus, the regimen should contain an anti-staphylococcal penicillin or cephalosporin. Vancomycin can be used to treat patients unable to tolerate a beta-lactam or if the infection is known or suspected to be caused by a methicillin-resistant strain of S aureus.
3See Table 33–3 for list of cardiac conditions.
is treated with a 6-week course of penicillin or ceftriaxone plus gentamicin as above.

Endocarditis caused by viridans streptococci with an MIC greater than 0.5 mcg/mL or by nutritionally deficient streptococci should be treated the same as enterococcal endocarditis.

B. Other Streptococci

Endocarditis caused by *S pneumoniae*, *S pyogenes* (group A streptococcus), or groups B, C, and G streptococci is unusual. *S pneumoniae* sensitive to penicillin (MIC less than 0.1 mcg/mL) can be treated with penicillin 18 million units intravenously either continuously or in four to six equally divided doses or cefazolin 6 g intravenously either continuously or in three equally divided doses, or ceftriaxone 2 g daily intravenously for 4 weeks. High-dose penicillin (24 million units) or a third-generation cephalosporin may be required for the treatment of endocarditis (without meningitis) caused by strains resistant to penicillin (MIC greater than 0.1 mcg/mL). The addition of vancomycin and rifampin to ceftriaxone may be considered in patients with *S pneumoniae* strains with cefotaxime MIC greater than 2 mcg/mL. Group A streptococcal infection can be treated with penicillin or ceftriaxone for 4–6 weeks. Groups B, C, and G streptococci tend to be more resistant to penicillin than group A streptococci, and some experts have recommended adding gentamicin, 3 mg/kg intravenously every 24 hours, to penicillin for the first 2 weeks of a 4- to 6-week course. Endocarditis caused by *S gallolyticus* (bovis) is associated with liver disease, especially cirrhosis, and gastrointestinal abnormalities, especially colon cancer. Colonoscopy should be performed to exclude the latter.

C. Enterococci

For enterococcal endocarditis, penicillin or ampicillin alone is inadequate. One recommended regimen is ampicillin, 2 g intravenously every 4 hours, or penicillin G, 18–30 million units intravenously continuously or in six equally divided doses plus gentamicin, 1 mg/kg intravenously every 8 hours. The second recommended regimen is ampicillin (2 g intravenously every 4 hours) plus ceftriaxone 2 g intravenously every 12 hours. The recommended duration of therapy is 4–6 weeks (the longer duration for patients with symptoms for more than 3 months, relapse, or prosthetic valve endocarditis). The combination of ampicillin plus ceftriaxone is recommended for patients with creatinine clearance less than 50 mL/min or whose enterococcal isolates are resistant to gentamicin. In patients intolerant of penicillin and ampicillin or who have enterococcal isolate resistant to these agents, vancomycin plus gentamicin can be used.

Endocarditis caused by strains resistant to penicillin and vancomycin are difficult to treat and should always be managed in consultation with an infectious diseases specialist.

D. Staphylococci

For methicillin-susceptible *S aureus* isolates, nafcillin or oxacillin, 12 g intravenously daily given continuously or in four to six divided doses or cefazolin, 6 g intravenously daily given continuously or in three divided doses for 6 weeks, is the preferred therapy. In cases of brain abscess resulting from methicillin-resistant *S aureus* endocarditis, nafcillin should be used instead of cefazolin. For patients with history of immediate type hypersensitivity to beta-lactams, a desensitization protocol should be undertaken. For patients with a history of nonanaphylactoid reactions to penicillins, cefazolin should be used. Patients who are infected with methicillin-resistant *S aureus* or who are unable to tolerate beta-lactam therapy should receive vancomycin, 30 mg/kg/day intravenously divided in two or three doses, to achieve a goal trough level of 15–20 mcg/kg, or daptomycin intravenously at greater than or equal to 8 mg/kg/day. Aminoglycoside combination regimens are not recommended. The effect of rifampin with antistaphylococcal drugs is variable, and its routine use is not recommended. Because coagulase-negative staphylococci—a common cause of prosthetic valve endocarditis—are routinely resistant to methicillin, beta-lactam antibiotics should not be used for this infection unless the isolate is demonstrated to be susceptible. A combination of vancomycin, 30 mg/kg/day intravenously divided in two or three doses for 6 weeks; rifampin, 300 mg every 8 hours for 6 weeks; and gentamicin, 3 mg/kg intravenously every 8 hours for the first 2 weeks, is recommended for prosthetic valve infection. If the organism is sensitive to methicillin, either nafcillin or oxacillin or cefazolin can be used in combination with rifampin and gentamicin. Combination therapy with nafcillin or oxacillin (vancomycin or daptomycin for methicillin-resistant strains), rifampin, and gentamicin is also recommended for treatment of *S aureus* prosthetic valve infection.

E. HACEK Organisms

HACEK organisms are slow-growing, fastidious gram-negative coccobaillci or bacilli (*H arophilus* [now *A phrophilus*], *A actinomyctecomitans*, *C hominis*, *E corrodens*, and *Kingella* species) that are normal oral flora and cause less than 5% of all cases of endocarditis. They may produce beta-lactamase, and thus the treatment of choice is ceftriaxone (or another third-generation cephalosporin), 2 g intravenously once daily for 4 weeks. Prosthetic valve endocarditis should be treated for 6 weeks. In the penicillin-allergic patient, experience is limited, but fluoroquinolones have in vitro activity and should be considered.

F. Culture-Negative Endocarditis

Failure to culture microorganisms from patients with suspected infective endocarditis may be due to infection from organisms not recovered in routine microbiology testing or previous administration of antimicrobial agents before blood cultures were obtained. These cases must be managed with the assistance of an infectious disease specialist. Pathogens that are not able to be cultured by commonly used techniques include *Bartonella* species, *Chlamydia* species, *Brucella* species, and *Tropheryma whipplei*. Serologic testing should be performed in patients who have epidemiologic risk factors for these infections. Treatment should...
be directed at likely pathogens while awaiting serologic results; treatment of patients given prior antimicrobials before cultures were obtained must also consider likely pathogens.

G. Role of Surgery

While many cases can be successfully treated medically, operative management is frequently required. Acute heart failure unresponsive to medical therapy is an indication for valve replacement even if active infection is present. Infections unresponsive to appropriate antimicrobial therapy after 7–10 days (ie, persistent fevers, positive blood cultures despite therapy) are more likely to be eradicated if the valve is replaced. Surgery is nearly always required for cure of fungal endocarditis and is more often necessary with highly resistant bacteria. It is also indicated when the infection involves the sinuses of Valsalva or produces septal abscesses. Recurrent infection with the same organism prompts an operative approach, especially with infected prosthetic valves. Continuing embolization presents a difficult problem when the infection is otherwise responding: surgery may be the proper approach. Particularly challenging is a large and fragile vegetation demonstrated by echocardiography in the absence of embolization. Most clinicians favor an operative approach with vegetectomy and valve repair if the patient is a good candidate. Operation without delay may be considered in patients with endocarditis and an ischemic stroke who have an indication for surgery. If not urgent or if intracranial hemorrhage is present, a delay of at least 4 weeks should be considered. Embolization after bacteriologic cure does not necessarily imply recurrence of endocarditis.

H. Role of Anticoagulation

Anticoagulation is contraindicated in native valve endocarditis because of an increased risk of intracerebral hemorrhage from mycotic aneurysms or embolic phenomena. The role of anticoagulant therapy during prosthetic valve endocarditis is more controversial. Reversal of anticoagulation may result in thrombosis of the mechanical prosthesis, particularly in the mitral position. Conversely, anticoagulation during active prosthetic valve endocarditis caused by *S aureus* has been associated with fatal intracerebral hemorrhage. One approach is to discontinue anticoagulation during the septic phase of *S aureus* prosthetic valve endocarditis. In patients with *S aureus* prosthetic valve endocarditis complicated by a CNS embolic event, anticoagulation should be discontinued for the first 2 weeks of therapy. Indications for anticoagulation following prosthetic valve implantation for endocarditis are the same as for patients with prosthetic valves without endocarditis (eg, nonporcine mechanical valves and valves in the mitral position).

Response to Therapy

If infection is caused by viridans streptococci, enterococci, or coagulase-negative staphylococci, defervescence occurs in 3–4 days on average, with *S aureus* or *Pseudomonas aeruginosa*, fever may persist for longer. Blood cultures should be obtained every 1–2 days to document sterilization. Other causes of persistent fever are myocardial or metastatic abscess, sterile embolization, superimposed hospital-acquired infection, and drug reaction. Most relapses occur within 1–2 months after completion of therapy. Obtaining one or two blood cultures during this period is prudent.

When to Refer

- Consider consulting an infectious diseases specialist in all cases of suspected infective endocarditis.
- Consult a cardiac surgeon in the situations mentioned in the Role of Surgery section above to prevent further embolic disease, heart failure, and other complications including death.

When to Admit

Patients with infective endocarditis should be hospitalized for expedited evaluation and treatment.

## INFECTIONS CAUSED BY GRAM-NEGATIVE BACTERIA

### BORDETELLA PERTUSSIS INFECTION

(Whooping Cough)

#### ESSENTIALS OF DIAGNOSIS

- Predominantly in infants under age 2 years; adolescents and adults are reservoirs of infection.
- Two-week prodromal catarrhal stage of malaise, cough, coryza, and anorexia.
- Paroxysmal cough ending in a high-pitched inspiratory “whoop.”
- Absolute lymphocytosis, often striking; culture confirms diagnosis.

#### General Considerations

Pertussis is an acute infection of the respiratory tract caused by *B pertussis* that is transmitted by respiratory...
droplets. The incubation period is 7–17 days. Half of all cases occur before age 2 years. Neither immunization nor disease confers lasting immunity to pertussis. Consequently, adults are an important reservoir of the disease.

**Clinical Findings**

The symptoms of classic pertussis last about 6 weeks and are divided into three consecutive stages. The catarrhal stage is characterized by its insidious onset, with lacrimation, sneezing, and coryza, anorexia and malaise, and a hacking night cough that becomes diurnal. The paroxysmal stage is characterized by bursts of rapid, consecutive coughs followed by a deep, high-pitched inspiration (whoop). The convalescent stage begins 4 weeks after onset of the illness with a decrease in the frequency and severity of paroxysms of cough. The diagnosis often is not considered in adults, who may not have a typical presentation. Cough persisting more than 2 weeks is suggestive. Infection may also be asymptomatic.

The white blood cell count is usually 15,000–20,000/mcL (rarely, as high as 50,000/mcL or more), 60–80% of which are lymphocytes. The diagnosis is established by isolating the organism from nasopharyngeal culture. A special medium (eg, Bordet-Gengou agar) must be requested. Polymerase chain reaction assays for diagnosis of pertussis may be available in some clinical or health department laboratories.

**Prevention**

Acellular pertussis vaccine is recommended for all infants, combined with diphtheria and tetanus toxoids (DTP). Infants and susceptible adults with significant exposure should receive prophylaxis with an oral macrolide. In recognition of their importance as a reservoir of disease, vaccination of adolescents and adults against pertussis is recommended (see Table 30–7 and www.cdc.gov/vaccines/schedules). Adolescents aged 11–18 years (preferably between 11 and 12 years of age) who have completed the DTP or DTPa vaccination series should receive a single dose of either Td or Tdap product instead of Td (tetanus and diphtheria toxoids vaccine) for booster immunization against tetanus, diphtheria, and pertussis. Adults of all ages (including those older than age 64 years) should receive a single dose of Tdap. In addition, pregnant women should receive a dose of Tdap during each pregnancy regardless of prior vaccination history, ideally between 27 and 36 weeks of gestation, in order to maximize the antibody response of the woman and the passive antibody transfer to the infant. For any woman who was not previously vaccinated with Tdap and for whom the vaccine was not given during her pregnancy, Tdap should be administered immediately postpartum. The CDC has eliminated the recommendation that a 2-year period window is needed between receiving the Td and Tdap vaccines based on data showing that there is not an increased risk of adverse events.

**Treatment**

Antibiotic treatment should be initiated in all suspected cases. Treatment options include erythromycin, 500 mg four times a day orally for 7 days; azithromycin, 500 mg orally on day 1 and 250 mg for 4 more days; or clarithromycin, 500 mg orally twice daily for 7 days. Trimethoprim-sulfamethoxazole, 160 mg–800 mg orally twice a day for 7 days, also is effective. Treatment shortens the duration of carriage and may diminish the severity of coughing paroxysms. These same regimens are indicated for prophylaxis of contacts to an active case of pertussis that are exposed within 3 weeks of the onset of cough in the index case.

**BACTERIAL & CHLAMYDIAL INFECTIONS**

**OLDER BORDETELLA INFECTIONS**

*Bordetella bronchiseptica* is a pleomorphic gram-negative coccobacillus causing kennel cough in dogs. On occasion it causes upper and lower respiratory infection in humans, principally HIV-infected patients. Infection has been associated with contact with dogs and cats, suggesting animal-to-human transmission. Treatment of *B bronchiseptica* infection is guided by results of in vitro susceptibility tests.

**MENINGOCOCCAL MENINGITIS**

**ESSENTIALS OF DIAGNOSIS**

- Fever, headache, vomiting, delirium, convulsions.
- Petechial rash of skin and mucous membranes in many.
- Neck and back stiffness and positive Kernig and Brudzinski signs are characteristic.
- Purulent spinal fluid with gram-negative intracellular and extracellular diplococci.
- Culture of cerebrospinal fluid, blood, or petechial aspiration confirms the diagnosis.

**General Considerations**

Meningococcal meningitis is caused by *Neisseria meningitidis* of groups A, B, C, Y, and W-135, among others. Meningitis due to serogroup A is uncommon in the United States. Serogroup B generally causes sporadic cases. Serogroup C meningococcus is the most common cause of epidemic disease in the United States. Up to 40% of persons are nasopharyngeal carriers of meningococci, but disease develops in relatively few of these persons. Infection is transmitted by droplets. The clinical illness may take the form of meningococcemia (a fulminating form of sepsisemia without meningitis), meningococcemia with meningitis, or meningitis. Recurrent meningococcemia with
fever, rash, and arthritis is seen rarely in patients with certain terminal complement deficiencies. Asplenic patients are also at risk.

**Clinical Findings**

**A. Symptoms and Signs**

High fever, chills, nausea, vomiting, and headache as well as back, abdominal, and extremity pains are typical. Rapidly developing confusion, delirium, seizures, and coma occur in some. On examination, nuchal and back rigidity are typical. Positive Kernig and Brudzinski signs (Kernig sign is pain in the hamstrings upon extension of the knee with the hip at 90-degree flexion; Brudzinski sign is flexion of the knee in response to flexion of the neck) are specific but not sensitive findings. A petechial rash appearing in the lower extremities and at pressure points is found in most cases. Petechiae may vary in size from pinpoint lesions to large ecchymoses or even skin gangrene that may later slough.

**B. Laboratory Findings**

Lumbar puncture typically reveals a cloudy or purulent cerebrospinal fluid, with elevated pressure, increased protein, and decreased glucose content. The fluid usually contains greater than 1000 cells/mcL, with polymorphonuclear cells predominating and containing gram-negative intracellular diplococci. The absence of organisms in a Gram-stained smear of the cerebrospinal fluid sediment does not rule out the diagnosis. The capsular polysaccharide can be demonstrated in cerebrospinal fluid or urine by latex agglutination; this is useful in partially treated patients, though sensitivity is 60–80%. The organism is usually demonstrated by smear and culture of the cerebrospinal fluid, oropharynx, blood, or aspirated petechiae.

Disseminated intravascular coagulation is an important complication of meningococcal infection and is typically present in toxic patients with ecchyemotic skin lesions.

**Differential Diagnosis**

Meningococcal meningitis must be differentiated from other meningitides. In small infants and in older adults, fever or stiff neck is often missing, and altered mental status may dominate the picture.

Rickettsial, echovirus, and, rarely, other bacterial infections (eg, staphylococcal infections, scarlet fever) also cause petechial rash.

**Prevention**

Four meningococcal vaccines are available. There are two vaccines with coverage against meningococcal serogroups A, C, Y, and W-135 and two with coverage against meningococcal serogroup B. The two vaccines effective for meningococcal serogroups A, C, Y, and W-135 are the meningococcal polysaccharide vaccine (MPSV4) indicated for vaccination of persons over age 55 and the conjugate meningococcal polysaccharide vaccine (MCV4) indicated for persons aged 2–55 years. The two vaccines against meningococcal serogroup B are MenB-FHbp and MenB-4C are approved for persons aged 10–25 years and are not interchangeable.

The Advisory Committee on Immunization Practices recommends immunization with a dose of MCV4 for preadolescents aged 11–12 with a booster at age 16 (see www.cdc.gov/vaccines/schedules/hcp/child-adolescent.html). For ease of program implementation, persons aged 21 years or younger should have documentation of receipt of a dose of MCV4 not more than 5 years before enrollment to college. If the primary dose was administered before the sixteenth birthday, a booster dose should be administered before enrollment. Vaccine is also recommended as a two-dose primary series administered 2 months apart for persons aged 2 through 54 years with persistent complement deficiency, persons with functional or anatomic asplenia, and for adolescents with HIV infection. All other persons at increased risk for meningococcal disease (eg, military recruits, microbiologists, or travelers to an epidemic or highly endemic country) should receive a single dose. One of the meningococcal serogroup B vaccines may be administered to persons 10 years of age or older who are at increased risk for meningococcal disease. These persons include those with persistent complement component deficiencies; persons with anatomic or functional asplenia; microbiologists routinely exposed to isolates of *Neisseria meningitidis*; and persons identified to be at increased risk because of a serogroup B meningococcal disease outbreak. Vaccination of persons aged 16–23 years may provide short-term protection against most strains of serogroup B meningococcal disease.

Eliminating nasopharyngeal carriage of meningococci is an effective prevention strategy in closed populations and to prevent secondary cases in household or otherwise close contacts. Rifampin, 600 mg orally twice a day for 2 days, ciprofloxacin, 500 mg orally once, or one intramuscular 250-mg dose of ceftriaxone is effective. Cases of fluoroquinolone-resistant meningococcal infections have been identified in the United States. However, ciprofloxacin remains a recommended empiric agent for eradication of nasopharyngeal carriage. School and work contacts ordinarily need not be treated. Hospital contacts receive therapy only if intense exposure has occurred (eg, mouth-to-mouth resuscitation). Accidentally discovered carriers without known close contact with meningococcal disease do not require prophylactic antimicrobials.

**Treatment**

Blood cultures must be obtained and intravenous antimicrobial therapy started immediately. This may be done prior to lumbar puncture in patients in whom the diagnosis is not straightforward and for those in whom MR or CT imaging is indicated to exclude mass lesions. Aqueous penicillin G is the antibiotic of choice (24 million units/24 h intravenously in divided doses every 4 hours). The prevalence of strains of *N meningitidis* with intermediate resistance to penicillin in vitro (MICs 0.1 to 1 mcg/mL) is increasing, particularly in Europe. At what level of resistance penicillin treatment failure can occur is not known. Penicillin-intermediate strains thus far remain fully susceptible to ceftriaxone and other third-generation cephalosporins used to treat meningitis, and these should be effective alternatives to penicillin. In penicillin-allergic
When to Admit

All patients with suspected meningococcal infection including meningitis and meningococcemia should be admitted for evaluation and empiric intravenous antibiotic therapy.

INFECTIONS CAUSED BY *HAEMOPHILUS* SPECIES

*H influenzae* and other *Haemophilus* species may cause sinusitis, otitis, bronchitis, epiglottitis, pneumonia, cellulitis, arthritis, meningitis, and endocarditis. Nontypeable strains are responsible for most disease in adults. Alcoholism, smoking, chronic lung disease, advanced age, and HIV infection are risk factors. *Haemophilus* species colonize the upper respiratory tract in patients with chronic obstructive pulmonary disease and frequently cause purulent bronchitis.

Beta-lactamase–producing strains are less common in adults than in children. For adults with sinusitis, otitis, or respiratory tract infection, oral amoxicillin, 750 mg twice daily for 10–14 days, is adequate. For beta-lactamase–producing strains, use of the oral fixed-drug combination of amoxicillin, 875 mg, with clavulanate, 125 mg, is indicated. For the penicillin-allergic patient, oral cefuroxime axetil, 250 mg twice daily; or a fluoroquinolone (ciprofloxacin, 500 mg orally twice daily; levofloxacin, 500–750 mg orally once daily; or moxifloxacin, 400 mg orally once daily) for 7 days is effective. Azithromycin, 500 mg orally once followed by 250 mg daily for 4 days, is preferred over clarithromycin when a macrolide is the preferred agent. Trimethoprim-sulfamethoxazole (160/800 mg orally twice daily) can be considered, but resistance rates have been reported to be up to 25%.

In the more seriously ill patient (eg, the toxic patient with multilobar pneumonia), ceftriaxone, 1 g/day intravenously, is recommended pending determination of whether the infecting strain is a beta-lactamase producer. A fluoroquinolone (see above for dosages) can be used for the penicillin-allergic patients for a 10- to 14-day course of therapy.

Epiglottitis is characterized by an abrupt onset of high fever, drooling, and inability to handle secretions. An important clue to the diagnosis is complaint of a severe sore throat despite an unimpressive examination of the pharynx. Stridor and respiratory distress result from laryngeal obstruction. The diagnosis is best made by direct visualization of the cherry-red, swollen epiglottis at laryngoscopy. Because laryngoscopy may provoke laryngospasm and obstruction, especially in children, it should be performed in an intensive care unit or similar setting, and only at a time when intubation can be performed promptly. Ceftriaxone, 1 g intravenously every 24 hours for 7–10 days, is the drug of choice. Trimethoprim-sulfamethoxazole or a fluoroquinolone (see above for dosage) may be used in the patient with serious penicillin allergy.

Meningitis, rare in adults, is a consideration in the patient who has meningitis associated with sinusitis or otitis. Initial therapy for suspected *H influenzae* meningitis should be with ceftriaxone, 4 g/day in two divided doses, until the strain is proved not to produce beta-lactamase. Meningitis is treated for at least 7 days. Dexamethasone, 0.15 mg/kg intravenously every 6 hours, may reduce the incidence of long-term sequelae, principally hearing loss.

INFECTIONS CAUSED BY *MORAXELLA CATARRHALIS*

*M. catarrhalis* is a gram-negative aerobic coccus morphologically and biochemically similar to *Neisseria*. It causes sinusitis, bronchitis, and pneumonia. Bacteremia and meningitis have also been reported in immunocompromised patients. The organism frequently colonizes the respiratory tract, making differentiation of colonization from infection difficult. If *M catarrhalis* is the predominant isolate, therapy is directed against it. *M catarrhalis* typically produces beta-lactamase and therefore is usually resistant to amoxicillin and amoxicillin-clavulanate. It is susceptible to amoxicillin-clavulanate, ampicillin-sulbactam, trimethoprim-sulfamethoxazole, ciprofloxacin, and second- and third-generation cephalosporins.

LEGIONNAIRES DISEASE

- Patients are often immunocompromised, smokers, or have chronic lung disease.
- Scant sputum production, pleuritic chest pain, toxic appearance.
- Chest radiograph: focal patchy infiltrates or consolidation.
- Gram stain of sputum: polymorphonuclear leukocytes and no organisms.
General Considerations

Legionella infection ranks among the three or four most common causes of community-acquired pneumonia and is considered whenever the etiology of a pneumonia is in question. Legionnaires disease is more common in immunocompromised persons, in smokers, and in those with chronic lung disease. Outbreaks have been associated with contaminated water sources, such as showerheads and faucets in patient rooms and air conditioning cooling towers.

Clinical Findings

A. Symptoms and Signs

Legionnaires disease is one of the atypical pneumonias, so called because a Gram-stained smear of sputum does not show organisms. However, many features of Legionnaires disease are more like typical pneumonia, with high fevers, toxic appearance, pleurisy, and grossly purulent sputum. Nausea, vomiting, and diarrhea may be prominent. There may be relative bradycardia. Classically, this pneumonia is caused by Legionella pneumophila, though other species can cause identical disease.

B. Laboratory Findings

There may be hyponatremia, hypophosphatemia, elevated liver enzymes, and elevated creatine kinase. Culture of Legionella species has a 80–90% sensitivity. Dieterle silver staining of tissue, pleural fluid, or other infected material is also a reliable method for detecting Legionella species. Direct fluorescent antibody stains and serologic testing of tissue, pleural fluid, or other infected material is also a reliable method for detecting Legionella species. Direct fluorescent antibody stains and serologic testing such as urinary antigen are less sensitive because these will detect only L pneumophila serotype 1. In addition, making a serologic diagnosis requires that the host respond with sufficient specific antibody production.

Treatment

Azithromycin (500 mg orally once daily), clarithromycin (500 mg orally twice daily), or a fluoroquinolone (eg, levofloxacin, 750 mg orally once daily), and not erythromycin, are the drugs of choice for treatment of legionellosis because of their excellent intracellular penetration and in vitro activity, as well as desirable pharmacokinetic properties that permit oral administration and once or twice daily dosing. Duration of therapy is 10–14 days, although a 21-day course of therapy is recommended for immunocompromised patients.

Clinical Findings

A. Symptoms and Signs

Most patients have fevers and chills, often with abrupt onset. However, 15% of patients are hypothermic (temperature 36.4°C or less) at presentation, and 5% never develop a temperature above 37.5°C. Hyperventilation with respiratory alkalosis and changes in mental status are important early manifestations. Hypotension and shock, which occur in 20–50% of patients, are unfavorable prognostic signs.

B. Laboratory Findings

Neutropenia or neutrophilia, often with increased numbers of immature forms of polymorphonuclear leukocytes, is the most common laboratory abnormality in septic patients. Thrombocytopenia occurs in 50% of patients, laboratory evidence of coagulation abnormalities in 10%, and overt disseminated intravascular coagulation in 2–3%. Both clinical manifestations and the laboratory abnormalities are nonspecific and insensitive, which accounts for the relatively low rate of blood culture positivity (approximately 20–40%). If possible, three blood cultures from separate sites should be obtained in rapid succession before starting antimicrobial therapy. The chance of recovering the organism in at least one of the three blood cultures is greater than 95%. The false-negative rate for a single culture of 5–10 mL of blood is 30%. This may be reduced to 5–10% (albeit with a slight false-positive rate due to isolation of contaminants) if a single volume of 30 mL is inoculated into several blood culture bottles. Because blood cultures may be falsely negative, when a patient with presumed septic shock, negative blood cultures, and inadequate explanation for the clinical course responds to antimicrobial agents, therapy should be continued for 10–14 days.

Treatment

Several factors are important in the management of patients with sepsis.

A. Removal of Predisposing Factors

This usually means decreasing or stopping immunosuppressive medications and, in certain circumstances, giving granulocyte colony-stimulating factor (filgrastim; G-CSF) to the neutropenic patient.

B. Identifying the Source of Bacteremia

By simply finding the source of bacteremia and removing it (central venous catheter) or draining it (abscess), a fatal disease becomes easily treatable.
C. Supportive Measures

The use of fluids, vasopressors, and corticosteroids in septic shock are discussed in Chapter 14; management of disseminated intravascular coagulation is discussed in Chapter 13.

D. Antibiotics

Antibiotics should be given as soon as the diagnosis is suspected, since delays in therapy have been associated with increased mortality rates, particularly once hypotension develops. In general, bacitracidial antibiotics should be used and given intravenously to ensure therapeutic serum levels. Penetration of antibiotics into the site of primary infection is critical for successful therapy—ie, if the infection originates in the CNS, antibiotics that penetrate the blood-brain barrier should be used—eg, third- or fourth-generation cephalosporins—but not first-generation cephalosporins or aminoglycosides, which penetrate poorly. Sepsis caused by gram-positive organisms cannot be differentiated on clinical grounds from the due to gram-negative bacteria. Therefore, initial therapy should include antibiotics active against both types of organisms.

The number of antibiotics necessary remains controversial and depends on the cause. Table 30–4 provides a guide for empiric therapy. Although a combination of antibiotics is often recommended for “synergism,” combination therapy has not been shown to be superior to a single-drug regimen with any of several broad-spectrum antibiotics (eg, a third-generation cephalosporin, piperacillin-tazobactam, carbapenem). If multiple drugs are used initially, the regimen should be modified and coverage narrowed based on the results of culture and sensitivity testing.

ESSENTIALS OF DIAGNOSIS

1. Enteric Fever (Typhoid Fever)

★ Gradual onset of malaise, headache, nausea, vomiting, abdominal pain.
★ Rose spots, relative bradycardia, splenomegaly, and abdominal distention and tenderness.
★ Slow (stepladder) rise of fever to maximum and then slow return to normal.
★ Leukopenia; blood, stool, and urine cultures positive for Salmonella.

General Considerations

Enteric fever is a clinical syndrome characterized by gastrointestinal symptoms as well as constitutional symptoms such as fever, malaise, and headache. It may have a long incubation period (6–30 days), and the gastrointestinal symptoms may resolve but then recur. Progressive infection often evolves with delirium. Enteric fever can be caused by any Salmonella species, including S typhi (typhoid fever) and non-typhoidal strains, especially S paratyphi subtype A in the United States. Infection begins when organisms breach the mucosal epithelium of the intestines. Having crossed the epithelial barrier, organisms invade and replicate in macrophages in Peyer patches, mesenteric lymph nodes, and the spleen. Serotypes other than typhi usually do not cause invasive disease, presumably because they lack the necessary human-specific virulence factors. Bacteremia occurs, and the infection then localizes principally in the lymphoid tissue of the small intestine. Peyer patches become inflamed and may ulcerate, with involvement greatest during the third week of disease. The organism may disseminate to the lungs, gallbladder, kidneys, or CNS.

Clinical Findings

A. Symptoms and Signs

During the prodromal stage, there is increasing malaise, headache, cough, and sore throat, often with abdominal pain and constipation, while the fever ascends in a stepwise fashion. After about 7–10 days, it reaches a plateau and the patient is much more ill. There may be marked constipation, especially early, or ‘pea soup’ diarrhea; marked abdominal distention occurs as well. If there are no complications, the patient’s condition will gradually improve over the third week of disease. The organism may disseminate to the lungs, gallbladder, kidneys, or CNS.

During the early prodrome, physical findings are few. Later, splenomegaly, abdominal distention and tenderness, relative bradycardia, and occasionally meningismus appear. The rash (rose spots) commonly appears during the second week of disease. The individual spot, found principally on the trunk, is a pink papule 2–3 mm in diameter that fades on pressure. It disappears in 3–4 days.

SALMONELLOSIS

Salmonellosis includes infection by any of approximately 2000 serotypes of salmonellae. All Salmonella serotypes are members of a single species, Salmonella enterica. Human infections are caused almost exclusively by S enterica subsp enterica, of which three serotypes—typhi, typhimurium, and choleraesuis—are predominantly isolated. Three clinical patterns of infection are recognized: (1) enteric fever, the best example of which is typhoid fever, due to serotype typhi; (2) acute enterocolitis, caused by serotype typhimurium, among others; and (3) the “septicemic” type, characterized by bacteremia and focal lesions, exemplified by infection with serotype choleraesuis. All types are transmitted by ingestion of the organism, usually from tainted food or drink.
B. Laboratory Findings

Leukopenia is typical. Typhoid fever is best diagnosed by blood culture, which is positive in the first week of illness in 80% of patients who have not taken antimicrobials. The rate of positivity declines thereafter, but one-fourth or more of patients still have positive blood cultures in the third week. Cultures of bone marrow occasionally are positive when blood cultures are not. Stool culture is unreliable because it may be positive in gastroenteritis without typhoid fever.

Differential Diagnosis

Enteric fever must be distinguished from other gastrointestinal illnesses and from other infections that have few localizing findings. Examples include tuberculosis, infective endocarditis, brucellosis, lymphoma, and Q fever. Often there is a history of recent travel to endemic areas, and viral hepatitis, malaria, or amebiasis may be in the differential.

Complications

Complications occur in about 30% of untreated cases and account for 75% of deaths. Intestinal hemorrhage, manifested by a sudden drop in temperature and signs of shock followed by dark or fresh blood in the stool, or intestinal perforation, accompanied by abdominal pain and tenderness, is most likely to occur during the third week. Appearance of leukocytosis and tachycardia should suggest these complications. Urinary retention, pneumonia, thrombophlebitis, myocarditis, psychosis, cholecystitis, nephritis, osteomyelitis, and meningitis are less often observed.

Prevention

Immunization is not always effective, but should be considered for household contacts of a typhoid carrier, for travelers to endemic areas, and during epidemic outbreaks. A multiple-dose oral vaccine and a single-dose parental vaccine are available. Their efficacies are similar, but oral vaccine causes fewer side effects. Boosters, when indicated, should be given every 5 years and 2 years for oral and parenteral preparations, respectively.

Adequate waste disposal and protection of food and water supplies from contamination are important public health measures to prevent salmonellosis. Carriers cannot work as food handlers.

Treatment

A. Specific Measures

Because of increasing antimicrobial resistance, fluoroquinolones—such as ciprofloxacin 750 mg orally twice daily or levofloxacin 500 mg orally once daily, 5–7 days for uncomplicated enteric fever and 10–14 days for severe infection—are the agents of choice for treatment of salmonella infections. Ceftriaxone, 2 g intravenously for 7 days, is also effective. Although resistance to fluoroquinolones or cephalosporins occurs uncommonly, the prevalence is increasing. When an infection is caused by a multidrug-resistant strain, select an antibiotic to which the isolate is susceptible in vitro. Alternatively, increasing the dose of ceftriaxone to 4 g/day and treating for 10–14 days or using azithromycin 500 mg orally for 7 days in uncomplicated cases may be effective. In years past, ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole had been effective treatments but resistance has spread globally.

B. Treatment of Carriers

Ciprofloxacin, 750 mg orally twice a day for 4 weeks, has proved to be highly effective in eradicating the carrier state. Cholecystectomy may also achieve this goal. When the isolate is susceptible, treatment of carriage with ampicillin, trimethoprim-sulfamethoxazole, or chloramphenicol may be successful.

Prognosis

The mortality rate of typhoid fever is about 2% in treated cases. Elderly or debilitated persons are likely to do worse. With complications, the prognosis is poor. Relapses occur in up to 15% of cases. A residual carrier state frequently persists in spite of therapy.

2. Salmonella Gastroenteritis

By far the most common form of salmonellosis is acute enterocolitis, which can be caused by both typhoidal and non-typhoidal Salmonella. The incubation period is 8–48 hours after ingestion of contaminated food or liquid.

Symptoms and signs consist of fever (often with chills), nausea and vomiting, cramping abdominal pain, and diarrhea, which may be grossly bloody, lasting 3–5 days. Differentiation must be made from viral gastroenteritis, food poisoning, shigellosis, amebic dysentery, and acute ulcerative colitis. The diagnosis is made by culturing the organism from the stool. The disease is usually self-limited, but bacteremia with localization in joints or bones may occur, especially in patients with sickle cell disease.

In most cases, treatment of uncomplicated enterocolitis is symptomatic only. However, patients who are malnourished or severely ill, patients with sickle cell disease, and patients who are immunocompromised (including those who are HIV-positive) should be treated with ciprofloxacin, 500 mg orally twice a day; ceftriaxone, 1 g intravenously once daily; trimethoprim-sulfamethoxazole, 160 mg/80 mg orally twice a day; or azithromycin, 500 mg orally once daily for 7–14 days (14 days for immunocompromised patients).

Crampy abdominal pain and systemic toxicity.

**Treatment**

Clinical Findings
Gastroenteritis caused by a variety of mechanisms. Enterotoxigenic *E. coli* (ETEC) elaborates either a heat-stable or heat-labile toxin that mediates the disease. ETEC is an important cause of traveler’s diarrhea. Enteroinvasive *E. coli* (EIEC) differs from other *E. coli* bowel pathogens in that these strains invade cells, causing bloody diarrhea and dysentery similar to infection with *Shigella* species. EIEC is uncommon in the United States. Neither ETEC nor EIEC

3. *Salmonella* Bacteremia

*Salmonella* infection may be manifested by prolonged or recurrent fevers accompanied by bacteremia and local infection in bone, joints, pleura, pericardium, lungs, or other sites. Mycotic abdominal aortic aneurysms may also occur. Serotypes other than typhi usually are isolated. This complication of bacteremia tends to occur in immunocompromised persons, including HIV-infected individuals, who typically have bacteremia without an obvious source. Treatment is the same as for typhoid fever, plus drainage of any abscesses. In HIV-infected patients, relapse is common, and lifelong suppressive therapy may be needed. Ciprofloxacin, 750 mg orally twice a day, is effective both for therapy of acute infection and for suppression of recurrence. Incidence of infections caused by drug-resistant strains may be on the rise.

**SHIGELLOSIS**

**ESSENTIALS OF DIAGNOSIS**

- Diarrhea, often with blood and mucus.
- Crampy abdominal pain and systemic toxicity.
- White blood cells in stools; organism isolated on stool culture.

**General Considerations**

*Shigella* dysentery is a common disease, often self-limited and mild but occasionally serious. *S. sonnei* is the leading cause in the United States, followed by *S. flexneri*. *S. dysenteriae* causes the most serious form of the illness. *Shigella* are invasive organisms. The infective dose is low at $10^2$–$10^3$ organisms. There has been a rise in strains resistant to multiple antibiotics.

**Clinical Findings**

**A. Symptoms and Signs**

The illness usually starts abruptly, with diarrhea, lower abdominal cramps, and tenesmus. The diarrheal stool often is mixed with blood and mucus. Systemic symptoms are fever, chills, anorexia and malaise, and headache. The abdomen is tender. Sigmoidoscopic examination reveals an inflamed, engorged mucosa with punctate and sometimes large areas of ulceration.

**B. Laboratory Findings**

The stool shows many leukocytes and red cells. Stool culture is positive for *shigellae* in most cases, but blood cultures grow the organism in less than 5% of cases.

**Differential Diagnosis**

Bacillary dysentery must be distinguished from salmonella enterocolitis and from disease due to enterotoxigenic *Escherichia coli*, *Campylobacter*, and *Yersinia enterocolitica*. Amebic dysentery may be similar clinically and is diagnosed by finding amoebas in the fresh stool specimen. Ulcerative colitis is also an important cause of bloody diarrhea.

**Complications**

Temporary disaccharidase deficiency may follow the diarrhea. Reactive arthritis is an uncommon complication, usually occurring in HLA-B27 individuals infected by *Shigella*. Hemolytic-uremic syndrome occurs rarely.

**Treatment**

Treatment of dehydration and hypotension is lifesaving in severe cases. Recommended empiric antimicrobial therapy is either a fluoroquinolone (ciprofloxacin, 750 mg orally twice daily for 7–10 days, or levofloxacin, 500 mg orally once daily for 3 days) or ceftriaxone, 1 g intravenously once daily for 5 days. If the isolate is susceptible, trimethoprim-sulfamethoxazole, 160/80 mg orally twice daily for 5 days, or azithromycin, 500 mg orally once daily for 3 days, is also effective. High rates of resistance to amoxicillin make it a less effective treatment option.

strains are routinely isolated and identified from stool cultures because there is no selective medium. Antimicrobial therapy against *Salmonella* and *Shigella*, such as ciprofloxacin 500 mg orally twice daily, shortens the clinical course, but the disease is self-limited.

Shiga-toxin–producing *E. coli* (STEC) infection can result in asymptomatic carrier stage, nonbloody diarrhea, hemorrhagic colitis, hemolytic-uremic syndrome, or thrombotic thrombocytopenic purpura. Although *E. coli* O157:H7 is responsible for most cases of STEC infection in the United States, other STEC strains that cause severe disease (such as *E. coli* O104:H4) have been reported in Europe. *E. coli* O157:H7 has caused several outbreaks of diarrhea and hemolytic-uremic syndrome related to consumption of undercooked hamburger, raw flour, unpasteurized apple juice, and spinach, while *E. coli* O145 was linked to the consumption of contaminated lettuce. Older individuals and young children are most affected, with hemolytic-uremic syndrome being more common in the latter group. STEC identification can be difficult and the CDC recommends that all stools submitted for routine testing from patients with acute community-acquired diarrhea be simultaneously cultured for *E. coli* O157:H7 and tested with an assay that detects Shiga toxins to detect non-O157 STEC, such as *E. coli* O145. Antimicrobial therapy does not alter the course of the disease and may increase the risk of hemolytic-uremic syndrome. Treatment is primarily supportive. Hemolytic-uremic syndrome or thrombotic thrombocytopenic purpura occurring in association with a diarrheal illness suggests the diagnosis and should prompt evaluation for STEC. Confirmed infections should be reported to public health officials.

Marder EP et al. Incidence and trends of infections with pathogenic *E. coli* responsible for most cases of STEC infection in the United States, other STEC strains that cause severe disease (such as *E. coli* O104:H4) have been reported in Europe. *E. coli* O157:H7 has caused several outbreaks of diarrhea and hemolytic-uremic syndrome related to consumption of undercooked hamburger, raw flour, unpasteurized apple juice, and spinach, while *E. coli* O145 was linked to the consumption of contaminated lettuce. Older individuals and young children are most affected, with hemolytic-uremic syndrome being more common in the latter group. STEC identification can be difficult and the CDC recommends that all stools submitted for routine testing from patients with acute community-acquired diarrhea be simultaneously cultured for *E. coli* O157:H7 and tested with an assay that detects Shiga toxins to detect non-O157 STEC, such as *E. coli* O145. Antimicrobial therapy does not alter the course of the disease and may increase the risk of hemolytic-uremic syndrome. Treatment is primarily supportive. Hemolytic-uremic syndrome or thrombotic thrombocytopenic purpura occurring in association with a diarrheal illness suggests the diagnosis and should prompt evaluation for STEC. Confirmed infections should be reported to public health officials.

CHOLEA

**ESSENTIALS OF DIAGNOSIS**

- History of travel in endemic area or contact with infected person.
- Voluminous diarrhea (up to 15 L/day).
- Characteristic “rice water stool.”
- Rapid development of marked dehydration.
- Positive stool cultures and agglutination of vibrios with specific sera.

**General Considerations**

Cholera is an acute diarrheal illness caused by certain serotypes of *Vibrio cholerae*. The disease is toxin-mediated, and fever is unusual. The toxin activates adenyl cyclase in intestinal epithelial cells of the small intestines, producing hypersecretion of water and chloride ion and a massive diarrhea of up to 15 L/day. Death results from profound hypovolemia. Cholera occurs in epidemics under conditions of crowding, war, and famine (eg, in refugee camps) and where sanitation is inadequate. Infection is acquired by ingestion of contaminated food or water. For over a century, cholera was rarely seen in the Western Hemisphere until an outbreak occurred in Peru, starting in the early 1990s and ending by 2001; the outbreak resulted in almost 400,000 cholera cases and more than 4,000 deaths. Cholera again became a rare disease in the Western Hemisphere until late 2010, when there was a massive earthquake in Haiti followed by a cholera outbreak that resulted in thousands of deaths.

**Clinical Findings**

Cholera is characterized by a sudden onset of severe, frequent watery diarrhea (up to 1 L/h). The liquid stool is gray, turbid, and without fecal odor, blood, or pus (“rice water stool”). Dehydration and hypotension develop rapidly. Stool cultures are positive, and agglutination of vibrios with specific sera can be demonstrated.

**Prevention**

A vaccine is available that confers short-lived, limited protection and may be required for entry into or reentry after travel to some countries. It is administered in two doses 1–4 weeks apart. A booster dose every 6 months is recommended for persons remaining in areas where cholera is a hazard.

Vaccination programs are expensive and not particularly effective in managing outbreaks of cholera. When outbreaks occur, efforts should be directed toward establishing clean water and food sources and proper waste disposal.

**Treatment**

Treatment is by replacement of fluids. In mild or moderate illness, oral rehydration usually is adequate. A simple oral replacement fluid can be made from 1 teaspoon of salt and 4 heaping teaspoons of sugar added to 1 L of water. Intravenous fluids are indicated for persons with signs of severe hypovolemia and those who cannot take adequate fluids orally. Lactated Ringer infusion is satisfactory.

Antimicrobials active against *V. cholerae* include tetracycline, ampicillin, chloramphenicol, trimethoprim-sulfamethoxazole, fluoroquinolones, and azithromycin. Multiple drug-resistant strains are increasingly encountered, so susceptibility testing, if available, is advisable. A single 1 g oral dose of azithromycin is effective for severe cholera caused by strains with reduced susceptibility to fluoroquinolones, but resistance is emerging to this drug as well.

**Vibrios other than V cholerae that cause human disease are Vibrio parahaemolyticus, V vulnificus, and V alginolyticus. All are halophilic marine organisms. Infection is acquired by exposure to organisms in contaminated, undercooked, or raw crustaceans or shellfish and warm (greater than 20°C [68.4°F]) ocean waters and estuaries. Infections are more common during the summer months from regions along the Atlantic coast and the Gulf of Mexico in the United States and from tropical waters around the world. Oysters are implicated in up to 90% of seafood-related cases. V parahaemolyticus causes an acute watery diarrhea with crampy abdominal pain and fever, typically occurring within 24 hours after ingestion of contaminated shellfish. The disease is self-limited, and antimicrobial therapy is usually not necessary. V parahaemolyticus may also cause cellulitis and sepsis, though these findings are more characteristic of V vulnificus infection.

V vulnificus and V alginolyticus—neither of which is associated with diarrheal illness—are important causes of cellulitis and primary bacteremia following ingestion of contaminated shellfish or exposure to sea water. Cellulitis with or without sepsis may be accompanied by bulla formation and necrosis with extensive soft tissue destruction, at times requiring debridement and amputation. The infection can be rapidly progressive and is particularly severe in immunocompromised individuals—especially those with cirrhosis—with death rates as high as 50%. Patients with chronic liver disease and those who are immunocompromised should be cautioned to avoid eating raw oysters.

Tetracycline at a dose of 500 mg orally four times a day for 7–10 days is the drug of choice for treatment of suspected or documented primary bacteremia or cellulitis caused by *Vibrio* species. *V vulnificus* is susceptible in vitro to penicillin, ampicillin, cephalosporins, chloramphenicol, aminoglycosides, and fluoroquinolones, and these agents may also be effective. *V parahaemolyticus* and *V alginolyticus* produce beta-lactamase and therefore are resistant to penicillin and ampicillin, but susceptibilities otherwise are similar to those listed for *V vulnificus*.

**BRUCELLOSIS**

**ESSENTIALS OF DIAGNOSIS**

- History of animal exposure, ingestion of unpasteurized milk or cheese.
- Insidious onset: fatigue, headache, arthralgia, anorexia, sweating, irritability.
- Intermittent and persistent fever.
- Cervical and axillary lymphadenopathy; hepatosplenomegaly.
- Lymphocytosis, positive blood culture, positive serologic test.

**General Considerations**

The infection is transmitted from animals to humans. *Brucella abortus* (cattle), *B suis* (hogs), and *B melitensis* (goats) are the main agents. Transmission to humans occurs by contact with infected meat (slaughterhouse workers), placenta of infected animals (farmers, veterinarians), or ingestion of infected unpasteurized milk or cheese. The incubation period varies from a few days to several weeks.
Brucellosis is a systemic infection that may become chronic. In the United States, brucellosis is very rare. Almost all US cases are imported from countries where brucellosis is endemic (eg, Mexico, Mediterranean Europe, Spain, South American countries).

Clinical Findings

A. Symptoms and Signs

The onset may be acute, with fever, chills, and sweats, but more often is insidious with symptoms of weakness, weight loss, low-grade fevers, sweats, and exhaustion upon minimal activity. Headache, abdominal or back pain with anorexia and constipation, and arthralgias are also common. The chronic form may assume an undulant nature, with periods of normal temperature between acute attacks; symptoms may persist for years, either continuously or intermittently.

Fever, hepatosplenomegaly, and lymphadenopathy are the most common physical findings. Infection may present with or be complicated by specific organ involvement with signs of endocarditis, meningitis, epididymitis, orchitis, arthritis (especially sacroiliitis), spondylitis, or osteomyelitis.

B. Laboratory Findings

The organism can be recovered from cultures of blood, cerebrospinal fluid, urine, bone marrow, or other sites. Cultures are more likely to be negative in chronic cases. The diagnosis often is made by serologic testing.

Differential Diagnosis

Brucellosis must be differentiated from any other acute febrile disease, especially influenza, tularemia, Q fever, mononucleosis, and enteric fever. In its chronic form it resembles Hodgkin disease, tuberculosis, HIV infection, malaria, and disseminated fungal infections such as histoplasmosis and coccidioidomycosis.

Complications

The most frequent complications are bone and joint lesions such as spondylitis and suppurative arthritis (usually of a single joint), endocarditis (often culture negative), and meningoencephalitis. Less common complications are pneumonitis with pleural effusion, hepatitis, and cholecystitis.

Treatment

Single-drug regimens are not recommended because the relapse rate may be as high as 50%. Combination regimens of two or three drugs are most effective. Regimens of doxycycline (200 mg/day orally for 6 weeks) plus rifampin (600 mg/day orally for 6 weeks) or streptomycin (1 g/day intramuscularly for 2 weeks) or gentamicin (240 mg intramuscularly once daily for 7 days) have the lowest recurrence rates. Longer courses of therapy may be required to prevent relapse of meningitis, osteomyelitis, or endocarditis.

Tularemia is a zoonotic infection of wild rodents and rabbits caused by Francisella tularensis. Humans usually acquire the infection by contact with animal tissues (eg, trapping muskrats, skinning rabbits) or from a tick or insect bite. Hamsters and prairie dogs also may carry the organism. An outbreak of pneumonic tularemia on Martha’s Vineyard in Massachusetts was linked to lawn-mowing and brush-cutting as risk factors for infection, underscoring the potential for probable aerosol transmission of the organism. F tularensis has been classified as a high-priority agent for potential bioterrorism use because of its virulence and relative ease of dissemination. Infection in humans often produces a local lesion and widespread organ involvement but may be entirely asymptomatic. The incubation period is 2–10 days.

General Considerations

Tularemia is a zoonotic infection of wild rodents and rabbits caused by *Francisella tularensis*. Humans usually acquire the infection by contact with animal tissues (eg, trapping muskrats, skinning rabbits) or from a tick or insect bite. Hamsters and prairie dogs also may carry the organism. An outbreak of pneumonic tularemia on Martha’s Vineyard in Massachusetts was linked to lawn-mowing and brush-cutting as risk factors for infection, underscoring the potential for probable aerosol transmission of the organism. *F tularensis* has been classified as a high-priority agent for potential bioterrorism use because of its virulence and relative ease of dissemination. Infection in humans often produces a local lesion and widespread organ involvement but may be entirely asymptomatic. The incubation period is 2–10 days.

Clinical Findings

A. Symptoms and Signs

Fever, headache, and nausea begin suddenly, and a local lesion—a papule at the site of inoculation—develops and widespread organ involvement but may be entirely asymptomatic. The incubation period is 2–10 days.

B. Laboratory Findings

Culturing the organism from blood or infected tissue requires special media. For this reason and because cultures of *F tularensis* may be hazardous to laboratory personnel,
Pneumonia or meningitis is often fatal.

Differential Diagnosis

Tularemia must be differentiated from rickettsial and meningococcal infections, cat-scratch disease, infectious mononucleosis, and various bacterial and fungal diseases.

Complications

Hematogenous spread may produce meningitis, perisplenia, pericarditis, pneumonia, and osteomyelitis.

Treatment

Streptomycin is the drug of choice for treatment of tularemia. The recommended dose is 7.5 mg/kg intramuscularly every 12 hours for 7–14 days. Gentamicin, which has good in vitro activity against F tularensis, is generally less toxic than streptomycin but some case series report lower treatment success rates. Doxycycline (200 mg/day orally) is also effective but has a higher relapse rate and should only be used for the less seriously ill. A variety of other agents (eg, fluoroquinolones) are active in vitro, but their clinical effectiveness is less well established.

B. Laboratory Findings

The plague bacillus may be found in smears from aspirates of buboes examined with Gram stain. Cultures from bubo aspirate or pus and blood are positive but may grow slowly. In convalescing patients, an antibody titer rise may be demonstrated by agglutination tests.

Differential Diagnosis

The lymphadenitis of plague is most commonly mistaken for the lymphadenitis accompanying staphylococcal or streptococcal infections of an extremity, sexually transmitted diseases such as lymphogranuloma venereum or syphilis, and tularemia. The systemic manifestations resemble those of enteric or rickettsial fevers, malaria, or influenza. The pneumonia resembles other bacterial pneumonias, and the meningitis is similar to those caused by other bacteria.

Prevention

Avoiding exposure to rodents and fleas in endemic areas is the best prevention strategy. Drug prophylaxis may provide temporary protection for persons exposed to the risk of plague infection, particularly by the respiratory route. Doxycycline, 100 mg twice daily for 7 days, is effective. No vaccine is available at this time.

PLAGUE

PLAGUE

ESSENTIALS OF DIAGNOSIS

- History of exposure to rodents endemic area.
- Sudden onset of high fever, muscular pains, and prostration.
- Axillary, cervical, or inguinal lymphadenitis (bubo).
- Pustule or ulcer at inoculation site.
- Pneumonia or meningitis is often fatal.
- Positive smear and culture from bubo and positive blood culture.

General Considerations

Plague is an infection of wild rodents with Yersinia pestis, a small bipolar-staining gram-negative rod. It is endemic in California, Arizona, Nevada, and New Mexico. Worldwide, Madagascar accounts for three-quarters of the global burden. It is transmitted among rodents and to humans by the bites of fleas or from contact with infected animals. Following a fleabite, the organisms spread through the lymphatics to the lymph nodes, which become greatly enlarged (buboes). They may then reach the bloodstream to involve all organs. When pneumonia or meningitis develops, the outcome is often fatal. The patient with pneumonia can transmit the infection to other individuals by droplets. The incubation period is 2–10 days. Because of its extreme virulence, its potential for dissemination and person-to-person transmission, and efforts to develop the organism as an agent of biowarfare, plague bacillus is considered a high-priority agent for bioterrorism.

Clinical Findings

A. Symptoms and Signs

The onset is sudden, with high fever, malaise, tachycardia, intense headache, delirium, and severe myalgias. The patient appears profoundly ill. If pneumonia develops, tachypnea, productive cough, blood-tinged sputum, and cyanosis also occur. There may be signs of meningitis. A pustule or ulcer at the site of inoculation and lymphangitis may be observed. Axillary, inguinal, or cervical lymph nodes become enlarged and tender and may suppurate and drain. With hematogenous spread, the patient may rapidly become toxic and comatose, with purpuric spots (black plague) appearing on the skin.

Primary plague pneumonia is a fulminant pneumonitis with bloody, frothy sputum and sepsis. It is usually fatal unless treatment is started within a few hours after onset.

B. Laboratory Findings

The plague bacillus may be found in smears from aspirates of buboes examined with Gram stain. Cultures from bubo aspirate or pus and blood are positive but may grow slowly. In convalescing patients, an antibody titer rise may be demonstrated by agglutination tests.
1.7 mg/kg every 8 hours intravenously, is effective. Alternatively, doxycycline, 100 mg orally or intravenously, may be used. The duration of therapy is 10 days. Patients with plague pneumonia are placed in strict respiratory isolation, and prophylactic therapy is given to any person who came in contact with the patient.

GONOCOCCAL INFECTIONS

ESSENTIALS OF DIAGNOSIS

- Purulent, profuse urethral discharge with dysuria, especially in men; yields positive smear.
- Men: epididymitis, prostatitis, perirectal inflammation, proctitis, pharyngitis.
- Women: cervicitis with purulent discharge, or asymptomatic, yielding positive culture; vaginitis, salpingitis, proctitis also occur.
- Disseminated disease: fever, rash, tenosynovitis, and arthritis.
- Gram-negative intracellular diplococci seen in a smear or cultured from the urethra, cervix, pharynx, or rectum.

General Considerations

Gonorrhea is caused by Neisseria gonorrhoeae, a gram-negative diplococcus typically found inside polymorphonuclear cells. It is transmitted during sexual activity and has its greatest incidence in the 15- to 29-year-old age group. The incubation period is usually 2–8 days.

Classification

A. Urethritis and Cervicitis

Initial symptoms seen in men include burning on urination and a serous or milky discharge. One to 3 days later, the urethral pain is more pronounced and the discharge becomes yellow, creamy, and profuse, sometimes blood-tinged. The disorder may regress and become chronic or progress to involve the prostate, epididymis, and perirectal glands with painful inflammation. Chronic infection leads to prostatitis and urethral strictures. Rectal infection is common in men who have sex with men. Atypical sites of primary infection (eg, the pharynx) must always be considered. Asymptomatic infection is common and occurs in both sexes.

Gonococcal infection in women often becomes symptomatic during menses. Women may have dysuria, urinary frequency, and urgency, with a purulent urethral discharge. Vaginitis and cervicitis with inflammation of Bartholin glands are common. Infection may be asymptomatic, with only slightly increased vaginal discharge and moderate cervicitis on examination. Infection may remain as a chronic cervicitis—an important reservoir of gonococci. It can progress to involve the uterus and tubes with acute and chronic salpingitis, with scarring of tubes and sterility. In pelvic inflammatory disease, anaerobes and chlamydiae often accompany gonococci. Rectal infection may result from spread of the organism from the genital tract or from anal coitus.

Nucleic acid amplification tests are the preferred method for diagnosing all types of gonorrhea given their excellent sensitivity and specificity. In women with suspected cervical infection, endocervical or vaginal swabs (clinician- or self-collected) as well as first catch AM urine specimen (later specimens have 10% reduced sensitivity) are options. In men with urethral infection, first catch AM urine is recommended. Nucleic acid amplification tests are also recommended by the CDC for oropharyngeal and rectal sites testing although they are not FDA approved for these specimen types. Gram stain of urethral or rectal discharge in men, especially during the first week after onset, shows gram-negative diplococci in polymorphonuclear leukocytes. Gram stain is less often positive in women. Cultures should still be obtained when evaluating a treatment failure to assess for antimicrobial resistance.

B. Disseminated Disease

Systemic complications follow the dissemination of gonococci from the primary site via the bloodstream. Two distinct clinical syndromes—either purulent arthritis or the triad of rash, tenosynovitis, and arthralgias—are commonly observed in patients with disseminated gonococcal infection, although overlap can be seen. The skin lesions can range from maculopapular to pustular or hemorrhagic, which tend to be few in number and peripherally located. The tenosynovitis is often found in the hands and wrists and feet and ankles. These unique findings can help distinguish among other infectious syndromes. The arthritis can occur in one or more joints and may be migratory. Gonococci are isolated by culture from less than half of patients with gonococcal arthritis. Rarely, gonococcal endocarditis or meningitis develops.

C. Conjunctivitis

The most common form of eye involvement is direct inoculation of gonococci into the conjunctival sac. In adults, this occurs by autoinoculation of a person with genital infection. The purulent conjunctivitis may rapidly progress to panophthalmitis and loss of the eye unless treated promptly. A single 1-g dose of ceftriaxone is effective.

Differential Diagnosis

Gonococcal urethritis or cervicitis must be differentiated from nongonococcal urethritis; cervicitis or vaginitis due to Chlamydia trachomatis, Gardnerella vaginalis, Trichomonas, Candida, and many other pathogens associated with sexually transmitted diseases; and pelvic inflammatory disease, arthritis, proctitis, and skin lesions. Often, several such pathogens coexist in a patient. Reactive arthritis...
(urethritis, conjunctivitis, arthritis) may mimic gonorrhea or coexist with it.

Prevention

Prevention is based on education and mechanical or chemical prophylaxis. The condom, if properly used, can reduce the risk of infection. Partner notification and referral of contacts for treatment has been the standard method used to control sexually transmitted diseases. Early treatment of contacts can halt the development of symptoms as well. Expedited treatment of sex partners by patient-delivered partner therapy is more effective than partner notification in reducing persistence and recurrence rates of gonorrhea and chlamydia.

Treatment

Therapy typically is administered before antimicrobial susceptibilities are known. The choice of which regimen to use should be based on the national prevalences of antibiotic-resistant organisms. Nationwide, strains of gonococci that are resistant to penicillin, tetracycline, or ciprofloxacin have been increasingly observed. Consequently, these drugs can no longer be considered first-line therapy. Resistance to azithromycin and to ceftriaxone has been reported. All sexual partners should be treated and tested for HIV infection and syphilis, as should the patient.

A. Uncomplicated Gonorrhea

Due to increasing resistance of *N gonorrhoeae* to cephalosporins, the CDC recommends a higher dose of intramuscular ceftriaxone in combination with a second drug (azithromycin or doxycycline) regardless of concern for possible secondary infection with chlamydia. For uncomplicated gonococcal infections of the cervix, urethra, and rectum, the recommended treatment is ceftriaxone (250 mg intramuscularly) plus azithromycin (1000 mg orally as a single dose). In cases where an oral cephalosporin is the only option, cefixime, 400 mg orally as a single dose, can be combined with azithromycin as above. When azithromycin is not an option, doxycycline at 100 mg orally twice daily for 7 days can be substituted. Fluoroquinolones are no longer recommended for treatment due to high rates of microbial resistance. Spectinomycin, 1 g intramuscularly once, may be used for the penicillin-allergic patient but is not currently available in the United States. Pharyngeal gonorrhea is also treated with ceftriaxone (250 mg intramuscularly) plus azithromycin (1000 mg orally as a single dose), but for conjunctival gonorrhea, the recommendation is for ceftriaxone (1 g intramuscularly) plus azithromycin (1000 mg orally as a single dose).

B. Treatment of Other Infections

Disseminated gonococcal infection (including arthritis and arthritis-dermatitis syndromes) should be treated with ceftriaxone (1 g intravenously daily) plus azithromycin (1000 mg orally as a single dose), until 48 hours after improvement begins, at which time therapy may be switched to cefixime (400 mg orally daily) to complete at least 1 week of antimicrobial therapy. Endocarditis should be treated with ceftriaxone (2 g every 24 hours intravenously) for at least 4 weeks.

Pelvic inflammatory disease requires cefoxitin (2 g parenterally every 6 hours) or cefotetan (2 g intravenously every 12 hours) plus doxycycline (100 mg every 12 hours). Clindamycin (900 mg intravenously every 8 hours) plus gentamicin (administered intravenously as a 2-mg/kg loading dose followed by 1.5 mg/kg every 8 hours) is also effective. Ceftriaxone (250 mg intramuscularly as a single dose) or cefoxitin (2 g intramuscularly) plus probenecid (1 g orally as a single dose) plus doxycycline (100 mg twice a day for 14 days), with or without metronidazole (500 mg twice daily for 14 days), is an effective outpatient regimen.

CHANCROID

Chancroid is a sexually transmitted disease caused by the short gram-negative bacillus *Haemophilus ducreyi*. The incubation period is 3–5 days. At the site of inoculation, a vesicopustule develops that breaks down to form a painful, soft ulcer with a necrotic base, surrounding erythema, and undermined edges. There may be multiple lesions due to autoinoculation. The adenitis is usually unilateral and consists of tender, matted nodes of moderate size with overlying erythema. These may become fluctuant and rupture spontaneously. With lymph node involvement, fever, chills, and malaise may develop. Balanitis and phimosis are frequent complications in men. Women may have no external signs of infection. The diagnosis is established by culturing a swab of the lesion onto a special medium.

Chancroid must be differentiated from other genital ulcers. The chancre of syphilis is clean and painless, with a hard base. Mixed sexually transmitted disease is very common (including syphilis, herpes simplex, and HIV infection), as is infection of the ulcer with fusiforms, spirochetes, and other organisms.

A single dose of either azithromycin, 1 g orally, or ceftriaxone, 250 mg intramuscularly, is effective treatment. Effective multiple-dose regimens are erythromycin, 500 mg orally four times a day for 7 days, or ciprofloxacin, 500 mg orally twice a day for 3 days.

GRANULOMA INGUINALE

Granuloma inguinale is a chronic, relapsing granulomatous anogenital infection due to *Calymmatobacterium (Donovania) granulomatis*. The pathognomonic cell, found
in tissue scrapings or secretions, is large (25–90 μm) and contains intracytoplasmic cysts filled with bodies (Donován bodies) that stain deeply with Giesma stain.

The incubation period is 8 days to 12 weeks. The onset is insidious. The lesions occur on the skin or mucous membranes of the genitalia or perineal area. They are relatively painless infiltrated nodules that soon slough. A shallow, sharply demarcated ulcer forms, with a beefy-red friable base of granulation tissue. The lesion spreads by contiguity. The advancing border has a characteristic rolled edge of granulation tissue. Large ulcerations may advance onto the lower abdomen and thighs. Scar formation and healing occur along one border while the opposite border advances.

Superinfection with spirochete-fusiform organisms is common. The ulcer then becomes purulent, painful, foul-smelling, and extremely difficult to treat.

Several therapies are available. Because of the indolent nature of the disease, duration of therapy is relatively long. The following recommended regimens should be given for 3 weeks or until all lesions have healed: doxycycline, 100 mg orally twice daily; or azithromycin, 1 g orally once weekly; or ciprofloxacin, 750 mg orally twice daily; or erythromycin, 500 mg orally four times a day.

BARTONELLA SPECIES

Bartonella species are responsible for a wide variety of clinical syndromes. Bacillary angiomatosis, an important manifestation of bartonellosis, is discussed in Chapter 31. A variety of atypical infections, including retinitis, encephalitis, osteomyelitis, and persistent bacteremia and endocarditis (especially consider in culture-negative endocarditis), have been described.

Trench fever is a self-limited, louse-borne relapsing febrile disease caused by B quintana. The disease has occurred epidemiologically in louse-infested troops and civilians during wars and endemically in residents of scattered geographic areas (eg, Central America). An urban equivalent of trench fever has been described among the homeless. Humans acquire infection when infected lice feces enter sites of skin breakdown. Onset of symptoms is abrupt and fever lasts 3–5 days, with relapses. The patient complains of weakness and severe pain behind the eyes and typically in the back and legs. Lymphadenopathy, splenomegaly, and a transient maculopapular rash may appear. Subclinical infection is frequent, and a carrier state is recognized. The differential diagnosis includes other febrile, self-limited states such as dengue, leptospirosis, malaria, relapsing fever, and typhus. Treatment is generally not required since spontaneous recovery occurs regularly.

Cat-scratch disease is an acute infection of children and young adults caused by Bartonella henselae. It is transmitted from cats to humans as the result of a scratch or bite. Within a few days, a papule or ulcer will develop at the inoculation site in one-third of patients. One to 3 weeks later, fever, headache, and malaise occur. Regional lymph nodes become enlarged, often tender, and may suppurate. Lymphadenopathy from cat scratches resembles that due to neoplasm, tuberculosis, lymphogranuloma venereum, and bacterial lymphadenitis. The diagnosis is usually made clinically. Special cultures for bartonellae, serology, or excisional biopsy, though rarely necessary, confirm the diagnosis. The biopsy reveals necrotizing lymphadenitis and is itself not specific for cat-scratch disease. Cat-scratch disease is usually self-limited, requiring no specific therapy. Encephalitis occurs rarely.

Disseminated forms of the disease—bacillary angiomatosis, peliosis hepatitis, and retinitis—occur most commonly in immunocompromised patients such as persons with late stages of HIV or solid organ transplant recipients. The lesions are vasculoproliferative and histopathologically distinct from those of cat-scratch disease. Unexplained fever in patients with late stages of HIV infection is not uncommonly due to bartonellosis. B quintana, the agent of trench fever, can also cause bacillary angiomatosis and persistent bacteremia or endocarditis (which will be “culture-negative” unless specifically sought), the latter two entities being associated with homelessness. Due to the fastidious nature of the organism and its special growth requirements, serologic testing (eg, demonstration of a high antibody titer in an indirect immunofluorescence assay) or nucleic acid amplification tests are often required to establish a diagnosis.

The disseminated forms of the disease (bacillary angiomatosis, peliosis hepatitis, and retinitis) require a prolonged course of antibiotic therapy often in combination with a second agent. Bacteremia and endocarditis can be effectively treated with a 6-week course of doxycycline (200 mg orally or intravenously in two divided doses per day) plus either gentamicin 3 mg/kg/day intravenously or rifampin 600 mg/day orally in two divided doses. Relapse may occur.

ANAEROBIC INFECTIONS

Anaerobic infections tend to be polymicrobial and abscesses are common. Pus and infected tissue often are malodorous. Septic thrombophlebitis and metastatic infection are frequent and may require incision and drainage. Diminished blood supply that favors proliferation of anaerobes because of reduced tissue oxygenation may interfere with the delivery of antimicrobials to the site of anaerobic infection. Cultures, unless carefully collected under anaerobic conditions, may yield negative results.

Important types of infections that are most commonly caused by anaerobic organisms are listed below. Treatment of all these infections consists of surgical exploration and judicious excision in conjunction with administration of antimicrobial drugs.
1. Head & Neck Infections

Preventella melanogenica (formerly Bacteroides melanogenicus) and anaerobic spirochetes are commonly involved in periodontal infections. These organisms, fusobacteria, and peptostreptococci may cause chronic sinusitis, periodontal abscess, chronic otitis media, and mastoiditis. F. necrophorum has been recognized as a common cause of pharyngitis in adolescents and young adults. F. necrophorum infection has been associated with septic internal jugular thrombophlebitis (Lemierre syndrome) and causes septic pulmonary embolization. Hygiene, drainage, and surgical debridement are as important in treatment as antimicrobials. Penicillin alone is inadequate treatment for infections from oral anaerobic organisms because of increasing penicillin resistance, usually due to beta-lactamase production. Therefore, ampicillin/sulbactam 1.5–3 g intravenously every 6 hours (if parenteral therapy is required), or amoxicillin/clavulanic acid 875 mg/125 mg orally twice daily, or clindamycin can be used (600 mg intravenously every 8 hours or 300 mg orally every 6 hours). Antimicrobial treatment is continued for a few days after symptoms and signs of infection have resolved. Indolent, established infections (eg, mastoiditis or osteomyelitis) may require prolonged courses of therapy, eg, 4–6 weeks or longer.

2. Chest Infections

Usually in the setting of poor oral hygiene and periodontal disease, aspiration of saliva (which contains 10^8 anaerobic organisms per milliliter in addition to aerobes) may lead to necrotizing pneumonia, lung abscess, and empyema. Polymicrobial infection is the rule, and anaerobes—particularly P. melanogenica, fusobacteria, and peptostreptococci—are common etiologic agents. Most pulmonary infections respond to antimicrobial therapy alone. Percutaneous chest tube or surgical drainage is indicated for empyema.

Penicillin-resistant Bacteroides fragilis and P. melanogenica are commonly isolated and have been associated with clinical failures. Clindamycin, 600 mg intravenously once, followed by 300 mg orally every 6–8 hours, is the treatment of choice for these infections. Metronidazole does not cover facultative streptococci, which often are present, and if used, a second agent that is active against streptococci, such as ceftriaxone 1 g intravenously or intramuscularly daily, should be added. Penicillin, 2 million units intravenously every 4 hours, followed by amoxicillin, 500 mg every 8 hours orally, is an alternative; however, increasing prevalence of beta-lactamase producing organisms is a concern. Moxifloxacin, 400 mg orally or intravenously once daily, may be used. Because these infections respond slowly, a prolonged course of therapy (eg, 4–6 weeks) is generally recommended.

3. Central Nervous System

Anaerobes are a common cause of brain abscess, subdural empyema, or septic CNS thrombophlebitis. The organisms reach the CNS by direct extension from sinusitis, otitis, or mastoiditis or by hematogenous spread from chronic lung infections. Antimicrobial therapy—eg, ceftriaxone, 2 g intravenously every 12 hours, plus metronidazole, 500 mg intravenously every 8 hours—is an important adjunct to surgical drainage. Duration of therapy is 6–8 weeks but should be based on follow-up imaging. Some small multiple brain abscesses can be treated with antibiotics alone without surgical drainage.

4. Intra-Abdominal Infections

In the colon there are up to 10^11 anaerobes per gram of content—predominantly B. fragilis, clostridia, and peptostreptococci. These organisms play a central role in most intra-abdominal abscesses following trauma to the colon, diverticulitis, appendicitis, or perirectal abscess and may also participate in hepatic abscess and cholecystitis, often in association with aerobic coliform bacteria. The bacteriology includes anaerobes as well as enteric gram-negative rods and on occasion enterococci. Therapy should be directed both against anaerobes and gram-negative aerobes. Agents that are active against B. fragilis include metronidazole, chloramphenicol, moxifloxacin, ticagycline, erapenem, imipenem, doripenem, ampicillin-sulbactam, ticarcillin-clavulanic acid, piperacillin-tazobactam, and cefotolozane/tazobactam. Resistance to cefoxitin, cefotetan, and clindamycin is increasingly encountered. Most third-generation cephalosporins have poor efficacy.

Table 33–6 summarizes the antibiotic regimens for management of moderate to moderately severe infections (eg, patient hemodynamically stable, good surgical drainage possible or established, low APACHE score, no multiple organ failure) and severe infections (eg, major peritoneal soilage, large or multiple abscesses, patient hemodynamically unstable), particularly if drug-resistant organisms are suspected. An effective oral regimen for patients able to take it is presented also.

5. Female Genital Tract & Pelvic Infections

The normal flora of the vagina and cervix includes several species of bacteroides, peptostreptococci, group B streptococci, lactobacilli, coliform bacteria, and, occasionally, spirochetes and clostridia. These organisms commonly cause genital tract infections and may disseminate from there.

While salpingitis is often caused by gonococci and chlamydiae, tubo-ovarian and pelvic abscesses are associated

with anaerobes in most cases. Postpartum infections may be caused by aerobic streptococci or staphylococci, but anaerobes are often found, and the worst cases of postpartum or postabortion sepsis are associated with clostridia and bacteroides. These have a high mortality rate, and treatment requires both antimicrobials directed against anaerobes and coliforms (similar to treatment of anaerobic intra-abdominal infections, Table 33–6) and abscess drainage or early hysterectomy.

6. Bacteremia & Endocarditis

Anaerobic bacteremia usually originates from the gastrointestinal tract, the oropharynx, pressure injuries, or the female genital tract. Endocarditis due to anaerobic and microaerophilic streptococci and bacteroides originates from the same sites. Most cases of anaerobic or microaerophilic streptococcal endocarditis can be effectively treated with 12–20 million units of penicillin G intravenously daily for 4–6 weeks, but optimal therapy of other types of anaerobic bacterial endocarditis must rely on laboratory guidance. Propionibacteria, clostridia, and bacteroides occasionally cause endocarditis.

7. Skin & Soft Tissue Infections

Anaerobic infections of the skin and soft tissue usually follow trauma, inadequate blood supply, or surgery and are most common in areas that are contaminated by oral or fecal flora. These infections also occur in injection drug users and persons sustaining animal bites. There may be progressive tissue necrosis (Figure 33–6) and a putrid odor.

Several terms, such as bacterial synergistic gangrene, synergistic necrotizing cellulitis, necrotizing fasciitis, and non-clostridial crepitant cellulitis, have been used to classify these infections. Although there are some differences in microbiology among them, their differentiation on clinical grounds alone is difficult. All are mixed infections caused by aerobic and anaerobic organisms and require aggressive surgical debridement of necrotic tissue for cure.

Broad-spectrum antibiotics active against both anaerobes and gram-positive and gram-negative aerobes (eg, vancomycin plus piperacillin-tazobactam) should be instituted empirically and modified by culture results (see Table 30–5). They are given for about a week after progressive tissue destruction has been controlled and the margins of the wound remain free of inflammation.

**ACTINOMYCOSIS**

### ESSENTIALS OF DIAGNOSIS

- History of recent dental infection, abdominal trauma, or intrauterine contraception device placement.
- Chronic pneumonia or indolent cervicofacial or intra-abdominal abscess.
- Sinus tract formation.

### General Considerations

*Actinomyces israelii* and other species of *Actinomyces* occur in the normal flora of the mouth and tonsillar crypts. They are anaerobic, gram-positive, branching filamentous bacteria (1 mcm in diameter) that may fragment into bacillary forms. When introduced into traumatized tissue and associated with other anaerobic bacteria, these actinomycetes become pathogens.

The most common site of infection is the cervicofacial area (about 60% of cases). Infection typically follows extraction of a tooth or other trauma. Lesions may develop in the gastrointestinal tract or lungs following ingestion or aspiration of the organism from its endogenous source in the mouth. Interestingly, *T whipplei*, the causative agent of Whipple disease, is an actinomycete and therefore is related to the species that cause actinomycosis.

### Clinical Findings

**A. Symptoms and Signs**

1. **Cervicofacial actinomycosis**—Cervicofacial actinomycosis develops slowly. The area becomes markedly indurated, and the overlying skin becomes reddish or cyanotic. Abscesses eventually draining to the surface persist for long periods. "Sulfur granules"—masses of filamentous organisms—may be found in the pus. There is usually little pain unless there is secondary infection. Trismus indicates that the muscles of mastication are involved. Radiography may reveal bony involvement. Cervicofacial or thoracic disease may occasionally involve the CNS, most commonly brain abscess or meningitis.

2. **Thoracic actinomycosis**—Thoracic involvement begins with fever, cough, and sputum production with night sweats and weight loss. Pleuritic pain may be present. Multiple sinuses may extend through the chest wall, to the heart, or into the abdominal cavity. Ribs may be involved. Radiography shows areas of consolidation and in many cases pleural effusion.

3. **Abdominal actinomycosis**—Abdominal actinomycosis usually causes pain in the ileocecal region, spiking fever and chills, vomiting, and weight loss; it may be confused with Crohn disease. Irregular abdominal masses may be palpated. Pelvic inflammatory disease caused by actinomycetes has been associated with prolonged use of an intrauterine contraceptive device. Sinuses draining to the exterior may develop. CT scanning reveals an inflammatory mass extended to involve bone.

**B. Laboratory Findings**

The anaerobic, gram-positive organism may be demonstrated as a granule or as scattered branching gram-positive filaments in the pus. Anaerobic culture is necessary to distinguish actinomycetes from nocardiae because specific therapy differs for the two infections. Histopathology examination of affected tissue and bone is useful in identifying organisms that are fastidious and slow to culture.

### Treatment

Penicillin G is the drug of choice. Ten to 20 million units are given via a parenteral route for 4–6 weeks, followed by oral penicillin V, 500 mg four times daily. Alternatives include ampicillin, 12 g/day intravenously for 4–6 weeks, followed by oral amoxicillin, 500 mg three times daily, or doxycycline, 100 mg twice daily intravenously or orally. Response to therapy is slow. Therapy should be continued for weeks to months after clinical manifestations have disappeared in order to ensure cure. Surgical procedures such as drainage and resection may be beneficial. With penicillin and surgery, the prognosis is good. The difficulties of...
diagnosis, however, may permit extensive destruction of tissue before the diagnosis is identified and therapy is started.

**Nocardiosis**

*Nocardia* species are aerobic filamentous soil bacteria that can cause pulmonary and systemic nocardiosis. Common *Nocardia* species include members of the *Nocardia asteroides* complex and *Nocardia brasiliensis*. Bronchopulmonary abnormalities (eg, alveolar proteinosis) predispose to colonization, but infection is unusual unless the patient is also receiving systemic corticosteroids or is otherwise immunosuppressed.

**Clinical Findings**

Pulmonary involvement usually begins with malaise, loss of weight, fever, and night sweats. Cough and production of purulent sputum are the chief complaints. Radiography may show infiltrates accompanied by pleural effusion. The lesions may penetrate to the exterior through the chest wall, invading the ribs.

Dissemination involves any organ. Brain abscesses and subcutaneous nodules are most frequent. Even in the absence of clinical symptoms and signs of CNS infection, clinicians should consider brain imaging in patients with nocardiosis to rule out an occult abscess.

*Nocardia* species are usually found as delicate, branching, gram-positive filaments. They may be weakly acid-fast, occasionally causing diagnostic confusion with tuberculosis. Identification is made by culture.

**Treatment**

For isolated cutaneous infections, therapy is initiated with trimethoprim-sulfamethoxazole administered at a dosage of 5–10 mg/kg/day (based on trimethoprim) as an oral or intravenous formulation. Surgical procedures such as drainage and resection may be needed as adjunctive therapy. A higher dose of 15 mg/kg/day (based on trimethoprim) should be used for disseminated or pulmonary infections. Resistance to trimethoprim-sulfamethoxazole is increasing and initiating treatment with two drugs while awaiting antibiotic susceptibilities in cases of disseminated or severe localized disease should be considered. Alternative agents or drugs that can be given in combination with trimethoprim-sulfamethoxazole include imipenem, 500 mg intravenously every 6 hours; amikacin, 7.5 mg/kg intravenously every 12 hours; or minocycline, 100–200 mg orally or intravenously twice daily. Consultation with an infectious diseases expert is encouraged.

Response may be slow, and therapy should be continued for at least 6 months. The prognosis in systemic nocardiosis is poor when diagnosis and therapy are delayed.

**Infections Caused by Mycobacteria**

About 10% of mycobacterial infections are caused by nontuberculous mycobacteria. Nontuberculous mycobacterial infections are among the most common opportunistic infections in advanced HIV disease. These organisms have distinctive laboratory characteristics, occur ubiquitously in the environment, are not communicable from person to person, and are often resistant to standard antitubercular drugs.

**1. Pulmonary Infections**

*Mycobacterium avium* complex (MAC) causes a chronic, slowly progressive pulmonary infection resembling tuberculosis in immunocompetent patients who typically have underlying pulmonary disease. Susceptibility testing for macrolide-resistance should be performed on clinical isolates. Treatment of nodular or bronchiectatic pulmonary disease is clarithromycin (1000 mg orally three times per week) or azithromycin (500 mg orally three times per week) plus rifampin (600 mg orally three times per week) or rifabutin (300 mg orally three times per week) plus ethambutol (25 mg/kg orally three times per week). Patients with fibrocavitary lung disease or severe nodular or bronchiectatic disease should receive three-drug therapy with clarithromycin (500–1000 mg orally daily) or azithromycin (500 mg orally daily) plus rifampin (600 mg orally daily) or rifabutin (300 mg orally daily) plus ethambutol (15 mg/kg orally daily). Therapy is continued for at least 12 months after sterilization of cultures.

*M. kansasii* can produce clinical disease resembling tuberculosis, but the illness progresses more slowly. Most such infections occur in patients with preexisting lung disease, though 40% of patients have no known pulmonary disease. Microbiologically, *M. kansasii* is similar to *M. tuberculosis* and is sensitive to the same drugs except pyrazinamide, to which it is resistant. Therapy withisoniazid, ethambutol, and rifampin for 2 years (or 1 year after sputum conversion) has been successful.

Less common causes of pulmonary disease include *M. xenopi, M. szulgai*, and *M. gordonae*. These organisms have
variable sensitivities, and treatment is based on results of sensitivity tests. The rapid growing mycobacteria, *M. abscessus*, *M. chelonae*, and *M. fortuitum*, also can cause pneumonia in the occasional patient.

2. Lymphadenitis

Most cases of lymphadenitis (scrofula) in adults are caused by *M. tuberculosis* and can be a manifestation of disseminated disease. In children, the majority of cases are due to nontuberculous mycobacterial species. Infection with nontuberculous mycobacteria can be successfully treated by surgical excision without antituberculous therapy.

3. Skin & Soft Tissue Infections

Skin and soft tissue infections such as abscesses, septic arthritis, and osteomyelitis can result from direct inoculation or hematogenous dissemination or may occur as a complication of surgery.

*M. abscessus*, *M. chelonae*, and *M. fortuitum* are frequent causes of these types of infections. Most cases occur in the extremities and initially present as nodules. Ulceration with abscess formation often follows. The organisms are resistant to the usual antituberculosis drugs and may have susceptibility to clarithromycin, azithromycin, doxycycline, amikacin, cefoxitin, sulfonamides, imipenem, and ciprofloxacin. Given the multidrug-resistant nature of these organisms, obtaining antibiotic susceptibility testing is recommended. Therapy often includes surgical debriement along with at least two active antibiotics. Antibiotic therapy is usually continued for 3 months, although this must be determined based on clinical response.

*M. marinum* infection (“swimming pool granuloma”) presents as a nodular skin lesion following exposure to nonchlorinated water. The lesions respond to therapy with clarithromycin, doxycycline, minocycline, or trimethoprim-sulfamethoxazole.

*M. ulcerans* infection (Buruli ulcer) is seen mainly in Africa and Australia and produces a large ulcerative lesion. Therapy consists of surgical excision and skin grafting.

4. Disseminated *Mycobacterium avium* Infection

MAC causes disseminated disease in immunocompromised patients, most commonly in patients in the late stages of HIV infection, when the CD4 cell count is less than 50/mcL (see Pulmonary Disease caused by Nontuberculous Mycobacteria, Chapter 9, for a discussion of the infection in immunocompetent persons). Persistent fever and weight loss are the most common symptoms. The organism can usually be cultured from multiple sites, including blood, liver, lymph node, or bone marrow. Blood culture is the preferred means of establishing the diagnosis and has a sensitivity of 98%.

Agents with proved activity against MAC are rifabutin, azithromycin, clarithromycin, and ethambutol. Amikacin and ciprofloxacin work in vitro, but clinical results are inconsistent. A combination of two or more active agents should be used to prevent rapid emergence of secondary resistance. Clarithromycin, 500 mg orally twice daily, plus ethambutol, 15 mg/kg/day orally as a single dose, with or without rifabutin, 300 mg/day orally, is the treatment of choice. Azithromycin, 500 mg orally once daily, may be used instead of clarithromycin. Insufficient data are available to permit specific recommendations about second-line regimens for patients intolerant of macrolides or those with macrolide-resistant organisms. MAC therapy may be discontinued in patients who have been treated with 12 months of therapy for disseminated MAC, who have no evidence of active disease, and whose CD4 counts exceed 100 cells/mcL for 6 months while receiving antiretroviral therapy (ART).

Antimicrobial prophylaxis of MAC prevents disseminated disease and prolongs survival. It is the standard of care to offer it to all HIV-infected patients with CD4 counts of 50/mcL or less. In contrast to active infection, single-drug oral regimens of clarithromycin, 500 mg twice daily, azithromycin, 1200 mg once weekly, or rifabutin, 300 mg once daily, are appropriate. Clarithromycin or azithromycin is more effective and better tolerated than rifabutin, and therefore preferred. Primary prophylaxis for MAC infection can be stopped in patients who have responded to antiretroviral combination therapy with elevation of CD4 counts of greater than 100 cells/mcL for 3 months.

**MYCOBACTERIUM TUBERCULOSIS INFECTIONS**

Tuberculosis is discussed in Chapter 9. Further information and expert consultation can be obtained from the Curry International Tuberculosis Center at the website www.currytbccenter.ucsf.edu or by telephone, 510-238-5100.
TUBERCULOUS MENINGITIS

ESSENTIALS OF DIAGNOSIS

» Gradual onset of listlessness and anorexia.
» Headache, vomiting, and seizures common.
» Cranial nerve abnormalities typical.
» Tuberculosis focus may be evident elsewhere.
» Cerebrospinal fluid shows several hundred lymphocytes, low glucose, and high protein.

General Considerations

Tuberculous meningitis is caused by rupture of a meningeal tuberculoma resulting from earlier hematogenous seeding of tubercle bacilli from a pulmonary focus, or it may be a consequence of miliary spread.

Clinical Findings

A. Symptoms and Signs

The onset is usually gradual, with listlessness, irritability, anorexia, and fever, followed by headache, vomiting, convulsions, and coma. In older patients, headache and behavioral changes are prominent early symptoms. Nuchal rigidity and cranial nerve palsies occur as the meningitis progresses. Evidence of active tuberculosis elsewhere or a history of prior tuberculosis is present in up to 75% of patients.

B. Laboratory Findings

The spinal fluid is frequently yellowish, with increased pressure, 100–500 cells/mcL (predominantly lymphocytes, though neutrophils may be present early during infection), increased protein, and decreased glucose. Acid-fast stains of cerebrospinal fluid usually are negative, and cultures also may be negative in 15–25% of cases. Nucleic acid amplification tests for rapid diagnosis of tuberculosis have variable sensitivity and specificity and none are FDA approved for use in meningitis. Chest radiographs often reveal abnormalities compatible with tuberculosis but may be normal.

Differential Diagnosis

Tuberculous meningitis may be confused with any other type of meningitis, but the gradual onset, the predominantly lymphocytic pleocytosis of the spinal fluid, and evidence of tuberculosis elsewhere often point to the diagnosis. The tuberculin skin test is usually (not always) positive. Fungal and other granulomatous meningitides, syphilis, and carcinomatous meningitis are in the differential diagnosis.

Complications

Complications of tuberculous meningitis include seizure disorders, cranial nerve palsies, stroke, and obstructive hydrocephalus with impaired cognitive function. These result from inflammatory exudate primarily involving the basilar meninges and arteries.

Treatment

Presumptive diagnosis followed by early, empiric antituberculous therapy is essential for survival and to minimize sequelae. Even if cultures are not positive, a full course of therapy is warranted if the clinical setting is suggestive of tuberculous meningitis.

Regimens that are effective for pulmonary tuberculosis are effective also for tuberculous meningitis (see Table 9–15). Rifampin, isoniazid, and pyrazinamide all penetrate into cerebrospinal fluid well. The penetration of ethambutol is more variable, but therapeutic concentrations can be achieved, and the drug has been successfully used for meningitis. Aminoglycosides penetrate less well. Regimens that do not include both isoniazid and rifampin may be effective but are less reliable and generally must be given for longer periods.

Many authorities recommend the addition of corticosteroids for patients with focal deficits or altered mental status. Dexamethasone, 0.15 mg/kg intravenously or orally four times daily for 1–2 weeks, then discontinued in a tapering regimen over 4 weeks, may be used.

LEPROSY (Hansen Disease)

ESSENTIALS OF DIAGNOSIS

» Pale, anesthetic macular—or nodular and erythematous—skin lesions.
» Superficial nerve thickening with resultant anesthesia.
» History of residence in endemic area in childhood.
» Acid-fast bacilli in skin lesions or nasal scrapings, or characteristic histologic nerve changes.

General Considerations

Leprosy (Hansen disease) is a chronic infectious disease caused by the acid-fast rod M leprae. The mode of transmission probably is respiratory and involves prolonged exposure in childhood. The disease is endemic in tropical and subtropical Asia, Africa, Central and South America, and the Pacific regions, and rarely seen sporadically in the southern United States.

Clinical Findings

A. Symptoms and Signs

The onset is insidious. The lesions involve the cooler body tissues: skin, superficial nerves, nose, pharynx, larynx,
eyes, and testicles. Skin lesions may occur as pale, anesthetic macular lesions 1–10 cm in diameter; discrete erythematous, infiltrated nodules 1–5 cm in diameter; or diffuse skin infiltration. Neurologic disturbances are caused by nerve infiltration and thickening, with resultant anesthesia, and motor abnormalities. Bilateral ulnar neuropathy is highly suggestive. In untreated cases, disfigurement due to the skin infiltration and nerve involvement may be extreme, leading to trophic ulcers, bone resorption, and loss of digits.

The disease is divided clinically and by laboratory tests into two distinct types: lepromatous and tuberculoid. The lepromatous type (also referred to as multibacillary leprosy) occurs in persons with defective cellular immunity. The course is progressive, with nodular skin lesions; slow, symmetric nerve involvement; abundant acid-fast bacilli in the skin lesions; and a negative lepromin skin test. In the tuberculoid type (paucibacillary leprosy), cellular immunity is intact and the course is more benign and less progressive, with macular skin lesions, severe asymmetric nerve involvement of sudden onset with few bacilli present in the lesions, and a positive lepromin skin test. Intermediate (“borderline”) cases are frequent. Eye involvement (keratitis and iridocyclitis), nasal ulcers, epistaxis, anemia, and lymphadenopathy may occur.

B. Laboratory Findings

Laboratory confirmation of leprosy requires the demonstration of acid-fast bacilli in a skin biopsy. Biopsy of skin or of a thickened involved nerve also gives a typical histologic picture. M leprae does not grow in artificial media, but does grow in the foot pads of armadillos.

▶ Differential Diagnosis

The skin lesions of leprosy often resemble those of lupus erythematosus, sarcoidosis, syphilis, erythema nodosum, erythema multiforme, cutaneous tuberculosis, and vitiligo.

▶ Complications

Kidney failure and hepatomegaly from secondary amyloidosis may occur with long-standing disease.

▶ Treatment

Combination therapy is recommended for treatment of all types of leprosy. Single-drug treatment is accompanied by emergence of resistance, and primary resistance to dapsone also occurs. For borderline and lepromatous cases (ie, multibacillary disease), the World Health Organization recommends a triple oral drug regimen of rifampin, 600 mg once a month; dapsone, 100 mg daily; and clofazimine, 300 mg once a month and 50 mg daily for 12 months, although longer courses may be needed for patients with high burden of disease. For indeterminate and tuberculoid leprosy (paucibacillary disease), the recommendation is rifampin, 600 mg once a month, plus dapsone, 100 mg daily for 6 months.

Two reactional states—erythema nodosum leprosum and reversal reactions—may occur as a consequence of therapy. The reversal reaction, typical of borderline lepromatous leprosy, probably results from enhanced host immunity. Skin lesions and nerves become swollen and tender, but systemic manifestations are not seen. Erythema nodosum leprosum, typical of lepromatous leprosy, is a consequence of immune injury from antigen-antibody complex deposition in skin and other tissues; in addition to skin and nerve manifestations, fever and systemic involvement may be seen. Prednisone, 60 mg/day orally, or thalidomide, 300 mg/day orally (in the nonpregnant patient only), is effective for erythema nodosum leprosum. Improvement is expected within a few days after initiating prednisone, and thereafter the dose may be tapered over several weeks to avoid recurrence. Thalidomide is also tapered over several weeks to a 100-mg bedtime dose. Erythema nodosum leprosum is usually confined to the first year of therapy, and prednisone or thalidomide can be discontinued. Thalidomide is ineffective for reversal reactions, and prednisone, 60 mg/day, is indicated. Reversal reactions tend to recur, and the dose of prednisone should be slowly tapered over weeks to months. Therapy for leprosy should not be discontinued during treatment of reactional states.
General Considerations

Lymphogranuloma venereum (LGV) is an acute and chronic sexually transmitted disease caused by *Chlamydia trachomatis* types L1–L3. The disease is acquired during intercourse or through contact with contaminated exudate from active lesions. The incubation period is 5–21 days. After the genital lesion disappears, the infection spreads to lymph channels and lymph nodes of the genital and rectal areas. Inapparent infections and latent disease are not uncommon.

Clinical Findings

A. Symptoms and Signs

In men, the initial vesicular or ulcerative lesion (on the external genitalia) is evanescent and often goes unnoticed. Inguinal buboes appear 1–4 weeks after exposure, are often bilateral, and have a tendency to fuse, soften, and break down to form multiple draining sinuses, with extensive scarring. In women, the genital lymph drainage is to the perirectal glands. Early anorectal manifestations are proctitis with tenesmus and bloody purulent discharge; late manifestations are chronic cicatrizing inflammation of the rectal and perirectal tissue. These changes lead to obstipation and rectal stricture and, occasionally, rectovaginal and perianal fistulas. They are also seen with anal coitus.

B. Laboratory Findings

The complement fixation test may be positive (titers greater than 1:64), but cross-reaction with other chlamydiae occurs. Although a positive reaction may reflect remote infection, high titers usually indicate active disease. Nucleic acid detection tests are sensitive, but not FDA approved for rectal specimens and cannot differentiate LGV from non-LGV strains.

Differential Diagnosis

The early lesion of LGV must be differentiated from the lesions of syphilis, genital herpes, and chancroid; lymph node involvement must be distinguished from that due to tularemia, tuberculosis, plague, neoplasm, or pyogenic infection; and rectal stricture must be distinguished from that due to neoplasm and ulcerative colitis.

Treatment

If diagnostic testing for LGV is not available, patients with a clinical presentation suggestive of LGV should be treated empirically. The antibiotic of choice is doxycycline (contraindicated in pregnancy), 100 mg orally twice daily for 21 days. Erythromycin, 500 mg orally four times a day for 21 days, is also effective. Azithromycin, 1 g orally once weekly for 3 weeks, may also be effective.

Chlamydial Urethritis & Cervicitis

2. Chlamydial Urethritis & Cervicitis

**ESSENTIALS OF DIAGNOSIS**

- *Chlamydia trachomatis*: common cause of urethritis, cervicitis, and postgonococcal urethritis.
- Diagnosis made by nucleic acid amplification of urine or swab specimen.

General Considerations

*C. trachomatis* immunotypes D–K are isolated in about 50% of cases of nongonococcal urethritis and cervicitis. In other cases, *Ureaplasma urealyticum* or *Mycoplasma genitalium* can be grown as a possible etiologic agent. *C. trachomatis* is an important cause of postgonococcal urethritis. Coinfection with gonococci and chlamydiae is common, and postgonococcal (ie, chlamydial) urethritis may persist after successful treatment of the gonococcal component. Occasionally, epididymitis, prostatitis, or proctitis is caused by chlamydial infection. Chlamydiae are a leading cause of infertility in females in the United States.

Clinical Findings

A. Symptoms and Signs

The urethral or cervical discharge due to *C. trachomatis* tends to be less painful, less purulent, and watery compared with gonococcal infection. Women infected with chlamydiae may be asymptomatic or may have symptoms and signs of cervicitis, salpingitis, or pelvic inflammatory disease. Long-term sequelae may include ectopic pregnancy and infertility.

B. Laboratory Findings

A patient with clinical signs and symptoms of urethritis or cervicitis is assumed to have chlamydial infection until proven otherwise. The diagnosis should be confirmed, whenever possible, by the FDA-approved, highly sensitive nucleic acid amplification tests for use with urine or vaginal swabs. A negative nucleic acid amplification test for chlamydia reliably excludes the diagnosis of chlamydial urethritis or cervicitis and therapy need not be administered.

Screening

Active screening for chlamydial infection is recommended in certain settings: pregnant women; all sexually active women 25 years of age and under; older women with risk factors for sexually transmitted diseases; and men with risk factors for sexually transmitted diseases, such as HIV-positive men or men who have sex with men.

Treatment

Recommended regimens are a single oral 1-g dose of azithromycin (preferred and safe in pregnancy), 100 mg of
doxycycline orally for 7 days (contraindicated in pregnancy), or 500 mg of levofloxacin once daily for 7 days (also contraindicated in pregnancy). Presumptively administered therapy still may be indicated for some patients, such as for an individual with gonococcal infection in whom no chlamydial testing was performed or a test other than a nucleic acid amplification test was used to exclude the diagnosis, or an individual for whom a test result is pending but is considered unlikely to follow up, and for sexual contacts of documented cases. As for all patients in whom sexually transmitted diseases are diagnosed, studies for HIV and syphilis should also be performed.

CHLAMYDOPHILA PSITTACI & PSITTACOSIS (Ornithosis)

ESSENTIALS OF DIAGNOSIS

» Fever, chills, and cough; headache common.
» Atypical pneumonia with slightly delayed appearance of signs of pneumonitis.
» Contact with infected bird (psittacine, pigeons, many others) 7–15 days previously.
» Isolation of chlamydiae or rising titer of complement-fixing antibodies.

General Considerations
Psittacosis is acquired from contact with birds (parrots, parakeets, pigeons, chickens, ducks, and many others), which may or may not be ill. The history may be difficult to obtain if the patient acquired infection from an illegally imported bird.

Clinical Findings
The onset is usually rapid, with fever, chills, myalgia, dry cough, and headache. Signs include temperature-pulse dissociation, dullness to percussion, and rales. Pulmonary findings may be absent early. Dyspnea and cyanosis may occur later. Endocarditis, which is culture-negative, may occur. The radiographic findings in typical psittacosis are those of atypical pneumonia, which tends to be interstitial and diffuse in appearance, though consolidation can occur. Psittacosis is indistinguishable from other bacterial or viral pneumonias by radiography.

The organism is rarely isolated from cultures. The diagnosis is usually made serologically; antibodies appear during the second week and can be demonstrated by complement fixation or immunofluorescence. Antibody response may be suppressed by early chemotherapy.

Differential Diagnosis
The illness is indistinguishable from viral, mycoplasmal, or other atypical pneumonias except for the history of contact with birds. Psittacosis is in the differential diagnosis of culture-negative endocarditis.

Treatment
Treatment consists of giving tetracycline, 0.5 g orally every 6 hours or 0.5 g intravenously every 12 hours, for 14–21 days. Erythromycin, 500 mg orally every 6 hours, may be effective as well.

CHLAMYDOPHILA PNEUMONIAE INFECTION

C pneumoniae causes pneumonia and bronchitis. The clinical presentation of pneumonia is that of an atypical pneumonia. The organism accounts for approximately 10% of community-acquired pneumonias, ranking second to mycoplasma as an agent of atypical pneumonia. A putative role in coronary artery disease has not held up to close scientific scrutiny.

Like C psittaci, strains of C pneumoniae are resistant to sulfonamides. Erythromycin or tetracycline, 500 mg orally four times a day for 10–14 days, appears to be effective therapy. Fluoroquinolones, such as levofloxacin (500 mg once daily for 7–14 days) or moxifloxacin (400 mg once daily for 7–14 days), are active in vitro against C pneumoniae and probably are effective. It is unclear if empiric coverage for atypical pathogens in hospitalized patients with community-acquired pneumonia provides a survival benefit or improves clinical outcome.

**SYPHILIS**

**NATURAL HISTORY & PRINCIPLES OF DIAGNOSIS & TREATMENT**

Syphilis is a complex infectious disease caused by *Treponema pallidum*, a spirochete capable of infecting almost any organ or tissue in the body and causing protean clinical manifestations (Table 34–1). Transmission occurs most frequently during sexual contact (including oral sex). The risk of acquiring syphilis after unprotected sex with an individual with infectious syphilis is approximately 30–50%. Rarely, it can also be transmitted through nonsexual contact, blood transfusion, or via the placenta from mother to fetus (congenital syphilis).

The natural history of acquired syphilis is generally divided into two major stages: **early (infectious) syphilis** and **late syphilis**. Infectious syphilis includes primary lesions (chancre and regional lymphadenopathy) appearing during primary syphilis, secondary lesions (commonly involving skin and mucous membranes, occasionally bone, central nervous system [CNS], or liver) appearing during secondary syphilis (when dissemination of *T. pallidum* produces systemic signs), relapsing lesions during early latency, and congenital lesions. The hallmark of these lesions is an abundance of spirochetes; tissue reaction is usually minimal. Late (tertiary) syphilis consists of so-called benign (gummatous) lesions involving skin, bones, and viscera; cardiovascular disease (principally aortitis); and a variety of CNS and ocular syndromes. These forms of syphilis are not contagious. The lesions contain few demonstrable spirochetes, but tissue reactivity (vasculitis, necrosis) is severe and suggestive of hypersensitivity phenomena. Between these stages are symptom-free latent phases. In early latent syphilis, which is defined as the symptom-free interval lasting up to 1 year after initial infection, infectious lesions can recur.

Public health efforts to control syphilis focus on the diagnosis and treatment of early (infectious) cases and their partners.

Most cases of syphilis in the United States continue to occur in men who have sex with men (MSM). Globally, the World Health Organization (WHO) estimates 5.6 million total incident syphilis infections occur annually, with a prevalence of 1% among pregnant women attending antenatal clinics. Preventing congenital syphilis is a major public health goal for the Centers for Disease Control and Prevention (CDC) and WHO.

**COURSE & PROGNOSIS**

The lesions associated with primary and secondary syphilis are self-limiting, even without treatment, and resolve with few or no residua. Ocular and otologic syphilis has been associated with permanent vision and hearing loss. Tertiary and congenital syphilis may be highly destructive and permanently disabling and may lead to death. Many experts now believe that while infection is almost never completely eradicated in the absence of treatment, most infections remain latent without sequelae, and only a small number of latent infections progress to further disease.

**CLINICAL STAGES OF SYPHILIS**

1. **Primary Syphilis**

   **ESSENTIALS OF DIAGNOSIS**

   - Painless ulcer on genitalia, perianal area, rectum, pharynx, tongue, lip, or elsewhere.
   - Fluid expressed from ulcer contains *T. pallidum* by immunofluorescence or darkfield microscopy.
   - Nontender enlargement of regional lymph nodes.
   - Serologic nontreponemal and treponemal tests may be positive.

   **Clinical Findings**

   **A. Symptoms and Signs**

   The typical lesion is the chancre at the site or sites of inoculation, most frequently located on the penis (Figure 34–1), labia, cervix, or anorectal region. Anorectal lesions are especially common among MSM. Chancre also occur...

Note: Central nervous system involvement may occur at any stage.

Occasionally in the oropharynx (lip, tongue, or tonsil) and rarely on the breast or finger or elsewhere. An initial small erosion appears 10–90 days (average, 3–4 weeks) after inoculation then rapidly develops into a painless superficial ulcer with a clean base and firm, indurated margins. This is associated with enlargement of regional lymph nodes, which are rubbery, discrete, and nontender. Healing occurs without treatment, but a scar may form, especially with secondary bacterial infection. Multiple chancres may be present, particularly in HIV-positive patients. Although the “classic” ulcer of syphilis has been described as nontender, nonpurulent, and indurated, only 31% of patients have this triad.

B. Laboratory Findings

1. Microscopic examination—in early (infectious) syphilis, darkfield microscopic examination by a skilled observer of fresh exudate from moist lesions or material aspirated from regional lymph nodes is up to 90% sensitive for diagnosis but is usually only available in select clinics that specialize in sexually transmitted disease.

An immunofluorescent staining technique for demonstrating *T. pallidum* in dried smears of fluid taken from early syphilitic lesions is also performed in only a few laboratories.

*T. pallidum* polymerase chain reaction (PCR) is available as a “home brew” test in select research, referral, and public health laboratories and has the highest yield in primary and secondary lesions. Organisms can also be detected in blood, especially in congenital and secondary syphilis cases.

2. Serologic tests for syphilis—(Table 34–2) Serologic tests (the mainstay of syphilis diagnosis) fall into two general categories: (1) Nontreponemal tests detect antibodies to lipoidal antigens present in the host after modification of untreated cases.

CIA, chemiluminescence assay; EIA, enzyme immunoassay; FTA-ABS, fluorescent treponemal antibody absorption assay; MHA-TP, microhemagglutination assay for *T. pallidum*; RPR, rapid plasma reagin test; TPPA, *T. pallidum* particle agglutination; VDRL, Venereal Disease Research Laboratory test.
by *T. pallidum*. (2) Treponemal tests use live or killed *T. pallidum* as antigen to detect antibodies specific for pathogenic treponemes.

### A. Nontreponemal Antibody Tests

The most commonly used nontreponemal antibody tests are the Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin (RPR) tests, which measure the ability of heated serum to flocculate a suspension of cardiolipin-cholesterol-lecithin. The flocculation tests are inexpensive, rapid, and easy to perform and have therefore been commonly used for routine screening. Quantitative expression of the reactivity of the serum, based on titration of dilutions of serum, is valuable in establishing the diagnosis and in evaluating the efficacy of treatment, since titers usually correlate with disease activity. A different, enzyme immunoassay (EIA)–based screening algorithm is discussed below.

Nontreponemal tests generally become positive 4–6 weeks after infection or 1–3 weeks after the appearance of a primary lesion; they are almost invariably positive in the secondary stage. These tests are nonspecific and may be positive in patients with non–sexually transmitted treponematoses. More important, false-positive serologic reactions are frequently encountered in a wide variety of other conditions, including connective tissue diseases, infectious mononucleosis, malaria, febrile diseases, leprosy, injection drug use, infective endocarditis, old age, hepatitis C viral infection, and pregnancy. False-positive nontreponemal tests are usually of low titer and transient and may be distinguished from true positives by correlating with clinical findings and performing a treponemal specific-antibody test. False-negative results can be seen when very high antibody titers are present (*the prozone phenomenon*). If syphilis is strongly suspected and the nontreponemal test is negative, the laboratory should be instructed to dilute the specimen to detect a positive reaction.

Nontreponemal antibody titers are used to monitor the response to therapy and should decline over time. The rate of decline depends on various factors. In general, persons with repeat infections, higher initial titers, more advanced stages of disease, or those who are HIV-infected at the time of infection have a slower seroconversion rate and are more likely to remain serostable (ie, titers decline but do not become nonreactive). The RPR and VDRL tests are equally reliable, but RPR titers tend to be higher than the VDRL. Thus, when these tests are used to follow disease activity, the same testing method should be used and preferably performed at the same laboratory.

### B. Treponemal Antibody Tests

These tests measure antibodies capable of reacting with *T. pallidum* antigens. Traditionally, they have been used to confirm a diagnosis following a positive nontreponemal test. The *T. pallidum* particle agglutination (TPPA) test has been one of the most commonly used treponemal tests, along with the fluorescent treponemal antibody absorption test (FTA-ABS). Newer treponemal tests used in reverse screening algorithms include the EIA and chemiluminescence assay (CIA).

In the traditional screening algorithm, the treponemal tests are used to confirm a positive nontreponemal test. Because of their sensitivity, particularly in the late stages of the disease, treponemal tests are also of value when there is clinical evidence of syphilis, but the nontreponemal serologic test for syphilis is negative. Treponemal tests are reactive in many patients with primary syphilis and in almost all patients with secondary syphilis (Table 34–2). Although a reactive treponemal-specific serologic test remains reactive throughout a patient’s life in most cases, it may (like nontreponemal antibody tests) revert to negative with adequate therapy. Final decisions about the significance of the results of serologic tests for syphilis must be based on a total clinical appraisal and may require expert consultation.

### C. Enzyme Immunoassay (EIA)-or Chemiluminescence Immunoassay (CIA)-Based Screening Algorithms

Newer screening algorithms reverse the traditional test order and begin with an automated treponemal antibody test (eg, EIA or CIA) and then follow up with a nontreponemal test (RPR or VDRL) if the treponemal test is positive. This algorithm is faster and decreases labor costs to laboratories when compared with traditional screening.

The reverse algorithms can cause challenges in clinical management. A positive treponemal test with a negative RPR or VDRL may represent prior, treated syphilis; untreated latent syphilis; or a false-positive treponemal test. Such results should be evaluated with a second treponemal test as a "tie-breaker," but interpretation of discordant results is not yet fully standardized and a clinician may benefit from an expert opinion. Reverse algorithms are recommended by several international organizations including the International Union against Sexually Transmitted Infections (IUSTI), but the CDC still recommends the traditional algorithm.

### D. Rapid Treponemal Tests

A single rapid point of care treponemal test is approved for use in the United States, including in outreach and other nonlaboratory settings. Other tests are available internationally and are commonly used in limited-resource settings. Sensitivity ranges from 62% to 100% and specificity from 83% to 95%.

### 3. Polymerase Chain Reaction

In the United States, there is no FDA-cleared PCR test or method for *T. pallidum* PCR, but it is available as a laboratory developed test in select research, referral, and public health laboratories and has the highest yield in primary and secondary lesions. There are no standards for these tests, but PCR has many advantages as a tool for direct detection, including high sensitivity and ability to use a wide range of clinical specimen types, including cerebrospinal fluid. PCR testing of blood has low sensitivity and is not recommended.

### 4. Cerebrospinal Fluid Examination

See Neurosyphilis section.

#### Differential Diagnosis

The syphilitic chancre may be confused with genital herpes, chancroid (usually painful and uncommon in the United States), lymphogranuloma venereum, or neoplasm. Any genital ulcer should be considered a possible primary syphilitic lesion. Simultaneous evaluation for herpes simplex virus types 1 and 2 using PCR or culture should also be done in these cases.
Prevention & Screening
Avoidance of sexual contact is the only completely reliable method of prevention but is an impractical public health measure. Latex or polyurethane condoms are effective but protect covered areas only. Men who have sex with men should be screened every 6–12 months, and as often as every 3 months in high-risk individuals (those who have multiple encounters with anonymous partners or who have sex in conjunction with the use of drugs). Pregnant women should be screened at the first prenatal visit and possibly again in the third trimester and at delivery if there are risk indicators, including poverty, sex work, illicit drug use, history of other sexually transmitted diseases, and residence in a community with high syphilis morbidity. Patients treated for other sexually transmitted diseases should also be tested for syphilis, and persons who have known or suspected sexual contact with patients who have syphilis should be evaluated and presumptively treated to abort development of infectious syphilis (see Treating Syphilis Contacts below).

Treatment

A. Antibiotic Therapy
Penicillin remains the preferred treatment for syphilis, since there have been no documented cases of penicillin-resistant *T. pallidum* (Table 34–3). In pregnant women, penicillin is the only option that reliably treats the fetus (see below).

</tbody>
</table>

¹Penicillin is the only documented effective treatment in pregnancy, so pregnant patients with true allergy should be desensitized and treated with penicillin according to stage of disease as above.

²Patients treated with alternative therapies require close clinical and serologic monitoring.

³Fewer data for ceftriaxone treatment; optimal dose or duration not known.

There are some alternatives to penicillin for nonpregnant patients, including doxycycline. There are also limited data for ceftriaxone, although optimum dose and duration are not well defined. Azithromycin has been shown to be effective in some parts of the world but should be used with caution; it should not be used at all in MSM due to demonstrated resistance. All patients treated with a non-penicillin regimen must have particularly close clinical and serologic follow-up.

B. Managing Jarisch–Herxheimer Reaction
The Jarisch–Herxheimer reaction, manifested by fever and aggravation of the existing clinical picture in the hours following treatment, is not an IgE-mediated immunologic reaction. It is most common in early syphilis, particularly secondary syphilis where it can occur in 66% of cases.

The reaction may be blunted by simultaneous administration of antipyretics, although no proven method of prevention exists. In cases with increased risk of morbidity due to the Jarisch–Herxheimer reaction (including CNS or cardiac involvement and pregnancy), consultation with an infectious disease expert is recommended. Patients should be reminded that the reaction does not signify an allergy to penicillin.

C. Local Measures (Mucocutaneous Lesions)
Local treatment is usually not necessary. No local antiseptics or topical antibiotics should be applied to a suspected syphilitic lesion until specimens for microscopy have been obtained.
D. Public Health Measures

Counsel patients with infectious syphilis to abstain from sexual activity for 7–10 days after treatment. All cases of syphilis must be reported to the appropriate local public health agency in order to identify and treat sexual contacts. In addition, all patients with syphilis who are not known to be HIV-infected should have an HIV test at the time of diagnosis. In areas of high HIV prevalence, a repeat HIV test should be performed in 3 months if the initial test result was negative.

E. Treating Syphilis Contacts

Patients who have been sexually exposed to infectious syphilis within the preceding 3 months may be infected but seronegative and thus should be treated as for early syphilis even if serologic tests are negative. Persons exposed more than 3 months previously should be treated based on serologic results; however, if the patient is unreliable for follow-up, empiric therapy is indicated.

Follow-Up Care

Because treatment failures and reinfection may occur, patients treated for syphilis should be monitored clinically and serologically with nontreponemal titers every 3–6 months. In primary and secondary syphilis, titers had been expected to decrease fourfold by 12 months; however, up to 20% of patients may fail to decrease. Optimal management of these patients is unclear, but at a minimum, close clinical and serologic follow-up is indicated. In HIV-uninfected patients, an HIV test should be repeated (all patients with syphilis should have an HIV test at the time of diagnosis); a thorough neurologic history and examination should be performed and lumbar puncture considered since unrecognized neurosyphilis can be a cause of treatment failure. If symptoms or signs persist or recur after initial therapy or there is a fourfold or greater increase in nontreponemal titers, the patient has been reinfected (more likely) or the therapy failed (if a non-penicillin regimen was used). In those individuals, an HIV test should be performed, a lumbar puncture done (unless reinfection is a certainty), and re-treatment given as indicated above.

2. Secondary Syphilis

ESSENTIALS OF DIAGNOSIS

- Generalized maculopapular skin rash.
- Mucous membrane lesions.
- Condyloma lata in moist skin areas.
- Generalized nontender lymphadenopathy.
- Fever may be present.
- Meningitis, hepatitis, osteitis, arthritis, iritis.
- Many treponemes in moist lesions by immunofluorescence or darkfield microscopy.
- Positive serologic tests for syphilis.

Clinical Findings

The secondary stage of syphilis usually appears a few weeks (or up to 6 months) after development of the chancre, when dissemination of *T pallidum* produces systemic signs (fever, lymphadenopathy) or infectious lesions at sites distant from the site of inoculation. The most common manifestations are skin and mucosal lesions. The skin lesions are nonpruritic, macular, papular, pustular, or follicular (or combinations of any of these types, but generally not vesicular) and generalized; involvement of the palms and soles (Figure 34–2) occurs in 80% of cases. Mucous membrane lesions may include mucous patches (Figure 34–3), which can be found on the lips, mouth, throat, genitalia, and anus. Specific lesions—condylomata lata (Figure 34–4)—are fused, weeping papules on the moist areas of the skin and mucous membranes and are sometimes mistaken for genital warts. Unlike the dry skin rashes, the mucous membrane lesions are highly infectious.

Meningeal (aseptic meningitis or acute basilar meningitis), hepatic, renal, bone, and joint invasion may occur, with resulting cranial nerve palsies, jaundice,
nephrotic syndrome, and periostitis. Alopecia (moth-eaten appearance) and uveitis may also occur.

The serologic tests for syphilis are positive in almost all cases (see Primary Syphilis and Table 34–2). The moist cutaneous and mucous membrane lesions often show *T. pallidum* on darkfield microscopic examination. A transient cerebrospinal fluid (CSF) pleocytosis is seen in 40% of patients with secondary syphilis. There may be evidence of hepatitis or nephritis (immune complex type) as circulating immune complexes are deposited in blood vessel walls.

Skin lesions may be confused with the infectious exanthems, pityriasis rosea, and drug eruptions. Visceral lesions may suggest nephritis or hepatitis due to other causes.

**Treatment**

Treatment is as for primary syphilis unless CNS or ocular disease or neurologic signs or symptoms are present, in which case a lumbar puncture should be performed and, if positive, treatment for neurosyphilis given (Table 34–3). See Primary Syphilis for follow-up care and treatment of contacts.

**3. Latent Syphilis**

**ESSENTIALS OF DIAGNOSIS**

- **Early latent syphilis**: infection less than 1 year.
- **Late latent syphilis**: infection more than 1 year.
- No physical signs.
- History of syphilis with inadequate treatment.
- Positive serologic tests for syphilis.

**General Considerations**

Latent syphilis is the clinically quiescent phase in the absence of primary or secondary lesions; the diagnosis is made by positive serologic tests. **Early latent syphilis** is defined as the first year after primary infection and may relapse to secondary syphilis if undiagnosed or inadequately treated. Relapse is almost always accompanied by a rising titer in quantitative serologic tests; indeed, a rising titer may be the first or only evidence of relapse. About 90% of relapses occur during the first year after infection.

Early latent infection can be diagnosed if there was documented seroconversion or a fourfold increase in nontreponemal titers in the past 12 months; the patient can recall symptoms of primary or secondary syphilis; or the patient had a sex partner with documented primary, secondary, or early latent syphilis.

After the first year of latent syphilis, the patient is said to be in the **late latent stage** and noninfectious to sex partners. Transmission to the fetus, however, is possible in any phase. A diagnosis of late latent syphilis is justified only when the history and physical examination show no evidence of tertiary disease or neurosyphilis. The latent stage may last from months to a lifetime.

**Treatment**

Treatment of early latent syphilis and follow-up are the same as for primary syphilis unless CNS disease is present (Table 34–3). Treatment of late latent syphilis is also shown in Table 34–3. The treatment of this stage of the disease is intended to prevent late sequelae. If there is evidence of CNS involvement, a lumbar puncture should be performed and, if positive, the patient should receive treatment for neurosyphilis. Titers may not decline as rapidly following treatment compared to early syphilis. Nontreponemal serologic tests should be repeated at 6, 12, and 24 months. If titers increase fourfold or if initially high titers (1:32 or higher) fail to decrease fourfold by 12–24 months or if symptoms or signs consistent with syphilis develop, an HIV test should be repeated in HIV-uninfected patients, lumbar puncture should be performed, and re-treatment given according to the stage of the disease.
4. Tertiary (Late) Syphilis

**ESSENTIALS OF DIAGNOSIS**
- Infiltrative tumors of skin, bones, liver (gummas).
- Aortitis, aneurysms, aortic regurgitation.
- CNS disorders: meningo-vascular and degenerative changes, paresthesias, shooting pains, abnormal reflexes, dementia, or psychosis.

**General Considerations**
This stage may occur at any time after secondary syphilis, even after years of latency, and is rarely seen in developed countries in the modern antibiotic era. Late lesions are thought to represent a delayed hypersensitivity reaction of the tissue to the organism and are usually divided into two types: (1) a localized gummatous reaction with a relatively rapid onset and generally prompt response to therapy and (2) diffuse inflammation of a more insidious onset that characteristically involves the CNS and large arteries, may not improve despite treatment, and is often fatal if untreated. Gummas may involve any area or organ of the body but most often affect the skin or long bones. Cardiovascular disease is usually manifested by aortic aneurysm, aortic regurgitation, or aortitis. Various forms of diffuse or localized CNS involvement may occur.

Late syphilis must be differentiated from neoplasms of the skin, liver, lung, stomach, or brain; other forms of meningitis; and primary neurologic lesions.

Although almost any tissue and organ may be involved in late syphilis, the following are the most common types of involvement: skin, mucous membranes, skeletal system, eyes, respiratory system, gastrointestinal system, cardiovascular system, and nervous system.

**Clinical Findings**

A. Symptoms and Signs

1. **Skin**—Cutaneous lesions of late syphilis are of two varieties: (1) multiple nodular lesions that eventually ulcerate (lues maligna) or resolve by forming atrophic, pigmented scars and (2) solitary gummas that start as painless subcutaneous nodules, then enlarge, attach to the overlying skin, and eventually ulcerate (Figure 34–5).

2. **Mucous membranes**—Late lesions of the mucous membranes are nodular gummas or leukoplakia, highly destructive to the involved tissue.

3. **Skeletal system**—Bone lesions are destructive, causing periostitis, osteitis, and arthritis with little or no associated redness or swelling but often marked myalgia and myositis of the neighboring muscles.

4. **Eyes**—Late ocular lesions are gummatous iritis, chorioretinitis, optic atrophy, and cranial nerve palsies, in addition to the lesions of CNS syphilis.

B. **Respiratory system**—Respiratory involvement is caused by gummatous infiltrates into the larynx, trachea, and pulmonary parenchyma, producing discrete pulmonary densities. There may be hoarseness, respiratory distress, and wheezing secondary to the gummatous lesion itself or to subsequent stenosis occurring with healing.

C. **Gastrointestinal system**—Gummas involving the liver may be benign but can cause cirrhosis. Gastric involvement can consist of diffuse infiltration into the stomach wall or focal lesions that endoscopically and microscopically can be confused with lymphoma or carcinoma. Epigastric pain, early satiety, regurgitation, belching, and weight loss are common symptoms.

D. **Cardiovascular system**—Cardiovascular lesions (10–15% of tertiary syphilitic lesions) are often progressive, disabling, and life-threatening. CNS lesions are often present concomitantly. Involvement usually starts as an arteritis in the supracardiac portion of the aorta and progresses to one or more of the following: (1) narrowing of the coronary ostia, with resulting decreased coronary circulation, angina, and acute myocardial infarction; (2) scarring of the aortic valves, producing aortic regurgitation, and eventually heart failure; and (3) weakness of the wall of the aorta, with saccular aneurysm formation (Figure 34–6) and associated pressure symptoms of dysphagia, hoarseness, brassy cough, back pain (vertebral erosion), and occasionally rupture of the aneurysm. Recurrent respiratory infections are common as a result of pressure on the trachea and bronchi.

E. **Nervous system (neurosyphilis)**—See next section.

**Treatment**
Treatment of tertiary syphilis (excluding neurosyphilis) is the same as late latent syphilis (Table 34–3); symptoms may not resolve after treatment. Positive serologic tests do not usually become negative.

The pretreatment clinical and laboratory evaluation should include neurologic, ocular, cardiovascular, psychiatric,
and CSF examinations. In the presence of definite CSF or neurologic abnormalities, one should treat for neurosyphilis.

5. Neurosyphilis

**ESSENTIALS OF DIAGNOSIS**

- Can occur at any stage of disease.
- Consider both clinical presentation and laboratory data.
- Carefully evaluate the neurologic examination in all patients and consider CSF evaluation for atypical symptoms or lack of decrease in nontreponemal serology titers.

**General Considerations**

Neurosyphilis can occur at any stage of disease and can be a progressive, disabling, and life-threatening complication. Asymptomatic CSF abnormalities and meningovascular syphilis occur earlier (months to years after infection, sometimes coexisting with primary and secondary syphilis) than tabes dorsalis and general paresis (2–50 years after infection).

**Clinical Findings**

A. Classification

1. Asymptomatic neuroinvasion—This form has been reported in up to 40% of patients with early syphilis and is characterized by spinal fluid abnormalities (positive spinal fluid serology, increased cell count, occasionally increased protein) without symptoms or signs of neurologic involvement. There are no clear data to support that these asymptomatic CSF abnormalities have clinical significance; therefore, unless treatment failure is suspected, routine CSF evaluation of asymptomatic patients is not recommended.

2. Meningovascular syphilis—This form is characterized by meningeal involvement or changes in the vascular structures of the brain (or both), producing symptoms of acute or chronic meningitis (headache, irritability); cranial nerve palsies (basilar meningitis); unequal reflexes; irregular pupils with poor light and accommodation reflexes; and when large vessels are involved, cerebrovascular accidents. The CSF shows increased cells (100–1000/mcL) and elevated protein, and may have a positive serologic test (CSF VDRL) for syphilis. The symptoms of acute meningitis are rare in late syphilis.

3. Tabes dorsalis—This is a chronic progressive degeneration of the parenchyma of the posterior columns of the spinal cord and of the posterior sensory ganglia and nerve roots. The symptoms and signs are impairment of proprioception and vibration sense, Argyll Robertson pupils (which react poorly to light but accommodate for near focus), and muscular hypotonia and hyporeflexia. Impaired proprioception results in a wide-based gait and inability to walk in the dark. Paresthesias, analgesia, or sharp recurrent pains in the muscles of the leg (“shooting” or “lightning” pains) may occur. Joint damage may occur as a result of lack of sensory innervation (Charcot joint, Figure 34–7). The CSF may have a normal or increased cell count, elevated protein, and variable results of serologic tests.

4. General paresis—This is generalized involvement of the cerebral cortex with insidious onset of symptoms. There is usually a decrease in concentrating power, memory loss, dysarthria, tremor of the fingers and lips, irritability, and mild headaches. Most striking is the change of personality; the patient may become slovenly, irresponsible, confused, and psychotic. The CSF findings resemble those of tabes dorsalis. Combinations of the various forms of neurosyphilis (especially tabes and paresis) are not uncommon.

B. Laboratory Findings

See Serologic Tests for Syphilis, above; these tests should also be performed in cases of suspected neurosyphilis.

1. Indications for a lumbar puncture—in early syphilis (primary and secondary syphilis and early latent syphilis of...
less than 1 year’s duration), invasion of the CNS by *T pallidum* with CSF abnormalities occurs commonly, but clinical neurosyphilis rarely develops in patients who have received standard therapy. Thus, unless clinical symptoms or signs of neurosyphilis or ocular involvement (uveitis, neuroretinitis, optic neuritis, iritis) are present, a lumbar puncture is not routinely recommended. CSF evaluation is recommended, however, if neurologic or ophthalmologic symptoms or signs are present, if there is evidence of treatment failure (see earlier discussion), or if there is evidence of active tertiary syphilis (eg, aortitis, iritis, optic atrophy, the presence of a gumma).

2. Spinal fluid examination—CSF findings in neurosyphilis are variable. In “classic” cases, there is an elevation of total protein, lymphocytic pleocytosis, and a positive CSF reagin test. VDRL is more sensitive and preferred over RPR. The serum nontreponemal titers will be reactive in most cases. In later stages of syphilis, normal CSF analysis in the presence of infection can occur, but it is unusual. Because the CSF VDRL may be negative in 30–70% of cases of neurosyphilis, a negative test does not exclude neurosyphilis, while a positive test confirms the diagnosis. The CSF FTA-ABS is sometimes used; it is a highly sensitive test but lacks specificity, and a high serum titer of FTA-ABS may result in a positive CSF titer in the absence of neurosyphilis.

Treatment

Neurosyphilis is treated with high doses of aqueous penicillin to achieve better penetration and higher levels of medication in the CSF than is possible with benzathine penicillin G (Table 34–3). There are limited data for using ceftriaxone to treat neurosyphilis as well, but because other regimens have not been adequately studied, patients with a history of an IgE-mediated reaction to penicillin may require skin testing for allergy to penicillin and, if positive, should be desensitized. Because of concerns about slowly dividing organisms that may persist after completing 10–14 days of therapy with short-acting aqueous penicillin G, many experts recommend subsequent administration of 2.4 million units of the longer-acting benzathine penicillin G intramuscularly once weekly for up to 3 weeks at the conclusion of treatment.

All patients treated for neurosyphilis should have nontreponemal serologic tests done every 3–6 months. Guidelines established by the CDC recommend spinal fluid examinations at 6-month intervals until the CSF cell count is normal; however, there are data to suggest that normalization of serum titers are an acceptable surrogate for CSF response. If the serum nontreponemal titers do not normalize, consider repeating the CSF analysis; expert consultation may be helpful in this scenario. A second course of penicillin therapy may be given if the CSF cell count has not decreased at 6 months or is not normal at 2 years.

6. Syphilis in HIV-Infected Patients

Syphilis is common among HIV-infected individuals. Some data suggest that syphilis coinfection is associated with an increase in HIV viral load and a decrease in CD4 count that normalizes with therapy; other studies have not found an association with HIV disease progression. Overall, for optimal patient care as well as prevention of transmission to partners, guidelines for the primary care of HIV-infected patients recommend at least annual syphilis screening.

Interpretation of serologic tests should be the same for HIV-positive and HIV-negative persons. If the diagnosis of syphilis is suggested on clinical grounds but nontreponemal tests are negative, consider the prozone effect caused by very high antibody titers (see nontreponemal tests, above), or try direct examination of primary or secondary lesions for spirochetes.

HIV-positive patients with primary and secondary syphilis should have careful clinical and serologic follow-up at 3-month intervals. The use of antiretroviral therapy has been associated with reduced serologic failure rates after syphilis treatment.

The diagnosis of neurosyphilis in HIV-infected patients is complicated by the fact that mild CSF abnormalities may be found in HIV infection alone. Like in HIV-uninfected patients, routine lumbar puncture is not recommended in asymptomatic patients; it should be reserved for cases in which neurologic symptoms or signs are present or there is concern for treatment failure. Following treatment, CSF white blood cell counts should normalize within 12 months regardless of HIV status, while the CSF VDRL may take longer. As discussed above, the same criteria for failure apply to HIV-positive and HIV-negative patients, and re-treatment regimens are the same. Treatment in HIV-infected and HIV-uninfected patients does not differ; there is no evidence to support prolonged or enhanced treatment regimens due to HIV coinfection.

Most clinical experience in treating HIV-infected patients with syphilis is based on penicillin regimens; fewer data exist for treating the penicillin-allergic patient. Doxycycline or tetracycline regimens can be used for primary, secondary, and early latent syphilis as well as for late latent syphilis and latent syphilis of unknown duration though with caution and close follow-up (Table 34–3). For neurosyphilis, limited efficacy data exist for ceftriaxone; close clinical and serologic follow-up after treatment is essential.

7. Syphilis in Pregnancy

All pregnant women should have a nontreponemal serologic test for syphilis at the time of the first prenatal visit (see Chapter 19). In women who may be at increased risk for syphilis or for populations in which there is a high prevalence of syphilis, additional nontreponemal tests should be performed during the third trimester at 28 weeks and again at delivery. The serologic status of all women who have delivered should be known before discharge from the hospital. Seropositive women should be considered infected and should be treated unless prior treatment with fall in antibody titer is medically documented.

The only recommended treatment for syphilis in pregnancy is penicillin in dosage schedules appropriate for the stage of disease. Penicillin prevents

By very high antibody titers (see nontreponemal tests, above), or try direct examination of primary or secondary lesions for spirochetes.

HIV-positive patients with primary and secondary syphilis should have careful clinical and serologic follow-up at 3-month intervals. The use of antiretroviral therapy has been associated with reduced serologic failure rates after syphilis treatment.

The diagnosis of neurosyphilis in HIV-infected patients is complicated by the fact that mild CSF abnormalities may be found in HIV infection alone. Like in HIV-uninfected patients, routine lumbar puncture is not recommended in asymptomatic patients; it should be reserved for cases in which neurologic symptoms or signs are present or there is concern for treatment failure. Following treatment, CSF white blood cell counts should normalize within 12 months regardless of HIV status, while the CSF VDRL may take longer. As discussed above, the same criteria for failure apply to HIV-positive and HIV-negative patients, and re-treatment regimens are the same. Treatment in HIV-infected and HIV-uninfected patients does not differ; there is no evidence to support prolonged or enhanced treatment regimens due to HIV coinfection.

Most clinical experience in treating HIV-infected patients with syphilis is based on penicillin regimens; fewer data exist for treating the penicillin-allergic patient. Doxycycline or tetracycline regimens can be used for primary, secondary, and early latent syphilis as well as for late latent syphilis and latent syphilis of unknown duration though with caution and close follow-up (Table 34–3). For neurosyphilis, limited efficacy data exist for ceftriaxone; close clinical and serologic follow-up after treatment is essential.

7. Syphilis in Pregnancy

All pregnant women should have a nontreponemal serologic test for syphilis at the time of the first prenatal visit (see Chapter 19). In women who may be at increased risk for syphilis or for populations in which there is a high prevalence of syphilis, additional nontreponemal tests should be performed during the third trimester at 28 weeks and again at delivery. The serologic status of all women who have delivered should be known before discharge from the hospital. Seropositive women should be considered infected and should be treated unless prior treatment with fall in antibody titer is medically documented.

The only recommended treatment for syphilis in pregnancy is penicillin in dosage schedules appropriate for the stage of disease. Penicillin prevents

By very high antibody titers (see nontreponemal tests, above), or try direct examination of primary or secondary lesions for spirochetes.

HIV-positive patients with primary and secondary syphilis should have careful clinical and serologic follow-up at 3-month intervals. The use of antiretroviral therapy has been associated with reduced serologic failure rates after syphilis treatment.

The diagnosis of neurosyphilis in HIV-infected patients is complicated by the fact that mild CSF abnormalities may be found in HIV infection alone. Like in HIV-uninfected patients, routine lumbar puncture is not recommended in asymptomatic patients; it should be reserved for cases in which neurologic symptoms or signs are present or there is concern for treatment failure. Following treatment, CSF white blood cell counts should normalize within 12 months regardless of HIV status, while the CSF VDRL may take longer. As discussed above, the same criteria for failure apply to HIV-positive and HIV-negative patients, and re-treatment regimens are the same. Treatment in HIV-infected and HIV-uninfected patients does not differ; there is no evidence to support prolonged or enhanced treatment regimens due to HIV coinfection.

Most clinical experience in treating HIV-infected patients with syphilis is based on penicillin regimens; fewer data exist for treating the penicillin-allergic patient. Doxycycline or tetracycline regimens can be used for primary, secondary, and early latent syphilis as well as for late latent syphilis and latent syphilis of unknown duration though with caution and close follow-up (Table 34–3). For neurosyphilis, limited efficacy data exist for ceftriaxone; close clinical and serologic follow-up after treatment is essential.

7. Syphilis in Pregnancy

All pregnant women should have a nontreponemal serologic test for syphilis at the time of the first prenatal visit (see Chapter 19). In women who may be at increased risk for syphilis or for populations in which there is a high prevalence of syphilis, additional nontreponemal tests should be performed during the third trimester at 28 weeks and again at delivery. The serologic status of all women who have delivered should be known before discharge from the hospital. Seropositive women should be considered infected and should be treated unless prior treatment with fall in antibody titer is medically documented.

The only recommended treatment for syphilis in pregnancy is penicillin in dosage schedules appropriate for the stage of disease. Penicillin prevents
congenital syphilis in 90% of cases, even when treatment is given late in pregnancy. Women with a history of penicillin allergy should be skin tested and desensitized if necessary. Tetracycline and doxycycline are contraindicated in pregnancy.

The infant should be evaluated immediately at birth, and, depending on the likelihood of infection, monitored for clinical and serologic manifestations in the first year of life.

**When to Refer**

- Consultation with the local public health department may help obtain all prior positive syphilis serologic results and may be helpful in complicated or atypical cases.
- Early (infectious) syphilis cases may be contacted for partner notification and treatment by local public health authorities.

**When to Admit**

- Pregnant women with syphilis and true penicillin allergy should be admitted for desensitization and treatment.
- Women in late pregnancy treated for early syphilis should have close outpatient monitoring or be admitted because the Jarisch–Herxheimer reaction can induce premature labor.
- Patients with neurosyphilis usually require admission for treatment with aqueous penicillin.

**YAWS (Frambesia)**

Yaws is a contagious disease largely limited to tropical regions that is caused by *T pallidum* subspecies *pertenue*. It is characterized by granulomatous lesions of the skin, mucous membranes, and bone. Yaws is rarely fatal, though if untreated it may lead to chronic disability and disfigurement. Yaws is acquired by direct nonsexual contact, usually in childhood, although it may occur at any age. The “mother yaw,” a painless papule that later ulcerates, appears 3–4 weeks after exposure. There is usually associated regional lymphadenopathy. Six to 12 weeks later, secondary lesions occur, which are raised papillomas and papules that weep highly infectious material and last for several months or years. Painful ulcerated lesions on the soles are called “crab yaws” because of the resulting gait. Late gummatous lesions may occur, with associated tissue destruction involving large areas of skin and subcutaneous tissues. The late effects of yaws, with bone change, shortening of digits, and contractions, may be confused with similar changes occurring in leprosy. CNS, cardiac, or other visceral involvement is rare. See above for therapy. The World Health Organization has set a goal of eliminating yaws by the year 2020 using mass treatment with azithromycin.

**PINTA**

Pinta is a non–sexually transmitted spirochetal infection caused by *T pallidum* subspecies *carateum*. It occurs endemically in rural areas of Latin America, especially in Mexico, Colombia, and Cuba, and in some areas of the Pacific. A nonulcerative, erythematous primary papule spreads slowly into a papulosquamous plaque showing a variety of color changes (slate, lilac, black). Secondary lesions resemble the primary one and appear within a year after it. These appear successively, new lesions together with older ones; are most common on the extremities; and later show atrophy and depigmentation. Some cases show pigmentary changes and atrophic patches on the soles and palms, with or without hyperkeratosis, that are indistinguishable from “crab yaws.” See above for therapy.

**ENDEMIC SYPHILIS (Bejel)**

Endemic syphilis is an acute or chronic infection caused by *T pallidum* subspecies *endemicum*. It has been reported in a number of countries, particularly in the eastern Mediterranean area, often with local names: bejel in Syria, Saudi Arabia, and Iraq, and dichuchwa, njoverya, and siti in Africa. It also occurs in Southeast Asia. The local forms have distinctive features. Moist ulcerated lesions of the skin or oral or nasopharyngeal mucosa are the most common manifestations. Generalized lymphadenopathy and secondary and tertiary bone and skin lesions are also common. Deep leg pain points to periostitis or osteomyelitis. In the late stages of disease, destructive gummatous lesions...
similar to those seen in yaws can develop, resulting in loss of cartilage and saber shin deformity. Cardiovascular and CNS involvement are rare. See above for therapy.

SELECTED SPIROCHETAL DISEASES

RELAPSING FEVER

The infectious organisms in relapsing fever are spirochetes of the genus *Borrelia*. The infection has two forms: tick-borne and louse-borne. The main reservoir for tick-borne relapsing fever is rodents, which serve as the source of infection for ticks. Tick-borne relapsing fever may be transmitted transovarially from one generation of ticks to the next. Humans can be infected by tick bites or by rubbing crushed tick tissues or feces into the bite wound. Tick-borne relapsing fever is endemic, but is not transmitted from person to person. In the United States, infected ticks are found throughout the West, especially in mountainous areas, but clinical cases are uncommon in humans.

The louse-borne form is primarily seen in the developing world, and humans are the only reservoir. Large epidemics may occur in louse-infested populations, and transmission is favored by crowding, malnutrition, and cold climate.

Clinical Findings

A. Symptoms and Signs

There is an abrupt onset of fever, chills, tachycardia, nausea and vomiting, arthralgia, and severe headache. Hepatomegaly and splenomegaly may develop, as well as various types of rashes (macular, papular, petechial) that usually occur at the end of a febrile episode. Delirium occurs with high fever, and there may be various neurologic and psychological abnormalities. The attack terminates, usually abruptly, after 3–10 days. After an interval of 1–2 weeks, relapse occurs, but often it is somewhat milder. Three to ten relapses may occur before recovery in tick-borne disease, whereas louse-borne disease is associated with only one or two relapses.

B. Laboratory Findings

During episodes of fever, large spirochetes are seen in thick and thin blood smears stained with Wright or Giemsa stain. The organisms can be cultured in special media but rapidly lose pathogenicity. The spirochetes can multiply in injected rats or mice and can be seen in their blood.

A variety of anti-*Borrelia* antibodies develop during the illness; sometimes the Weil–Felix test for rickettsioses and nontreponemal serologic tests for syphilis may also be falsely positive. Infection can cause false-positive indirect fluorescent antibody and Western blot tests for *Borrelia burgdorferi*, causing some cases to be misdiagnosed as Lyme disease. PCR assays have been developed but are not widely available.

CSF abnormalities occur in patients with meningeal involvement. Mild anemia and thrombocytopenia are common, but the white blood cell count tends to be normal.

Differential Diagnosis

The manifestations of relapsing fever may be confused with malaria, leptospirosis, meningococcemia, yellow fever, typhus, or rat-bite fever.

Prevention

Prevention of tick bites (as described for rickettsial diseases) and delousing procedures applicable to large groups can prevent illness. Arthropod vectors should be controlled if possible.

Postexposure prophylaxis with doxycycline 200 mg orally on day 1 and 100 mg daily for 4 days has been shown to prevent recurrent fever following tick bites in highly endemic areas.

Treatment

A single dose of tetracycline or erythromycin, 0.5 g orally, or a single dose of procaine penicillin G, 600,000–800,000 units intramuscularly (adults) or 400,000 units intramuscularly (children), probably constitutes adequate treatment for louse-borne relapsing fevers; however, some experts advocate for longer courses of treatment to prevent persistent infection. In severe cases of tick-borne disease, treatment begins with penicillin G, 3 million units intravenously every 4 hours, or ceftriaxone, 1 g intravenously daily; with clinical improvement, a 10-day course can be completed with 0.5 g of tetracycline or erythromycin given orally four times daily. If CNS invasion is suspected, intravenous penicillin G or ceftriaxone should be continued for 10–14 days. Jarisch–Herxheimer reactions occur commonly following treatment and may be life-threatening, so patients should be closely monitored (see Syphilis, above). One study in patients with louse-borne relapsing fever showed that administration of anti-TNF antibodies prior to antibiotic therapy can be effective in preventing the reaction.

Prognosis

The overall mortality rate is usually about 5%. Fatalities are most common in older, debilitated, or very young patients. With treatment, the initial attack is shortened and relapses are largely prevented.

RAT-BITE FEVER

Rat-bite fever is an uncommon acute infectious disease caused by the treponeme *Spirillum minus* (Asia), or the bacteria *Streptobacillus moniliformis* (North America). It is transmitted to humans by the bite of a rat. Inhabitants of rat-infested dwellings, owners of pet rats, and laboratory workers are at greatest risk.
Clinical Findings

A. Symptoms and Signs

In *Spirillum* infections, the original rat bite, unless secondarily infected, heals promptly, but 1 to several weeks later the site becomes swollen, indurated, and painful; assumes a dusky purplish hue; and may ulcerate. Regional lymphangitis and lymphadenitis, fever, chills, malaise, myalgia, arthralgia, and headache are present. Splenomegaly may occur. A sparse, dusky-red maculopapular rash appears on the trunk and extremities in many cases, and there may be frank arthritis.

After a few days, both the local and systemic symptoms subside, only to reappear several days later. This relapsing pattern of fever for 3–4 days alternating with afebrile periods lasting 3–9 days may persist for weeks. The other features, however, usually recur only during the first few relapses. Endocarditis is a rare complication of infection.

B. Laboratory Findings

Leukocytosis is often present, and the nontreponemal test for syphilis is often falsely positive. The organism may be identified in darkfield examination of the ulcer exudate or aspirated lymph node material; more commonly, it is observed after inoculation of a laboratory animal with the patient’s exudate or blood. It has not been cultured in artificial media.

Differential Diagnosis

Rat-bite fever must be distinguished from the rat-bite–induced lymphadenitis and rash of streptobacillary fever. Clinically, the severe arthritis and myalgias seen in streptobacillary disease are rarely seen in disease caused by *S minus*. Reliable differentiation requires an increasing titer of agglutinins against *S moniliformis* or isolation of the causative organism. Other diseases in the differential include tularemia, rickettsial disease, *Pasteurella multocida* infections, and relapsing fever.

Treatment

In acute illness, intravenous penicillin, 1–2 million units every 4–6 hours is given initially; ceftriaxone 1 g intravenously daily is another option. Once improvement has occurred, therapy may be switched to oral penicillin V 500 mg four times daily, or amoxicillin 500 mg three times daily, to complete 10–14 days of therapy. For the penicillin-allergic patient, tetracycline 500 mg orally four times daily or doxycycline 100 mg twice a day can be used.

Prognosis

The reported mortality rate of about 10% should be markedly reduced by prompt diagnosis and antimicrobial treatment.

B. Laboratory Findings

The leukocyte count may be normal or as high as 30,000/mcL (0.05/L), with neutrophils predominating. The urine may contain bile, protein, casts, and red cells. Oliguria is common, and in severe cases uremia may occur. Elevated bilirubin and aminotransferases are seen in 75%, and elevated creatinine (greater than 1.5 mg/dL) 132.6 mcmol/L is seen in 50% of cases. Serum creatine kinase is usually elevated in persons with leptospirosis and normal in persons with hepatitis. In cases with meningeal involvement, organisms may be found in the CSF during the first 10 days of illness. Early in the disease, the organism may be identified by darkfield examination of the patient’s blood (a test requiring expertise since false-positives are frequent in inexperienced hands) or by culture on a semisolid medium (eg, Fletcher EMJH). Cultures take 1–6 weeks to become positive but may remain negative if antibiotics were started before culture was obtained. The organism may also be grown from the urine from the tenth day to the sixth week. Diagnosis is usually made by means of serologic tests, including the microscopic agglutination test (considered the gold standard but not widely available), and enzyme-linked immunosorbent assay (ELISA). PCR molecular diagnostics are not widely available but appear to be sensitive, specific, positive early in disease, and able to detect leptospiral DNA in blood, urine, CSF, and aqueous humor.

Complications

Myocarditis, aseptic meningitis, acute kidney injury, and pulmonary infiltrates with hemorrhage are not common in severe cases. Iridocyclitis may occur.

Prevention

The mainstay of prevention is avoidance of potentially contaminated food and water.

Prophylaxis with doxycycline (200 mg orally once a week) has been effective in trials and may be useful if a person is at high risk due to being in an area or season (eg, monsoon flooding) where exposure would be more likely. Human vaccine is used in some limited settings but is not widely available.

Treatment

Many cases are self-limited without specific treatment. Various antimicrobial medications, including penicillin, ceftriaxone, and tetracyclines, show antileptospiral activity; however, meta-analysis has not demonstrated a clear survival benefit for any antibiotic. Doxycycline (100 mg every 12 hours orally or intravenously), penicillin (eg, 1.5 million units every 6 hours intravenously), and ceftriaxone (1 g daily intravenously) are used in severe leptospirosis. Jarisch–Herxheimer reactions may occur (see Syphilis, above). Although therapy for mild disease is controversial, most clinicians treat with doxycycline, 100 mg orally twice daily, for 7 days, or amoxicillin, 50 mg/kg, divided into three doses daily. Azithromycin is also active, but clinical experience is limited.

ESSENTIALS OF DIAGNOSIS

- Erythema migrans: a flat or slightly raised red lesion that expands with central clearing.
- Headache or stiff neck.
- Arthralgias, arthritis, and myalgias; arthritis is often chronic and recurrent.

Prognosis

Without jaundice, the disease is almost never fatal. With jaundice, the mortality rate is 5% for those under age 30 years and 40% for those over age 60 years.

When to Admit

Patients with jaundice or other evidence of severe disease should be admitted for close monitoring and may require admission to an intensive care unit.

LYME DISEASE (Lyme Borreliosis)

This illness, named after the town of Old Lyme, Connecticut, is the most common tick-borne disease in the United States and Europe and is caused by genospecies of the spirochete B burgdorferi. Most US cases are reported from the mid-Atlantic, northeastern, and north central regions of the country. The true incidence of Lyme disease is not known for a number of reasons: (1) serologic tests are not standardized (see below); (2) clinical manifestations are nonspecific; and (3) even with reliable testing, serology is insensitive in early disease.

The tick vector of Lyme disease varies geographically and is Ixodes scapularis in the northeastern, north central, and mid-Atlantic regions of the United States; Ixodes pacificus on the West Coast; Ixodes ricinus in Europe; and Ixodes persulcatus in Asia. The disease also occurs in Australia. Mice and deer make up the major animal reservoir of B burgdorferi, but other rodents and birds may also be infected. Domestic animals such as dogs, cattle, and horses can also develop clinical illness, usually manifested as arthritis.

Under experimental conditions, ticks must feed for 24–36 hours or longer to transmit infections. Most cases are reported in the spring and summer months. In addition, the percentage of ticks infected varies on a regional basis. In the northeastern and midwestern United States, 15–65% of I scapularis ticks are infected with the
spirochete; in the west, only 2% of *I. pacificus* are infected. These are important epidemiologic features in assessing the likelihood that tick exposure will result in disease. Eliciting a history of brushing a tick off the skin (ie, the tick was not feeding) or removing a tick on the same day as exposure (ie, the tick did not feed long enough) decreases the likelihood that infection will develop.

Because the *Ixodes* tick is so small, the bite is usually painless and goes unnoticed. After feeding, the tick drops off in 2–4 days. If a tick is found, it should be removed immediately. The best way to accomplish this is to use fine-tipped tweezers to pull firmly and repeatedly on the tick’s mouth part—not the tick’s body—until the tick releases its hold. Saving the tick in a bottle of alcohol for future identification may be useful, especially if symptoms develop.

### Clinical Findings

Prior clinical description of Lyme disease divided the illness into three stages: stage 1, flu-like symptoms and a typical skin rash (*erythema migrans*, see Figure 6–26); stage 2, weeks to months later, facial (cranial nerve VII) palsy or meningitis; and stage 3, months to years later, arthritis. The problem with this simplified scheme is that there is a great deal of overlap, and the skin, CNS, and musculoskeletal system can be involved early or late. A more accurate classification divides disease into early and late manifestations and specifies whether disease is localized or disseminated.

#### A. Symptoms and Signs

1. **Stage 1, early localized infection**—Stage 1 infection is characterized by *erythema migrans*. About 1 week after the tick bite (range, 3–30 days; median 7–10 days), a flat or slightly raised red lesion appears at the site, which is commonly seen in areas of tight clothing such as the groin, thigh, or axilla. This lesion expands over several days. Although originally described as a lesion that progresses with central clearing (“bulls-eye” lesion), often there is a more homogeneous appearance or even central intensification. About 10–20% of patients either do not have typical skin lesions or the lesions go unnoticed. Most patients with *erythema migrans* will have a concomitant viral-like illness (the “summer flu”) characterized by myalgias, arthralgias, headache, and fatigue. Fever may or may not be present. Even without treatment, the symptoms and signs of *erythema migrans* resolve in 3–4 weeks. Although the classic lesion of *erythema migrans* is not difficult to recognize, atypical forms can occur that may lead to misdiagnosis. Southern tick–associated rash illness (STARI) has a similar appearance, but it occurs in geographically distinct areas of the United States.

   Completely asymptomatic disease, without *erythema migrans* or flu-like symptoms, can occur but is very uncommon in the United States.

2. **Stage 2, early disseminated infection**—Up to 50–60% of patients with *erythema migrans* are bacteremic and within days to weeks of the original infection, secondary skin lesions develop in about 50% of patients. These lesions are similar in appearance to the primary lesion but are usually smaller. Malaise, fatigue, fever (sometimes severe), neck pain, and generalized achingness are common with the skin lesions. Most symptoms are transient, although fatigue may persist for months. After hematogenous spread, some patients experience cardiac (4–10% of patients) or neurologic (10–15% of patients) manifestations, including myopericarditis, with atrial or ventricular arrhythmias and heart block. Neurologic manifestations include both the central and peripheral nervous systems. The most common CNS manifestation is aseptic meningitis with mild headache and neck stiffness. The most common peripheral manifestation is a cranial nerve VII neuropathy, ie, facial palsy (usually unilateral but can be bilateral, see Figure 24–1). A sensory or motor radiculopathy and mononeuritis multiplex occur less frequently. Conjunctivitis, keratitis, and, rarely, panophthalmitis can also occur. Rarely, skin involvement can be manifested as a cutaneous hypopigmented lesion called a borrelial lymphocytoma.

3. **Stage 3, late persistent infection**—Stage 3 infection occurs months to years after the initial infection and again primarily manifests itself as musculoskeletal, neurologic, and skin disease. In early reports, musculoskeletal complaints developed in up to 60% of patients, but with early recognition and treatment of disease, this has decreased to less than 10%. The classic manifestation of late disease is a monarticular or oligoarticular arthritis most commonly affecting the knee or other large weight bearing joints. While these joints may be quite swollen, these patients generally report less pain compared to patients with bacterial septic arthritis. Even if untreated, the arthritis is self-limited, resolving in a few weeks to months. Multiple recurrences are common but are usually less severe than the original disease. Joint fluid reflects an inflammatory arthritis with a mean white blood cell count of 25,000/mcL (0.025/L) with a predominance of neutrophils. Chronic arthritis develops in about 10% of patients. The pathogenesis of chronic Lyme arthritis may be an immunologic phenomenon rather than persistence of infection.

   Rarely, the nervous system (both central and peripheral) can be involved in late Lyme disease. In the United States, a subacute encephalopathy, characterized by memory loss, mood changes, and sleep disturbance, is seen. In Europe, a more severe encephalomyelitis caused by *B. garinii* is seen and presents with cognitive dysfunction, spastic paraparesis, ataxia, and bladder dysfunction. Peripheral nervous system involvement includes intermittent paresthesias, often in a stocking glove distribution, or radicular pain.

   The cutaneous manifestation of late infection, which can occur up to 10 years after infection, is acrodermatitis chronicum atrophicans. It has been described mainly in Europe after infection with *B. afzelii*, a genospecies that commonly causes disease in Europe but not the United States. There is usually bluish-red discoloration of a distal extremity with associated swelling. These lesions become atrophic and sclerotic with time and eventually resemble localized scleroderma. Cases of diffuse fasciitis with eosinophilia, an entity that resembles scleroderma, have been rarely associated with infection with *B. burgdorferi*.

01/07/19  2:47 PM
B. Laboratory Findings

The diagnosis of Lyme disease is based on both clinical manifestations and laboratory findings. The US Surveillance Case Definition specifies a person with exposure to a potential tick habitat (within the 30 days just prior to developing erythema migrans) with (1) erythema migrans diagnosed by a physician or (2) at least one late manifestation of the disease and (3) laboratory confirmation as fulfilling the criteria for Lyme disease.

Non-specific laboratory abnormalities can be seen, particularly in early disease. The most common are an elevated sedimentation rate of more than 20 mm/h seen in 50% of cases, and mildly abnormal liver biochemical tests are present in 30%. The abnormal liver biochemical tests are transient and return to normal within a few weeks of treatment. A mild anemia, leukocytosis (11,000–18,000/mcL) (0.011–0.018/L), and microscopic hematuria have been reported in 10% or less of patients.

Laboratory confirmation requires serologic tests to detect specific antibodies to B. burgdorferi in serum, preferably by ELISA and not by indirect immunofluorescence assay (IFA), which is less sensitive and specific and can cause misdiagnosis. A two-test approach is recommended for the diagnosis of active Lyme disease, with all specimens positive or equivocal by ELISA then confirmed with a Western immunoblot assay that can detect both IgM and IgG antibodies. A positive immunoblot requires that antibodies are detected against two (for IgM) or five (for IgG) specific protein antigens from B. burgdorferi.

If a patient with suspected early Lyme disease has negative serologic studies, acute and convalescent titers should be obtained since up to 50% of patients with early disease can be antibody negative in the first several weeks of illness. A fourfold rise in antibody titer would be diagnostic of recent infection. In patients with later stages of disease, almost all are antibody positive. False-positive reactions in the ELISA and IFA have been reported in juvenile rheumatoid arthritis, rheumatoid arthritis, systemic lupus erythematosus, infectious mononucleosis, subacute infective endocarditis, syphilis, relapsing fever, leptospirosis, enteroviral and other viral illnesses, and patients with gingival disease (presumably because of cross-reactivity with oral treponemes). False-negative serologic reactions occur early in illness, and antibiotic therapy early in disease can abort subsequent seroconversion.

The diagnosis of late nervous system Lyme disease is often difficult since clinical manifestations, such as subtel memory impairment, may be difficult to document. Most patients have a history of previous erythema migrans or monarticular or polyarticular arthritis, and the vast majority have antibody present in serum. Patients with late disease and peripheral neuropathy almost always have positive serum antibody tests, usually have abnormal electrophysiology tests, and may have abnormal nerve biopsies showing perivascular collections of lymphocytes; however, the CSF is usually normal and does not demonstrate local antibody production.

Caution should be exercised in interpreting serologic tests because they are not subject to national standards, and inter-laboratory variation is a major problem. In addition, some laboratories perform tests that are entirely unreliable and should never be used to support the diagnosis of Lyme disease (eg, the Lyme urinary antigen test, immunofluorescent staining for cell wall–deficient forms of B. burgdorferi, lymphocyte transformation tests, using PCR on inappropriate specimens such as blood or urine). Finally, testing is often done in patients with non-specific symptoms such as headache, arthralgia, myalgia, fatigue, and palpitations. Even in endemic areas, the pretest probability of having Lyme disease is low in these patients, and the probability of a false-positive test result is greater than that of a true-positive result. For these reasons, the CDC has established guidelines for laboratory evaluation of patients with suspected Lyme disease:

1. The diagnosis of early Lyme disease is clinical (ie, exposure in an endemic area, with physician-documented erythema migrans), and does not require laboratory confirmation. (Tests are often negative at this stage.)

2. Late disease requires objective evidence of clinical manifestations (recurrent brief attacks of monarticular or oligoarticular arthritis of the large joints; lymphocytic meningitis, cranial neuritis [facial palsy], peripheral neuropathy or, rarely, encephalomyelitis—but not headache, fatigue, paresthesias, or stiff neck alone; atrioventricular conduction defects with or without myocarditis) and laboratory evidence of disease (two-stage testing with ELISA or IFA followed by Western blot, as described above).

3. Patients with nonspecific symptoms without objective signs of Lyme disease should not have serologic testing done. It is in this setting that false-positive tests occur more commonly than true-positive tests.

4. The role of serologic testing in nervous system Lyme disease is unclear, as sensitivity and specificity of CSF serologic tests have not been determined. However, it is rare for a patient to have positive serologic tests on CSF without positive tests on serum (see below).

5. Other tests such as the T cell proliferative assay and urinary antigen detection have not yet been studied well enough to be routinely used.

Cultures for B. burgdorferi can be performed but are not routine and are usually reserved for clinical studies. PCR is very specific for detecting the presence of Borrelia DNA, but sensitivity is variable and depends on which body fluid is tested, the stage of the disease, and collection and testing technique. In general, PCR is more sensitive than culture, especially in chronic disease but is not available in many clinical laboratories. Testing should not be done on blood or urine but has been successfully performed on synovial fluid and CSF. A negative PCR result does not rule out disease.

Complications

Based on several observational studies, B. burgdorferi infection in pregnant women has not been associated with congenital syndromes, unlike other spirochetal illnesses such as syphilis.

Some patients and advocacy groups have claimed either a post–Lyme syndrome (in the presence of positive
laboratory tests and after appropriate treatment) or “chronic Lyme disease” in which tests may all be negative. Both entities include nonspecific symptoms such as fatigue, myalgias, and cognitive difficulties (see Prognosis below). Expert groups are in agreement that there are no data to support that ongoing infection is the cause of either syndrome.

Prevention

There is no human vaccine currently available. Simple preventive measures such as avoiding tick-infested areas, covering exposed skin with long-sleeved shirts and wearing long trousers tucked into socks, wearing light-colored clothing, using repellents, and inspecting for ticks after exposure would greatly reduce the number of tick bites. Environmental controls directed at limiting ticks on residential property would be helpful, but trying to limit the deer, tick, or white-footed mouse populations over large areas is not feasible.

Prophylactic antibiotics following tick bites is recommended in certain high-risk situations if all of the following criteria are met: (1) a tick identified as an adult or nymphal I scapularis has been attached for at least 36 hours; (2) prophylaxis can be started within 72 hours of the time the tick was removed; (3) more than 20% of ticks in the area are known to be infected with B burgdorferi; and (4) there is no contraindication to the use of doxycycline (not pregnant, age greater than 8 years, not allergic). The medication of choice for prophylaxis is a single 200-mg dose of doxycycline. If doxycycline is contraindicated, no prophylaxis should be given and the patient should be closely monitored for early disease, since short course prophylactic therapy with other agents has not been studied, and if early disease does develop, appropriate therapy is very effective in preventing long-term sequelae. Individuals who have removed ticks (including those who have had prophylaxis) should be monitored carefully for 30 days for possible coinfections.

Coinfections

Lyme disease, babesiosis (see Chapter 35), and human granulocytic anaplasmosis (formerly human granulocytic ehrlichiosis) (see Chapter 32) are endemic in similar areas of the country and are transmitted by the same tick, I scapularis. Coinfection with two or even all three of these organisms can occur, causing a clinical picture that is not “classic” for any of these diseases. The presence of erythema migrans is highly suggestive of Lyme disease, whereas flu-like symptoms without rash are more suggestive of babesiosis or anaplasmosis. Coinfection should be considered and excluded in patients who have persistent high fevers 48 hours after starting appropriate therapy for Lyme disease; in patients with persistent symptoms despite resolution of rash; and in those with anemia, leukopenia, or thrombocytopenia.

Treatment

Present recommendations for therapy are outlined in Table 34–4. For erythema migrans, antibiotic therapy shortens the duration of rash and prevents late sequelae. Doxycycline is most commonly used and has the advantage of being active against Anaplasma phagocytophilum (formerly Ehrlichia). It has proven effective in shorter courses of 10–14 days compared to other regimens. Amoxicillin is also effective and is recommended for pregnant or lactating women and for those who cannot tolerate doxycycline. Cefuroxime axetil is as effective as doxycycline, but because of its cost, it should be considered an alternative choice for those who cannot tolerate doxycycline or amoxicillin or for those in whom the medications are contraindicated. Erythromycin and azithromycin are less effective, associated with higher rates of relapse, and are not recommended as first-line therapy.

Isolated facial palsy (without meningitis or peripheral neuropathy) can be treated with doxycycline, amoxicillin, or cefuroxime axetil for 2–3 weeks. Although therapy

1Patients who cannot tolerate tetracyclines or beta-lactams can be treated with azithromycin 500 mg orally daily for 10 days.
2Symptomatic patients, those with second- or third-degree block, and those with first-degree block with a PR interval ≥ 300 milliseconds should be hospitalized for observation.
does not affect the rate of resolution of the cranial neuropathy, it does prevent development of late manifestations of disease.

The need for a lumbar puncture in patients with seventh nerve palsy is controversial. Some clinicians perform lumbar puncture on all patients with facial palsy and others only if there are symptoms or signs of meningitis. If meningitis is present, therapy with a parenteral antibiotic is indicated. Ceftriaxone is most commonly used, but penicillin is equally efficacious. In European countries, doxycycline 400 mg/d orally for 14 days is frequently used and is comparable in efficacy to ceftriaxone.

Patients with atrioventricular block or myopericarditis (or both) can be treated with either oral or parenteral agents for 2–3 weeks. Hospitalization and observation is indicated for symptomatic patients, those with second- or third-degree block, and those with first-degree block with a PR interval of 300 milliseconds or more. Once stabilized, hospitalized patients can be transitioned to one of the oral regimens to complete therapy.

Therapy of arthritis is difficult because some patients do not respond to any therapy, and those who do respond may do so slowly. Oral agents (doxycycline, amoxicillin, or ceftriaxone axetil) are as effective as intravenous regimens (ceftriaxone, cefotaxime, or penicillin). A reasonable approach to the patient with Lyme arthritis is to start with oral therapy for 28 days. If there is partial resolution, re-treat with an additional 28 days of the same oral regimen. If arthritis persists after re-treatment, symptomatic therapy with nonsteroidal anti-inflammatory drugs is recommended. For severe refractory pain, synovectomy may be required.

Based on the limited published data, therapy of Lyme disease in pregnancy should be the same as therapy in other patients with the exception that doxycycline should not be used.

Clinicians may encounter patients with nonspecific symptoms (such as fatigue and myalgias) and positive serologic tests for Lyme disease who request (or demand) therapy for their illness. It is important in managing these patients to remember (1) that nonspecific symptoms alone are not diagnostic; (2) that serologic tests are fraught with difficulty (as noted above), and in areas where disease prevalence is low, false-positive serologic tests are much more common than true-positive tests; and (3) that parenteral therapy with ceftriaxone for 2–4 weeks is costly and has been associated with significant adverse effects, including cholelithiasis and Clostridioides difficile colitis. Parenteral therapy should be reserved for those most likely to benefit, i.e., those with cutaneous, neurologic, cardiac, or rheumatic manifestations that are characteristic of Lyme disease.

**Prognosis**

Most patients respond to appropriate therapy with prompt resolution of symptoms within 4 weeks. True treatment failures are thus uncommon, and in most cases re-treatment or prolonged treatment of Lyme disease is instituted because of misdiagnosis or misinterpretation of serologic results (both IgG and IgM antibodies can persist for prolonged periods despite adequate therapy) rather than inadequate therapy or response. Prolonged courses of antibiotic therapy for nonspecific symptoms that persist after completion of appropriate assessment (and treatment, if necessary) for Lyme disease is not recommended.

The long-term outcome of adult patients with Lyme disease is generally favorable, but some patients have chronic complaints. Joint pain, memory impairment, and poor functional status secondary to pain are common subjective complaints in patients with Lyme disease, but physical examination and neurocognitive testing fail to document the presence of these symptoms as objective sequelae. Similarly, in highly endemic areas, patients with a diagnosis of Lyme disease commonly complain of pain, fatigue, and an inability to perform certain physical activities when followed for several years. However, these complaints occur just as commonly in age-matched controls without a history of Lyme disease.

Immunity is not complete after Lyme disease. Reinfection, although uncommon, is predominantly seen in patients successfully treated for early disease (erythema migrans) in whom antibody titers do not develop. Clinical manifestations and serologic response are similar to an initial infection.

**When to Refer**

Consultation with an infectious diseases specialist with experience in diagnosing and treating Lyme disease can be helpful in atypical or prolonged cases.

**When to Admit**

Admission for parenteral antibiotics is indicated for any patient with symptomatic CNS or cardiac disease as well as those with second- or third-degree atrioventricular block, or first-degree block with a PR interval of 300 milliseconds or more.

African trypanosomiasis is caused by the hemoflagellates *Trypanosoma brucei rhodesiense* and *Trypanosoma brucei gambiense*. The organisms are transmitted by bites of tsetse flies (genus *Glossina*), which inhabit shaded areas along streams and rivers. Trypanosomes ingested in a blood meal develop over 18–35 days in the fly; when the fly feeds again on a mammalian host, the infective stage is injected.

Human disease occurs in rural areas of sub-Saharan Africa from south of the Sahara to about 30 degrees south latitude. *T. b. gambiense* causes West African trypanosomiasis, and is transmitted in the moist sub-Saharan savannas and forests of west and central Africa. *T. b. rhodesiense* causes East African trypanosomiasis, and is transmitted in the savannas of east and southeast Africa.

*T. b. rhodesiense* infection is primarily a zoonosis of game animals and cattle; humans are infected sporadically. Humans are the principal mammalian host for *T. b. gambiense*, but domestic animals can be infected. The number of reported cases increased from the 1960s to the 1990s and has since decreased greatly, although cases are reported from over 20 countries. Total incidence has been estimated at less than 5000 cases per year, mostly due to *T. b. gambiense*, with the largest number in the Democratic Republic of the Congo. Infections are rare among travelers, including visitors to game parks.

### Clinical Findings

#### A. Symptoms and Signs

1. **West African trypanosomiasis**—Chancres at the site of the bite are uncommon. After an asymptomatic period that may last for months, hemolymphatic disease presents with fever, headache, myalgias, arthralgias, weight loss, and lymphadenopathy, with discrete, nontender, rubbery nodes, referred to as Winterbottom sign when in a posterior cervical distribution. Other common signs are mild splenomegaly, transient edema, and a pruritic erythematous rash. Febrile episodes may be broken by afebrile periods of up to several weeks. The hemolymphatic stage progresses over months to meningoencephalitic disease, with somnolence, irritability, personality changes, severe headache, and parkinsonian symptoms progressing to coma and death.

2. **East African trypanosomiasis**—Chancres at the bite site are more commonly recognized with *T. b. rhodesiense* infection, with a painful lesion of 3–10 cm and regional lymphadenopathy that appears about 48 hours after the tsetse fly bite and lasts 2–4 weeks. East African disease follows a much more acute course, with the onset of symptoms usually within a few days of the insect bite. The hemolymphatic stage includes intermittent fever and rash, but lymphadenopathy is less common than with West African disease. Myocarditis can cause tachycardia and death due to arrhythmias or heart failure. If untreated, East African trypanosomiasis progresses over weeks to months to meningoencephalitic disease, somnolence, coma, and death.

#### B. Laboratory Findings

Diagnosis can be difficult, and definitive diagnosis requires identification of trypanosomes. Microscopic examination of fluid expressed from a chancre or lymph node may show motile trypanosomes or, in fixed specimens, parasites stained with Giemsa. During the hemolymphatic stage,
detection of parasites in Giemsa-stained blood smears is common in East African disease but difficult in West African disease. Serial specimens should be examined, since parasitemias vary greatly over time. Meningoencephalitic (or second stage) disease is defined by the World Health Organization (WHO) as cerebrospinal fluid (CSF) showing at least five mononuclear cells per microliter, elevated protein, or presence of trypanosomes. Concentration techniques can aid identification of parasites in blood or CSF. Serologic tests are also available. The card agglutination test for trypanosomes (CATT) has excellent sensitivity and specificity for West African disease and can be performed in the field, but the diagnosis should be confirmed by identification of the parasites. Field-applicable immunochromatographic lateral flow rapid diagnostic tests that cost less than CATT and are simpler to perform are available; combining tests improves sensitivity and specificity. Molecular diagnostic tests, including PCR and field-friendly loop-mediated isothermal amplification (LAMP) are available, but these are not yet standardized or routinely available.

**Treatment**

Detection of trypanosomes is a prerequisite for treatment of African trypanosomiasis because of the significant toxicity of most available therapies. Treatment recommendations depend on the type of trypanosomiasis (Table 35–1), which is determined by geography, and stage of disease, which requires examination of CSF. Eflornithine, nifurtimox, suramin, and melarsoprol are available in the United States from the CDC Drug Service (www.cdc.gov/laboratory/drugservice).

### A. West African Trypanosomiasis

1. **Early stage infection**—Pentamidine (4 mg/kg intramuscularly or intravenously every day or every other day for 7 days) is used to treat infection that does not involve the central nervous system (CNS). The side effects of pentamidine include immediate hypotension; tachycardia; gastrointestinal symptoms during administration; sterile abscesses; and pancreatic (hypoglycemia), liver, and kidney abnormalities. An alternate drug is eflornithine (100 mg/kg/day intravenously every 6 hours for 14 days).

2. **Late stage infection**—The treatment of choice for CNS infection is a combination of intravenous eflornithine (400 mg/kg/day in two doses for 7 days) and oral nifurtimox (15 mg/kg/day in three doses for 10 days), which has improved efficacy and less toxicity than older regimens. Eflornithine, though less toxic than older trypanocidal drugs, can cause gastrointestinal symptoms, bone marrow suppression, seizures, and alopecia. An alternative agent is melarsoprol. Fexinidazole, a new agent, is as effective and safe as eflornithine plus nifurtimox when administered orally over 10 days; this drug has received international approval and offers an important alternative therapy.

### B. East African Trypanosomiasis

Pentamidine and eflornithine are not reliably effective, and early disease is treated with suramin. The dosing regimens of suramin vary (eg, 100–200 mg test dose, then 20 mg/kg [maximum 1 g] intravenously on days 1, 3, 7, 14, and 21 or weekly for five doses). Suramin toxicities include vomiting and, rarely, seizures and shock during infusions as well as subsequent fever, rash, headache, neuropathy, and kidney and bone marrow dysfunction.

Suramin does not enter the CNS, so East African trypanosomiasis involving the CNS is treated with melarsoprol (three series of 3.6 mg/kg/day intravenously for 3 days, with 7-day breaks between the series or a 10-day intravenous course with 0.6 mg/kg on day 1, 1.2 mg/kg on day 2, and 1.8 mg/kg on days 3–10). Melarsoprol also acts against West African disease, but eflornithine plus nifurtimox is preferred due to its lower toxicity. Immediate side effects of melarsoprol include fever and gastrointestinal symptoms. The most important side effect is a reactive encephalopathy that can progress to seizures, coma, and death. To help avoid this side effect, corticosteroids are coadministered (dexamethasone 1 mg/kg/day intravenously for 2–3 days or oral prednisolone 1 mg/kg/day for 5 days, and then 0.5 mg/kg/day until treatment completion). In addition, increasing resistance to melarsoprol is a serious concern.

### Prevention & Control

Individual prevention in endemic areas should include long sleeves and pants, insect repellents, and mosquito nets. Control programs focusing on vector elimination and treatment of infected persons and animals have shown good success in many areas but suffer from limited resources.

AMERICAN TRYpanosomiASIS
(Chagas Disease)

ESSENTIALS OF DIAGNOSIS

Acute stage
- Inflammatory lesion at inoculation site.
- Fever.
- Hepatosplenomegaly; lymphadenopathy.
- Myocarditis.
- Parasites in blood are diagnostic.

Chronic stage
- Heart failure, cardiac arrhythmias.
- Thromboembolism.
- Megaesophagus; megacolon.
- Serologic tests are usually diagnostic.

General Considerations
Chagas disease is caused by Trypanosoma cruzi, a protozoan parasite found only in the Americas; it infects wild animals and, to a lesser extent, humans from southern South America to the southern United States. An estimated 8–10 million people are infected, mostly in rural areas, with the highest national prevalence in Bolivia, Argentina, Paraguay, Ecuador, El Salvador, and Guatemala. Control efforts in endemic countries have decreased disease incidence to about 40,000 new infections and 12,500 deaths per year. The disease is often acquired in childhood. In many countries in South America, Chagas disease is the most important cause of heart disease. The vector is endemic in the southern United States where some animals are infected and a few instances of local transmission have been reported.

T. cruzi is transmitted by reduviid (triatomine) bugs infected by ingesting blood from animals or humans who have circulating trypanosomes. Multiplication occurs in the digestive tract of the bug and infective forms are eliminated in feces. Infection in humans occurs when the parasite penetrates the skin through the bite wound, mucous membranes, or the conjunctiva. Transmission can also occur by blood transfusion, organ or bone marrow transplantation, congenital transfer, or ingestion of food contaminated with vector feces. From the bloodstream, T. cruzi invades many cell types but has a predilection for myocardium, smooth muscle, and CNS glial cells. Multiplication causes cellular destruction, inflammation, and fibrosis, with progressive disease over decades.

Clinical Findings

A. Symptoms and Signs
As many as 70% of infected persons remain asymptomatic. The acute stage is seen principally in children and lasts 1–2 months. The earliest findings are at the site of inoculation either in the eye—Româña sign (unilateral edema, conjunctivitis, and lymphadenopathy)—or in the skin—a chagoma (swelling with local lymphadenopathy). Subsequent findings include fever, malaise, headache, mild hepatosplenomegaly, and generalized lymphadenopathy. Acute myocarditis and meningoencephalitis are rare but can be fatal.

An asymptomatic latent period (indeterminate phase) may last for life, but symptomatic disease develops in 10–30% of infected individuals, commonly many years after infection.

Chronic Chagas disease generally manifests as abnormalities in cardiac and smooth muscle. Cardiac disease includes arrhythmias, heart failure, and embolic disease. Smooth muscle abnormalities lead to megaesophagus and megacolon, with dysphagia, regurgitation, aspiration, constipation, and abdominal pain. These findings can be complicated by superinfections. In immunosuppressed persons, including AIDS patients and transplant recipients, latent Chagas disease may reactivate; findings have included brain abscesses and meningoencephalitis.

B. Diagnostic Testing
The diagnosis is made by detecting parasites in persons with suggestive findings who have resided in an endemic area. With acute infection, evaluation of fresh blood oruffy coats may show motile trypanosomes, and fixed preparations may show Giemsa-stained parasites. Concentration methods increase diagnostic yields. Trypanosomes may be identified in lymph nodes, bone marrow, or pericardial or spinal fluid. Molecular tests are highly sensitive and can be used to detect parasites in organ transplant recipients or after accidental exposure. When initial tests are unrevealing, xenodiagnosis using laboratory vectors, laboratory culture, or animal inoculation may provide a diagnosis, but these methods are expensive and slow.

Chronic Chagas disease is usually diagnosed serologically. Many different serologic assays are available, but sensitivity and specificity are not ideal; confirmatory assays are advised after an initial positive test, as is standard for blood bank testing in South America. The diagnosis of chronic disease with PCR remains suboptimal.

Treatment
Treatment is inadequate because the two drugs used, benznidazole and nifurtimox, often cause severe side effects, must be used for long periods, and are ineffective against chronic infection. In acute and congenital infections, the drugs can reduce the duration and severity of infection, but cure is achieved in only about 70% of patients. During the chronic phase of infection, although parasitemia may disappear in up to 70% of patients, treatment does not clearly alter the progression of the disease. In a 2015 trial for Chagas cardiomyopathy, benznidazole significantly reduced parasite detection but not progression of cardiac disease. Nevertheless, there is general consensus that treatment should be considered in all T. cruzi–infected persons regardless of clinical status or time since infection. In particular, treatment is recommended for acute, congenital, and reactivated infections and for children and young
adults with chronic disease. Benznidazole is FDA-approved for the treatment of Chagas disease in children 2–12 years old. Both benznidazole and nifurtimox are available in the United States from the CDC Drug Service (www.cdc.gov/labdrugservice).

Benznidazole is generally preferred due to better efficacy and safety profiles. It is given orally at a dosage of 5 mg/kg/day in two divided doses for 60 days. Its side effects include granulocytopenia, rash, and peripheral neuropathy. Nifurtimox is given orally in daily doses of 8–10 mg/kg in four divided doses after meals for 90–120 days. Side effects include gastrointestinal (anorexia, vomiting) and neurologic (headaches, ataxia, insomnia, seizures) symptoms, which appear to be reversible and to lessen with dosage reduction. For both drugs, some recommendations suggest higher dosing for acute infections. Patients with chronic Chagas disease may also benefit from antiarrhythmic therapy, standard therapy for heart failure, and conservative and surgical management of megaesophagus and megacolon.

**Prevention & Control**

In South America, a major eradication program based on improved housing, use of residual pyrethroid insecticides and pyrethroid-impregnated bed curtains, and screening of blood donors has achieved striking reductions in new infections. In endemic areas and ideally in donors from endemic areas, blood should not be used for transfusion unless at least two serologic tests are negative.

**Clinical Findings**

A. Symptoms and Signs

1. **Visceral leishmaniasis** (kala azar)—Most infections are subclinical, but a small number progress to full-blown disease. A local nonulcerating nodule at the site of the sand fly bite may precede systemic manifestations but usually is inapparent. The onset of illness may be acute, within 2 weeks of infection, or insidious. Symptoms and signs include fever, chills, diaphoresis, weakness, anorexia, weight loss, cough, and diarrhea. The spleen progressively becomes greatly enlarged, firm, and nontender. The liver is somewhat enlarged, and generalized lymphadenopathy may occur. Hyperpigmentation of skin can be seen, leading to the name kala azar (“black fever”). Other signs include skin lesions, petechiae, gingival bleeding, jaundice, edema, and ascites. As the disease progresses, severe wasting and malnutrition are seen; death eventually occurs, often due to secondary infections, within months to a few years. Post-kala azar dermal leishmaniasis may appear after apparent cure in the Indian subcontinent and Sudan. It may simulate leprosy, with hypopigmented macules or nodules developing on preexisting lesions. Viscerotropic leishmaniasis has been reported in small numbers of American military personnel in the Middle East, with mild systemic febrile illnesses after *L. tropica* infections.
Leishmaniasis is an opportunistic infection in persons with AIDS. Visceral leishmaniasis can present late in the course of HIV infection, with fever, hepatosplenomegaly, and pancytopenia. The gastrointestinal tract, respiratory tract, and skin may also be involved.

B. Laboratory Findings

Identifying amastigotes within macrophages in tissue samples provides a definitive diagnosis. In visceral leishmaniasis, fine-needle aspiration of the spleen for culture and tissue evaluation is generally safe, and yields a diagnosis in over 95% of cases. Bone marrow aspiration is less sensitive but safer and diagnostic in most cases, and Giemsa-stained buffy coat of peripheral blood may occasionally show organisms. Cultures with media available from the CDC will grow promastigotes within a few days to weeks. Molecular assays can also be diagnostic. Serologic tests may facilitate diagnosis, but none are sufficiently sensitive or specific to be used alone. Numerous antibody-based rapid diagnostic tests are available; these have shown good specificity but limitations in sensitivity outside of India. Antigen-based rapid diagnostic tests may offer improved sensitivity. For cutaneous lesions, biopsies should be taken from the raised border of a skin lesion, with samples for histopathology, touch preparation, and culture. The histopathology shows inflammation with mononuclear cells. Macrophages filled with amastigotes may be present, especially early in infection. An intradermal leishmanin (Montenegro) skin test is positive in most individuals with cutaneous disease but negative in those with progressive visceral or diffuse cutaneous disease; this test is not approved in the United States. In mucocutaneous leishmaniasis, diagnosis is established by detecting amastigotes in scrapings, biopsy preparations, or aspirated tissue fluid, but organisms may be rare. Cultures from these samples may grow organisms. Serologic studies are often negative, but the leishmanin skin test is usually positive.

A. Visceral Leishmaniasis

The treatment of choice for visceral leishmaniasis on the Indian subcontinent is liposomal amphotericin B (approved by the FDA), which is generally effective and well tolerated but expensive. Standard dosing is 3 mg/kg/day intravenously on days 1–5, 14, and 21. Simpler regimens that have shown good efficacy in India include four doses of 5 mg/kg over 4–10 days and a single dose of 15 mg/kg. A single infusion of an amphotericin B lipid emulsion, which is more affordable than liposomal preparations, showed excellent efficacy, albeit lower than that of the liposomal formulation. Conventional amphotericin B deoxycholate, which is much less expensive, is also highly effective but with more toxicity. It is administered as a slow intravenous infusion of 1 mg/kg/day for 15–20 days or 0.5–1 mg/kg every second day for up to 8 weeks. Infusion-related side effects with conventional or liposomal amphotericin B include gastrointestinal symptoms, fever, chills, dyspnea, hypotension, and hepatic and renal toxicity.

Pentavalent antimonials remain the most commonly used drugs to treat leishmaniasis in most areas. Response rates are good outside India, but in India, resistance is a major problem. Two preparations are available, sodium stibogluconate in the United States and many other areas and meglumine antimonate in Latin America and francophone countries; the compounds appear to have comparable

2. Old World and New World cutaneous leishmaniasis—

Cutaneous swellings appear 1 week to several months after sand fly bites and can be single or multiple. Characteristics of lesions and courses of disease vary depending on the leishmanial species and host immune response. Lesions begin as small papules and develop into nonulcerated dry plaques or large encrusted ulcers with well-demarcated raised and indurated margins (Figure 35–1). Satellite lesions may be present. The lesions are painless unless secondarily infected. Local lymph nodes may be enlarged. Systemic symptoms are uncommon, but fever, constitutional symptoms, and regional lymphadenopathy may be seen. For most species, healing occurs spontaneously in months to a few years, but scarring is common.

Leishmaniasis recidivans is a relapsing form of L tropica infection associated with hypersensitivity, in which the primary lesion heals centrally, but spreads laterally, with extensive scarring. Diffuse cutaneous leishmaniasis involves spread from a primary lesion, with local dissemination of nodules and a protracted course. Disseminated cutaneous leishmaniasis involves multiple nodular or ulcerated lesions, often with mucosal involvement.

3. Mucocutaneous leishmaniasis (espundia)—In Latin America, mucosal lesions develop in a small percentage of persons infected with L braziliensis and some other species, usually months to years after resolution of a cutaneous lesion. Nasal congestion is followed by ulceration of the nasal mucosa and septum, progressing to involvement of the mouth, lips, palate, pharynx, and larynx. Extensive destruction can occur, and secondary bacterial infection is common.

4. Infections in patients with AIDS—Leishmaniasis is an opportunistic infection in persons with AIDS. Visceral leishmaniasis can present late in the course of HIV infection, with fever, hepatosplenomegaly, and pancytopenia. The gastrointestinal tract, respiratory tract, and skin may also be involved.

Figure 35–1. Skin ulcer due to cutaneous leishmaniasis. Note the classic morphologic characteristics of this wound with its erythematous, nodular interior, surrounded by a raised border. (From Dr. Mae Melvin, Public Health Image Library, CDC.)
activities. In the United States, sodium stibogluconate can be obtained from the CDC Drug Service (www.cdc.gov/laboratory/drugservice). Standard dosing for either antimonial is 20 mg/kg once daily intravenously (preferred) or intramuscularly for 20 days for cutaneous leishmaniasis and 28 days for visceral or mucocutaneous disease. Toxicity increases over time, with development of gastrointestinal symptoms, fever, headache, myalgias, arthralgias, pancreatitis, and rash. Intramuscular injections can cause sterile abscesses. Monitoring should include serial ECGs, and changes are indications for discontinuation to avoid progression to serious arrhythmias.

The efficacy of amphotericin B is lower in East Africa than in Asia, and the standard treatment is a combination of sodium stibogluconate (20 mg/kg/day intravenously) plus paromomycin (15 mg/kg/day intramuscularly) for 17 days, with demonstrated excellent efficacy; liposomal amphotericin B may be considered in elderly or pregnant patients due to toxicity concerns.

Miltefosine is the first oral drug for the treatment of leishmaniasis, and it is registered in India for this indication. It initially demonstrated excellent results in India, but efficacy is decreasing due to drug resistance. It can be administered at a daily oral dose of 2.5 mg/kg in two divided doses for 28 days. A 28-day course of miltefosine (2.5 mg/kg/day) is also effective for the treatment of New World cutaneous leishmaniasis. Vomiting, diarrhea, and elevations in transaminases and kidney function studies are common, but generally short-lived, side effects.

The aminoglycoside paromomycin (11 mg/kg/day intramuscularly for 21 days) was shown to be similarly efficacious to amphotericin B for the treatment of visceral disease in India, where it is approved for this indication. It is much less expensive than liposomal amphotericin B or miltefosine. The drug is well tolerated; side effects include ototoxicity and reversible elevations in liver enzymes.

The use of drug combinations to improve treatment efficacy, shorten treatment courses, and reduce the selection of resistant parasites has been actively studied. In India, compared to a standard 30-day (treatment on alternate days) course of amphotericin, noninferior efficacy and decreased adverse events were seen with a single dose of liposomal amphotericin plus a 7-day course of miltefosine, a single dose of liposomal amphotericin plus a 10-day course of paromomycin, or a 10-day course of miltefosine plus paromomycin. As above, a combination of sodium stibogluconate and paromomycin is the standard treatment in East Africa.

B. Cutaneous Leishmaniasis

In the Old World, cutaneous leishmaniasis is generally self-healing over some months and does not metastasize to the mucosa, so it may be justified to withhold treatment in regions without mucocutaneous disease if lesions are small and cosmetically unimportant. Lesions on the face or hands are generally treated. New World leishmaniasis has a greater risk of progression to mucocutaneous disease, so treatment is more often warranted. Standard therapy is with pentavalent antimonials for 20 days, as described above. Other treatments include those discussed above for visceral disease, azole antifungals, and allopurinol. In studies in South America, a 28-day course of miltefosine was superior to a 20-day course of meglumine antimoniate, and oral fluconazole also showed good efficacy. Topical therapy has included intralvesional antimony, intralesional pentamidine, paromomycin ointment, cryotherapy, local heat, and surgical removal. Diffuse cutaneous leishmaniasis and related chronic skin processes generally respond poorly to therapy.

C. Mucocutaneous Leishmaniasis

Cutaneous infections from regions where parasites include those that cause mucocutaneous disease (eg, *L. braziliensis* in parts of Latin America) should all be treated to help prevent disease progression. Treatment of mucocutaneous disease with antimonials is disappointing, with responses in only about 60% in Brazil. Other therapies listed above for visceral leishmaniasis may also be used, although they have not been well studied for this indication.

**Prevention & Control**

Personal protection measures for avoidance of sand fly bites include use of insect repellants, fine-mesh insect netting, long sleeves and pants, and avoidance of warm shaded areas where flies are common. Disease control measures include destruction of animal reservoir hosts, mass treatment of humans in disease-prevalent areas, residual insecticide spraying in dwellings, limiting contact with dogs and other domesticated animals, and use of permethrin-impregnated collars for dogs.

General Considerations

Malaria is the most important parasitic disease of humans, causing hundreds of millions of illnesses and hundreds of thousands of deaths each year. The disease is endemic in most of the tropics, including much of South and Central America, Africa, the Middle East, the Indian subcontinent, Southeast Asia, and Oceania. Transmission, morbidity, and mortality are greatest in Africa, where most deaths from malaria are in young children. Malaria is also common in travelers from nonendemic areas to the tropics. Although the disease remains a major problem, impressive advances have been made in many regions. A 2016 study estimated a 57% decrease in the malaria death rate and 37% decrease in the annual number of malaria deaths in the past 15 years. However, after marked gains, morbidity and mortality appear to have stabilized, with WHO estimates showing modest annual increases in incidence, but decreases in deaths (219 million cases and 435,000 deaths estimated in 2017); other estimates suggest greater morbidity and mortality.

Four species of the genus Plasmodium classically cause human malaria. Plasmodium falciparum is responsible for nearly all severe disease. It is endemic in most malarious areas and is by far the predominant species in Africa. Plasmodium vivax is about as common as P falciparum, except in Africa. P vivax uncommonly causes severe disease, although this outcome may be more common than previously appreciated. Plasmodium ovale and Plasmodium malariae are much less common causes of disease, and generally do not cause severe illness. Plasmodium knowlesi, a parasite of macaque monkeys, is now recognized to cause occasional illnesses, including some severe disease, in humans in Southeast Asia.

Malaria is transmitted by the bite of infected female anopheline mosquitoes. During feeding, mosquitoes inject sporozoites, which circulate to the liver, and rapidly infect hepatocytes, causing asymptomatic liver infection. Merozoites are subsequently released from the liver, and they rapidly infect erythrocytes to begin the asexual erythrocytic stage of infection that is responsible for human disease. Multiple rounds of erythrocytic development, with production of merozoites that invade additional erythrocytes, lead to large numbers of circulating parasites and clinical illness. Some erythrocytic parasites also develop into sexual gametocytes, which are infectious to mosquitoes, allowing completion of the life cycle and infection of others.

Malaria may uncommonly be transmitted from mother to infant (congenital malaria), by blood transfusion, and in nonendemic areas by mosquitoes infected after biting infected immigrants or travelers. In P vivax and P ovale, parasites also form dormant liver hypnozoites, which are not killed by most drugs, allowing subsequent relapses of illness after initial elimination of erythrocytic infections. For all plasmodial species, parasites may recurdecese following initial clinical improvement after suboptimal therapy.

In highly endemic regions, where people are infected repeatedly, antimalarial immunity prevents severe disease in most older children and adults. However, young children, who are relatively nonimmune, are at high risk for severe disease from P falciparum infection, and this population is responsible for most deaths from malaria. Pregnant women are also at increased risk for severe falciparum malaria. In areas with lower endemicity, individuals of all ages commonly present with uncomplicated or severe malaria. Travelers, who are generally nonimmune, are at high risk for severe disease from falciparum malaria at any age.

Clinical Findings

A. Symptoms and Signs

An acute attack of malaria typically begins with a prodrome of headache and fatigue, followed by fever. A classic malarial paroxysm includes chills, high fever, and then sweats. Patients may appear to be remarkably well between febrile episodes. Fevers are usually irregular, especially early in the illness, but without therapy may become regular, with 48-hour (P vivax and P ovale) or 72-hour (P malariae) cycles, especially with non-falciparum disease. Headache, malaise, myalgias, arthralgias, cough, chest pain, abdominal pain, anorexia, nausea, vomiting, and diarrhea are common. Seizures may represent simple febrile convulsions or evidence of severe neurologic disease. Physical findings may be absent or include signs of anemia, jaundice, splenomegaly, and mild hepatomegaly. Rash and lymphadenopathy are not typical in malaria, and thus suggestive of another cause of fever.

In the developed world, it is imperative that all persons with suggestive symptoms, in particular fever, who have traveled in an endemic area be evaluated for malaria. The risk for falciparum malaria is greatest within 2 months of return from travel; other species may cause disease many months—and occasionally more than a year—after return from an endemic area.

Severe malaria is characterized by signs of severe illness, organ dysfunction, or a high parasite load (peripheral parasitemia greater than 5% or greater than 200,000 parasites/μL). It is principally a result of P falciparum infection because this species uniquely infects erythrocytes of all ages and mediates the sequestration of infected erythrocytes in small blood vessels, thereby evading clearance of infected erythrocytes by the spleen.

Severe falciparum malaria can include dysfunction of any organ system, including neurologic abnormalities progressing to alterations in consciousness, repeated seizures, and coma (cerebral malaria); severe anemia; hypotension and shock; noncardiogenic pulmonary edema and the acute respiratory distress syndrome; acute kidney injury due to acute tubular necrosis or, less commonly, severe hemolysis; hypoglycemia; acidosis; hemolysis with jaundice; hepatic dysfunction; retinal hemorrhages and other fundoscopic abnormalities; bleeding abnormalities, including disseminated intravascular coagulation; and secondary bacterial infections, including pneumonia and Salmonella bacteremia. In the developing world, severe malaria and deaths from the disease are mostly in young children, in particular from cerebral malaria and severe anemia. Cerebral malaria is a consequence of a single severe infection while severe anemia follows multiple malarial infections, intestinal helminths, and nutritional deficiencies. In a large trial of African children, acidosis, impaired consciousness, convulsions, renal impairment, and underlying chronic illness were associated with poor outcome.
Uncommon disorders resulting from immunologic responses to chronic infection are massive splenomegaly and, with *P. malariae* infection, immune complex glomerulopathy with nephrotic syndrome. HIV-infected individuals are at increased risk for malaria and for severe disease, in particular with advanced immunodeficiency.

**B. Laboratory Findings**

Giemsa-stained blood smears remain the mainstay of diagnosis (Figures 35–2, 35–3, 35–4, and 35–5), although other routine stains (eg, Wright stain) will also demonstrate parasites. Thick smears provide efficient evaluation of large volumes of blood, but thin smears are simpler for inexperienced personnel and better for discrimination of parasite species. Single smears are usually positive in infected individuals, although parasitemias may be very low in nonimmune individuals. If illness is suspected, repeating smears at 8- to 24-hour intervals is appropriate. The severity of malaria correlates only loosely with the quantity of infecting parasites, but high parasitemias (especially greater than 10–20% of erythrocytes infected or greater than 200,000–500,000 parasites/mcL) or the presence of malarial pigment (a breakdown product of hemoglobin) in more than 5% of neutrophils is associated with a particularly poor prognosis.

A second means of diagnosis is rapid diagnostic tests to identify circulating plasmodial antigens with a simple “dipstick” format. These tests are not well standardized but are widely available. At best, they offer sensitivity and specificity near that of high-quality blood smear analysis and are simpler to perform. However, *P. falciparum* lacking the most common rapid diagnostic test antigen, histidine-rich protein 2 (HRP2), has been identified in some areas, leading to concern that HRP2-based tests may miss some cases of falciparum malaria.

Serologic tests indicate history of disease but are not useful for diagnosis of acute infection. PCR and related molecular tests (eg, LAMP) are highly sensitive but not available for routine diagnosis. In immune populations, highly sensitive tests, such as PCR, have limited value because subclinical infections, which are not routinely treated, are common.

1Not available in the United States.

Other diagnostic findings with uncomplicated malaria include thrombocytopenia, anemia, leukocytosis or leukopenia, liver function abnormalities, and hepatosplenomegaly. Severe malaria can present with the laboratory abnormalities expected for the advanced organ dysfunction discussed above.

Treatment

Malaria is the most common cause of fever in much of the tropics and in travelers seeking medical attention after return from endemic areas. Fevers are often treated presumptively in endemic areas, but ideally, treatment should follow definitive diagnosis, especially in non-immune individuals.

Symptomatic malaria is caused only by the erythrocytic stage of infection. Available antimalarial drugs (Table 35–2) act against this stage, except for primaquine, which acts principally against hepatic parasites.

A. Non-Falciparum Malaria

The first-line drug for non-falciparum malaria from most areas remains chloroquine. Due to increasing resistance of *P vivax* to chloroquine, alternative therapies are recommended when resistance is suspected, particularly for infections acquired in Indonesia, Oceania, and South America. These infections can be treated with artemisinin-based combination therapies (ACTs) or other first-line regimens for *P falciparum* infections as discussed below. For *P vivax* or *P ovale*, eradication of erythrocytic parasites with chloroquine should be accompanied by treatment with primaquine (after evaluating for glucose-6-phosphate dehydrogenase [G6PD] deficiency; see below) to eradicate dormant liver stages (hypnozoites), which may lead to relapses with recurrent erythrocytic infection and malaria symptoms after weeks to months if left untreated. Taenoquine, which is related to primaquine, appears to offer similar efficacy with simpler dosing, but it also engenders potential toxicity in those with G6PD deficiency, and it remains under study. *P malariae* infections need only be treated with chloroquine.

B. Uncomplicated Falciparum Malaria

*P falciparum* is resistant to chloroquine and sulfadoxine-pyrimethamine in most areas, with the exceptions of Central America west of the Panama Canal and Hispaniola. Falciparum malaria from other areas should not be treated with these older drugs, and decisions regarding chemoprophylaxis should follow the same geographic considerations.

ACTs, all including a short-acting artemisinin and longer-acting partner drug, are first-line therapies in nearly all endemic countries. WHO recommends six ACTs to treat falciparum malaria (Table 35–3), but the efficacy of these regimens varies. Other combination therapies are under development. Quinine generally remains effective for
falciparum malaria, but it must be taken for 7 days and is poorly tolerated, and should best be reserved for the treatment of severe malaria and for treatment after another regimen has failed (Table 35–4).

In developed countries, malaria is an uncommon but potentially life-threatening infection of travelers and immigrants, many of whom are nonimmune, so they are at risk for rapid progression to severe disease. Nonimmune individuals with falciparum malaria should generally be admitted to the hospital due to risks of rapid progression of disease. A number of options are available for the treatment of uncomplicated falciparum malaria in the United States (Table 35–4).

C. Severe Malaria

Severe malaria is a medical emergency. Parenteral treatment is indicated for severe malaria, as defined above, and with inability to take oral drugs. With appropriate prompt therapy and supportive care, rapid recoveries may be seen even in very ill individuals.

The standard of care for severe malaria is intravenous artesunate, which has demonstrated superior efficacy and better tolerability than quinine. In the United States, intravenous artesunate is available on an investigational basis through the CDC (for enrollment call 770-488-7788; if approved, the drug is provided emergently from CDC Quarantine Stations. The drug is administered in four doses of 2.4 mg/kg over 3 days, every 12 hours on day 1, and then daily. If artesunate cannot be obtained promptly, severe malaria should be treated with intravenous quinine (available in most countries but not the United States) or quinidine (available in the United States). In endemic regions, if parenteral therapy is not available, intrarectal administration of artemether or artesunate is also effective. Patients receiving intravenous quinine or quinidine should receive continuous cardiac monitoring; if QTc prolongation exceeds 25% of baseline, the infusion rate should be reduced. Blood glucose should be monitored every 4–6 hours, and 5–10% dextrose may be coadministered to decrease the likelihood of hypoglycemia.

Appropriate care of severe malaria includes maintenance of fluids and electrolytes; respiratory and hemodynamic support; and consideration of blood transfusions, anticonvulsants, antibiotics for bacterial infections, and hemofiltration or hemodialysis. With high parasitemia (greater than 5–10%), exchange transfusion has been used, but beneficial effects have not clearly been demonstrated and it is generally no longer recommended.

D. Antimalarial Drugs

1. Chloroquine—Chloroquine remains the drug of choice for the treatment of sensitive P. falciparum and other species of malaria parasites (Table 35–4). Chloroquine is active against erythrocytic parasites of all human malaria species. It does not eradicate hepatic stages, so it must be used with primaquine to eradicate P. vivax and P. ovale infections. Chloroquine-resistant P. falciparum is widespread in nearly all areas of the world with falciparum malaria, with the exceptions of Central America west of the Panama Canal and Hispaniola. Chloroquine-resistant P. vivax has been reported from a number of areas, most notably Southeast Asia and Oceania.

Chloroquine is the drug of choice for the treatment of non-falciparum and sensitive falciparum malaria. It rapidly terminates fever (in 24–48 hours) and clears parasitemia (in 48–72 hours) caused by sensitive parasites. Chloroquine is also the preferred chemoprophylactic agent in malarious regions without resistant falciparum malaria.

Chloroquine is usually well tolerated, even with prolonged use. Pruritus is common, primarily in Africans. Nausea, vomiting, abdominal pain, headache, anorexia, malaise, blurring of vision, and urticaria are uncommon. Dosing after meals may reduce some adverse events.

2. Amodiaquine, piperaquine, and pyronaridine—Amodiaquine is a 4-aminoquinoline that is closely related to chloroquine. Amodiaquine has been widely used to treat malaria because of its low cost, limited toxicity and, in some areas, effectiveness against chloroquine-resistant strains of P. falciparum. Use of amodiaquine decreased after recognition of rare but serious side effects, notably agranulocytosis, aplastic anemia, and hepatotoxicity. However, serious side effects are rare with short-term use, and artesunate-amodiaquine is one of the standard ACTs recommended to treat falciparum malaria (Table 35–3). Chemoprophylaxis with amodiaquine is best avoided because of increased toxicity with long-term use.

Piperaquine is another 4-aminoquinoline that has been coformulated with dihydroartemisinin in an ACT. Piperaquine appears to be well tolerated and in combination with dihydroartemisinin to offer a highly efficacious therapy for falciparum and vivax malaria. Due to the long half-life of

piperaquine (~3 weeks), dihydroartemisinin-piperaquine offers the longest period of posttreatment prophylaxis of available ACTs. However, resistance to piperaquine has emerged in southeast Asia, with consequent treatment failures of dihydroartemisinin-piperaquine in that region.

Pyronaridine is a benzonaphthyridine that was also previously used as a monotherapy to treat malaria in China and acts against many drug-resistant strains of *P. falciparum*. The combination of artesunate plus pyronaridine has shown excellent efficacy against falciparum and vivax malaria and has been well tolerated, although elevated transaminases can be seen.

### 3. Mefloquine

Mefloquine is effective against many chloroquine-resistant strains of *P. falciparum* and against other malarial species. Although toxicity is a concern, mefloquine is also a recommended chemoprophylactic drug. Resistance to mefloquine has been reported sporadically from many areas, but it appears to be uncommon except in regions of Southeast Asia with high rates of multidrug resistance (especially border areas of Thailand).

For treatment of uncomplicated malaria, mefloquine can be administered as a single dose or in two doses over 1 day. It is used in combination with artesunate as an artesinin-based combination therapy (ACT) for falciparum Table 35–4. Treatment of malaria.

1. All dosages are oral and refer to salts unless otherwise indicated. See text for additional information on all agents, including toxicities and cautions. See CDC guidelines (phone: 877-FYI-TRIP; http://www.cdc.gov/malaria/) for additional information and pediatric dosing.
2. Not available in the United States.
3. Available in the United States only on an investigational basis through the CDC (phone: 770-488-7788).
4. Cardiac monitoring should be in place during intravenous administration of quinidine or quinine.
5. Avoid loading doses in persons who have received quinine, quinidine, or mefloquine in the prior 24 hours.
6. With all parenteral regimens, change to an oral regimen as soon as the patient can tolerate it.

G6PD, glucose-6-phosphate dehydrogenase.
malaria, although resistance limits efficacy in Southeast Asia. It should be taken with meals and swallowed with a large amount of water. Mefloquine is recommended by the CDC for chemoprophylaxis in all malarious areas except those with no chloroquine resistance (where chloroquine is preferred) and some rural areas of Southeast Asia with a high prevalence of mefloquine resistance.

Adverse effects with weekly dosing of mefloquine for chemoprophylaxis include nausea, vomiting, dizziness, sleep and behavioral disturbances, epigastric pain, diarrhea, abdominal pain, headache, rash and, uncommonly, seizures and psychosis. There is an FDA black box warning about neuropsychiatric toxicity, possibly including rare, irreversible effects. Mefloquine should be avoided in persons with histories of psychiatric disease or seizures.

Adverse effects are more common (up to 50% of treatments) with the higher dosages of mefloquine required for treatment. These effects may be lessened by splitting administration into two doses separated by 6–8 hours. Serious neuropsychiatric toxicities (depression, confusion, acute psychosis, or seizures) have been reported in less than 1 in 1000 treatments, but some authorities believe that these are more common. Mefloquine can also alter cardiac conduction, and so it should not be coadministered with quinine, quinidine, or halofantrine, and caution is required if these drugs are used to treat malaria after mefloquine chemoprophylaxis. Mefloquine is generally considered safe in young children and pregnant women.

4. Quinine and quinidine—Quinine dihydrochloride and quinidine gluconate remain first-line therapies for falciparum malaria, especially severe disease, although toxicity concerns complicate therapy (Table 35–4). Quinine acts rapidly against the four species of human malaria parasites. Quinidine, the dextrorotatory stereoisomer of quinine, is at least as effective as quinine in the treatment of severe falciparum malaria.

Resistance of P falciparum to quinine is common in some areas of Southeast Asia, where the drug may fail if used alone to treat falciparum malaria. However, quinine still provides at least a partial therapeutic effect in most patients.

Quinine and quinidine are effective treatments for severe falciparum malaria, although intravenous artesunate is the standard of care. The drugs can be administered in divided doses or by continuous intravenous infusion; treatment should begin with a loading dose to rapidly achieve effective plasma concentrations. Intravenous quinine and quinidine should be administered with cardiac monitoring because of their cardiac toxicity and the relative unpredictability of their pharmacokinetics. Therapy should be changed to an oral agent as soon as the patient has improved and can tolerate oral medications.

In areas without newer combination regimens, oral quinine sulfate is an alternative first-line therapy for uncomplicated falciparum malaria, although poor tolerance may limit compliance. Quinine is commonly used with a second drug (most often doxycycline) to shorten the duration of use (to 3 days) and to limit toxicity. Therapeutic dosages of quinine and quinidine commonly cause tinnitus, headache, nausea, dizziness, flushing, and visual disturbances. Hematologic abnormalities include hemolysis (especially with G6PD deficiency), leukopenia, agranulocytosis, and thrombocytopenia. Therapeutic doses may cause hypoglycemia through stimulation of insulin release; this is a particular problem in severe infections and in pregnant patients, who have increased sensitivity to insulin. Overly rapid infusions can cause severe hypotension. ECG abnormalities (QT prolongation) are fairly common, but dangerous arrhythmias are uncommon when the drugs are administered appropriately. Quinine should not be given concurrently with mefloquine and should be used with caution in a patient who has previously received mefloquine.

5. Primaquine and tafenoquine—Primaquine phosphate, a synthetic 8-aminoquinoline, is the drug of choice for the eradication of dormant liver forms of P vivax and P ovale (Table 35–4). Primaquine is active against hepatic stages of all human malaria parasites. This action is optimal soon after therapy with chloroquine or other agents. Primaquine also acts against erythrocytic stage parasites, although this activity is too weak for the treatment of active disease, and against gametocytes. As a new strategy to lower transmission, a single low dose of primaquine in conjunction with an ACT to treat uncomplicated falciparum malaria was well tolerated and lowered transmission to mosquitoes in subjects with normal G6PD levels.

For P vivax and P ovale infections, chloroquine or other drugs are used to eradicate erythrocytic forms, and if the G6PD level is normal, a 14-day course of primaquine (52.6 mg primaquine phosphate [30 mg base] daily) is initiated to eradicate liver hypnozoites and prevent a subsequent relapse. Some strains of P vivax, particularly in New Guinea and Southeast Asia, are relatively resistant to primaquine, and the drug may fail to eradicate liver forms.

Standard chemoprophylaxis does not prevent a relapse of P vivax or P ovale infections, since liver hypnozoites are not eradicated by chloroquine or other standard treatments. To diminish the likelihood of relapse, some authorities advocate the use of a treatment course of primaquine after the completion of travel to an endemic area. Primaquine can also be used for chemoprophylaxis to prevent P falciparum and P vivax infection in persons with normal levels of G6PD.

Primaquine in recommended doses is generally well tolerated. It infrequently causes nausea, epigastric pain, abdominal cramps, and headache, especially when taken on an empty stomach. Rare adverse effects include leukopenia, agranulocytosis, leukocytosis, and cardiac arrhythmias. Standard doses of primaquine may cause hemolysis or methemoglobinemia (manifested by cyanosis), especially in persons with G6PD deficiency and other hereditary metabolic defects. Patients should be tested for G6PD deficiency before primaquine is prescribed. Primaquine should be discontinued if there is evidence of hemolysis or anemia and should be avoided in pregnancy.

Tafenoquine, an 8-aminoquinoline, has a much longer half-life than primaquine. These two medications share the risk of hemolysis with G6PD deficiency and probably other toxicities; tafenoquine should not be used during pregnancy or in those with G6PD deficiency. Tafenoquine is FDA-approved for patients at least 16 years of age for two indications, but with different formulations, marketed by different companies, for the two indications. To eliminate
hepatic stages of *P. vivax*, a single dose (Krintafel, two 150-mg tablets once daily) is taken with food soon after initiation of primary therapy (with chloroquine or other agents). For malaria chemoprophylaxis, the drug (Arakoda, two 100-mg tablets) is taken once daily for 3 days and then weekly until 1 week after the last exposure.

6. Inhibitors of folate synthesis—Inhibitors of two parasite enzymes involved in folate metabolism, dihydrofolate reductase (DHFR) and dihydropteroate synthase (DHPS), are used, generally in combination regimens, for the treatment and prevention of malaria, although the drugs are rather slow acting and now limited by resistance.

Fansidar is a fixed combination of sulfadoxine (500 mg) and pyrimethamine (25 mg). It is no longer advised for chemoprophylaxis due to rare serious side effects with long-term dosing. For treatment, advantages of sulfadoxine-pyrimethamine include ease of administration (a single oral dose) and low cost. However, resistance is now a major problem.

Sulfadoxine-pyrimethamine plus artesunate has shown efficacy for malaria treatment in some areas but is best replaced by more effective ACTs. Sulfadoxine-pyrimethamine is recommended by WHO for monthly preventive therapy in pregnant women in areas of high endemicity, although its efficacy is limited by resistance. Amodiaquine plus sulfadoxine-pyrimethamine is recommended monthly during the rainy season for chemoprophylaxis in regions of West Africa with seasonal malaria transmission and limited drug resistance. Another antifolate combination, trimethoprim-sulfamethoxazole (TMP-SMZ), is widely used to prevent coinfections in patients infected with HIV, and it offers partial protection against malaria.

7. Artemisinins—Artemisinin (qinghaosu) is a sesquiterpene lactone endoperoxide, the active component of an herbal medicine that has been used for various indications in China for over 2000 years. Analogs have been synthesized to increase solubility and improve antimalarial efficacy. The most important of these analogs are artesunate, artemether, and dihydroartemisinin. WHO encourages availability of oral artemisinins only in coformulated combination regimens.

Artemisinins act very rapidly against all erythrocytic-stage human malaria parasites. Of concern, delayed clearance of parasites and clinical failures have been seen after treatment with artesunate in parts of Southeast Asia, heralding the emergence of artemisinin resistance in this region.

Artemisinins play a vital role in the treatment of malaria, including multidrug-resistant *P. falciparum* malaria. Due to their short plasma half-lives, recrudescence rates are unacceptably high after short-course therapy, leading to approved use only as initial therapy for severe malaria and in ACTs for uncomplicated malaria. The ACTs that are currently most advocated in Africa are artesunate plus amodiaquine (ASAQ) and artemether plus lumefantrine (Coartem), each of which is available as a coformulated product. Another ACT, artesunate plus mefloquine is used mostly outside of Africa; its efficacy may be declining in parts of Asia. Dihydroartemisinin-piperaquine has shown excellent efficacy and is the first-line regimen in some countries in Southeast Asia, but efficacy has declined in Cambodia due to decreased activity of both components of the regimen. The newest approved ACT, artesunate-pyronaridine, is approved in some countries, but little used to date. Other ACTs not recommended by the WHO are available in some countries and have shown good efficacy in limited studies, including arteether-piperaquine, artemisinin-piperaquine, and artemisinin-naphthoquine.

In studies of severe malaria, intramuscular artesunate was at least as effective as intramuscular quinine, and intravenous artesunate was superior to intravenous quinine in terms of efficacy and tolerability. Thus, the standard of care for severe malaria is intravenous artesunate, when it is available, although parenteral quinine and quinidine remain acceptable alternatives. Artesunate and artemether have also been effective in the treatment of severe malaria when administered rectally, offering a valuable treatment modality when parenteral therapy is not available.

Artemisinins are very well tolerated. The most commonly reported adverse effects have been nausea, vomiting, and diarrhea, which may often be due to acute malaria, rather than drug toxicity. Neutropenia, anemia, hemolysis, and elevated levels of liver enzymes have been noted rarely. Hemolysis may occur weeks after therapy with intravenous artesunate. Artemisinins are teratogenic in animals, but with good safety seen in humans, and the importance of effectively treating malaria during pregnancy, the WHO now recommends ACTs to treat uncomplicated malaria and intravenous artesunate to treat complicated malaria during all trimesters of pregnancy.

8. Atovaquone plus proguanil (Malarone)—Atovaquone, a hydroxynaphthoquinone, is not effective when used alone, due to rapid development of drug resistance. However, Malarone, a fixed combination of atovaquone (250 mg) and the antifolate proguanil (100 mg), is highly effective for both the treatment and chemoprophylaxis of *falciparum* malaria, and it is approved for both indications in the United States (Table 35–4). It also appears to be active against other species of malaria parasites. Unlike most other antimalariais, Malarone provides activity against both erythrocytic and hepatic stage parasites.

For treatment, Malarone is given at an adult dose of four tablets daily for 3 days. For chemoprophylaxis, Malarone must be taken daily. It has an advantage over mefloquine and doxycycline in requiring shorter durations of treatment before and after the period at risk for malaria transmission, due to activity against liver-stage parasites. It should be taken with food.

Malarone is generally well tolerated. Adverse effects include abdominal pain, nausea, vomiting, diarrhea, headache, and rash, and these are more common with the higher dose required for treatment. Reversible elevations in liver enzymes have been reported. The safety of atovaquone in pregnancy is unknown.

9. Antibiotics—A number of antibacterials in addition to the folate antagonists and sulfonamides are slow-acting antimalariais. None of the antibiotics should be used as single agents for the treatment of malaria due to their slow rate of action.
Doxycycline is commonly used in the treatment of falciparum malaria in conjunction with quinidine or quinine, allowing a shorter and better-tolerated course of those drugs (Table 35–4). Doxycycline is also a standard chemoprophylactic drug, especially for use in areas of Southeast Asia with high rates of resistance to other antimalarials, including mefloquine. Doxycycline side effects include gastrointestinal symptoms, candidal vaginitis, and photosensitivity. The drug should be taken while upright with a large amount of water to avoid esophageal irritation. Clindamycin can be used in conjunction with quinine or quinidine in those for whom doxycycline is not recommended, such as children and pregnant women (Table 35–4). The most common toxicities with clindamycin are gastrointestinal.

10. Lumefantrine—Lumefantrine, an aryl alcohol related to halofantrine, is available only as a fixed-dose combination with artemether (Coartem or Riemet). Oral absorption is highly variable and improved when the drug is taken with food. Use of Coartem with a fatty meal is recommended. Coartem is highly effective for the treatment of falciparum malaria, but it requires twice-daily dosing. Despite this limitation, due to its reliable efficacy against falciparum malaria, Coartem is the first-line therapy for malaria in many malarious countries. Coartem is well tolerated; side effects include headache, dizziness, loss of appetite, gastrointestinal symptoms, and palpitations. Importantly, Coartem does not generally cause QT prolongation or the serious cardiac toxicity seen with halofantrine.

**Prevention**

Malaria is transmitted by night-biting anopheline mosquitoes. Bed nets, in particular nets treated with permethrin insecticides, are heavily promoted as inexpensive means of non-pharmacologic prevention. Insecticide-treated bed nets are particularly effective in reducing malaria incidence in children and pregnant women (Table 35–4). The most common toxicities with clindamycin are gastrointestinal.

<sup>1</sup>Recommendations may change, as resistance to all available drugs is increasing. See text for additional information on toxicities and cautions. For additional details and pediatric dosing, see CDC guidelines (phone: 800-CDC-INFO; http://wwwnc.cdc.gov/travel/). Recommendations for travel to different locales are available from the CDC (www.cdc.gov; 877-FYI-TRIP). Recommendations from the CDC include the use of chloroquine for chemoprophylaxis in the few areas with only chloroquine-sensitive malaria parasites (primarily the Caribbean and Central America west of the Panama Canal), and Malarone, mefloquine, or doxycycline for other areas (Table 35–5).
Primaquine and tafenoquine are also effective but not used as often. Recommendations should be checked regularly because they may change in response to changing resistance patterns and increasing experience with new drugs. In some circumstances, it may be appropriate for travelers to not use chemoprophylaxis but to carry supplies of drugs with them in case a febrile illness develops and medical attention is unavailable. Regimens for self-treatment include ACTs, Malarone, and quinine. Most authorities do not recommend routine terminal chemoprophylaxis with primaquine to eradicate dormant hepatic stages of *P. vivax* and *P. ovale* after travel, but this may be appropriate in some circumstances, especially for travelers with major exposure to these parasites.

Regular chemoprophylaxis is not a standard management practice in developing world populations due to the expense and potential toxicities of long-term therapy. However, the strategy of intermittent preventive therapy, whereby at-risk populations (in particular pregnant women and children) receive antimalarial therapy at set intervals, may decrease the incidence of malaria while allowing antimalarial immunity to develop. During pregnancy, intermittent preventive therapy with sulfadoxine-pyrimethamine, provided once during both the second and third trimesters, has improved pregnancy outcomes. With increasing resistance, the preventive efficacy of sulfadoxine-pyrimethamine is likely falling, and the long-acting ACT dihydroartemisinin-piperaquine is a promising replacement. In areas with seasonal malaria transmission and limited drug resistance, principally the Sahel subregion of West Africa, the policy is to administer amodiaquine and sulfadoxine-pyrimethamine to children monthly during the transmission season.

**Prognosis**

When treated appropriately, uncomplicated malaria generally responds well, with resolution of fevers within 1–2 days and a mortality of about 0.1%. Severe malaria can commonly progress to death, but many children respond well to therapy. In the developed world, mortality from malaria is mostly in adults, and often follows extended illnesses and secondary complications long after eradication of the malarial infection. Pregnant women are at particular risk during their first pregnancy. Malaria in pregnancy also increases the likelihood of poor pregnancy outcomes, with increased prematurity, low birth weight, and mortality.

**When to Refer**

Referral to an expert on infectious diseases or travel medicine is important with all cases of malaria in the United States, and in particular for falciparum malaria; referral should not delay initial diagnosis and therapy, since delays in therapy can lead to severe illness or death.

**When to Admit**

- Admission for non-falciparum malaria is warranted only if specific problems that require hospital management are present.
- Patients with falciparum malaria are generally admitted because the disease can progress rapidly to severe illness; exceptions may be made with individuals who are from malaria-endemic areas, and thus expected to have a degree of immunity, who are without evidence of severe disease, and who are judged able to return promptly for medical attention if their disease progresses.

**BABESIOSIS**

**ESSENTIALS OF DIAGNOSIS**

- History of tick bite or exposure to ticks.
- Fever, flu-like symptoms, anemia.
- Intraerythrocytic parasites on Giemsa-stained blood smears.
- Positive serologic tests.

**General Considerations**

Babesiosis is an uncommon intraerythrocytic infection caused mainly by two *Babesia* species and transmitted by *Ixodes* ticks. In the United States, hundreds of cases of babesiosis have been reported, and infection is caused by *Babesia microti*, which also infects wild mammals. Most cases of babesiosis in the United States occurs in the coastal northeast, with some cases also in the upper midwest, following the geographic range of the vector *Ixodes scapularis*, and Lyme disease and anaplasmosis, which are spread by the same vector. The incidence of the disease appears to be increasing in some areas. Babesiosis is caused by *Babesia divergens* in Europe and by *Babesia venatorum* in China. Babesiosis due to *Babesia*...
**Clinical Findings**

**A. Symptoms and Signs**

Serosurveys suggest that asymptomatic infections are common in endemic areas. With *B. microti* infections, symptoms appear 1 to several weeks after a tick bite; parasitemia is evident after 2–4 weeks. Patients usually do not recall the tick bite. The typical flu-like illness develops gradually and is characterized by fever, fatigue, headache, arthralgia, and myalgia. Other findings may include nausea, vomiting, abdominal pain, sore throat, depression, emotional lability, anemia, thrombocytopenia, and splenomegaly. Parasitemia may continue for months to years, with or without symptoms, and the disease is usually self-limited. Severe complications are most likely to occur in older persons or in those who have had splenectomy. Serious complications include respiratory failure, hemolytic anemia, disseminated intravascular coagulation, heart failure, and acute kidney injury. In a study of hospitalized patients, the mortality rate was 6.5%. Most recognized *B. divergens* infections in Europe have been in patients who have had splenectomy. These infections progress rapidly with high fever, severe hemolytic anemia, jaundice, hemoglobinuria, and acute kidney injury, with death rates over 40%.

**B. Laboratory Findings**

Identification of the intraerythrocytic parasite on Giemsa-stained blood smears establishes the diagnosis (Figure 35–6). These can be confused with malaria parasites, but the morphology is distinctive. Repeated smears are often necessary because well under 1% of erythrocytes may be infected, especially early in infection, although parasitemias can exceed 10%. Diagnosis can also be made by PCR, which is more sensitive than blood smear. An indirect immunofluorescent antibody test for *B. microti* is available from the CDC; antibody is detectable within 2–4 weeks after the onset of symptoms and persists for months.

**Treatment**

Most patients have a mild illness and recover without therapy. Standard therapy for mild to moderate disease is a 7-day course of atovaquone (750 mg orally every 12 hours) plus azithromycin (600 mg orally once daily), which is equally effective and better tolerated than the alternative regimen, a 7-day course of quinine (650 mg orally three times daily) plus clindamycin (600 mg orally three times daily). However, there is more experience using quinine plus clindamycin, and this regimen is recommended for severe disease. Exchange transfusion has been used successfully in severely ill asplenic patients and those with parasitemia greater than 10%.

**Sanchez E et al.** Diagnosis, treatment, and prevention of Lyme disease, human granulocytic anaplasmosis, and babesiosis: a review. JAMA. 2016 Apr 26;315(16):1767–77. [PMID: 27115378]

rarely, direct inoculation of trophozoites via blood transfusion or organ transplantation. *Toxoplasma* seroprevalence varies widely. It has decreased in the United States to 20–30% or less, but it is much higher in other countries in both the developed and developing worlds, where it may exceed 80%. In the United States, *T. gondii* is estimated to infect 1.1 million persons each year, with resultant chorioretinitis developing in 21,000 and vision loss in 4800.

### Clinical Findings

#### A. Symptoms and Signs

The clinical manifestations of toxoplasmosis may be grouped into four syndromes.

1. **Primary infection in the immunocompetent person**—After ingestion, *T. gondii* infection progresses from the gastrointestinal tract to lymphatics, and then dissemination. Most acute infections are asymptomatic. About 10–20% are symptomatic after an incubation period of 1–2 weeks. Acute infections in immunocompetent persons typically present as mild, febrile illnesses that resemble infectious mononucleosis. Nontender cervical or diffuse lymphadenopathy may persist for weeks to months. Systemic findings may include fever, malaise, headache, sore throat, rash, myalgias, hepatosplenomegaly, and atypical lymphocytosis. Rare severe manifestations are pneumonitis, meningoencephalitis, hepatitis, myocarditis, polymyositis, and retinochoroiditis. Symptoms may fluctuate, but most patients recover spontaneously within at most a few months.

2. **Congenital infection**—Congenital transmission occurs as a result of infection, which may be symptomatic or asymptomatic, in a nonimmune woman during pregnancy. Fetal infection follows maternal infection in 30–50% of cases, but this risk varies by trimester: 10–25% during the first, 30–50% during the second, and 60% or higher during the third trimester. In the United States, an estimated 400 to 4000 congenital infections occur yearly. While the risk of fetal infection increases, the risk of severe fetal disease decreases over the course of pregnancy. Early fetal infections commonly lead to spontaneous abortion, stillbirths, or severe neonatal disease, including neurologic manifestations. Retinochoroiditis and other sight-threatening eye lesions may develop. Infections later in pregnancy less commonly lead to major fetal problems. Most infants appear normal at birth, but they may have subtle abnormalities and progress to symptoms and signs of congenital toxoplasmosis later in life.

3. **Retinochoroiditis**—The most common late presentation of congenital toxoplasmosis is retinochoroiditis, which presents weeks to years after congenital infection, commonly in teenagers or young adults. Retinochoroiditis is also seen in persons who acquire infection early in life, and these patients more often present with unilateral disease. Uveitis is also seen. Disease presents with pain, photophobia, and visual changes, usually without systemic symptoms. Signs and symptoms eventually improve, but visual defects may persist. Rarely, progression may result in glaucoma and blindness.

4. **Disease in the immunocompromised person**—Reactivated toxoplasmosis occurs in patients with AIDS, cancer, or those given immunosuppressive drugs. In patients with advanced AIDS, the most common manifestation is encephalitis, with multiple necrotizing brain lesions. The encephalitis usually presents subacutely, with fever, headache, altered mental status, focal neurologic findings, and other evidence of brain lesions. Less common manifestations of toxoplasmosis in patients with AIDS are chorioretinitis and pneumonitis. Chorioretinitis presents with ocular pain and alterations in vision. Pneumonitis presents with fever, cough, and dyspnea. Toxoplasmosis can develop in seronegative recipients of solid organ or bone marrow transplants due to reactivation or, more rarely, transmission of infection. Reactivation can also occur in those with hematologic malignancies or treated with immunosuppressive drugs. With primary or reactivated disease in those with immunodeficiency due to malignancy or immunosuppressive drugs, toxoplasmosis is similar to that in individuals with AIDS, but pneumonitis and myocarditis are more common.

#### B. Diagnostic Testing

1. **Identification of parasites**—Organisms can be seen in tissue or body fluids, although they may be difficult to identify; special staining techniques can facilitate identification. The demonstration of tachyzoites indicates acute infection; cysts may represent either acute or chronic infection. With lymphadenopathy due to toxoplasmosis, examination of lymph nodes usually does not show organisms. Parasite identification can also be made by inoculation of tissue culture or mice. PCR can be used for sensitive identification of organisms in amniotic fluid, blood, CSF, aqueous humor, and bronchoalveolar lavage fluid.

2. **Serologic diagnosis**—Multiple serologic methods are used, including the Sabin-Feldman dye test, enzyme-linked immunosorbent assay (ELISA), indirect fluorescent antibody test, and agglutination tests. IgG antibodies are seen within 1–2 weeks of infection and usually persist for life. IgM antibodies peak earlier than IgG and decline more rapidly, although they may persist for years. In immunocompromised individuals in whom reactivation is suspected, a positive IgG assay indicates distant infection, and thus the potential for reactivated disease; a negative IgG argues strongly against reactivation toxoplasmosis. With reactivation in immunocompromised persons, IgM tests are generally negative.

3. **During pregnancy and in newborns**—Conversion from a negative to positive serologic test or rising titers are suggestive of acute infection, but tests are not routinely performed during pregnancy. When pregnant women are screened, negative IgG and IgM assays exclude active infection, but indicate the risk of infection during the pregnancy. Positive IgG with negative IgM is highly suggestive of chronic infection, with no risk of congenital disease unless the mother is severely immunocompromised. A positive IgM test is concerning for new infection because of the risk of congenital disease. Confirmatory testing should be performed before consideration of treatment or possible
termination of pregnancy due to the limitations of available tests. Tests of the avidity of anti-IgG antibodies can be helpful, but a battery of tests is needed for confirmation of acute infection during pregnancy. When acute infection during pregnancy is suspected, PCR of amniotic fluid offers a sensitive assessment for congenital disease. In newborns, positive IgM or IgA antibody tests are indicative of congenital infection, although the diagnosis is not ruled out by a negative test. Positive IgG assays may represent transfer of maternal antibodies without infection of the infant, but persistence of positive IgG beyond 12 months of age is diagnostic of congenital infection. PCR of blood, CSF, or urine can also be helpful for early diagnosis of congenital disease.

4. In immunocompetent individuals — Individuals with a suggestive clinical syndrome should be tested for IgG and IgM antibodies. Seroconversion, a 16-fold rise in antibody titer, or an IgM titer greater than 1:64 is suggestive of acute infection, although false-positive results may occur. Acute infection can also be diagnosed by detection of tachyzoites in tissue, culture of organisms, or PCR of blood or body fluids. Histologic evaluation of lymph nodes can show characteristic morphology, with or without organisms.

5. In immunodeficient individuals — A presentation consistent with toxoplasmic encephalitis warrants imaging of the brain. CT and MRI scans typically show multiple ring-enhancing cerebral lesions, most commonly involving the corticomedullary junction and basal ganglia. MRI is the more sensitive imaging modality. In AIDS patients with a positive IgG serologic test and no recent antitoxoplasma or antiviral therapy, the predictive value of a typical imaging study is about 80%. The other common diagnosis in this setting is CNS lymphoma, which more typically causes a single brain lesion. The differential diagnosis also includes tuberculoma, bacterial brain abscess, fungal abscess, and carcinoma. Diagnosis of CNS toxoplasmosis is most typically made after a therapeutic trial, with clinical and radiologic improvement expected within 2–3 weeks. Definitive diagnosis requires brain biopsy and search for organisms and typical histology. In retinochoroiditis, funduscopic examination shows vitreous inflammatory reaction, white retinal lesions, and pigmented scars. Diagnosis of other clinical entities in immunocompromised individuals is generally based on histology.

**Treatment**

**A. Approach to Treatment**

Therapy is generally not necessary in immunocompetent persons, since primary illness is self-limited. However, for severe, persistent, or visceral disease, treatment for 2–4 weeks may be considered. Treatment is appropriate for primary infection during pregnancy because the risk of fetal transmission or the severity of congenital disease may be reduced. For retinochoroiditis, most episodes are self-limited, and opinions vary on indications for treatment. Treatment is often advocated for episodes with decreases in visual acuity, multiple or large lesions, macular lesions, significant inflammation, or persistence for over a month.

Immunocompromised patients with active infection must be treated. For those with transient immunodeficiency, therapy can be continued for 4–6 weeks after cessation of symptoms. For those with persistent immunodeficiency, such as AIDS patients, full therapy for 4–6 weeks is followed by maintenance therapy with lower doses of drugs. Immunodeficient patients who are asymptomatic but have a positive IgG serologic test should receive long-term chemoprophylaxis.

**B. Medications**

Drugs for toxoplasmosis are active only against tachyzoites, so they do not eradicate infection. Standard therapy is the combination of pyrimethamine (200 mg loading dose, then 50–75 mg [1 mg/kg] orally once daily) plus sulfadiazine (1–1.5 g orally four times daily), with folinic acid (10–20 mg orally once daily) to prevent bone marrow suppression. Patients should be screened for a history of sulfonamide sensitivity (skin rashes, gastrointestinal symptoms, hepatotoxicity). To prevent crystal-induced nephrotoxicity, good urinary output should be maintained. Pyrimethamine side effects include headache and gastrointestinal symptoms. Even with folinic acid therapy, bone marrow suppression may occur; platelet and white blood cell counts should be monitored at least weekly. A first-line alternative is clindamycin (600 mg orally four times daily) replacing sulfadiazine as the standard therapy regimen. Another alternative is TMP-SMZ. Pyrimethamine is not used during the first trimester of pregnancy due to its teratogenicity. Standard therapy for acute toxoplasmosis during pregnancy is spiramycin (1 g orally three times daily until delivery) to decrease the risk of fetal infection; it reduces the frequency of transmission to the fetus by about 60%. Spiramycin does not cross the placenta, so when fetal infection is documented or for acute infections late in pregnancy (which commonly lead to fetal transmission) treatment with combination regimens as described above is indicated.

**Prevention**

Prevention of primary infection centers on avoidance of undercooked meat or contact with material contaminated by cat feces, particularly for seronegative pregnant women and immunocompromised persons. Irradiation, cooking to 66°C, or freezing to ~20°C kills tissue cysts. Thorough cleaning of hands and surfaces is needed after contact with raw meat or areas contaminated by cats. Oocysts passed in cat feces can remain infective for a year or more, but fresh oocysts are not infective for 48 hours. For best protection, litter boxes should be changed daily and soaked in boiling water for 5 minutes, gloves should be worn when gardening, fruits and vegetables should be thoroughly washed, and ingestion of dried meat should be avoided.

Universal screening of pregnant women for *T gondii* antibodies is conducted in some countries but not the United States. Pregnant women should ideally have their serum examined for IgG and IgM antibody, and those with negative titers should adhere to the prevention measures described above. Seronegative women who continue to
have environmental exposure should undergo repeat serologic screening several times during pregnancy. For immunocompromised individuals, chemoprophylaxis to prevent primary or reactivated infection is warranted. For hematopoietic cell transplant recipients and advanced AIDS patients, chemoprophylaxis with TMP-SMZ (one double-strength tablet daily or two tablets three times weekly), used for protection against *Pneumocystis*, is effective against *T gondii*. Alternatives are pyrimethamine plus either sulfadoxine or dapsone (various regimens). In AIDS patients, chemoprophylaxis can be discontinued if antiretroviral therapy leads to immune reconstitution.

Humans are the only established *E histolytica* host. Transmission occurs through ingestion of cysts from fecally contaminated food or water, facilitated by person-to-person spread, flies and other arthropods as mechanical vectors, and use of human excrement as fertilizer. Urban outbreaks have occurred because of common-source water contamination.

## Clinical Findings

### A. Symptoms and Signs

#### 1. Intestinal amebiasis

In most infected persons, the organism lives as a commensal, and the carrier is without symptoms. With symptomatic disease, diarrhea may begin within a week of infection, although an incubation period of 2–4 weeks is more common, with gradual onset of abdominal pain and diarrhea. Fever is uncommon. Periods of remission and recurrence may last days to weeks or longer. Abdominal examination may show distention, tenderness, hyperperistalsis, and hepatomegaly. Microscopic hematochezia is common. More severe presentations include colitis and dysentery, with more extensive diarrhea (10–20 stools per day) and bloody stools. With dysentery, physical findings include high fevers, prostration, vomiting, abdominal pain and tenderness, hepatic enlargement, and hypotension. Severe presentations are more common in young children, pregnant women, those who are malnourished, and those receiving corticosteroids. Thus, in endemic regions, corticosteroids should not be started for presumed inflammatory bowel disease without first ruling out amebiasis. Fulminant amebic colitis can progress to necrotizing colitis, intestinal perforation, mucus sloughing, and severe hemorrhage, with mortality rates over 40%. More chronic complications of intestinal amebiasis include chronic diarrhea with weight loss, which may last for months to years; bowel ulcers; and amebic appendicitis. Localized granulomatous lesions (amebomas) can present after either dysentery or chronic intestinal infection. Clinical findings include pain, obstructive symptoms, and hemorrhage and may suggest intestinal carcinoma.

#### 2. Extraintestinal amebiasis

The most common extraintestinal manifestation is amebic liver abscess. This can occur with colitis, but more frequently presents without history of prior intestinal symptoms. Patients present with the acute or gradual onset of abdominal pain, fever, an enlarged and tender liver, anorexia, and weight loss. Diarrhea is present in a small number of patients. Physical examination may show intercostal tenderness. Amebic abscesses are most commonly single and in the right lobe of the liver, and they are much more common in men. Without prompt treatment, amebic abscesses may rupture into the pleural, peritoneal, or pericardial space, which is often fatal. Amebic infections may rarely occur throughout the body, including the lungs, brain, and genitourinary system.

### B. Laboratory Findings

Laboratory studies with intestinal amebiasis show leukocytosis and hematochezia, with fecal leukocytes not present in all cases. With extraintestinal amebiasis, leukocytosis and elevated liver function studies are seen.
C. Diagnostic Testing

Diagnosis is by finding *E histolytica* or its antigen or by serologic tests. However, each method has limitations.

1. Intestinal amebiasis—Diagnosis is most commonly made by identifying organisms in the stool. *E histolytica* and *E dispar* cannot be distinguished, but the identification of amebic trophozoites or cysts in a symptomatic patient is highly suggestive of amebiasis. Stool evaluation for organisms is not highly sensitive (~30–50% for amebic colitis), and at least three stool specimens should be evaluated after concentration and staining. Multiple serologic assays are available; these tests are fairly sensitive, although sensitivity is lower (~70% in colitis) early in illness, and they cannot distinguish recent and old disease, as they remain positive for years after infection. Commercially available stool antigen tests (TechLab II, CELISA, QUIK CHEK) can distinguish *E histolytica* from nonpathogenic species and offer improved sensitivity (greater than 90% for colitis). The QUIK CHEK assay is FDA-approved, offers rapid point-of-care diagnosis, and is available in a combined assay for amebiasis, giardiasis, and cryptosporidiosis. Highly sensitive molecular tests are not used routinely but increasingly available (in high resource settings) within commercial panels for identifying gut pathogens. Colonoscopy of uncleansed bowel typically shows no specific findings in mild intestinal disease; in severe disease, ulcers may be found with intact intervening friable mucosa, resembling inflammatory bowel disease (Figure 35–7). Examination of fresh ulcer exudate for motile trophozoites and for *E histolytica* antigen may yield a diagnosis.

2. Hepatic abscess—Serologic tests for anti-amebic antibodies are almost always positive, except very early in the infection. Thus, a negative test in a suspicious case should be repeated in about a week. The TechLab II antigen test can be used to test serum, with good sensitivity if used before the initiation of therapy. Examination of stools for organisms or antigen is frequently negative; the antigen test is positive in ~40% of cases. As imaging studies cannot distinguish amebic and pyogenic abscesses, when a diagnosis is not available from serologic studies, percutaneous aspiration may be indicated, ideally with an image-guided needle. Aspiration typically yields brown or yellow fluid. Detection of organisms in the aspirate is uncommon, but detection of *E histolytica* antigen is very sensitive and diagnostic. The key risk of aspiration is peritoneal spillage leading to peritonitis from amoebas or other (pyogenic or echinococcal) organisms.

D. Imaging

Liver abscesses can be identified by ultrasonography, CT, or MRI, typically with round or oval low-density nonhomogeneous lesions, with abrupt transition from normal liver to the lesion, and hypoechoic centers. Abscesses are most commonly single, but more than one may be present. The right lobe is usually involved.

![Figure 35–7. Gross pathology showing intestinal ulcers due to amebiasis. (From Dr. Mae Melvin, Public Health Image Library, CDC.)](image)

**Treatment**

Treatment of amebiasis generally entails the use of metronidazole or tinidazole to eradicate tissue trophozoites and a luminal amebicide to eradicate intestinal cysts (Table 35–6). Asymptomatic infection with *E dispar* does not require therapy. This organism cannot be differentiated morphologically from *E histolytica*, but with negative serology *E dispar* colonization is likely, and treatment is not indicated. Colonization with *E histolytica* is generally treated with a luminal agent. Effective luminal agents are diloxanide furoate (500 mg orally three times daily with meals for 10 days), iodoquinol (diiodohydroxyquin; 650 mg orally three times daily for 21 days), and paromomycin (30-mg/kg base orally, maximum 3 g, in three divided doses after meals daily for 7 days). Side effects associated with luminal agents are flatulence with diloxanide furoate, mild diarrhea with iodoquinol, and gastrointestinal symptoms with paromomycin. Relative contraindications are thyroid disease for iodoquinol and kidney disease for iodoquinol or paromomycin.

Treatment of intestinal amebiasis requires tinidazole (2 g orally once daily for 3–5 days) or metronidazole (750 mg orally three times daily for 10 days) plus a luminal agent (Table 35–6). Tinidazole offers simpler dosing and fewer side effects than metronidazole whose side effects include transient nausea, vomiting, epigastric discomfort, headache, or a metallic taste. A disulfiram-like reaction may occur if alcohol is coingested. Metronidazole should be avoided in pregnant or nursing mothers if possible. The same toxicities and concerns probably apply for tinidazole, although it appears to be better tolerated. Fluid and electrolyte replacement is also important for patients with significant diarrhea. Surgical management of acute complications of intestinal amebiasis is best avoided whenever possible. Successful therapy of severe amebic colitis may be followed by postdysenteric colitis, with continued diarrhea without persistent infection; this syndrome generally resolves in weeks to months.

Amebic liver abscess is also treated with metronidazole or tinidazole plus a luminal agent (even if intestinal infection is not documented; Table 35–6). Metronidazole can be
used intravenously when necessary. With failure of initial response to metronidazole or tinidazole, chloroquine, emetine, or dehydroemetine may be added. Needle aspiration may be helpful for large abscesses (over 5–10 cm), in particular if the diagnosis remains uncertain, if there is an initial lack of response, or if a patient is very ill, suggesting imminent abscess rupture. With successful therapy, abscesses disappear slowly (over months).

**Prevention & Control**

Prevention requires safe water supplies; sanitary disposal of human feces; adequate cooking of food; protection of food from fly contamination; hand washing; and, in endemic areas, avoidance of fruits and vegetables that cannot be cooked or peeled. Water supplies can be boiled, treated with iodine (0.5-mL tincture of iodine per liter for 20 minutes; cysts are resistant to standard concentrations of chlorine), or filtered.

### COCCIDIOSIS (Cryptosporidiosis, Isosporiasis, Cyclosporiasis, Sarcocystosis) & MICROSPORIDIOSIS

**ESSENTIALS OF DIAGNOSIS**

- Acute diarrhea, especially in children in developing countries.
- Outbreaks of diarrhea secondary to contaminated water or food.
- Prolonged diarrhea in immunocompromised persons.
- Diagnosis mostly by identifying organisms in specially stained stool specimens.

**General Considerations**

The causes of coccidiosis are *Cryptosporidium* species (*C parvum, C hominis, and others); *Cyclospora* (formerly *Isospora*) *belli; Cyclospora cayetanensis; and Sarcocystis* species. Microsporidiosis is caused by at least 14 species, most commonly *Enterocytozoon bieneusi* and *Encephalitozoon*...
variable, but patients commonly have chronic diarrhea of highly active antiretroviral therapy, particularly with diarrhea in those with AIDS. It was common before the advent of highly active antiretroviral therapy. Mild illness and asymptomatic infection are also common. Fever is usually not seen. Other illnesses in immunocompromised persons, isosporiasis more commonly causes severe and chronic diarrhea, with complications including marked dehydration, malnutrition, and hemorrhagic colitis. Extrainestinal disease has been reported rarely.

2. Isosporiasis—The incubation period for \( C. belli \) is about 1 week. In immunocompetent persons, it usually causes a self-limited watery diarrhea lasting 2–3 weeks, with abdominal cramps, anorexia, malaise, and weight loss. Fever is unusual. Chronic symptoms may persist for months. In immunocompromised patients, isosporiasis more commonly causes severe and chronic diarrhea, with complications including marked dehydration, malnutrition, and hemorrhagic colitis. Extrainestinal disease has been reported rarely.

3. Cyclosporiasis—\( C. cayetanensis \) oocysts must undergo a period of sporulation of 7 days or more after shedding before they become infectious. Therefore, person-to-person spread is unlikely, and spread has typically been due to contaminated food (especially fresh produce) and water. The incubation period is 1–11 days. Infections can be asymptomatic. Cyclosporiasis causes an illness similar to that described for the other pathogens described in this section, with watery diarrhea, abdominal cramps, nausea, fatigue, and anorexia. Fever is seen in 25% of cases. Symptoms typically continue for 2 weeks or longer and may persist for months. Relapses of diarrhea are common. Diarrhea may be preceded by a flu-like prodrome and followed by persistent fatigue. In immunocompromised patients, cyclosporiasis is typically more severe and prolonged, with chronic fulminant watery diarrhea and weight loss.

4. Sarcocystosis—\( Sarcocystis \) infection may be common in some developing countries, but it is usually asymptomatic. Infection appears to most commonly follow the ingestion of undercooked beef or pork, leading to the development of cysts in muscle, with myalgias, fever, bronchospasm, pruritic rash, lymphadenopathy, and subcutaneous nodules. Ingestion of fecal sporocysts may lead to gastrointestinal symptoms.

5. Microsporidiosis—Microsporidia are obligate intracellular protozoans that cause a wide spectrum of diseases. Many infections are of zoonotic origin, but human-to-human transmission has been documented. Infection is mainly by ingestion of spores, but also by direct inoculation of the eyes. In immunocompetent hosts, microsporidian infections most commonly present as self-limited diarrhea. Ocular infections have also been described. Disease from microsporidia is seen mainly in immunocompromised persons, particularly those with AIDS. Infections in AIDS patients are most commonly with \( E. bieneusi \) and \( E. intestinalis \). They cause chronic diarrhea, with anorexia, bloating, weight loss, and wasting, especially in those with advanced immunodeficiency. Fever is usually not seen. Other illnesses in immunocompromised persons associated with microsporidians (including the genera \( Enteroctozoon, Encephalitozoon, Brachiola, Vittaforma, Pleistophora, Trachipleistophora, and Microsporidium \) include biliary tract disease (AIDS cholangiopathy), genitourinary infection with cystitis, kidney disease, hepatitis, peritonitis, myocarditis, respiratory infections
including sinusitis, central nervous system infections including granulomatous encephalitis, and disseminated infections. Ocular infections with *Encephalitozoon* species cause conjunctivitis and keratitis, presenting as redness, photophobia, and loss of visual acuity.

**B. Laboratory Findings**

1. **Cryptosporidiosis**—Typically, stool is without blood or leukocytes. Diagnosis is traditionally made by detecting the organism in stool using a modified acid-fast stain; this technique is relatively insensitive, and multiple specimens should be evaluated before ruling out the diagnosis. Of note, routine evaluation for ova and parasites typically does not include a modified acid-fast stain, so this must be specifically requested in many laboratories. Various antigen detection methods, including immunofluorescence microscopy, ELISA, and immunochromatography, offer improved sensitivity and specificity, both over 90% with available assays, and these methods may be considered the optimal means of diagnosis. Molecular diagnostic panels that recognize *Cryptosporidium* and other enteropathogens in stool are available but expensive.

2. **Isosporiasis**—Diagnosis of isosporiasis is by examination of stool wet mounts or after modified acid-fast staining, in which the organism is clearly distinguishable from other parasites. Other stains also show the organism. Shedding of oocysts may be intermittent, so the sensitivity of stool evaluation is not high, and multiple samples should be examined. The organism may also be identified in duodenal aspirates or small bowel biopsies.

3. **Cyclosporiasis**—Diagnosis is made by examination of stool wet mounts or after modified acid-fast staining. Multiple specimens may need to be examined to make a diagnosis. The organism can also be identified in small bowel aspirates or biopsy specimens.

4. **Sarcocystosis**—Eosinophilia and elevated creatine kinase may be seen. Diagnosis is by identification of the acid-fast organisms in stool or by identification of trophozoites or bradyzoites in tissue biopsies.

5. **Microsporidiosis**—Diagnosis can be made by identification of organisms in specially stained stool, fluid, or tissue specimens, for example with Weber chromatopoe-based stain. Electron microscopy is helpful for confirmation of the diagnosis and speciation. PCR and culture techniques are available but not used routinely.

**Treatment**

Most acute infections with these pathogens in immunocompetent persons are self-limited and do not require treatment. Supportive treatment for severe or chronic diarrhea includes fluid and electrolyte replacement and, in some cases, parenteral nutrition.

1. **Cryptosporidiosis**—Treatment of cryptosporidiosis is challenging. No agent is clearly effective. Modest benefits have been seen in some (but not other) studies with paromomycin, a nonabsorbed aminoglycoside (25–35 mg/kg orally for 14 days has been used), and nitazoxanide (500 mg–1 g orally twice daily for 3 days in nonimmunocompromised and 2–8 weeks in advanced AIDS patients), which is approved in the United States for this indication. Other agents that have been used with mixed success in AIDS patients with cryptosporidiosis include azithromycin, spiramycin, bovine hyperimmune colostrum, and octreotide. Reversing immunodeficiency with effective antiretroviral therapy is of greatest importance.

2. **Isosporiasis**—Isosporiasis is effectively treated in immunocompetent and immunosuppressed persons with TMP-SMZ (160 mg/800 mg orally two to four times daily for 10 days, with the higher dosage for patients with AIDS). An alternative therapy is pyrimethamine (75 mg orally in four divided doses) with folic acid (10–25 mg/day orally). Maintenance therapy with low-dose TMP-SMZ (160 mg/800 mg daily or three times per week) or Fansidar (1 tablet weekly) prevents relapse in those with persistent immunosuppression.

3. **Cyclosporiasis**—Cyclosporiasis is also treated with TMP-SMZ (dosing as for isosporiasis). With AIDS, long-term maintenance therapy (160 mg/ 800 mg three times weekly) helps prevent relapse. For patients intolerant of TMP-SMZ, ciprofloxacin (500 mg orally twice daily for 7 days) showed efficacy, albeit with less ability to clear the organism than TMP-SMZ.

4. **Sarcocystosis**—For sarcocystosis, no specific treatment is established, but patients may respond to therapy with albendazole or TMP-SMZ.

5. **Microsporidiosis**—Treatment of microsporidiosis is complex. Infections with most species, including those causing gastrointestinal and other manifestations, should be treated with albendazole (400 mg orally twice daily for 2–4 weeks), which has activity against a number of species, but relatively poor efficacy (about 50%) against *E. bieneusi*, the most common microsporidial cause of diarrhea in AIDS patients. Fumagillin, which is used to treat honeybees and fish with microsporidian infections, has shown benefit in clinical trials at a dose of 20 mg three times per day for 14 days; treatment was accompanied by reversible thrombocytopenia. As with cryptosporidiosis, the best means of controlling microsporidiosis in AIDS patients is to restore immune function with effective antiretroviral therapy. Ocular microsporidiosis can be treated with fumagillin solution (3 mg/mL); this probably should be given with concurrent systemic therapy with albendazole. Adjunctive management may include corticosteroids to decrease inflammation and keratoconjunctivitis.

**Prevention**

Water purification is important for control of these infections. Chlorine disinfection is not effective against cryptosporidial oocysts, so other purification measures are needed. Immunocompromised patients should boil or filter drinking water and should consider avoidance of lakes and swimming pools. Routine precautions (hand washing, gloves, disinfection) should prevent institutional patient-to-patient spread. Optimal means of preventing microsporidial infections are not well understood, but water purification and body substance precautions for immunocompromised and hospitalized individuals are likely effective.
Abdominal cramps, distention, flatulence, and diarrhea are common symptoms of giardiasis. Clinical Findings

A. Symptoms and Signs

It is estimated that about 50% of infected persons have no discernible infection, about 10% become asymptomatic cyst passers, and 25–50% develop an acute diarrheal syndrome. Acute diarrhea may clear spontaneously but is commonly followed by chronic diarrhea. The incubation period is usually 1–3 weeks but may be longer. The illness may begin gradually or suddenly. Cysts may not be detected in the stool at the onset of the illness. The acute phase may last days or weeks, and is usually self-limited, although cyst excretion may be prolonged. The initial illness may include profuse watery diarrhea, and hospitalization may be required due to dehydration, particularly in young children. Typical symptoms of chronic disease are abdominal cramps, bloating, flatulence, nausea, malaise, and anorexia. Fever and vomiting are uncommon. Diarrhea is usually not severe in the chronic stage of infection; stools are greasy or frothy and foul smelling, without blood, pus, or mucus. The diarrhea may be daily or recurrent; intervening periods may include constipation. Symptoms can persist for weeks to months. Weight loss is frequent. Chronic disease can include malabsorption, including fat and protein-losing enteropathy and vitamin deficiencies.

B. Laboratory Findings

Most patients seek medical attention after having been ill for over a week, commonly with weight loss of 5 kg or more. Stool is generally without blood or leukocytes. Diagnosis is traditionally made by the identification of trophozoites or cysts in stool. A wet mount of liquid stool may identify motile trophozoites. Sensitivity of stool analysis is not ideal, estimated at 50–80% for a single specimen and over 90% for three specimens. Sampling of duodenal contents with a string test or biopsy is no longer generally recommended, but biopsies may be helpful in very ill or immunocompromised patients. When giardiasis is suspected, antigen assays are simpler and cheaper than repeated stool examinations, but these tests will not identify other stool pathogens. Multiple tests, which identify antigens of trophozoites or cysts, are available. They are generally quite sensitive (85–98%) and specific (90–100%). Molecular diagnostic panels that recognize Giardia and other enteropathogens in stool are available but expensive.

Treatment

The treatments of choice for giardiasis are metronidazole (250 mg orally three times daily for 5–7 days) or tinidazole (2 g orally once). The drugs are not universally effective; cure rates for single courses are typically about 80–95%. Toxicities are as described for treatment of amebiasis, but the lower dosages used for giardiasis limit side effects. Albendazole (400 mg orally once daily for 5 days) and nitazoxanide (500 mg orally twice daily for 3 days) both appear to have similar efficacy and fewer side effects compared with metronidazole, although data are limited, and a 2016 meta-analysis suggested superiority in efficacy of tinidazole over albendazole. Nitazoxanide is generally well tolerated but may cause mild gastrointestinal side effects. Other drugs with activity against Giardia include furazolidone (100 mg orally four times a day for 7 days), which is about as effective as the other named drugs but causes gastrointestinal side effects, and paromomycin (500 mg orally three times a day for 7 days), which appears to have somewhat lower efficacy but unlike metronidazole, tinidazole, and furazolidone is safe in pregnancy. Symptomatic giardiasis should always be treated. Treatment of asymptomatic patients should be considered, since they can transmit the infection. With a suggestive presentation but negative diagnostic studies, an empiric course of treatment...
may be appropriate. Household or day care contacts with an index case should be tested and treated if infected.

**Prevention**

Community chlorination (0.4 mg/L) of water is relatively ineffective for inactivating cysts, so filtration is required. For wilderness or international travelers, bringing water to a boil for 1 minute or filtration with a pore size less than 1 μm are adequate. In day care centers, appropriate disposal of diapers and frequent hand washing are essential.

**General Considerations**

Trichomoniasis is caused by the protozoan *Trichomonas vaginalis* and is among the most common sexually transmitted diseases, causing vaginitis in women and nongonococcal urethritis in men. It can also occasionally be acquired by other means, since it can survive in moist environments for several hours.

**Clinical Findings**

**A. Symptoms and Signs**

*T vaginalis* is often harbored asymptptomatically. For women with symptomatic disease, after an incubation period of 5 days to 4 weeks, a vaginal discharge develops, often with vulvovaginal discomfort, pruritus, dysuria, dyspareunia, or abdominal pain. Examination shows a copious discharge, which is usually not foul smelling but is often frothy and yellow or green in color. Inflammation of the vaginal walls and cervix with punctate hemorrhages are common. Most men infected with *T vaginalis* are asymptomatic, but it can be isolated from about 10% of men with nongonococcal urethritis. In men with trichomonal urethritis, the urethral discharge is generally more scanty than with other causes of urethritis.

**B. Diagnostic Testing**

Diagnosis is traditionally made by identifying the organism in vaginal or urethral secretions. Examination of wet mounts will show motile organisms. Tests for bacterial vaginosis (pH > 4.5, fishy odor after addition of potassium hydroxide) are often positive with trichomoniasis. Newer point-of-care antigen detection and nucleic acid probe hybridization tests and nucleic acid amplification assays offer improved sensitivity compared to wet mount microscopy and excellent specificity.

**Treatment**

The treatment of choice is tinidazole or metronidazole, each as a 2 g single oral dose. Tinidazole may be better tolerated and active against some resistant parasites. Toxicities of these drugs are discussed in the section on amebiasis. If the large single dose cannot be tolerated, an alternative metronidazole dosage is 500 mg orally twice daily for 1 week. A meta-analysis suggested that multiple dose regimens offer improved efficacy, although this is not standard. All infected persons should be treated, even if asymptomatic, to prevent subsequent symptomatic disease and limit spread. Treatment failure suggests reinfection, but metronidazole-resistant organisms have been reported. These may be treated with trichomone, longer courses of metronidazole, intravaginal paromomycin, or other experimental therapies (see Chapter 18).

**Essentials of Diagnosis**

- **Women:** copious vaginal discharge.
- **Men:** nongonococcal urethritis.
- **Motile trichomonads on wet mounts.**

**SCHISTOSOMIASIS (Bilharziasis)**

**General Considerations**

Schistosomiasis, which affects more than 200 million persons worldwide, leads to severe consequences in 20 million persons and about 100,000 deaths annually. The disease is caused by six species of trematode blood flukes. Five species cause intestinal schistosomiasis, with infection of mesenteric venules: *Schistosoma mansoni*, which is present...
Clinical Findings

A. Symptoms and Signs

1. Cercarial dermatitis—Following cercarial penetration, localized erythema develops in some individuals, which can progress to a pruritic maculopapular rash that persists for some days. Dermatitis can be caused by human schistosomes and, in nontropical areas, by bird schistosomes that cannot complete their life cycle in humans (swimmer’s itch).

2. Acute schistosomiasis (Katayama syndrome)—A febrile illness may develop 2–8 weeks after exposure in persons without prior infection, most commonly after heavy infection with *S. mansoni* or *S. japonicum*. Presenting symptoms and signs include acute onset of fever; headache; myalgias; cough; malaise; urticaria; diarrhea, which may be bloody; hepatosplenomegaly; lymphadenopathy; and pulmonary infiltrates. Localized lesions may occasionally cause severe manifestations, including CNS abnormalities and death. Acute schistosomiasis usually resolves in 2–8 weeks.

3. Chronic schistosomiasis—Many infected persons have light infections and are asymptomatic, but an estimated 50–60% have symptoms and 5–10% have advanced organ damage. Asymptomatic infected children may suffer from anemia and growth retardation. Symptomatic patients with intestinal schistosomiasis typically experience abdominal pain, fatigue, diarrhea, and hepatomegaly. Over years, anorexia, weight loss, weakness, colonic polyps, and features of portal hypertension develop. Late manifestations include hematemesis from esophageal varices, hepatic failure, and pulmonary hypertension. Urinary schistosomiasis may present within months of infection with hematuria and dysuria, most commonly in children and young adults. Fibrotic changes in the urinary tract can lead to hydroureter, hydronephrosis, bacterial urinary infections and, ultimately, kidney disease or bladder cancer.

B. Laboratory Findings

Microscopic examination of stool or urine for eggs, evaluation of tissue, or serologic tests establish the diagnosis. Characteristic eggs can be identified on smears of stool or urine. The most widely used stool test is the Kato-Katz technique. Quantitative tests that yield more than 400 eggs per gram of feces or 10 mL of urine are indicative of heavy infections with increased risk of complications. Diagnosis can also be made by biopsy of the rectum, colon, liver, or bladder. Serologic tests include an ELISA available from the CDC that is 99% specific for all species, but cannot distinguish acute and past infection. Sensitivity of the test is 99% for *S. mansoni*, 95% for *S. haematobium*, but less than 50% for *S. japonicum*. Serology is of limited use in endemic settings, but can be helpful in travelers from nonendemic regions. Point-of-care assays to detect circulating schistosome antigens in serum and urine are also available; the most widely used tests target circulating anodic and cathodic antigens. Antigen tests have better sensitivity than stool smears, especially for *S. mansoni*; sensitivity is lower for *S. haematobium*. Molecular tests for schistosomiasis have been developed but are not routinely used for diagnosis. In acute schistosomiasis, leukocytosis and marked eosinophilia may occur; serologic tests may become positive before eggs are seen in stool or urine. After therapy, eggs may be shed in stool or urine for months, and so the identification of eggs in fluids or tissue cannot distinguish past or active disease. With a diagnosis of schistosomiasis, evaluation for the extent of disease is warranted, including liver function studies and imaging of the liver with intestinal disease and ultrasound or other imaging studies of the urinary system in urinary disease.

Treatment

Treatment is indicated for all schistosome infections. In areas where recurrent infection is common, treatment is valuable in reducing worm burdens and limiting clinical complications. The drug of choice for schistosomiasis is praziquantel. The drug is administered for 1 day at an oral dose of 40 mg/kg (in one or two doses) for *S. mansoni*, *S. haematobium*, *S. intercalatum*, and *S. guineensis* infections and a dose of 60 mg/kg (in two or three doses) for *S. japonicum* and *S. mekongi*. Cure rates are generally greater than 80% after a single treatment, and those not cured have marked reduction in the intensity of infection. Praziquantel is active against invading cercariae but not developing schistosomulae. Therefore, the drug may not prevent illness when given after exposure and, for recent infections, a repeat course after a few weeks may be appropriate. Praziquantel may be used during pregnancy. Resistance to
praziquantel has been reported. Toxicities include abdominal pain, diarrhea, urticaria, headache, nausea, vomiting, and fever, and may be due both to direct effects of the drug and responses to dying worms. Alternative therapies are oxamniquine for *S mansoni* infection and meflotrinate for *S haemotobium* infection. Both of these drugs currently have limited availability (they are not available in the United States), and resistance may be a problem. No second-line drug is available for *S japonicum* infections. The antimalarial drug artemether has activity against schistosomulae and adult worms and may be effective in chemoprophylaxis; however, it is expensive, and long-term use in malarious areas might select for resistant malaria parasites. With severe disease, use of corticosteroids in conjunction with praziquantel may decrease complications. Treatment should be followed by repeat examinations for eggs about every 3 months for 1 year after therapy, with retreatment if eggs are seen.

### Prevention

Travelers to endemic areas should avoid freshwater exposure. Vigorous toweling after exposure may limit cercarial penetration. Chemoprophylaxis with artemether has shown efficacy but is not standard practice. Community control of schistosomiasis includes improved sanitation and water supplies, elimination of snail habitats, and intermittent treatment to limit worm burdens.

### Fascioliasis

Infection by *Fasciola hepatica*, the sheep liver fluke, results from ingestion of encysted metacercariae on watercress or other aquatic vegetables. Infection is prevalent in sheep-raising areas in many countries, especially parts of South America, the Middle East, and southern Europe, and it has increasingly been recognized in travelers to these areas. *Fasciola gigantica* has a more restricted distribution in Asia and Africa and causes similar findings. Eggs are passed from host feces into freshwater, leading to infection of snails, and then deposition of metacercariae on vegetation. In humans, metacercariae excyst, penetrate into the peritoneum, migrate through the liver, and mature in the bile ducts, where they cause local necrosis and abscess formation.

Two clinical syndromes are seen, related to acute migration of worms and chronic infection of the biliary tract. Symptoms related to migration of larvae present 6–12 weeks after ingestion. Typical findings are abdominal pain, fever, malaise, weight loss, urticaria, eosinophilia, and leukocytosis. Tender hepatomegaly and elevated liver biochemical tests may be seen. Rarely, migration to other organs may lead to localized disease. The symptoms of worm migration subside after 2–4 months, followed by asymptomatic infection by adult worms or intermittent symptoms of biliary obstruction, with biliary colic and, at times, findings of cholangitis. Early diagnosis is difficult, as eggs are not found in the feces during the acute migratory phase of infection. Clinical suspicion should be based on clinical findings and marked eosinophilia in at risk individuals. CT and other imaging studies show hypodense migratory lesions of the liver. Definitive diagnosis is made by the identification of characteristic eggs in stool. Repeated examinations may be necessary. In chronic infection, imaging studies show masses obstructing the extrahepatic biliary tract. Serologic assays have sensitivity and specificity greater than 90%, but cannot distinguish between past and current infection. Antigen tests with excellent sensitivity and specificity are available in veterinary medicine and show promise for humans.

Fascioliasis is unusual among fluke infections, in that it does not respond well to treatment with praziquantel. The treatment of choice is triclabendazole, which is also used in veterinary medicine. It is not routinely available in the United States, but is available through the CDC under an investigational protocol. Standard dosing of 10 mg/kg orally in a single dose or two doses over 12 hours achieves a cure rate of about 80%, but repeat dosing is indicated if abnormal radiologic findings or eosinophilia do not resolve. Of concern, resistance to triclabendazole has been widely reported in animal infections. The second-line drug for fascioliasis is bithionol (30–50 mg/kg/day orally in three divided doses on alternate days for 10–15 days); this drug is no longer available in the United States. Treatment with either drug can be accompanied by abdominal pain and other gastrointestinal symptoms. Other potential therapies are emetine and dehydroemetine, both widely used in the past but quite toxic, and nitazoxanide. Prevention of fascioliasis involves avoidance of ingestion of raw aquatic plants.

### Clonorchiasis & Opisthorchiasis

Infection by *Clonorchis sinensis*, the Chinese liver fluke, is endemic in areas of Japan, Korea, China, Taiwan, Southeast Asia, and the far eastern part of Russia. An estimated 15 million people are infected (13 million in China); in some communities, prevalence can reach 80%. Opisthorchiasis is principally caused by *Opisthorchis felineus* (regions of the former Soviet Union) or *Opisthorchis viverrini* (Thailand, Laos, Vietnam). Clonorchiasis and opisthorchiasis are clinically indistinguishable. Parasite eggs are shed into water in human or animal feces, where they infect snails, which release cercariae, which infect fish. Human infection follows ingestion of raw, uncooked, or pickled freshwater fish containing metacercariae. These parasites excyst in the duodenum and ascend into the biliary tract, where they mature and remain for many years, shedding eggs in the bile.

Most patients harbor few parasites and are asymptomatic. An acute illness can occur 2–3 weeks after initial infection, with fever, abdominal pain, tender hepatomegaly, urticaria, and eosinophilia. The acute syndrome is difficult to diagnose, since ova may not appear in the feces until 3–4 weeks after onset of symptoms. In chronic heavy infections, findings include abdominal pain, anorexia, weight loss, and tender hepatomegaly. More serious findings can include recurrent bacterial cholangitis and sepsis, cholecystitis, liver
abscess, and pancreatitis. An increased risk of cholangiocarcinoma has been documented.

Early diagnosis is presumptive, based on clinical findings and epidemiology. Subsequent diagnosis is made by finding characteristic eggs in stool or duodenal or biliary contents. The stool Kato-Katz test is widely used; performing repeated tests improves sensitivity. Imaging studies show characteristic biliary tract dilations with filling defects due to flukes. Serologic assays for clonorchiasis with excellent sensitivity are available but cannot distinguish between past and current infection. Molecular tests have been developed but are not widely used.

The drug of choice is praziquantel, 25 mg/kg orally three times daily for 2 days, which provides cure rates over 95%. One day of treatment may be sufficient. Re-treatment may be required, especially in some areas with known decreased praziquantel efficacy. The second-line drug is albendazole (400 mg orally twice daily for 7 days), which appears to be somewhat less effective. Tribendimidine, which is approved in China, has shown efficacy for clonorchiasis similar to that of praziquantel.

PARAGONIMIASIS

Eight species of Paragonimus lung flukes cause human disease. The most important is Paragonimus westermani. Paragonimus species are endemic in East Asia, Oceania, West Africa, and South America, where millions of persons are infected; rare infections caused by Paragonimus kellicotti have occurred in North America. Eggs are released into freshwater, where parasites infect snails, and then cercariae infect crabs and crayfish. Human infection follows consumption of raw, undercooked, or pickled freshwater shellfish. Metacercariae then encyst, penetrate into the peritoneum, and pass into the lungs, where they mature into adult worms over about 2 months.

Most persons have moderate worm burdens and are asymptomatic. In symptomatic cases, abdominal pain and diarrhea develop 2 days to 2 weeks after infection, followed by fever, cough, chest pain, urticaria, and eosinophilia. Acute symptoms may last for several weeks. Chronic infection can cause cough productive of brown sputum, hemoptysis, dyspnea, and chest pain, with progression to chronic bronchitis, bronchiectasis, bronchopneumonia, lung abscess, and pleural disease. Ectopic infections can cause disease in other organs, most commonly the CNS, where disease can present with seizures, headaches, and focal neurologic findings due to parasite meningitis and to intracerebral lesions.

The diagnosis of paragonimiasis is made by identifying characteristic eggs in sputum or stool or identifying worms in biopsied tissue. Multiple examinations and concentration techniques may be needed. Serologic tests may be helpful; an ELISA available from the CDC has sensitivity and specificity more than 95%. Chest radiographs may show varied abnormalities of the lungs or pleura, including infiltrates, nodules, cavities, and fibrosis, and the findings can be confused with those of tuberculosis. With CNS disease, skull radiographs can show clusters of calcified cysts, and CT or MRI can show clusters of ring-enhancing lesions.

Treatment is with praziquantel (25 mg/kg orally three times daily for 2 days), which provides efficacy of at least 90%. Alternative therapies are bithionol and triclabendazole. As with cysticercosis, for cerebral paragonimiasis, praziquantel should generally be used with corticosteroids. Chronic infection may lead to permanent lung dysfunction and pleural disease requiring drainage procedures.

INTESTINAL FLUKES

The large intestinal fluke, Fasciolopsis buski, is a common parasite of pigs and humans in eastern and southern Asia. Eggs shed in stools hatch in freshwater, followed by infection of snails, and release of cercariae that encyst on aquatic plants. Humans are infected by eating uncooked plants, including water chestnuts, bamboo shoots, and watercress. Adult flukes mature in about 3 months and live in the small intestine attached to the mucosa, leading to local inflammation and ulceration. Other intestinal flukes that cause similar syndromes include Heterophyes (North Africa and Turkey) and Metagonimus (East Asia) species; these species are transmitted by undercooked freshwater fish.

Infections with intestinal flukes are often asymptomatic, although eosinophilia may be marked. In symptomatic cases, after an incubation period of 1–2 months, manifestations include epigastric pain and diarrhea. Other gastrointestinal symptoms, ileus, edema, and ascites may be seen uncommonly. Diagnosis is based on identification of characteristic eggs or adult flukes in the stool. In contrast to other fluke infections, illness more than 6 months after travel in an endemic area is unlikely. The drug of choice is praziquantel, 25 mg/kg orally as a single dose. Alternative therapies are triclabendazole and niclosamide (for most species).

NONINVASIVE CESTODE INFECTIONS

The four major tapeworms that cause noninvasive infections in humans are the beef tapeworm Taenia saginata, the pork tapeworm Taenia solium, the fish tapeworm Diphyllobothrium latum, each of which can reach many meters in length, and the dwarf tapeworm Hymenolepis nana. Taenia and Hymenolepis species are broadly distributed, especially in the tropics; D latum is most prevalent in temperate regions. Other tapeworms that can cause noninvasive human disease include the rodent tapeworm Hymenolepis diminuta, the dog tapeworm Diphyllolothrium caninum, and other Taenia and Diphyllobothrium species. Invasive tapeworm infections, including T solium (when infective eggs,
rather than cysticerci are ingested) and *Echinococcus* species, will be discussed separately.

1. **Beef Tapeworm**

   Infection is most common in cattle breeding areas. Humans are the definitive host. Gravid segments of *T solium* are passed in human feces to soil, where they are ingested by grazing animals, especially cattle. The eggs then hatch to release embryos that encyst in muscle as cysticerci. Humans are infected by eating raw or undercooked infected beef. Most individuals infected with *T saginata* are asymptomatic, but abdominal pain and other gastrointestinal symptoms may be present. Eosinophilia is common. The most common presenting finding is the passage of proglottids in the stool.

2. **Pork Tapeworm**

   *T solium* is transmitted to pigs that ingest human feces. Humans can be either the definitive host (after consuming undercooked pork, leading to tapeworm infection) or the intermediate host (after consuming food contaminated with human feces containing *T solium* eggs, leading to cysticercosis, which is discussed under Invasive Cestode Infections). As with the beef tapeworm, infection with *T solium* adult worms is generally asymptomatic, but gastrointestinal symptoms may occur. Infection is generally recognized after passage of proglottids. Autoinfection with eggs can progress to cysticercosis.

3. **Fish Tapeworm**

   Infection with *D latum* follows ingestion of undercooked freshwater fish, most commonly in temperate regions. Eggs from human feces are taken up by crustaceans, these are eaten by fish, which are then infectious to humans. Infection with multiple worms over many years can occur. Infections are most commonly asymptomatic, but nonspecific gastrointestinal symptoms, including diarrhea, may occur. Diagnosis usually follows passage of proglottids. Prolonged heavy infection can lead to megaloblastic anemia and neuropathy from vitamin B<sub>12</sub> deficiency, which is due to infection-induced dissociation of the vitamin from its intrinsic factor and to utilization of the vitamin by worms.

4. **Dwarf Tapeworm**

   *H nana* is the only tapeworm that can be transmitted between humans. Infections are common in warm areas, especially with poor hygiene and institutionalized populations. Infection follows ingestion of food contaminated with human feces. Eggs hatch in the intestines, where oncospheres penetrate the mucosa, encyst as cysticercoid larvae, and then rupture after about 4 days to release adult worms. Autoinfection can lead to amplification of infection. Infection with *H nana*, the related rodent tapeworm *H diminuta*, or the dog tapeworm *D caninum* can also follow accidental ingestion of infected insects. *H nana* are dwarf in size relative to other tapeworms but can reach 5 cm in length. Heavy infection is common, especially in children, and can be accompanied by abdominal discomfort, anorexia, and diarrhea.

### Laboratory Findings

Diagnosis is usually made based on the identification of characteristic eggs or proglottids in stool. Egg release may be irregular, so examination of multiple specimens or concentration techniques may be needed.

### Treatment

The treatment of choice for noninvasive tapeworm infections is praziquantel. A single dose of praziquantel (5–10 mg/kg orally) is highly effective, except for *H nana*, for which the dosage is 25 mg/kg. Treatment of *H nana* is more difficult, as the drug is not effective against maturing cysts. Therefore, a repeat treatment after 1 week and screening after therapy to document cure are appropriate with heavy infections. Therapy can be accompanied by headache, malaise, dizziness, abdominal pain, and nausea.

The alternative therapy for these infections is niclosamide. A single dose of niclosamide (2 g chewed) is effective against *D latum*, *Taenia*, and *D caninum* infections. For *H nana*, therapy is continued daily for 1 week. Niclosamide may cause nausea, malaise, and abdominal pain.

Clinical Findings

A. Symptoms and Signs

Neurocysticercosis can cause intracerebral, subarachnoid, and spinal cord lesions and intraventricular cysts. Single or multiple lesions may be present. Lesions may persist for years before symptoms develop, generally due to local inflammation or ventricular obstruction. Presenting symptoms include seizures, focal neurologic deficits, altered cognition, and psychiatric disease. Symptoms develop more quickly with intraventricular cysts, with findings of hydrocephalus and meningeal irritation, including severe headache, vomiting, papilledema, and visual loss. A particularly aggressive form of the disease, racemose cysticercosis, involves proliferation of cysts at the base of the brain, leading to alterations of consciousness and death. Spinal cord lesions can present with progressive focal findings.

Cysticercosis of other organ systems is usually clinically benign. Involvement of muscles can uncommonly cause discomfort and is identified by radiographs of muscle showing multiple calcified lesions. Subcutaneous involvement presents with multiple painless palpable skin lesions. Involvement of the eyes can present with ptosis due to extraocular muscle involvement or intraocular abnormalities.

B. Laboratory Findings and Imaging

Diagnosis generally requires consideration of both laboratory and imaging findings. The updated Del Brutto diagnostic criteria, which include laboratory and imaging findings, have demonstrated good sensitivity and specificity.

CSF examination may show lymphocytic or eosinophilic pleocytosis, decreased glucose, and elevated protein. Serology plays an important role in diagnosis; both antibody and antigen detection assays are available. ELISAs and related immunoblott assays have excellent sensitivity and specificity, but sensitivity is lower with only single or calcified lesions.

With neuroimaging by CT or MRI, multiple parenchymal cysts are most typically seen. Parenchymal calcification is also common. Performing both CT and MRI is ideal because CT is better for identification of calcification and MRI for smaller and ventricular lesions. Typical findings can be highly suggestive of the diagnosis.

Treatment

The medical management of neurocysticercosis has been controversial because the benefits of cyst clearance must be weighed against potential harm of an inflammatory response to dying worms. Anthelminthic therapy hastens radiologic improvement in parenchymal cysticercosis, but some randomized trials have shown that corticosteroids alone are as effective as specific therapy plus corticosteroids for controlling seizures. Overall, most authorities recommend treatment of active lesions, in particular lesions with a high likelihood of progression, such as intraventricular cysts. At the other end of the spectrum, inactive calcified lesions probably do not benefit from therapy. In addition, cysticidal therapy should be avoided if there is a high risk of hydrocephalus, as with subarachnoid involvement. When treatment is deemed appropriate, standard therapy consists of albendazole (10–15 mg/kg/day orally for 8 days) or praziquantel (50 mg/kg/day orally for 15–30 days). Albendazole is probably preferred, since it has shown better efficacy in some comparisons and since corticosteroids appear to lower circulating praziquantel levels but increase albendazole levels. Increasing the dosage of albendazole to 30 mg/kg/day orally may improve outcomes. Combining albendazole plus praziquantel improved outcomes compared to albendazole alone in patients with multiple viable intraparenchymal cysts. Corticosteroids are usually administered concurrently, but dosing is not standardized. Patients should be observed for evidence of localized inflammatory responses. Anticonvulsant therapy is provided if needed, and shunting is performed if required for elevated intracranial pressure. Surgical removal of cysts may be helpful for some difficult cases of neurocysticercosis and for symptomatic non-neurologic disease.

2. Echinococcosis

ESSENTIALS OF DIAGNOSIS

- History of exposure to dogs or wild canines in an endemic area.
- Large cystic lesions, most commonly of the liver or lung.
- Positive serologic tests.

General Considerations

Echinococcosis occurs when humans are intermediate hosts for canine tapeworms. Infection is acquired by ingesting food contaminated with canine feces containing parasite eggs. The principal species that infect humans are Echinococcus granulosus, which causes cystic hydatid disease, and Echinococcus multilocularis, which causes alveolar hydatid disease. E granulosus is transmitted by domestic dogs in areas with livestock (sheep, goats, camels, and horses) as intermediate hosts, including Africa, the Middle East, southern Europe, South America, Central Asia, Australia, New Zealand, and the southwestern United States. E multilocularis, which much less commonly causes human disease, is transmitted by wild canines, and endemic in northern forest areas of the Northern Hemisphere, including...
Central Europe, Siberia, northern Japan, northwestern Canada, and western Alaska. An increase in the fox population in Europe has been associated with an increase in human cases. The disease range has also extended southward in Central Asia and China. Other species that cause limited disease in humans are endemic in South America and China.

After humans ingest parasite eggs, the eggs hatch in the intestines to form oncospheres, which penetrate the mucosa, enter the circulation, and encyst in specific organs as hydatid cysts. E. granulosus forms cysts most commonly in the liver (65%) and lungs (25%), but the cysts may develop in any organ, including the brain, bones, skeletal muscles, kidneys, and spleen. Cysts are most commonly single. The cysts can persist and slowly grow for many years.

**Clinical Findings**

**A. Symptoms and Signs**

Infections are commonly asymptomatic and may be noted incidentally on imaging studies or present with symptoms caused by an enlarging or superinfected mass. Findings may include abdominal or chest pain, biliary obstruction, cholangitis, portal hypertension, cirrhosis, bronchial obstruction leading to segmental lung collapse, and abscesses. Cyst leakage or rupture may be accompanied by a severe allergic reaction, including fever and hypotension. Seeding of cysts after rupture may extend the infection to new areas.

E. multilocularis generally causes a more aggressive disease than E. granulosus, with initial infection of the liver, but then local and distant spread commonly suggesting a malignancy. Symptoms based on the areas of involvement gradually worsen over years, with the development of obstructive findings in the liver and elsewhere.

**B. Laboratory Findings**

Serologic tests, including ELISA and immunoblot, offer sensitivity and specificity over 80% for E. granulosus liver infections, but lower sensitivity for involvement of other organs. Serologic tests may also distinguish the two major echinococcal infections.

**C. Imaging**

Diagnosis is usually based on imaging studies, including ultrasonography, CT, and MRI. In E. granulosus infection, a large cyst containing daughter cysts is highly suggestive of the diagnosis. In E. multilocularis infection, imaging shows an irregular mass, often with areas of calcification.

**Treatment**

The treatment of cystic hydatid disease is with albendazole, often with cautious surgical resection of cysts. When used alone, as in cases where surgery is not possible, albendazole (10–15 mg/kg/day orally) has demonstrated efficacy, with courses of 3 months or longer duration, in some cases with alternating cycles of treatment and rest. Mebendazole (40–50 mg/kg/day orally) is an alternative drug, and praziquantel may also be effective. In some cases, medical therapy is begun, with surgery performed if disease persists after some months of therapy. Another approach, in particular with inoperable cysts, is percutaneous aspiration, injection, and reaspiration (PAIR). In this approach (which should not be used if cysts communicate with the biliary tract), patients receive anthelmintic therapy, and the cyst is partially aspirated. After diagnostic confirmation by examination for parasite protoscolices, a scolicidal agent (95% ethanol, hypertonic saline, or 0.5% cetrimide) is injected, and the cyst is reaspirated after about 15 minutes. PAIR includes a small risk of anaphylaxis, which has been reported in about 2% of procedures, but death due to anaphylaxis has been rare. Treatment of alveolar cyst disease is challenging, generally relying on wide surgical resection of lesions. Therapy with albendazole before or during surgery may be beneficial and may also provide improvement or even cure in inoperable cases.

**ESSENTIALS OF DIAGNOSIS**

- Transient cough, urticaria, pulmonary infiltrates, eosinophilia.
- Nonspecific abdominal symptoms.
- Eggs in stool; adult worms occasionally passed.

**General Considerations**

Ascaris lumbricoides is the most common of the intestinal helminths, causing about 800 million infections, 12 million acute cases, and 10,000 or more deaths annually. Prevalence is high wherever there is poor hygiene and sanitation or where human feces are used as fertilizer. Heavy infections are most common in children.

Infection follows ingestion of eggs in contaminated food. Larvae hatch in the small intestine, penetrate into the bloodstream, migrate to the lungs, and then travel via airways back to the gastrointestinal tract, where they develop to adult worms, which can be up to 40 cm in length, and live for 1–2 years.

**Clinical Findings**

Most persons with Ascaris infection are asymptomatic. In a small proportion of patients, symptoms develop during migration of worms through the lungs, with fever,
nonproductive cough, chest pain, dyspnea, and eosinophilia, occasionally with eosinophilic pneumonia. Rarely, larvae lodge ectopically in the brain, kidney, eye, spinal cord, and other sites and may cause local symptoms.

Light intestinal infections usually produce no symptoms. With heavy infection, abdominal discomfort may be seen. Adult worms may also migrate and be coughed up, be vomited, or may emerge through the nose or anus. They may also migrate into the common bile duct, pancreatic duct, appendix, and other sites, which may lead to cholangitis, cholecystitis, pyogenic liver abscess, pancreaticitis, obstructive jaundice, or appendicitis. With very heavy infestations, masses of worms may cause intestinal obstruction, volvulus, intussusception, or death. Although severe manifestations of infection are uncommon, the very high prevalence of ascariasis leads to large numbers of individuals, especially children, with important sequelae. Moderate to high worm loads in children are also associated with nutritional abnormalities due to decreased appetite and food intake, and also decreased absorption of nutrients.

The diagnosis of ascariasis is made after adult worms emerge from the mouth, nose, or anus, or by identifying characteristic eggs in the feces, usually with the Kato-Katz technique. Imaging studies demonstrate larvae, with filling defects in contrast studies and at times evidence of intestinal or biliary obstruction. Eosinophilia is marked during worm migration but may be absent during intestinal infection.

▶ Treatment

All infections should ideally be treated. Treatments of choice are albendazole (single 400-mg oral dose), mebendazole (single 500-mg oral dose or 100 mg twice daily for 3 days), or pyrantel pamoate (single 11-mg/kg oral dose, maximum 1 g). These drugs are all well tolerated but may cause mild gastrointestinal toxicity. They are considered safe for children above 1 year of age and in pregnancy, although use in the first trimester is best avoided. An alternative is ivermectin (single 200 mcg/kg oral dose). In endemic areas, reinfection after treatment is common. Intestinal obstruction usually responds to conservative management and antihelminthic therapy. Surgery may be required for appendicitis and other gastrointestinal complications.

TRICHURIASIS

Trichuris trichiura, the whipworm, infects about 500 million persons throughout the world, particularly in humid tropical and subtropical environments. Infection is heaviest and most frequent in children. Infections are acquired by ingestion of eggs. The larvae hatch in the small intestine and mature in the large bowel to adult worms of about 4 cm in length. The worms do not migrate through tissues.

Most infected persons are asymptomatic. Heavy infections may be accompanied by abdominal cramps, tenesmus, diarrhea, distention, nausea, and vomiting. The Trichuris dysentery syndrome may develop, particularly in malnourished young children, with findings resembling inflammatory bowel disease including bloody diarrhea and rectal prolapse.

Trichuriasis is diagnosed by identification of characteristic eggs and sometimes adult worms in stools. Eosinophilia is common. Treatment is typically with albendazole (400 mg/day orally) or mebendazole (200 mg/day orally), for 1–3 days for light infections or 3–7 days for heavy infections, but cure rates are lower than for ascariasis or hookworm infection. An alternative is ivermectin (200 mcg/kg orally once daily for 3 days). Oxantel pamoate (one dose of 15–30 mg/kg) has shown good efficacy in clearing infections, and randomized trials showed albendazole plus oxantel pamoate (31% cure; 96% egg reduction) to be superior to mebendazole, and albendazole plus oxantel pamoate (69% cure; 99% egg reduction) and albendazole plus ivermectin (28% cure; 95% egg reduction) to be superior to albendazole plus mebendazole. Oxantel pamoate has low efficacy against Ascaris and hookworm infection.

HOOKWORM DISEASE

▶ ESSENTIALS OF DIAGNOSIS

- Transient pruritic skin rash and lung symptoms.
- Anorexia, diarrhea, abdominal discomfort.
- Iron deficiency anemia.
- Characteristic eggs and occult blood in the stool.

▶ General Considerations

Infection with the hookworms Ancylostoma duodenale and Necator americanus is very common, especially in most tropical and subtropical regions. Both worms are broadly distributed. Prevalence is estimated at about 500 million, causing approximately 65,000 deaths each year. When eggs are deposited on warm moist soil they hatch, releasing larvae that remain infective for up to a week. With contact, the larvae penetrate skin and migrate in the bloodstream to the pulmonary capillaries. In the lungs, the larvae penetrate into alveoli and then are carried by ciliary action upward to the bronchi, trachea, and mouth. After being swallowed, they reach and attach to the mucosa of the upper small bowel, where they mature to adult worms. Ancylostoma infection can also be acquired by ingestion of the larvae in food or water. Hookworms attach to the intestinal mucosa and suck blood. Blood loss is proportionate to the worm burden.

▶ Clinical Findings

A. Symptoms and Signs

Most infected persons are asymptomatic. A pruritic maculopapular rash (ground itch) may occur at the site of larval penetration, usually in previously sensitized persons. Pulmonary symptoms may be seen during larval migration through the lungs, with dry cough, wheezing, and low-grade fever, but these symptoms are less common than with ascariasis. About 1 month after infection, as maturing worms attach to the small intestinal mucosa, gastrointestinal symptoms may develop, with epigastric pain, anorexia, and
diarrhea, especially in previously unexposed individuals. Persons chronically infected with large worm burdens may have abdominal pain, anorexia, diarrhea, and findings of marked iron-deficiency anemia and protein malnutrition. Anemia can lead to pallor, weakness, dyspnea, and heart failure, and protein loss can lead to hypoalbuminemia, edema, and ascites. These findings may be accompanied by impairment in growth and cognitive development in children. Infection with the dog hookworm _Ancylostoma caninum_ can uncommonly lead to abdominal pain, diarrhea, and eosinophilia, with intestinal ulcerations and regional lymphadenitis.

**B. Laboratory Findings**

Diagnosis is based on the demonstration of characteristic eggs in feces; concentration techniques are usually not needed. Microcytic anemia, occult blood in the stool, and hypoalbuminemia are common. Eosinophilia is common, especially during worm migration.

**Treatment**

Treatment is with albendazole (single 400-mg oral dose) or mebendazole (100 mg orally twice daily for 3 days). Occasional adverse effects are diarrhea and abdominal pain. Pyrantel pamoate and levamisole are also effective. Anemia should be managed with iron replacement and, for severe symptomatic anemia, blood transfusion. Mass treatment of children with single doses of albendazole or mebendazole at regular intervals limits worm burdens and the extent of disease and is advocated by WHO.

**STRONGYLOIDIASIS**

**ESSENTIALS OF DIAGNOSIS**

- Transient pruritic skin rash and lung symptoms.
- Anorexia, diarrhea, abdominal discomfort.
- Larvae detected in stool.
- Hyperinfection in the immunocompromised; larvae detected in sputum or other fluids.
- Eosinophilia.

**General Considerations**

Strongyloidiasis is caused by infection with _Strongyloides stercoralis_. Although much less prevalent than ascariasis, trichuriasis, or hookworm infections, strongyloidiasis is nonetheless a significant problem, infecting tens of millions of individuals in tropical and subtropical regions. Infection is also endemic in some temperate regions of North America, Europe, Japan, and Australia. Of particular importance is the predilection of the parasite to cause severe infections in immunocompromised individuals due to its ability to replicate in humans. A related parasite, _Strongyloides fuelleborni_, infects humans in parts of Africa and New Guinea.

Among nematodes, _S. stercoralis_ is uniquely capable of maintaining its full life cycle both within the human host and in soil. Infection occurs when filariform larvae in soil penetrate the skin, enter the bloodstream, and are carried to the lungs, where they escape from capillaries into alveoli, ascend the bronchial tree, and are then swallowed and carried to the duodenum and upper jejunum, where maturation to the adult stage takes place. Females live embedded in the mucosa for up to 5 years, releasing eggs that hatch in the intestines as free rhabditiform larvae that pass to the ground via the feces. In moist soil, these larvae metamorphose into infective filariform larvae. Autoinfection can occur in humans, when some rhabditiform larvae develop into filariform larvae that penetrate the intestinal mucosa or perianal skin, and enter the circulation. The most dangerous manifestation of _S. stercoralis_ infection is the hyperinfection syndrome, with dissemination of large numbers of filariform larvae to the lungs and other tissues in immunocompromised individuals. Mortality with this syndrome approaches 100% without treatment and has been about 25% with treatment. The hyperinfection syndrome is seen in patients receiving corticosteroids and other immunosuppressive medications; patients with hematologic malignancies, malnutrition, or alcoholism; or persons with AIDS. The risk seems greatest for those receiving corticosteroids.

**Clinical Findings**

**A. Symptoms and Signs**

As with other intestinal nematodes, most infected persons are asymptomatic. An acute syndrome can be seen at the time of infection, with a pruritic, erythematous, maculopapular rash, usually of the feet. These symptoms may be followed by pulmonary symptoms (including dry cough, dyspnea, and wheezing) and eosinophilia after a number of days, followed by gastrointestinal symptoms after some weeks, as with hookworm infections. Chronic infection may be accompanied by epigastric pain, nausea, diarrhea, and anemia. Maculopapular or urticarial rashes of the buttocks, perineum, and thighs, due to migrating larvae, may be seen. Large worm burdens can lead to malabsorption or intestinal obstruction. Eosinophilia is common but may fluctuate.

With hyperinfection large numbers of larvae can migrate to many tissues, including the lungs, CNS, kidneys, and liver. Gastrointestinal symptoms can include abdominal pain, nausea, vomiting, diarrhea, and more severe findings related to intestinal obstruction, perforation, or hemorrhage. Bacterial sepsis, probably secondary to intestinal ulcerations, is a common presenting finding. Pulmonary findings include pneumonia, cough, hemoptysis, and respiratory failure. Sputum may contain adult worms, larvae, and eggs. CNS disease includes meningitis and brain abscesses; the CSF may contain larvae. Various presentations can progress to shock and death.

**B. Laboratory Findings**

The diagnosis of strongyloidiasis can be difficult, as eggs are seldom found in feces. Diagnosis is usually based on the identification of rhabditiform larvae in the stool or
duodenal contents. These larvae must be distinguished from hookworm larvae, which may hatch after stool collection. Repeated examinations of stool or examination of duodenal fluid may be required for diagnosis because the sensitivity of individual tests is only about 30%. Hyperinfection is diagnosed by the identification of large numbers of larvae in stool, sputum, or other body fluids. An ELISA from the CDC offers about 90% sensitivity and specificity, but cross-reactions with other helminths may occur. Eosinophilia and mild anemia are common, but eosinophilia may be absent with hyperinfection. Hyperinfection may include extensive pulmonary infiltrates, hypoproteinemia, and abnormal liver function studies.

C. Screening

It is important to be aware of the possibility of strongyloidiasis in persons with even a distant history of residence in an endemic area, since the infection can be latent for decades. Screening of at-risk individuals for infection is appropriate before institution of immunosuppressive therapy. Screening can consist of serologic tests, with stool examinations in those with positive serologic tests, but consideration of presumptive treatment even if the stool evaluations are negative (see below).

Treatment

Full eradication of *S. stercoralis* is more important than with other intestinal helminths due to the ability of the parasite to replicate in humans. The treatment of choice for routine infection is ivermectin (200 mcg/kg orally daily for 1–2 days). Less effective alternatives are albendazole (400 mg orally twice daily for 3 days) and thiabendazole (25 mg/kg orally twice daily for 3 days). For hyperinfection, ivermectin should be administered daily until the clinical syndrome has resolved and larvae have not been identified for at least 2 weeks. Follow-up examinations for larvae in stool or sputum are necessary, with repeat dosing if the infection persists. With continued immunosuppression, eradication may be difficult, and regular repeated therapy (eg, monthly ivermectin) may be required.

**ENTEROBIASIS**

- **ESSENTIALS OF DIAGNOSIS**
  - Nocturnal perianal pruritus.
  - Identification of eggs or adult worms on perianal skin or in stool.

- **General Considerations**

  *Enterobius vermicularis*, the pinworm, is a common cause of intestinal infections worldwide, with maximal prevalence in school-aged children. Enterobiasis is transmitted person-to-person via ingestion of eggs after contact with the hands or perianal region of an infected individual, food or fomites that have been contaminated by an infected individual, or infected bedding or clothing. Autoinfection also occurs. Eggs hatch in the duodenum and larvae migrate to the cecum. Females mature in about a month, and remain viable for about another month. During this time, they migrate through the anus to deposit large numbers of eggs on the perianal skin. Due to the relatively short life span of these helminths, continuous reinfection, as in institutional settings, is required, for long-standing infection.

- **Clinical Findings**

  A. Symptoms and Signs

  Most individuals with pinworm infection are asymptomatic. The most common symptom is perianal pruritus, particularly at night, due to the presence of the female worms or deposited eggs. Insomnia, restlessness, and enuresis are common in children. Perianal scratching may result in excoriation and impetigo. Many mild gastrointestinal symptoms have also been attributed to enterobiasis, but associations are not proven. Serious sequelae are uncommon. Rarely, worm migration results in inflammation or granulomatous reactions of the gastrointestinal or genitourinary tracts. Colonic ulceration and eosinophilic colitis have been reported.

  B. Laboratory Findings

  Pinworm eggs are usually not found in stool. Diagnosis is made by finding adult worms or eggs on the perianal skin. A common test is to apply clear cellophane tape to the perianal skin, ideally in the early morning, followed by microscopic examination for eggs. The sensitivity of the tape test is reported to be about 50% for a single test and 90% for three tests. Nocturnal examination of the perianal area or gross examination of stools may reveal adult worms, which are about 1 cm in length. Eosinophilia is rare.

  Treatment

  Treatment is with single oral doses of albendazole (400 mg), mebendazole (100 mg) or pyrantel pamoate (11 mg/kg, to a maximum of 1 g). The dose is repeated in 2 weeks due to frequent reinfection. Other infected family members should be treated concurrently, and treatment of all close contacts may be appropriate when rates of reinfection are high in family, school, or institutional settings. Standard hand washing and hygiene practices are helpful in limiting spread. Perianal scratching should be discouraged. Washing of clothes and bedding should kill pinworm eggs.
TRICHINOSIS

ESSENTIALS OF DIAGNOSIS
- Ingestion of inadequately cooked pork or game.
- Transient intestinal symptoms followed by fever, myalgias, and periorbital edema.
- Eosinophilia and elevated serum muscle enzymes.

General Considerations
Trichinosis (or trichinellosis) is caused worldwide by Trichinella spiralis and related Trichinella species. The disease is spread by ingestion of undercooked meat, most commonly pork in areas where pigs feed on garbage. When infected raw meat is ingested, Trichinella larvae are freed from cyst walls by gastric acid and pass into the small intestine. The larvae then invade intestinal epithelial cells, develop into adults, and the adults release infective larvae. These parasites travel to skeletal muscle via the bloodstream. They invade muscle cells, enlarge, and form cysts. These larvae may be viable for years. Pigs and other animals become infected by eating infected uncooked food scraps or other animals, such as rats.

The worldwide incidence of trichinosis has decreased, but human infections continue to occur sporadically or in outbreaks, with estimates of ~10,000 cases annually. In addition to undercooked pork, infections have been transmitted by ingestion of game and other animals, including bear and walrus in North America and wild boar and horse in Europe. In the United States, about 20 infections are reported annually, mostly from ingesting wild game.

Clinical Findings
A. Symptoms and Signs
Most infections are asymptomatic. In symptomatic cases, gastrointestinal symptoms, including diarrhea, vomiting, and abdominal pain, develop within the week after ingestion of contaminated meat. These symptoms usually last for less than a week but can occasionally persist for much longer. During the following week, symptoms and signs related to migrating larvae are seen. These findings include, most notably, fever, myalgias, periorbital edema, and eosinophilia. Additional findings may include headache, cough, dyspnea, hoarseness, dysphagia, macular or petechial rash, and subconjunctival and retinal hemorrhages. Systemic symptoms usually peak within 2–3 weeks, and commonly persist for about 2 months. In severe cases, generally with large parasite burdens, muscle involvement can be pronounced, with severe muscle pain, edema, and weakness, especially in the head and neck. Muscle pain may persist for months. Uncommon severe findings include myocarditis, pneumonitis, and meningoencephalitis, sometimes leading to death.

B. Laboratory Findings
The clinical diagnosis is supported by findings of elevated serum muscle enzymes (creatine kinase, lactate dehydrogenase, aspartate aminotransferase). The erythrocyte sedimentation rate is usually normal, which may help distinguish trichinosis from autoimmune myopathies. A commercial ELISA assay is available in the United States. Serologic tests become positive 2 or more weeks after infection, but cross-reactivity can be seen with other parasites. Rising antibody titers are highly suggestive of the diagnosis. Muscle biopsy can usually be avoided, but if the diagnosis is uncertain, biopsy of a tender, swollen muscle may identify Trichinella larvae. For maximal yield, biopsy material should be examined histologically, and a portion enzymatically digested to release larvae, but evaluation before 3 weeks after infection may not show muscle larvae. Serum and muscle biopsy analysis are available from the CDC.

Treatment
No effective specific therapy for full-blown trichinosis has been identified. However, if infection is suspected early in the course of illness, treatment with mebendazole (2.5 mg/kg orally twice daily) or albendazole (5–7.5 mg/kg orally twice daily) will kill intestinal worms and may limit progression to tissue invasion. Supportive therapy for systemic disease consists of analgesics, antipyretics, bed rest and, in severe illness, corticosteroids. Infection is prevented by cooking to a temperature of at least 71°C for at least 1 minute. Irradiation of meat is also effective in eliminating Trichinella larvae, but freezing is not reliable.

TOXOCARIASIS

General Considerations
The dog roundworm Toxocara canis, the cat roundworm Toxocara cati, and less commonly other helminths may cause visceral larva migrans. T. canis is highly prevalent in dogs. Humans are infected after ingestion of eggs in material contaminated by dog or other feces. Infection is spread principally by puppies and lactating females, and the eggs must be on the ground for several weeks before they are infectious. After ingestion by humans, larvae migrate to various tissues but cannot complete their life cycle.

Clinical Findings
Visceral larva migrans is seen principally in young children. Most infections are asymptomatic. The most commonly involved organs are the liver and lungs. Presentations include cough, fever, wheezing, hepatomegaly, splenomegaly, lymphadenopathy, pulmonary infiltrates, and eosinophilia. Involvement of the CNS can occur rarely, leading to eosinophilic meningitis and other abnormalities. Ocular
Cutaneous larva migrans is a distinct syndrome, usually in children older than is typical for visceral larva migrans. Children present with visual deficits, pain, and a retinal mass, which can be confused with retinoblastoma. *Baylisa* *carias procyonis*, a roundworm of raccoons, can rarely cause visceral larva migrans in humans, typically with similar, but more severe manifestations than *T canis*.

The diagnosis of visceral larva migrans is suggested by the finding of eosinophilia in a child with hepatomegaly or other signs of the disease, especially with a history of exposure to puppies. The diagnosis is confirmed by the identification of larvae in a biopsy of infected tissue, usually performed when other diseases are suspected. Serologic tests may be helpful; an ELISA against a group of excreted antigens has shown good sensitivity and specificity. Molecular assays can identify specific pathogens. Most patients recover without specific therapy, although symptoms may persist for months.

**Treatment**

Treatment with antihelminthics or corticosteroids may be considered in severe cases. No drugs have been proven to be effective, but albendazole (400 mg orally twice daily for 5 days), mebendazole, diethylcarbamazine, and ivermectin have been used, and albendazole has been recommended as the treatment of choice.

**CUTANEOUS LARVA MIGRANS** *(Creeping Eruption)*

Cutaneous larva migrans is caused principally by larvae of the dog and cat hookworms, *Ancylostoma braziliense* and *A caninum*. Other animal hookworms, gnathostomiasis, and strongyloidiasis may also cause this syndrome. Infections are common in warm areas, including the southeastern United States. They are most common in children. The disease is caused by the migration of worms through skin; the nonhuman parasites cannot complete their life cycles, so only cause cutaneous disease.

**Clinical Findings**

Intensely pruritic erythematous papules develop, usually on the feet or hands, followed within a few days by serpiginous tracks marking the course of the parasite, which may travel several millimeters per day (Figure 35–8). Several tracks may be present. The process may continue for weeks, with lesions becoming vesiculated, encrusted, or secondarily infected. Systemic symptoms and eosinophilia are uncommon.

The diagnosis is based on the characteristic appearance of the lesions. Biopsy is usually not indicated.

**FILARIASIS**

**LYMPHATIC FILARIASIS**

**ESSENTIALS OF DIAGNOSIS**

- Episodic attacks of lymphangitis, lymphadenitis, and fever.
- Chronic progressive swelling of extremities and genitals; hydrocele; chyluria; lymphedema.
- Microfilariae in blood, chyluria, or hydrocele fluid; positive serologic tests.

**General Considerations**

Lymphatic filariasis is caused by three filarial nematodes: *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*, and is among the most important parasitic diseases of man. Approximately 120 million people are infected with these organisms in tropical and subtropical countries, about a third of these suffer clinical consequences of the infections, and many are seriously disfigured. *W bancrofti*...
causes about 90% of episodes of lymphatic filariasis. It is transmitted by Culex, Aedes, and Anopheles mosquitoes and is widely distributed in the tropics and subtropics, including sub-Saharan Africa, Southeast Asia, the western Pacific, India, South America, and the Caribbean. B. malayi is transmitted by Mansonella and Anopheles mosquitoes and is endemic in parts of China, India, Southeast Asia, and the Pacific. B. timori is found only in islands of southeastern Indonesia. Mansonella are filarial worms transmitted by midges and other insects in Africa and South America.

Humans are infected by the bites of infected mosquitoes. Larvae then move to the lymphatics and lymph nodes, where they mature over months to thread-like adult worms, and then can persist for many years. The adult worms produce large numbers of microfilariae, which are released into the circulation, and infective to mosquitoes, particularly at night (except for the South Pacific, where microfilaremia peaks during daylight hours).

### Clinical Findings

#### A. Symptoms and Signs

Many infections remain asymptomatic despite circulating microfilariae. Clinical consequences of filarial infection are principally due to inflammatory responses to developing, mature, and dying worms. The initial manifestation of infection is often acute lymphangitis, with fever, painful lymph nodes, edema, and inflammation spreading peripherally from involved lymph nodes (in contrast to bacterial lymphangitis, which spreads centrally). Lymphangitis and lymphadenitis of the upper and lower extremities is common (Figure 35–9); genital involvement, including epididymitis and orchitis, with scrotal pain and tenderness, occurs principally only with W. bancrofti infection. Acute attacks of lymphangitis last for a few days to a week and may recur a few times per year. Filarial fevers may also occur without lymphatic inflammation.

The most common chronic manifestation of lymphatic filariasis is swelling of the extremities or genitals due to chronic lymphatic inflammation and obstruction. Extremities become increasingly swollen, with a progression over time from pitting edema, to nonpitting edema, to sclerotic changes of the skin that are referred to as elephantiasis. Genital involvement, particularly with W. bancrofti, occurs more commonly in men, progressing from painful epididymitis to hydroceles that are usually painless but can become very large, with inguinal lymphadenopathy, thickening of the spermatic cord, scrotal lymphedema, thickening and fissuring of the scrotal skin, and occasionally chyluria. Lymphedema of the female genitalia and breasts may also occur.

Tropical pulmonary eosinophilia is a distinct syndrome principally affecting young adult males with either W. bancrofti or B. malayi infection, but typically without microfilaremia. This syndrome is characterized by asthmalike symptoms, with cough, wheezing, dyspnea, and low-grade fevers, usually at night. Without treatment, tropical pulmonary eosinophilia can progress to interstitial fibrosis and chronic restrictive lung disease. Mansonella can inhabit serous cavities, the retroperitoneum, the eye, or the skin, and cause abnormalities related to inflammation at these sites.

#### B. Laboratory Findings

The diagnosis of lymphatic filariasis is strongly suggested by characteristic findings of lymphangitis or lymphatic obstruction in persons with risk factors for the disease. The diagnosis is confirmed by finding microfilariae, usually in blood, but microfilariae may be absent, especially early in the disease progression (first 2–3 years) or with chronic obstructive disease. To increase yields, blood samples are obtained at about midnight in most areas, but during daylight hours in the South Pacific. Smears are evaluated by wet mount to identify motile parasites and by Giemsa staining; these examinations can be delayed until the following morning, with storage of samples at room temperature. Of note, the periodicity of microfilaremia is variable, and daytime samples may yield positive results. Microfilariae may also be identified in hydrocele fluid or chylous urine. Eosinophilia is usually absent, except during acute inflammatory syndromes. Serologic tests may be helpful but cannot distinguish past and active infections. Rapid antigen tests with sensitivity and specificity over 90% are available for detection of W. bancrofti. These can be considered the diagnostic tests of choice and are increasingly used to guide control programs. However, cross-reactivity with Loa loa infections has been described. Due to potential severe toxicity, caution is appropriate before treatment with ivermectin for positive W. bancrofti antigen tests in areas also endemic for L. loa infection. Multiple molecular tests, including field-friendly LAMP assays, have been developed. Adult worms may also be found in lymph node
biopsy specimens (although biopsy is not usually clinically indicated) or by ultrasound of a scrotal hydrocele or lymphedematous breast. When microfilariae is lacking, especially if sophisticated techniques are not available, diagnoses may need to be made on clinical grounds.

**Treatment & Control**

### A. Drug Treatment

Diethylcarbamazine is the drug of choice, but it cannot cure infections due to its limited action against adult worms. Asymptomatic infection and acute lymphangitis are treated with this drug (2 mg/kg orally three times daily) for 10–14 days, leading to a marked decrease in microfilaremia. Therapy may be accompanied by allergic symptoms, including fever, headache, malaise, hypotension, and bronchospasm, probably due to release of antigens from dying worms. For this reason, treatment courses may begin with a lower dosage, with escalation over the first 4 days of treatment. Single annual doses of diethylcarbamazine (6 mg/kg orally), alone or with ivermectin (400 mcg/kg orally) or albendazole (400 mg orally) may be as effective as longer courses of diethylcarbamazine. A single dose of all three drugs cleared parasites in more than 95% of persons for 3 years and offered superior clearance compared to a single dose of diethylcarbamazine plus albendazole and noninferiority compared to three annual doses of the two-drug regimen. When onchocerciasis or loiasis is suspected, it may be appropriate to withhold diethylcarbamazine to avoid severe reactions to dying microfilariae; rather, ivermectin or albendazole may be given, although these drugs are less active than diethylcarbamazine against adult worms. Appropriate management of advanced obstructive disease is uncertain. Drainage of hydroceles provides symptomatic relief, although they will recur. Therapy with diethylcarbamazine cannot reverse chronic lymphatic changes, but is typically provided to lower worm burdens. An interesting approach under study is to treat with doxycycline (100–200 mg/day orally for 4–6 weeks), which kills obligate intracellular *Wolbachia* bacteria. Disease is due to responses to released from the nodules and migrate through subcutaneous muscle nodules for a decade or more. Microfilariae are released from the nodules and migrate through subcutaneous nodules. Secondary bacterial infections must be treated. Surgical correction may be helpful in some cases.

### B. Disease Control

Avoidance of mosquitoes is a key measure; preventive measures include the use of screens, bed nets (ideally treated with insecticide), and insect repellents. Community-based treatment with single annual doses of effective drugs offers a highly effective means of control. The current WHO strategy for control includes mass treatment of at-risk communities with single annual doses of diethylcarbamazine plus albendazole or, for areas with onchocerciasis, albendazole plus ivermectin; in some circumstances, more frequent dosing offers improved control.

---

**ONCHOERCIASIS**

### ESSENTIALS OF DIAGNOSIS

- Conjunctivitis progressing to blindness.
- Severe pruritus; skin excoriations, thickening, and depigmentation; and subcutaneous nodules.
- Microfilariae in skin snips and on slit-lamp examination; adult worms in subcutaneous nodules.

### General Considerations

Onchocerciasis, or river blindness, is caused by *Onchocerca volvulus*. An estimated 37 million persons are infected, of whom 3–4 million have skin disease, 500,000 have severe visual impairment, and 300,000 are blinded. Over 99% of infections are in sub-Saharan Africa, especially the West African savanna, with about half of cases in Nigeria and Congo. In some hyperendemic African villages, close to 100% of individuals are infected, and 10% or more of the population is blind. The disease is also prevalent in the southwestern Arabian peninsula and Latin America, including southern Mexico, Guatemala, Venezuela, Colombia, Ecuador, and northwestern Brazil. Onchocerciasis is transmitted by simulium flies (blackflies). These insects breed in fast-flowing streams and bite during the day.

After the bite of an infected blackfly, larvae are deposited in the skin, where adults develop over 6–12 months. Adult worms live in subcutaneous connective tissue or muscle nodules for a decade or more. Microfilariae are released from the nodules and migrate through subcutaneous and ocular tissues. Disease is due to responses to worms and to intracellular *Wolbachia* bacteria.

### Clinical Findings

#### A. Symptoms and Signs

After an incubation period of up to 1–3 years, the disease typically produces an erythematous, papular, pruritic rash, which may progress to chronic skin thickening and depigmentation. Itching may be severe and unresponsive to medications, such that more disability-adjusted life years are lost to onchocercal skin problems than to blindness. Numerous firm, nontender, movable subcutaneous nodules of about 0.5–3 cm, which contain adult worms, may be present. Due to differences in vector habits, these nodules are more commonly on the lower body in Africa but on the head and upper body in Latin America. Inguinal and femoral lymphadenopathy is common, at times resulting in a “hanging groin,” with lymph nodes hanging within a sling of atrophic skin. Patients may also have systemic symptoms, with weight loss and musculoskeletal pain.

The most serious manifestations of onchocerciasis involve the eyes. Microfilariae migrating through the eyes elicit host responses that lead to pathology. Findings include punctate keratitis and corneal opacities, progressing to...
Encephalitis, which may be brought on by treatment with diethylcarbamazine is highly suggestive of the diagnosis. This test should only be used after other tests are negative, since treatment can elicit severe skin and eye reactions in heavily infected individuals. A related and safer test using topical diethylcarbamazine is also available. Eosinophilia is a common, but inconsistent finding. Antigen and antibody detection tests are under study.

**Treatment & Control**

The treatment of choice is ivermectin, which kills microfilariae, but not adult worms, so disease control requires repeat administrations. Treatment is with a single oral dose of 150 mcg/mL, but schedules for re-treatment have not been standardized. One regimen is to treat every 3 months for 1 year, followed by treatment every 6–12 months for the suspected life span of adult worms (about 15 years). Treatment results in marked reduction in numbers of microfilariae in the skin and eyes, although its impact on the progression of visual loss remains uncertain. Toxicities of ivermectin are generally mild; fever, pruritus, urticaria, myalgias, edema, hypotension, and tender lymph adenopathy may be seen, presumably due to reactions to dying worms. Ivermectin should be used with caution in patients also at risk for loiasis, since it can elicit severe reactions including encephalopathy. As with other filarial infections, doxycycline acts against *O. volvulus* by killing intracellular *Wolbachia* bacteria. A course of 100 mg/day for 4–6 weeks kills the bacteria and prevents parasite embryogenesis for at least 18 months. Doxycycline shows promise as a first-line agent to treat onchocerciasis because of its improved activity against adult worms compared to other agents and limited toxicity due to the slow action of the drug.

Protection against onchocerciasis includes avoidance of biting flies. Major efforts are underway to control insect vectors in Africa. In addition, mass distribution of ivermectin for intermittent administration at the community level is ongoing, and the prevalence of severe skin and eye disease is decreasing.

**LOIASIS**

**General Considerations**

Loiasis is a chronic filarial disease caused by infection with *Loa loa*. The infection occurs in humans and monkeys in rainforest areas of West and central Africa. An estimated 3–13 million persons are infected. The disease is transmitted by chrysops flies, which bite during the day. Over 6–12 months after infection, larvae develop into adult worms, which migrate through subcutaneous tissues, including the subconjunctiva (leading to the term “eye worm”). Adults can live for up to 17 years.

**Clinical Findings**

**A. Symptoms and Signs**

Many infected persons are asymptomatic, although they may have high levels of microfilaremia and eosinophilia. Transient subcutaneous swellings (Calabar swellings) develop in symptomatic persons. The swellings are nonerythematous, up to 20 cm in diameter, and may be preceded by local pain or pruritus. They usually resolve after 2–4 days but occasionally persist for several weeks. Calabar swellings are commonly seen around joints and may recur at the same or different sites. Visitors from nonendemic areas are more likely to have allergic-type reactions, including pruritus, urticaria, and angioedema. Adult worms may be seen to migrate across the eye, with either no symptoms or conjunctivitis, with pain and edema. The most serious complication of loiasis is encephalitis, which is most common in those with high-level microfilaremia and microfilariae in the CSF. Symptoms may range from headache and insomnia to coma and death. Encephalitis may be brought on by treatment with diethylcarbamazine or ivermectin. Other complications of loiasis include kidney disease, with hematuria and proteinuria; endomyocardial fibrosis; and peripheral neuropathy.

**B. Laboratory Findings**

The diagnosis is established by identifying microfilariae in blood. Blood is evaluated as for lymphatic filariasis, but for loiasis blood should be obtained during the day. The failure
to find microfilariae does not rule out the diagnosis. Identification of a migrating eye worm is also diagnostic. Serologic tests may be helpful in persons from nonendemic areas who may be acutely ill without detectable microfilaremia, but such tests have limited utility for residents of endemic areas because most of them will have positive test results. Field-friendly methods, including LAMP assays and a mobile phone–based video microscope, are available to rule out high-density loiasis before administration of ivermectin for the control of other filarial infections.

### Treatment

The treatment of choice is diethylcarbamazine, which eliminates microfilariae and has some activity against adult worms. Treatment is with 8–10 mg/kg/day orally for 21 days; repeat courses may be needed. Mild side effects are common, including fever, pruritus, arthralgias, nausea, diarrhea, and Calabar swellings. These symptoms may be lessened by antihistamines or corticosteroids. Patients with large worm burdens are at greater risk for serious complications of therapy, including kidney injury, shock, encephalitis, coma, and death. Treatment with ivermectin, which is highly active against microfilariae, but not adult worms, entails a higher risk of severe reactions. To attempt to avoid these sequelae, pretreatment with corticosteroids and antihistamines, and escalating dosage of diethylcarbamazine have been used, but this strategy does not prevent encephalitis. The circulating parasite load that indicates particular risk for severe complications with therapy has been estimated at 2500/mL. Strategies to treat patients with high parasite loads include (1) no treatment; (2) apheresis, if available, to remove microfilariae prior to therapy with diethylcarbamazine; or (3) therapy with albendazole, which appears to be well tolerated due to its slow antiparasitic effects, prior to therapy with diethylcarbamazine or ivermectin. Doxycycline is not effective for loiasis.

CANDIDIASIS

ESSENTIALS OF DIAGNOSIS

- Common normal flora but opportunistic pathogen.
- Mucosal disease, particularly vaginitis and esophagitis.
- Risk factors for fungemia: neutropenia, intravenous catheter, abdominal surgery, total parenteral nutrition, kidney disease, broad-spectrum antibiotics.

General Considerations

*Candida albicans* can be cultured from the mouth, vagina, and feces of most people. Cutaneous and oral lesions are discussed in Chapters 6 and 8, respectively. The risk factors for invasive candidiasis include prolonged neutropenia, recent abdominal surgery, broad-spectrum antibiotic therapy, kidney disease, and the presence of intravascular catheters (especially when providing total parenteral nutrition). Cellular immunodeficiency predisposes to mucocutaneous disease. When no other underlying cause is found, persistent oral or vaginal candidiasis should arouse a suspicion of HIV infection.

Clinical Findings

A. Mucosal Candidiasis

Esophageal involvement is the most frequent type of significant mucosal disease. Presenting symptoms include substernal odynophagia, gastrolesophageal reflux, or nausea without substernal pain. Oral candidiasis, though often associated, is not invariably present. Diagnosis is best confirmed by endoscopy with biopsy and culture.

*Vulvovaginal candidiasis* occurs in an estimated 75% of women during their lifetime. Risk factors include pregnancy, uncontrolled diabetes mellitus, broad-spectrum antimicrobial treatment, corticosteroid use, and HIV infection. Symptoms include acute vulvar pruritus, burning vaginal discharge, and dyspareunia.

B. Candidal Funguria

Most cases of candidal funguria are asymptomatic and represent specimen contamination or bladder colonization. However, symptoms and signs of true *Candida* urinary tract infections are indistinguishable from bacterial urinary tract infections and can include urgency, hesitancy, fever, chills, or flank pain.

C. Invasive Candidiasis

Invasive candidiasis can be (1) candidemia (bloodstream infection) without deep-seated infection; (2) candidemia with deep-seated infection (typically eyes, kidney, or abdomen); and (3) deep-seated candidiasis in the absence of bloodstream infection. Varying ratios of these clinical entities depends on the predominating risk factors for affected patients (ie, neutropenia, dialysis, postsurgical). The clinical presentation of candidemia varies from minimal fever to septic shock that can resemble a severe bacterial infection. The diagnosis of invasive *Candida* infection is problematic because *Candida* species are often isolated from mucosal sites in the absence of invasive disease while blood cultures are positive only 50% of the time in invasive infection. Consecutively positive (1,3)-beta-D-glucan results may be used to guide empiric therapy in high-risk patients even in the absence of positive blood cultures.

Hepatosplenic candidiasis can occur following prolonged neutropenia in patients with underlying hematologic cancers, but this entity is less common in the era of widespread antifungal prophylaxis. Typically, fever and variable abdominal pain present weeks after chemotherapy, when neutrophil counts have recovered. Blood cultures are generally negative.

D. Candidal Endocarditis

Candidal endocarditis is a rare infection affecting patients with prosthetic heart valves or prolonged candidemia, such as with indwelling catheters. The diagnosis is established definitively by culturing *Candida* from emboli or from vegetations at the time of valve replacement.
Treatment

A. Mucosal Candidiasis

Therapy of esophageal candidiasis depends on the severity of disease. If patients are able to swallow and take adequate amounts of fluid orally, fluconazole, 200–400 mg daily for 10–14 days, is recommended (Table 36–1). In the individual who is more ill or in whom esophagitis has developed while taking fluconazole, options include oral itraconazole solution, 200 mg daily; oral or intravenous voriconazole, 200 mg twice daily; intravenous amphotericin B, 0.3 mg/kg/day; intravenous caspofungin, 50 mg/day; intravenous anidulafungin, 100 mg on day 1, then 50 mg/day; or intravenous micafungin, 150 mg/day. Posaconazole tablets, 300 mg/day, may also be considered for fluconazole-refractory disease. Relapse is common with all agents.

(continued)
when there is underlying HIV infection without adequate immune reconstitution.

**Vulvovaginal candidiasis** can be treated with various topical azole preparations (eg, clotrimazole, 100-mg vaginal tablet for 7 days, or miconazole, 200-mg vaginal suppository for 3 days). The efficacy of one 150-mg oral dose of fluconazole is equivalent to topical preparations with better patient acceptance. Disease recurrence is common but can be decreased with weekly fluconazole therapy (150 mg weekly).

### B. Candidal Funguria

Candidal funguria frequently resolves with discontinuance of antibiotics or removal of bladder catheters. Clinical benefit from treatment of asymptomatic candiduria has not been demonstrated, but persistent funguria should raise the suspicion of invasive infection. When symptomatic funguria persists, oral fluconazole, 200 mg/day for 7–14 days, can be used (Table 36–1).

#### C. Invasive Candidiasis

The 2016 guidelines for management of candidemia recommend an echinocandin such as caspofungin (loading dose of 70 mg intravenously once, then 50 mg intravenously daily), micafungin (100 mg intravenously daily), or anidulafungin (loading dose of 200 mg intravenously once, then 100 mg intravenously daily) (Table 36–1). Fluconazole
(loading dose of 800 mg [12 mg/kg] intravenously, then 400 mg [6 mg/kg] intravenously daily) is an acceptable alternative for less critically ill patients without recent azole exposure. Therapy for candidemia should be continued for 2 weeks after the last positive blood culture and resolution of symptoms and signs of infection. A dilated funduscopic examination is recommended for patients with candidemia to exclude endophthalmitis and repeat blood cultures should be drawn to demonstrate organism clearance. Susceptibility testing is recommended on all bloodstream Candida isolates; once patients have become clinically stable, parenteral therapy can be discontinued and treatment can be completed with oral fluconazole, 400 mg daily orally for susceptible isolates. Removal or exchange of intravascular catheters is generally recommended for patients with candidemia in whom the catheter is the suspected source of infection. Hepatosplenic candidiasis requires treatment until lesions have resolved radiographically.

Non-albicans species of Candida account for over 50% of clinical bloodstream isolates and often have resistance patterns that are different from C. albicans. An echinocandin is recommended for treatment of C. glabrata infection with a transition to oral fluconazole or voriconazole reserved for patients whose isolates are known to be susceptible to these agents. C. glabrata that is resistant to azoles and echinocandins is being increasingly reported. Similarly, Candida krusei is generally fluconazole-resistant and so should be treated with an alternative agent, such as an echinocandin or voriconazole. Fluconazole may be optimal for Candida parapsilosis due to possible echinocandin resistance in such isolates. Cases of health care-associated infections due to multidrug-resistant Candida auris have been described from several countries, including the United States, with most cases having been treated with echinocandins plus environmental source control.

D. Candidal Endocarditis
Best results are achieved with a combination of medical and surgical therapy. Lipid formulation amphotericin B (3–5 mg/kg/day) or high-dose echinocandin (caspofungin 150 mg/day, micafungin 150 mg/day, or anidulafungin 200 mg/day) is recommended as initial therapy (Table 36–1). Step-down or long-term suppressive therapy for nonsurgical candidates may be done with fluconazole at 6–12 mg/kg/day for susceptible organisms.

E. Prevention of Invasive Candidiasis
In high-risk patients undergoing induction chemotherapy, bone marrow transplantation, or liver transplantation, prophylaxis with antifungal agents has been shown to prevent invasive fungal infections, although the effect on mortality and the preferred agent remain debated. Although the isolation of Candida species from mucosal sites raises the possibility of invasive candidiasis among critically ill patients, trials of empiric antifungal agents in such situations have not shown clear clinical benefit.

HISTOPLASMOSIS

ESSENTIALS OF DIAGNOSIS

- Exposure to bird and bat droppings; common along river valleys (especially the Ohio River and the Mississippi River valleys).
- Most patients asymptomatic; respiratory illness most common clinical problem.
- Disseminated disease common in AIDS or other immunosuppressed states; poor prognosis.
- Blood and bone marrow cultures and urine polysaccharide antigen are useful in diagnosis of disseminated disease.

General Considerations
Histoplasmosis is caused by Histoplasma capsulatum, a dimorphic fungus that has been isolated from soil contaminated with bird or bat droppings in endemic areas (central and eastern United States, eastern Canada, Mexico, Central America, South America, Africa, and Southeast Asia). Infection presumably takes place by inhalation of conidia. These convert into small budding cells that are engulfed by phagocytes in the lungs. The organism proliferates and undergoes lymphohematogenous spread to other organs.

Clinical Findings
A. Symptoms and Signs
Most cases of histoplasmosis are asymptomatic or mild and thus go unrecognized. Past infection is recognized by pulmonary and splenic calcification noted on incidental radiographs. Symptomatic infection may present with mild influenza-like illness, often lasting 1–4 days. Moderately severe infections are frequently diagnosed as atypical pneumonia. These patients have fever, cough, and mild central chest pain lasting 5–15 days.

Clinically evident infections occur in several forms: (1) Acute pulmonary histoplasmosis frequently occurs in epidemics, often when soil containing infected bird or bat droppings is disturbed. Clinical manifestations can vary from a mild influenza-like illness to severe pneumonia. The illness may last from 1 week to 6 months but is almost never fatal. (2) Progressive disseminated histoplasmosis is commonly seen in patients with underlying HIV infection (with CD4 cell counts usually less than 100 cells/mcL) or other conditions of impaired cellular immunity.
Disseminated histoplasmosis has also been reported in patients from endemic areas taking tumor necrosis factor (TNF)-alpha inhibitors. It is characterized by fever and multiple organ system involvement. Chest radiographs may show a miliary pattern. Presentation may be fulminating, simulating septic shock, with death ensuing rapidly unless treatment is provided. Symptoms usually consist of fever, dyspnea, cough, loss of weight, and prostration. Ulcers of the mucous membranes of the oropharynx may be present. The liver and spleen are nearly always enlarged, and all the organs of the body are involved, particularly the adrenal glands; this results in adrenal insufficiency in about 50% of patients. Gastrointestinal involvement may mimic inflammatory bowel disease. Central nervous system (CNS) invasion occurs in 5–10% of individuals with disseminated disease. (3) **Chronic pulmonary histoplasmosis** is usually seen in older patients who have underlying chronic lung disease. Chest radiographs show various lesions including complex apical cavities, infiltrates, and nodules. (4) **Complications of pulmonary histoplasmosis** include granulomatous mediastinitis characterized by persistently enlarged mediastinal lymph nodes and fibrosing mediastinitis in which an excessive fibrotic response to Histoplasma infection results in compromise of pulmonary vascular structures.

### B. Laboratory Findings

Most patients with chronic pulmonary disease show anemia of chronic disease. Bone marrow involvement with pancytopenia may be prominent in disseminated forms. Marked lactate dehydrogenase (LD) and ferritin elevations are also common, as are mild elevations of serum aspartate aminotransferase.

With pulmonary involvement, sputum culture is rarely positive except in chronic disease; antigen testing of bronchoalveolar lavage fluid may be helpful in acute disease. The combination of a first morning urine and serum polysaccharide antigen assays has an 83% sensitivity for the diagnosis of acute pulmonary histoplasmosis. Blood or bone marrow cultures from immunocompromised patients with acute disseminated disease are positive more than 80% of the time, but may take several weeks for growth. The urine antigen assay has a sensitivity of greater than 90% for disseminated disease in immunocompromised patients and a declining titer can be used to follow response to therapy. Diagnosis of CNS disease requires antigen and antibody testing of the cerebrospinal fluid (CSF) and serum as well as urine antigen testing.

#### Treatment

For progressive localized disease and for mild to moderately severe nonmeningeal disseminated disease in immunocompetent or immunocompromised patients, itraconazole, 200–400 mg/day orally divided into two doses, is the treatment of choice with an overall response rate of approximately 80% (Table 36–1). The oral solution is better absorbed than the capsule formulation, which requires gastric acid for absorption. Therapeutic drug monitoring of itraconazole levels should be performed to assess adequacy of drug absorption. Duration of therapy ranges from weeks to several months depending on the severity of illness. Intravenous liposomal amphotericin B, 3 mg/kg/day, is used in patients with more severe illness such as meningitis. Patients with AIDS-related histoplasmosis require lifelong suppressive therapy with itraconazole, 200 mg/day orally, although secondary prophylaxis may be discontinued if immune reconstitution occurs in response to antiretroviral therapy. Criteria for discontinuing secondary prophylaxis include 1 year of successful antifungal therapy and a CD4 cell count of greater than 150 cells/mcL and 6 months or more of antiretroviral treatment (ART). There is no clear evidence that antifungal or anti-inflammatory agents are of benefit for patients with granulomatous mediastinitis or fibrosing mediastinitis although oral itraconazole is often used. Reported outcomes in patients with fibrosing mediastinitis treated with either surgical procedures or nonsurgical intravascular interventions appear to be relatively good.

---

---

**COCCIDIOIDOMYCOSIS**

### ESSENTIALS OF DIAGNOSIS

- Influenza-like illness during acute infection: malaise, fever, backache, headache, and cough.
- Erythema nodosum common with acute infection.
- Dissemination may result in meningitis, bony lesions, or skin and soft tissue abscesses.
- Chest radiograph findings vary from pneumonitis to cavitation.
- Serologic tests useful; large spherules containing endospores demonstrable in sputum or tissues.

#### General Considerations

Coccidioidomycosis should be considered in the diagnosis of any obscure illness in a patient who has lived in or visited an endemic area. Infection results from the inhalation of arthroconidia of *Coccidioides immitis* or *C posadasii*; both organisms are molds that grow in soil in certain arid regions of the southwestern United States, in Mexico, and in Central and South America. Less than 1% of immunocompetent persons show dissemination, but among these patients, the mortality rate is high.

In HIV-infected people in endemic areas, coccidioidomycosis is a common opportunistic infection. In these patients, disease manifestations range from focal pulmonary infiltrates to widespread miliary disease with multiple organ involvement and meningitis; severity is inversely related to the extent of control of the HIV infection.
Clinical Findings

A. Symptoms and Signs

Symptoms of primary coccidioidomycosis occur in about 40% of infections. Symptom onset (after an incubation period of 10–30 days) is usually that of a respiratory tract illness with fever and occasionally chills. Coccidioidomycosis is a common, frequently unrecognized, etiology of community-acquired pneumonia in endemic areas.

Erythema nodosum may appear 2–20 days after onset of symptoms. Persistent pulmonary lesions, varying from cavities and abscesses to parenchymal nodular densities or bronchiectasis, occur in about 5% of diagnosed cases.

Disseminated disease occurs in about 0.1% of white and 1% of nonwhite patients. Filipinos and blacks are especially susceptible, as are pregnant women of all races. Any organ may be involved. Pulmonary findings usually become more pronounced, with mediastinal lymph node enlargement, cough, and increased sputum production. Lung abscesses may rupture into the pleural space, producing an empyema. Complicated skin and bone infections may develop. Fungemia may occur and is characterized clinically by a diffuse miliary pattern on chest radiograph and by early death. The course may be particularly rapid in immunosuppressed patients. Clinicians caring for immunosuppressed patients in endemic areas need to consider that patients may be latently infected.

Meningitis occurs in 30–50% of cases of dissemination and may result in chronic basilar meningitis. Subcutaneous abscesses and verrucous skin lesions are especially common in fulminating cases. HIV-infected persons with disseminated disease have a higher incidence of miliary infiltrates, lymphadenopathy, and meningitis, but skin lesions are uncommon.

B. Laboratory Findings

In primary coccidioidomycosis, there may be moderate leukocytosis and eosinophilia. Serologic testing is useful for both diagnosis and prognosis. The immunodiffusion tube precipitin test and enzyme-linked immunosorbent assay (ELISA) detect IgM antibodies and are both useful for diagnosis early in the disease process. A persistently rising IgG complement fixation titer (1:16 or more) is suggestive of disseminated disease; in addition, immunodiffusion complement fixation titers can be used to assess the adequacy of therapy. Serum complement fixation titers may be low when there is meningitis but no other disseminated disease. In patients with HIV-related coccidioidomycosis, the false-negative rate may be as high as 30%. Blood cultures are rarely positive.

Patients in whom coccidioidomycosis is diagnosed should undergo evaluation for meningeal involvement when CNS symptoms or neurologic signs are present. Demonstrable complement-fixing antibodies in spinal fluid are diagnostic of coccidioidal meningitis. These are found in over 90% of cases; Coccidioides antigen or (1,3)-beta-D-glucan testing may augment (not replace) CSF antibody testing. Spinal fluid findings include increased cell count with lymphocytosis and reduced glucose. Spinal fluid culture is positive in approximately 30% of meningitis cases.

C. Imaging

Radiographic findings vary, but patchy, nodular, and lobar upper lobe pulmonary infiltrates are most common. Hilar lymphadenopathy may be visible and is seen in localized disease; mediastinal lymphadenopathy suggests dissemination. There may be pleural effusions and lytic lesions in bone with accompanying complicated soft tissue collections.

Treatment

For progressive pulmonary or extrapulmonary disease, liposomal amphotericin B intravenously is used although oral azoles may be used for mild cases. Duration of therapy is determined by a declining complement fixation titer and a favorable clinical response. For meningitis, treatment usually is with high-dose oral fluconazole (400–1200 mg/day), although lumbar or cisternal intrathecal administration of amphotericin B daily in increasing doses up to 1–1.5 mg/ day is used initially by some clinicians or in cases refractory to fluconazole. Systemic therapy with liposomal amphotericin B, 3–5 mg/kg/day intravenously, is generally given concurrently with intrathecal therapy, but is not sufficient alone for the treatment of meningeal disease. Once the patient is clinically stable, oral therapy with an azole, usually with fluconazole (400 mg daily) and given lifelong, is the recommended alternative to intrathecal amphotericin B therapy.

Surgical drainage is necessary for management of soft tissue abscesses, necrotic bone, and complicated pulmonary disease (eg, rupture of coccidioidal cavity).

Prognosis

The prognosis for patients with limited disease is good, but persistent pulmonary cavities may cause complications such as hemoptysis or rupture producing pyopneumothorax. Serial complement fixation titers should be performed after therapy for patients with coccidioidomycosis; rising titers warrant reinitiation of therapy because relapse is likely. Late CNS complications of adequately treated meningitis include cerebral vasculitis with stroke and hydrocephalus that may require shunting. There may be a benefit from short-term systemic corticosteroids following cerebrovascular events associated with coccidioides meningitis. Disseminated and meningeal forms still have mortality rates exceeding 50% in the absence of therapy.

PNEUMOCYSTOSIS (Pneumocystis jirovecii Pneumonia)

**ESSENTIALS OF DIAGNOSIS**
- Fever, dyspnea, dry cough, hypoxia.
- Often only slight lung physical findings.
- Chest radiograph: diffuse interstitial disease or normal.
- *P. jirovecii* in sputum, bronchoalveolar lavage fluid, or lung tissue; PCR of bronchoalveolar lavage; (1,3)-beta-D-glucan in blood.

**General Considerations**

*Pneumocystis jirovecii*, the *Pneumocystis* species that affects humans, is distributed worldwide. Although symptomatic *P. jirovecii* disease is rare in the general population, serologic evidence indicates that asymptomatic infections have occurred in most persons by a young age. Accumulating evidence suggests airborne transmission. Following asymptomatic primary infection, latent and presumably inactive organisms are sparsely distributed in the alveoli. De novo infection and reactivation of latent disease likely contribute to the mechanism of acute disease in older children and adults.

The overt infection is an acute interstitial plasma cell pneumonia that occurs with high frequency among two groups: (1) as epidemics of primary infections among premature infants on hospital wards in underdeveloped parts of the world, and (2) as sporadic cases among older children and adults who have an abnormal or altered cellular immunity, either due to an underlying disease process (eg, cancer, malnutrition, stem cell or organ transplantation or, most commonly, AIDS) or due to treatment with immunosuppressive medications, such as corticosteroids or cytotoxic agents.

*Pneumocystis* pneumonia occurs in up to 80% of AIDS patients not receiving prophylaxis and is a major cause of death. Its incidence increases in direct proportion to the fall in CD4 cells, with most cases occurring at CD4 cell counts less than 200/mcL. In non-AIDS patients receiving immunosuppressive therapy, symptoms frequently begin after corticosteroids have been tapered or discontinued.

**Clinical Findings**

**A. Symptoms and Signs**

Findings are usually limited to the pulmonary parenchyma. In the sporadic form of the disease associated with deficient cell-mediated immunity, the onset may be subacute, characterized by dyspnea on exertion and nonproductive cough. Pulmonary physical findings may be slight and disproportionate to the degree of illness and the radiologic findings; many patients have bibasilar crackles. Without treatment, the course is usually one of rapid deterioration and death. Adult patients may present with spontaneous pneumothorax, usually in patients with previous episodes or those receiving aerosolized pentamidine prophylaxis. Patients with AIDS will usually have other evidence of HIV-associated disease, including fever, fatigue, and weight loss, for weeks or months preceding the illness.

**B. Laboratory Findings**

Chest radiographs most often show diffuse “interstitial” infiltration, which may be heterogeneous, miliary, or patchy early in infection. There may also be diffuse or focal consolidation, cystic changes, nodules, or cavitation within nodules. Pleural effusions are not seen. About 5–10% of patients with *Pneumocystis* pneumonia have normal chest films. High-resolution chest CT scans may be quite suggestive of *P. jirovecii* pneumonia, helping distinguish it from other causes of pneumonia.

Arterial blood gas determinations usually show hypoxemia with hypocapnia but may be normal; however, rapid desaturation occurs if patients exercise before samples are drawn. Serologic tests are not helpful in diagnosis; measurement of serum (1,3)-beta-D-glucan levels has good sensitivity, although specificity is compromised by being positive in other fungal infections. The organism cannot be cultured, and definitive diagnosis depends on morphologic demonstration of the organisms in respiratory specimens using specific stains, such as immunofluorescence. Polymerase chain reaction (PCR) of bronchoalveolar lavage is overly sensitive in that the test can be positive in colonized, noninfected persons but quantitative values may help with identifying infected patients, although precise cutoffs have not been established. A negative PCR from bronchoalveolar lavage rules out disease. Open lung biopsy and needle lung biopsy are infrequently done but may need to be performed to diagnose a granulomatous form of *Pneumocystis* pneumonia.

**Treatment**

(See Table 31–3.) It is appropriate to start empiric therapy for *P. jirovecii* pneumonia if the disease is suspected clinically; however, in both AIDS patients and non-AIDS patients with mild to moderately severe disease, continued treatment should be based on a proved diagnosis because of clinical overlap with other infections, the toxicity of therapy, and the possible coexistence of other infectious organisms. Oral trimethoprim-sulfamethoxazole (TMP-SMZ) is the preferred agent because of its low cost and excellent bioavailability in both AIDS patients and non-AIDS patients with mild to moderately severe disease. Patients suffering from nausea and vomiting or intractable diarrhea should be given intravenous TMP-SMZ until they can tolerate the oral formulation. The best-studied second-line option is a combination of primaquine and clindamycin, although dapsone/trimethoprim, pentamidine, and atovaquone have also been used. Therapy should be continued with the selected medication for at least 5–10 days before considering changing agents, as fever, tachypnea, and pulmonary infiltrates persist for 4–6 days after starting treatment. Some patients have a transient worsening of their disease during the first 3–5 days, which may be related to an inflammatory response secondary to the presence of dead or dying organisms. Early addition of corticosteroids may attenuate this response (see below). Some
clinchists prefer to treat episodes of AIDS-associated *Pneumocystis* pneumonia for 21 days rather than the usual 14 days recommended for non-AIDS cases.

**A. Trimethoprim-Sulfamethoxazole**

The dosage of TMP/SMZ is 15–20 mg/kg/day (based on trimethoprim component) given orally or intravenously daily in three or four divided doses for 14–21 days. Patients with AIDS have a high frequency of hypersensitivity reactions (approaching 50%), which may include fever, rash, malaise, neutropenia, hepatitis, nephritis, thrombocytopenia, hyperkalemia, and hyperbilirubinemia.

**B. Primaquine/Clindamycin**

A meta-analysis suggested that primaquine, 15–30 mg/day, plus clindamycin, 600 mg three times daily, is the best second-line therapy with superior results when compared with pentamidine. Primaquine may cause hemolytic anemia in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency.

**C. Pentamidine Isethionate**

The use of pentamidine has decreased as alternative agents have been studied. This medication is administered intravenously (preferred) or intramuscularly as a single dose of 3–4 mg (salt)/kg/day for 14–21 days. Pentamidine causes side effects in nearly 50% of patients. Hypoglycemia (often clinically inapparent), hyperglycemia, hyponatremia, and delayed nephrotoxicity with azotemia may occur.

**D. Atovaquone**

Atovaquone is FDA approved for patients with mild to moderate disease who cannot tolerate TMP-SMZ or pentamidine, but failure is reported in 15–30% of cases. Mild side effects are common, but no serious reactions have been reported. The dosage is 750 mg three times daily for 21 days. Atovaquone should be administered with a fatty meal.

**E. Other Medications**

Trimethoprim, 15 mg/kg/day in three divided doses daily, plus dapsone, 100 mg/day, is an alternative oral regimen for mild to moderate disease or for continuation of therapy after intravenous therapy is no longer needed.

**F. Prednisone**

Based on studies done in patients with AIDS, prednisone is given for moderate to severe pneumonia (when PaO₂ on admission is less than 70 mm Hg or oxygen saturation is less than 90%) in conjunction with antimicrobials. The dosage of prednisone is 40 mg twice daily orally for 5 days, then 40 mg daily for 5 days, and then 20 mg daily until therapy is completed. The role of prednisone in non-AIDS patients is less clear, although a 2018 large observational study suggested that adjunctive corticosteroids were associated with reduced mortality in non-AIDS patients with *Pneumocystis* pneumonia and severe hypoxia (PaO₂ 60 mm Hg or less).

**Prevention**

Primary prophylaxis for *Pneumocystis* pneumonia in HIV-infected patients should be given to persons with CD4 counts less than 200 cells/μL, a CD4 percentage below 14%, or weight loss or oral candidiasis (see Table 31–6). Primary prophylaxis is often used in patients with hematologic malignancy and transplant recipients, although the clinical characteristics of persons with these conditions who would benefit from *Pneumocystis* prophylaxis have not been clearly defined. Patients with a history of *Pneumocystis* pneumonia should receive secondary prophylaxis until they have had a durable virologic response to antiretroviral therapy for at least 3–6 months and maintained a CD4 count of greater than 200 cells/μL.

**Prognosis**

In the absence of early and adequate treatment, the fatality rate for the endemic infantile form of *Pneumocystis* pneumonia is 20–50%; for the sporadic form in immunodeficient persons, the fatality rate is nearly 100%. Early treatment reduces the mortality rate to about 3% in the former and 10–20% in AIDS patients. The mortality rate in other immunodeficient patients is still 30–50%, probably because of failure to make a timely diagnosis. In immunodeficient patients who do not receive prophylaxis, recurrences are common (30% in AIDS).

**ESSENTIALS OF DIAGNOSIS**

- Most common cause of fungal meningitis.
- Predisposing factors: chemotherapy for hematologic malignancies, Hodgkin lymphoma, corticosteroid therapy, transplant recipients, TNF-alpha inhibitor therapy, and HIV infection.
- Headache, abnormal mental status; meningitis not seen occasionally, though rarely in HIV-infected patients.
- Demonstration of capsular polysaccharide antigen or positive culture in CSF is diagnostic.

**CRYPTOCOCCOSIS**

**General Considerations**

Cryptococcosis is mainly caused by *Cryptococcus neoformans*, an encapsulated budding yeast that has been found worldwide in soil and on dried pigeon dung. *C. gattii* is a
closely related species that also causes disease in humans, although *C. gattii* may affect more ostensibly immunocompetent persons. It is a major cause of cryptococcosis in the Pacific northwestern region of the United States and may result in more severe disease than *C. neoformans*.

Infections are acquired by inhalation. In the lung, the infection may remain localized, heal, or disseminate. Clinically apparent cryptococcal pneumonia rarely develops in immunocompetent persons. Progressive lung disease and dissemination most often occur in the setting of cellular immunodeficiency, including underlying hematologic malignancies under treatment, Hodgkin lymphoma, long-term corticosteroid therapy, solid-organ transplant, TNF-alpha inhibitor therapy, or HIV infection.

▶ **Clinical Findings**

**A. Symptoms and Signs**

Pulmonary disease ranges from simple nodules to widespread infiltrates leading to respiratory failure. Disseminated disease may involve any organ, but CNS disease predominates. Headache is usually the first symptom of meningitis. Confusion and other mental status changes as well as cranial nerve abnormalities, nausea, and vomiting may be seen as the disease progresses. Nuchal rigidity and meningeal signs occur about 50% of the time but are uncommon in HIV-infected patients. Communicating hydrocephalus may complicate the course. *C. gattii* infection frequently presents with respiratory symptoms along with neurologic signs caused by space-occupying lesions in the CNS. Primary *C. neoformans* infection of the skin may mimic bacterial cellulitis, especially in persons receiving immunosuppressive therapy such as corticosteroids. Paradoxical clinical worsening associated with improved immunologic status has been reported in HIV-positive and transplant patients with cryptococcosis; this entity has been labeled the immune reconstitution inflammatory syndrome (IRIS).

**B. Laboratory Findings**

Respiratory tract disease is diagnosed by culture of respiratory secretions or pleural fluid. For suspected meningeval disease, lumbar puncture is the preferred diagnostic procedure. Spinal fluid findings include increased opening pressure, variable pleocytosis, increased protein, and decreased glucose, though as many as 50% of AIDS patients have no pleocytosis. Gram stain of the CSF usually reveals budding, encapsulated fungi. Cryptococcal capsular antigen in CSF and culture together establish the diagnosis over 90% of the time. Patients with AIDS often have the antigen in both CSF and serum, and extrameningeal disease (lungs, blood, urinary tract) is common. In patients with AIDS, the serum cryptococcal antigen is also a sensitive screening test for meningitis, being positive in over 95% of cases. MRI is more sensitive than CT in finding CNS abnormalities such as cryptococcomas. Antigen testing by lateral flow assay appears to have improved sensitivity and specificity over the conventional latex agglutination test and can provide more rapid diagnostic results.

▶ **Treatment**

Because of decreased efficacy, initial therapy with an azole alone is not recommended for treatment of acute cryptococcal meningitis. Liposomal amphotericin B, 3–4 mg/kg/day intravenously for 14 days, is the preferred agent for induction therapy, followed by an additional 8 weeks of fluconazole, 400 mg/day orally (Table 36–1). This regimen is quite effective, achieving clinical responses and CSF sterilization in about 70% of patients. The addition of flucytosine has been associated with improved survival, but toxicity is common. Flucytosine is administered orally at a dose of 100 mg/kg/day divided into four equal doses and given every 6 hours. Hematologic parameters should be closely monitored during flucytosine therapy, and it is important to adjust the dose for any decreases in kidney function. Fluconazole (800–1200 mg orally daily) may be given with amphotericin B when flucytosine is not available or patients cannot tolerate it. Frequent, repeated lumbar punctures or ventricular shunting should be performed to relieve high CSF pressures or if hydrocephalus is a complication. Corticosteroids should not be used. *Failure to adequately relieve raised intracranial pressure is a major cause of morbidity and mortality.* The end points for amphotericin B therapy and for switching to oral fluconazole are a favorable clinical response (decrease in temperature; improvement in headache, nausea, vomiting, and Mini-Mental State Examination scores), improvement in CSF biochemical parameters and, most importantly, conversion of CSF culture to negative.

A similar approach is reasonable for patients with cryptococcal meningitis in the absence of AIDS, though the mortality rate is higher. Therapy is generally continued until CSF cultures become negative. Maintenance antifungal therapy is important after treatment of an acute episode in HIV-related cases, since otherwise the rate of relapse is greater than 50%. Fluconazole, 200 mg/day orally, is the maintenance therapy of choice, decreasing the relapse rate approximately tenfold compared with placebo and threefold compared with weekly amphotericin B in patients whose CSF has been sterilized by the induction therapy. After successful therapy of cryptococcal meningitis, it is possible to discontinue secondary prophylaxis with fluconazole in individuals with AIDS who have had a satisfactory response to antiretroviral therapy (eg, CD4 cell count greater than 100–200 cells/mcL, for at least 6 months). Among clinicians treating patients without AIDS, there has been a trend in recent years to prescribe a course (eg, 6–12 months) of fluconazole as maintenance therapy following successful treatment of the acute illness; published guidelines suggest this as an option.

▶ **Prognosis**

Factors that indicate a poor prognosis include the activity of the predisposing conditions, older age, organ failure, lack of spinal fluid pleocytosis, high initial antigen titer in either serum or CSF, decreased mental status, increased intracranial pressure, and the presence of disease outside the nervous system.
ASPERGILLOSIS

**ESSENTIALS OF DIAGNOSIS**

- Most common cause of non-candidal invasive fungal infection in transplant recipients and in patients with hematologic malignancies.
- Predisposing factors: leukemia, bone marrow or organ transplant, late HIV infection.
- Pulmonary, sinus, and CNS are most common disease sites.
- Detection of galactomannan by ELISA or PCR in serum or other body fluids is useful for early diagnosis and treatment.

**General Considerations**

*Aspergillus fumigatus* is the usual cause of aspergillosis, though many species of *Aspergillus* may cause a wide spectrum of disease. The lungs, sinuses, and brain are the organs most often involved. Clinical illness results either from an aberrant immunologic response or tissue invasion.

**Clinical Findings**

**A. Symptoms and Signs**

1. **Allergic forms of aspergillosis**—Allergic bronchopulmonary aspergillosis (ABPA) occurs in patients with preexisting asthma or cystic fibrosis who develop worsening bronchospasm and fleeting pulmonary infiltrates accompanied by eosinophilia, high levels of IgE, and IgG *Aspergillus* precipitins in the blood. Allergic aspergillus sinusitis produces a chronic sinus inflammation characterized by eosinophilic mucus and noninvasive hyphal elements.

2. **Chronic aspergillosis**—Chronic pulmonary aspergillosis produces a spectrum of disease that usually occurs when there is preexisting lung damage but not significant immunocompromise. Disease manifestations range from aspergillomas that develop in a lung cavity to chronic fibrosing pulmonary aspergillosis in which the majority of lung tissue is replaced with fibrosis. Long-standing (longer than 3 months) pulmonary and systemic symptoms such as cough, shortness of breath, weight loss, and malaise are common.

3. **Invasive aspergillosis**—Invasive aspergillosis most commonly occurs in profoundly immunodeficient patients, such as those who have undergone hematopoietic stem cell transplantation or have prolonged, severe neutropenia, but it can occur among critically ill immunocompetent patients as well. Specific risk factors in patients who have undergone a hematopoietic stem cell transplant include cytopenias, corticosteroid use, iron overload, cytomegalovirus disease, and graft-versus-host disease. Pulmonary disease is most common, with patchy infiltration leading to a severe necrotizing pneumonia. Invasive sinus disease also occurs. At any time, there may be hematogenous dissemination to the CNS, skin, and other organs. Early diagnosis and reversal of any correctable immunosuppression are essential.

**B. Laboratory Findings**

There is eosinophilia, high levels of total IgE, and IgE and IgG specific for *Aspergillus* in the blood of patients with ABPA.

Blood cultures have very low yield in any form of aspergillosis. Detection of galactomannan by ELISA or *Aspergillus* DNA by PCR, or both, has been used for the early diagnosis of invasive disease, though multiple determinations should be done and usefulness is decreased in patients receiving anti-mold prophylaxis (ie, voriconazole or posaconazole). Galactomannan levels and *Aspergillus* DNA PCR can be tested in serum or in bronchoalveolar lavage fluid, which may be more sensitive than serum. Higher galactomannan levels are correlated with increased mortality, and failure of galactomannan levels to fall in response to therapy portends a worse outcome. Isolation of *Aspergillus* from pulmonary secretions does not necessarily imply invasive disease, although its positive predictive value increases with more advanced immunosuppression. Therefore, a definitive diagnosis requires demonstration of *Aspergillus* in tissue or culture from a sterile site. CT scan of the chest may show characteristics quite suggestive of invasive aspergillosis (eg, “halo sign,” which is a zone of diminution of ground glass around a consolidation).

**Prevention**

The high mortality rate and difficulty in diagnosis of invasive aspergillosis often lead clinicians to institute prophylactic therapy for patients with profound immunosuppression. The best-studied agents include voriconazole and posaconazole, although patient and agent selection criteria remain undefined. Widespread use of broad-spectrum azoles raises concern for development of invasive disease by highly resistant fungi.

**Treatment**

1. **Allergic forms of aspergillosis**—Itraconazole is the best studied agent for the treatment of allergic aspergillosis sinusitis with topical corticosteroids being the cornerstone of therapy for ongoing care. For acute exacerbations of ABPA, oral prednisone is begun at a dose of 0.5 mg/kg/day and then tapered slowly over several months. Itraconazole at a dose of 200 mg orally daily for 16 weeks appears to improve pulmonary function and decrease corticosteroid requirements in these patients, although voriconazole is increasingly being used (Table 36–1).
MUCORMYCOSIS

2. Chronic aspergillosis—The most effective therapy for symptomatic aspergillosis remains surgical resection. Other forms of chronic aspergillosis are generally treated with at least 4–6 months of oral azole therapy (itraconazole 200 mg twice daily, voriconazole 200 mg twice daily, or posaconazole 300 mg daily).

3. Invasive aspergillosis—The 2016 Infectious Diseases Society of America guidelines consider voriconazole (6 mg/kg intravenously twice on day 1 and then 4 mg/kg every 12 hours thereafter) as optimal therapy for invasive aspergillosis. A randomized controlled trial did not find an overall benefit with the addition of anidulafungin (200 mg on day 1 and then 100 mg daily) to voriconazole, but among patients in whom galactomannan was detected, those who received combination therapy had better outcomes. Isavuconazole (372 mg of prodrug on days 1 and 2 and then 372 mg once daily) was equivalent to voriconazole. Alternatives include a lipid formulation of amphotericin B (3–5 mg/kg/day), caspofungin (70 mg intravenously on day 1 and then 50 mg/day thereafter), and posaconazole oral tablets (300 mg twice daily on day 1 and then 300 mg daily thereafter). Oral dosing of voriconazole at 4 mg/kg twice daily can be used for less serious infections or as a step-down strategy after intravenous therapy. Therapeutic drug monitoring should be considered for both voriconazole and posaconazole given variations in metabolism and absorption.

Surgical debridement is generally done for sinusitis, and can be useful for focal pulmonary lesions, especially for treatment of life-threatening hemoptysis and infections recalcitrant to medical therapy. The mortality rate of pulmonary or disseminated disease in the immunocompromised patient remains high, particularly in patients with refractory neutropenia.

General Considerations

The term “mucormycosis” is applied to opportunistic infections caused by members of the genera Rhizopus, Mucor, Lichtheimia (formerly Absidia), and Cunninghamamella. Pre-disposing conditions include hematologic malignancy, stem cell transplantation, solid organ transplantation, diabetic ketoacidosis, chronic kidney disease, and treatment with desferoxamine, corticosteroids, or cytotoxic drugs.

Clinical Findings

Invasive disease of the sinuses, orbits, and the lungs may occur. Necrosis is common due to hyphal tissue invasion that may manifest as ulceration of the hard palate or nasal palate or hemoptysis. Widely disseminated disease can occur. No serologic or laboratory findings assist with diagnosis, and blood cultures are unhelpful. A reverse “halo sign” (focal area of ground glass diminution surrounded by a ring of consolidation) may be seen on chest CT. Biopsy of involved tissue remains the cornerstone of diagnosis, although cultures are frequently negative. The organisms appear in tissues as broad, branching nonseptate hyphae.

Treatment

Optimal therapy of mucormycosis involves reversal of predisposing conditions (if possible), surgical debridement, and prompt antifungal therapy. A prolonged course of a lipid preparation of intravenous liposomal amphotericin B (5 mg/kg with higher doses possibly given for CNS disease) should be started early (Table 36–1). Depending on in vitro susceptibility, posaconazole 300 mg/day orally can be used after disease has been stabilized. Combination therapy with amphotericin and posaconazole is not proven but is commonly used because of the poor response to monotherapy. Other azoles are not effective. There are limited data suggesting beneficial synergistic activity when amphotericin and caspofungin are used in combination for rhino-orbital mucormycosis in diabetic patients. Despite favorable animal studies, a pilot study in humans incorporating adjunctive iron chelation therapy with deferasirox demonstrated a higher mortality rate than antifungal therapy alone. Control of diabetes and other underlying conditions, along with extensive repeated surgical removal of necrotic, non-perfused tissue, is essential. Even when these measures are introduced in a timely fashion, the prognosis remains guarded.

BLASTOMYCOSIS

Blastomycosis occurs most often in men infected during occupational or recreational activities outdoors and in a geographically limited area of the south central and mid-western United States and Canada. Disease usually occurs in immunocompetent individuals.

MUCORMYCOSIS

**ESSENTIALS OF DIAGNOSIS**

- Most common cause of non-Aspergillus invasive mold infection.
- Predisposing factors: poorly controlled diabetes, leukemia, transplant recipient, wound contamination by soil.
- Pulmonary, rhinocerebral, and skin are most common disease sites.
- Rapidly fatal without multidisciplinary interventions.
Chronic pulmonary infection is most common and may be asymptomatic. When dissemination takes place, lesions are most frequently seen in the skin, bones, and urogenital system. Cough, moderate fever, dyspnea, and chest pain are common. These may resolve or progress, with purulent sputum production, pleurisy, fever, chills, loss of weight, and prostration. Radiologic studies, either chest radiographs or CT scans, usually reveal lobar consolidation or masses.

Raised, verrucous cutaneous lesions are commonly present in disseminated blastomycosis. Bones—often the ribs and vertebrae—are frequently involved. Epididymitis, prostatitis, and other involvement of the male urogenital system may occur. Although they do not appear to be at greater risk for acquisition of disease, infection in HIV-infected persons may progress rapidly, with dissemination common.

Laboratory findings usually include leukocytosis and anemia, though these are not specific. The organism is found in clinical specimens, such as exsanguinated sputum or tissue biopsies, as a thick-walled cell 5–20 mcm in diameter that may have a single broad-based bud. It grows readily on culture. A urinary antigen test is available, but it has considerable cross reactivity with other dimorphic fungi; it may be useful in monitoring disease resolution or progression. A serum enzyme immunoassay based on the surface protein BAD-1 has much better sensitivity and specificity than the urinary antigen test, but it is not yet commercially available.

Itraconazole, 200–400 mg/day orally for at least 6–12 months, is the therapy of choice for nonmeningeal disease, with a response rate of over 80% (Table 36–1). Liposomal amphotericin B, 3–5 mg/kg/day intravenously, is given initially for severe disease, treatment failures, or CNS involvement.

Clinical follow-up for relapse should be made regularly for several years so that therapy may be resumed or another drug instituted.

**PARACOCCIDIOIDOMYCOSIS (South American Blastomycosis)**

*Paracoccidioides brasiliensis* and *Paracoccidioides lutzii* infections have been found only in patients who have resided in South or Central America or Mexico. Long asymptomatic periods enable patients to travel far from the endemic areas before developing clinical problems. An acute form of the disease affects predominately younger patients and involves the mononuclear phagocytic system, resulting in progressive lymphadenopathy. A more chronic form affects mostly adult men and involves the lung, skin, mucous membranes, and lymph nodes. Weight loss, pulmonary complaints, or mucosal ulcerations are the most common symptoms. Extensive coalescent ulcerations may eventually result in destruction of the epiglottis, vocal cords, and uvula. Extension to the lips and face may occur. Lymph node enlargement may follow mucocutaneous lesions, eventually ulcerating and forming draining sinuses; in some patients, it is the presenting symptom. Hepatosplenomegaly may be present as well. HIV-infected patients with paracoccidioidomycosis are more likely to have extrapulmonary dissemination and a more rapid clinical disease course.

Laboratory findings are nonspecific. Serology by immunodiffusion is positive in more than 80% of cases. Complement fixation titers correlate with progressive disease and fall with effective therapy. The fungus is found in clinical specimens as a spherical cell that may have many buds arising from it. If direct examination of secretions does not reveal the organism, biopsy with Gomori staining may be helpful.

Itraconazole, 100 mg twice daily orally, is the treatment of choice and generally results in a clinical response within 1 month and effective control after 2–6 months. TMP-SMZ (480 mg/1200 mg) twice daily orally is equally effective and less costly but associated with more adverse effects and longer time to clinical cure. Amphotericin B, 0.7–1.0 mg/kg/day intravenously, is the medication of choice for severe and life-threatening infection.

**SPOROTRICHOSIS**

Sporotrichosis is a chronic fungal infection caused by organisms of the *Sporothrix schenckii* complex. It is worldwide in distribution; most patients have had contact with soil, sphagnum moss, or decaying wood. Infection takes place when the organism is inoculated into the skin—usually on the hand, arm, or foot, especially during gardening. The most common form of sporotrichosis begins with a hard, nontender subcutaneous nodule. This later becomes adherent to the overlying skin and ulcerates. Within a few days to weeks, lymphocutaneous spread along the lymphatics draining this area occurs, which may result in ulceration. Cavitary pulmonary disease occurs in individuals with underlying chronic lung disease.

Disseminated sporotrichosis is rare in immunocompetent persons but may present with widespread cutaneous, lung, bone, joint, and CNS involvement in immunocompromised patients, especially those with cellular immunodeficiencies, including AIDS and alcohol abuse.

Cultures are needed to establish diagnosis. The usefulness of serologic tests is limited, but may be helpful in diagnosing disseminated disease, especially meningitis.

Itraconazole, 200–400 mg orally daily for several months, is the treatment of choice for localized disease and some milder cases of disseminated disease (Table 36–1). Terbinafine, 500 mg orally twice daily, also appears to have good efficacy in lymphocutaneous disease. Amphotericin B intravenously, 0.7–1.0 mg/kg/day, or a lipid amphotericin B preparation, 3–5 mg/kg/day are used for severe systemic infection. Surgery may be indicated for complicated pulmonary cavitary disease, and joint involvement may require arthrodesis.
The prognosis is good for lymphocutaneous sporotrichosis; pulmonary, joint, and disseminated disease respond less favorably.

**MYCETOMA (Eumycetoma & Actinomycetoma)**

Mycetoma is a chronic local, slowly progressive destructive infection that usually involves the foot; it begins in subcutaneous tissues, frequently after advanced trauma, and then spreads to contiguous structures with sinus tracts and extruding grains. Eumycetoma (also known as maduromycosis) is the term used to describe mycetoma caused by true fungi. The disease begins as a papule, nodule, or abscess that over months to years progresses slowly to form multiple abscesses and sinus tracts ramifying deep into the tissue. Secondary bacterial infection may result in large open ulcers. Radiographs may show destructive changes in the underlying bone. Causative species can often be suggested by the color of the characteristic grains and hyphal size within the infected tissues but definitive diagnosis requires culture.

The prognosis for eumycetoma is poor, though surgical debridement along with prolonged oral itraconazole therapy, 200 mg twice daily, or combination therapy including itraconazole and terbinafine may result in a response rate of 70% (Table 36–1). The various etiologic agents may respond differently to antifungal agents, so culture results are invaluable. Amputation is necessary in far advanced cases.

**OTHER OPPORTUNISTIC MOLD INFECTIONS**

Fungi previously considered to be harmless colonizers, including *Pseudallescheriaboydii* (*Scedosporium apiospermum*), *Scedosporium prolificans*, *Fusarium*, *Paecilomyces*, *Trichoderma longibrachiatum*, and *Trichosporon*, are now significant pathogens in immunocompromised patients. This occurs most often in patients being treated for hematopoietic malignancies and in those receiving broad-spectrum antifungal prophylaxis. Infection may be localized in the skin, lungs, or sinuses, or widespread disease may appear with lesions in multiple organs. Fusariosis should be suspected in severely immunosuppressed persons in whom multiple, painful skin lesions develop; blood cultures are often positive. Sinus infection may cause bony erosion. Infection in subcutaneous tissues following traumatic implantation may develop as a well-circumscribed cyst or an ulcer.

Nonpigmented septate hyphae are seen in tissue and are indistinguishable from those of *Aspergillus* when infections are due to *S apiospermum* or species of *Fusarium*, *Paecilomyces*, *Penicillium*, or other hyaline molds. Spores or mycetoma-like granules are rarely present in tissue. The differentiation of *S apiospermum* and *Aspergillus* is particularly important, since the former is uniformly resistant to amphotericin B but may be sensitive to azole antifungals (eg, voriconazole). Infection by any of a number of black molds is designated as phaeohyphomycosis. These black molds (eg, *Exophiala*, *Bipolaris*, *Cladosiphialophora*, *Curvularia*, *Alternaria*) are common in the environment, especially on decaying vegetation. In tissues of patients with phaeohyphomycosis, the mold is seen as black or faintly brown hyphae, yeast cells, or both. Culture on appropriate medium is needed to identify the agent. Histologic demonstration of these organisms is definitive evidence of invasive infection; positive cultures must be interpreted cautiously and not assumed to be contaminants in immunocompromised hosts.

**HOUSEHOLD MOLDS**

> Molds are very common indoors where moisture exists in enclosed spaces.
> Most common indoor molds are *Cladosporium*, *Penicillium*, *Aspergillus*, and *Alternaria*.
> People most at risk for health problems include those with allergies, asthma, and underlying immunocompromising conditions.

Molds are commonly present in homes, particularly in the presence of moisture, and patients will commonly seek assessment for whether their illness is due to molds. Invasive disease due to environmental fungi can occur in the immunocompromised patient (eg, see section on Invasive Aspergillosis), but there are no data that mold exposure can induce immune dysfunction. Similarly, the concept of toxic-mold syndrome or cognitive impairment due to inhalation of mycotoxins has not been validated despite scrutiny by expert panels. Allergic symptoms (eg, asthma, hypersensitivity pneumonitis) can be worsened by environmental mold exposure, and reduction of household mold in such patients may lead to clinical improvement. The presence of mold in the household is typically easily discernable with visual inspection or detection by odor; if present, predisposing conditions should be corrected by individuals experienced in mold remediation.

**ANTIFUNGAL THERAPY**

Table 36–1 summarizes the major properties of currently available antifungal agents. Two different lipid-based amphotericin B formulations are used to treat systemic
invasive fungal infections. Their principal advantage appears to be substantially reduced nephrotoxicity, allowing administration of much higher doses. Three agents of the echinocandin class, caspofungin acetate, anidulafungin, and micafungin sodium, are approved for use. The echinocandins have relatively few adverse effects and are useful for the treatment of invasive Candida infections, although resistance is beginning to emerge clinically; C. glabrata in particular has shown resistance to this class of antifungals. Caspofungin acetate is also approved for use in refractory cases of invasive aspergillosis. Voriconazole has excellent activity against a broad range of fungal pathogens and has been FDA approved for use in invasive Aspergillus cases, Fusarium and Scedosporium infections, Candida esophagitis, deep Candida infections, and candidemia. Posaconazole has good activity against a broad range of filamentous fungi, including the Mucorales. Some experts recommend therapeutic drug monitoring in individuals with severe invasive fungal infections receiving these newer azoles because of unreliable serum levels due to either metabolic alterations as a result of genetic polymorphisms (voriconazole) or erratic absorption (posaconazole). A delayed-release tablet preparation of posaconazole provides more reliable pharmacokinetics. Isavuconazole has been approved for the treatment of aspergillosis and mucormycosis, although the data for use in the latter are scanty; it is available in an intravenous form that does not utilize the cyclodextrin carrier like previous azoles as well as an oral form with relatively reliable pharmacokinetic properties.

The human body maintains a steady temperature through the balance of internal heat production and environmental heat loss. Heat exchange between the body and environment occurs via four common processes: radiation, evaporation, conduction, and convection. In extreme temperatures, the body's thermoregulation may fail. This results in the core body temperature moving toward the temperature of the external environment. Cold and heat exposure may cause a wide spectrum of conditions that can lead to death; the severity varies considerably among individuals. Many of these conditions are preventable with appropriate education and planning. Preventive measures must be implemented on an individual and population level.

The likelihood and severity of extreme temperature-related conditions depend on physiologic and environmental factors. Physiologic risk factors include extremes of age; cognitive impairment; poor physical conditioning, sedentary lifestyle or immobility; poor acclimatization; concurrent injury; prior temperature-related injury; and numerous underlying medical conditions, especially those affecting cognition and thermoregulation. Pharmacologic risk factors include medications, holistic or alternative treatments, illicit drugs, tobacco, and alcohol. There is a subset of medications associated with a particularly high likelihood of worsening temperature-related conditions, such as those that impact sweating and the central nervous system and those that affect cutaneous blood flow such as peripheral vasoconstrictors or vasodilators. Environmental risk factors include changing weather conditions, inadequate clothing or housing (homelessness, or housing with inadequate temperature control), and occupational or recreational exposure.

Heat-related illnesses are among the most commonly seen environmental emergencies presenting to emergency departments. The amount of heat retained in the body is determined by internal metabolic function and environmental conditions, including temperature and humidity. Hyperthermia results from the body's inability to maintain normal internal temperature through heat loss. Hyperthermia results from either compromised heat dissipation mechanisms or abnormally high heat production. Heat loss occurs primarily through sweating and peripheral vasodilation. The direct transfer of heat from the skin to the surrounding air, by convection or conduction, occurs with diminishing efficiency as ambient temperature rises, especially above 37.2°C, at which point heat transfer reverses direction. At normal temperatures, evaporation accounts for approximately 20% of the body’s heat loss, but at high temperatures it becomes the major mechanism for dissipation of heat. This mechanism diminishes as humidity rises.

Heat stress can be caused by a combination of environmental heat and metabolic heat. For children under the age of 15, heat stroke is the largest cause of non-accident-related deaths in cars. This is despite substantial campaigns and preventive devices to alert drivers to check the back seat when turning off the car. Climate change may significantly contribute to the risk of heat-related conditions.

There is a spectrum of preventable heat stress conditions, ranging from mild forms, such as heat cramps, to severe forms, such as heat stroke. Risk factors include longer duration of exertion, hot environment, insufficient acclimatization, and dehydration. Additional risk factors...
include skin disorders or other medical conditions that inhibit sweat production or evaporation, obesity, prolonged seizures, hypotension, reduced cutaneous blood flow, reduced cardiac output, the use of drugs that increase metabolism or muscle activity or impair sweating, and withdrawal syndromes. Illicit drugs can cause increased muscle activity and thus generate increased body heat.

Classic (nonexertional) heat-related illness may occur in any individual in a hot, relaxing environment with increased severity in individuals with the risk factors mentioned above, even despite minimal physical activity.

Heat cramping results from dilutional hyponatremia as sweat losses are replaced with water alone. Heat exhaustion results from prolonged strenuous activity in a hot environment without adequate water or salt intake. It is characterized by dehydration, sodium depletion, or isotonic fluid loss with accompanying cardiovascular changes.

Heat syncope or sudden collapse may result in unconsciousness from volume depletion and cutaneous vasodilation with subsequent systemic and cerebral hypotension. Exercise-associated postural hypotension is usually the cause of heat syncope and may occur during or immediately following exercise. Heat stroke, the hallmark of which is cerebral dysfunction with core body temperature over 40°C, presents in one of two forms: classic and exertional. Classic (nonexertional) heat stroke occurs in patients with impaired thermoregulatory mechanisms or in extreme environmental conditions. Exertional heat stroke occurs in healthy persons undergoing strenuous exertion in a hot or humid environment. Persons at greatest risk are those who are at the extremes of age, chronically debilitated, and taking medications that interfere with heat-dissipating mechanisms.

**Clinical Findings**

When diagnosing and treating heat-related illnesses, use of an internal rectal, Foley, or esophageal thermometer is necessary because the skin temperature may not accurately reflect core body temperature. Heat cramps are painful skeletal muscle contractions and severe muscle spasms with onset during or shortly after exercise. Examination findings typically include stable vital signs; normal or slightly increased core body temperature; moist and cool skin; and tender, hard, lumpy, painful muscles that may be twitching. The diagnosis is made clinically.

Heat exhaustion is diagnosed based on symptoms and clinical findings of a core body temperature slightly elevated but less than 40°C, tachycardia, and moist skin. Symptoms are similar to those of heat syncope and heat cramps. Additional symptoms include nausea, vomiting, malaise, myalgias, hyperventilation, thirst, and weakness. Central nervous system symptoms include headache, dizziness, fatigue, anxiety, paresthesias, impaired judgment, and occasionally psychosis. Heat exhaustion may progress to heat stroke if sweating ceases and mental status declines.

Heat syncope generally occurs in the setting of prolonged vigorous physical activity or prolonged standing in a hot humid environment followed by a sudden collapse. Physical examination may reveal cool and moist skin, a weak pulse, and low systolic blood pressure.

Heat stroke is a life-threatening emergency. The hallmark of heat stroke is cerebral dysfunction when the core body temperature is over 40°C. Presenting symptoms include all findings seen in heat exhaustion with additional neurologic symptoms such as dizziness, weakness, emotional lability, confusion, delirium, blurred vision, convulsions, collapse, and unconsciousness. Physical examination findings may be variable and therefore unreliable. Exertional heat stroke may present with sudden collapse and loss of consciousness followed by irrational behavior. Sweating may not be present. Providers must be vigilant in monitoring for kidney injury, liver failure, metabolic derangements, respiratory compromise, coagulopathy, and ischemia. Initial laboratory findings are nonspecific to this condition.

**Treatment**

**A. Heat Cramps**

The patient must be moved to a shaded, cool environment and given oral rehydration solution to replace both electrolytes and water. Oral salt tablets are not recommended. The patient may have to rest for at least 2 days with continued dietary supplementation before returning to work or resuming strenuous activity in the heat.

**B. Heat Exhaustion**

Treatment consists of moving patients to a shaded, cool environment, providing adequate fluid and electrolyte replacement, and initiating active cooling measures if necessary. Physiologic saline or isotonic glucose solution may be administered intravenously when oral administration is not appropriate. At least 48 hours of rest and rehydration are recommended.

**C. Heat Syncope**

Treatment consists of rest and recumbency in a shaded, cool place, and fluid and electrolyte replacement by mouth, or intravenously if necessary.

**D. Heat Stroke**

Initially, the patient’s ABCs (airway, breathing, circulation) must be addressed and stabilized, then treatment is aimed at rapidly reducing the core body temperature within 1 hour while supporting circulation and perfusion. Patients should be observed using pulse oximetry and cardiac monitors while continuing to measure core body temperature and fluid input and output. The patient should also be observed for complications such as hypovolemic or cardiogenic shock, metabolic abnormalities, cardiac arrhythmias, coagulopathy, acute respiratory distress syndrome (ARDS), hypoglycemia, rhabdomyolysis, seizures, organ dysfunction, infection, and severe edema that can progress to a compartment syndrome. Circulatory failure in heat-related illness is mostly due to shock from relative or absolute hypovolemia. Oral or intravenous fluid administration must be provided to ensure adequate urinary output. Clinicians must also assess for and treat concurrent conditions such as infection, trauma, and drug effects.
Choice of cooling method depends on which can be instituted the fastest with the least compromise to the overall care of the patient. Evaporative cooling is preferred for nonexertional heat stroke and conductive-based cooling for exertional heat stroke. **Evaporative cooling** is a noninvasive, effective, quick, and easy way to reduce temperature. This is accomplished by placing the undressed patient in lateral recumbent position or supported in a hands-and-knees position to expose maximum skin surface to the air while the entire undressed body is sprayed with lukewarm water (20°C) and cooled by large fans circulating room air. Addition of inhaled cool air or oxygen may aid in cooling but must not be used alone. **Conductive-based cooling** involves cool fluid infusion, gastric or bladder lavage, ice packs, and immersion into ice water or cool water. When immersion in ice water or cold water is available in the field, it is the preferred method of cooling for exertional heat stroke. Ice packs are most effective when covering the whole body, as opposed to the traditional method of placing in the axilla and groin only. Intravascular heat exchange catheter systems as well as hemodialysis using cold dialysate (30–35°C) have been successful in reducing core body temperature.

Shivering must be avoided because it inhibits the effectiveness of cooling by increasing internal heat production. Medications can be used to suppress shivering including magnesium, quick-acting opioid analgesics, benzodiazepines, and quick-acting anesthetic agents. Skin massage is recommended to prevent cutaneous vasoconstriction. **Antipyretics** (aspirin, acetaminophen) have no effect on environmentally induced hyperthermia and are contraindicated. Treatment must be continued until the core body temperature drops to 39°C.

**Prognosis**

Mortality is high from heat stroke, most frequently secondary to multiorgan dysfunction. The patient is also at risk for rhabdomyolysis, ARDS, and inflammation even after temperature has normalized. Following heat stroke, immediate reexposure to ambient heat must be avoided.

**When to Refer**

Potential consultants include a surgeon for suspicion of compartment syndrome, nephrologist for kidney injury, and transplant surgeon for fulminant liver failure.

**When to Admit**

All patients with suspected heat stroke must be admitted to a hospital with intensive care capability for close monitoring.

**Prevention**

Education is necessary to improve prevention and early recognition of heat-related disorders. Individuals may take steps to reduce personal risk factors and to gradually acclimatize to hot environments. For prevention of occupational heat-related illness, a comprehensive preventive program should assess personal risk factors, estimated wet-bulb globe temperature, workload, acclimatization status, and early symptom recognition.

Coaches, athletic trainers, athletes, and parents of young athletes must be educated about heat-related illness, specifically about prevention, risks, symptoms and signs, and treatment. Medical evaluation and monitoring should be used to identify the individuals and the weather conditions that increase the risk of heat-related disorders.

Those who are physically active in a hot environment must increase fluid consumption before, during, and after physical activities. Fluid consumption should include balanced electrolyte fluids and water. Water consumption alone may lead to electrolyte imbalance, particularly hypokalemia. **It is not recommended to have salt tablets available for use because of the risk of hypertonic hypernatremia.** Close monitoring of fluid and electrolyte intake and early intervention are recommended in situations necessitating exertion or activity in hot environments.

**Systemic hypothermia** is a core body temperature below 35°C. **Accurate core body temperature measurement must be obtained using a low-reading core temperature probe that measures as low as 25°C.** **Core body temperature must be over 32°C before terminating resuscitation efforts.**

**Extracorporeal membrane oxygenation (ECMO) or cardiopulmonary bypass may be considered in hypothermic patients with hemodynamic instability or cardiac arrest.**

**General Considerations**

Systemic hypothermia is defined as core body temperature below 35°C. This may be primary, from exposure to prolonged ambient, extremely low temperature, or secondary, due to thermoregulatory dysfunction. Both may be present at the same time.

Hypothermia must be considered in any patient with prolonged exposure to an ambient cold environment, especially in any patients with prior cold weather injury as well as risk factors listed in the Cold & Heat section. In prolonged or repetitive cold exposure, hypothermia ensues if the body’s thermoregulatory responses become impaired.
Clinical Findings

Symptoms and signs of hypothermia are typically nonspecific and markedly variable based on the patient’s underlying health and circumstances of cold exposure. Laboratory studies must assess acid-base status; electrolytes, particularly potassium and glucose; kidney, liver, and pancreas function; coagulation; and rhabdomyolysis. Inaccurate laboratory values will occur if the blood sample is warmed to 37°C for testing. All patients must be evaluated for associated conditions including hypoglycemia, trauma, infection, overdose, and peripheral cold injury.

Accurate core body temperature measurements must be obtained using a low-reading core temperature probe that measures as low as 25°C. Stage I hypothermia is typically seen when the core body temperature is between 32°C and 35°C and is defined by shivering and possibly poor judgment or coordination but with hemodynamic stability and a normal level of consciousness. Stage II hypothermia correlates with core body temperature 28–32°C. Shivering stops. Bradycardia, dilated pupils, slowed reflexes, cold diuresis, and confusion and lethargy ensue. The electrocardiogram (ECG) may reveal a J wave or Osborn wave (positive deflection in the terminal portion of the QRS complex, most notable in leads II, V5, and V6) (Figure 37–1). When the core body temperature is below 28°C, the likelihood of hemodynamic instability and cardiac arrest increase dramatically. Stage III hypothermia (core body temperature 24–28°C) is characterized by loss of consciousness but present vital signs. Stage IV hypothermia (core body temperature less than 24°C) is the loss of vital signs. Coma, loss of reflexes, asystole, or ventricular fibrillation may falsely lead the clinician to assume the patient is dead despite reversible hypothermia.

Treatment

Rewarming is the initial, imperative treatment for all hypothermic patients. Resuscitation begins with rapid assessment and support of airway, breathing, and circulation, simultaneously with the initiation of rewarming, and prevention of further heat loss. All cold, wet clothing must be removed and replaced with warm, dry clothing and blankets.

Mild or stage I hypothermia can be treated with passive external rewarming (ie, removing and replacing wet clothes with dry ones) or by active external rewarming. In contrast to those with more severe hypothermia, it is safe and recommended for the uninjured patient with mild hypothermia to become physically active to generate heat. Active external rewarming is noninvasive, highly effective, and safe for mild hypothermia. It involves applying external heat to the patient’s skin. Examples include warm bedding, heated blankets, heat packs, and immersion into a 40°C bath. Warm bath immersion limits the ability to monitor the patient or treat other coexisting conditions. Patients with mild hypothermia and previous good health usually respond well to passive and active external warming.

Stage II and III hypothermia are treated as above with the addition of more aggressive rewarming strategies. This requires close monitoring of vital signs and cardiac rhythm during rewarming. Warm intravenous fluids (38–42°C) are considered minimally invasive and effective.

As hypothermia becomes more severe, there are increased complications of both hypothermia itself and of rewarming. Complications of rewarming occur as colder peripheral blood returns to central circulation. This may result in core temperature afterdrop, rewarming lactic acidosis from shunting lactate into the circulation, rewarming shock from peripheral vasodilation and hypovolemia, ventricular fibrillation, and other cardiac arrhythmias. Afterdrop can be lessened by active external rewarming of the trunk but not the extremities and by avoiding any muscle movement by the patient. Extreme caution must be taken when handling the hypothermic patient to avoid triggering potentially fatal arrhythmias in a phenomenon known as rescue collapse.

Early recognition and advance management guidelines are needed for patients with stage IV hypothermia. For hypothermic patients in cardiac arrest, high-quality CPR must be initiated and continued until the patient’s core body temperature is at least 32°C. Below 30°C, arrhythmias and asystole may be refractory to drug therapy until the patient has been rewarmed; therefore, treatment should focus on excellent CPR technique and aggressive rewarming of the patient done in conjunction. Epinephrine or vasopressin may be given in cardiac arrest of the severely hypothermic patient. International Commission for Mountain Emergency Medicine recommends extracorporeal life support as the treatment of choice for patients at high risk for hypothermic cardiac arrest. Extracorporeal life support has been shown to substantially improve survival of patients with unstable circulation or cardiac arrest.

Any hypothermic patient with return of spontaneous circulation must be monitored very closely because of the high likelihood of subsequent multiorgan system failure.

When to Admit

Hypothermia patients must undergo close monitoring for potential complications. This is typically done during an inpatient admission or prolonged emergency department observation.

Figure 37–1. Electrocardiogram shows leads II and V5 in a patient whose body temperature is 24°C. Note the bradycardia and Osborn waves. These findings become more prominent as the body temperature lowers and gradually resolve with rewarming. Osborn waves have an extra positive deflection in the terminal portion of the QRS complex and are best seen in the inferior and lateral precordial leads (most notably in leads II, V5, and V6).
Clinical Findings

Cold exposure of the extremities produces immediate localized and then generalized vasoconstriction, which may result in a wide range of injuries. Tissue damage occurs because of ischemia and intravascular thromboses, endothelial damage, or actual freezing. Freezing (frostbite) may occur when skin temperatures drop or in the presence of wind, water, immobility, malnutrition, or vascular disease.

For all forms of cold-induced injury to an extremity, caution must be taken to avoid rubbing or massaging the injured area and to avoid applying moisture, ice, or heat. The cold-injured extremity must be protected from trauma, secondary infection, and further cold exposure.

Prevention

“Keep warm, keep dry, and keep moving.” For optimal prevention of frostbite, individuals must wear warm, dry clothing. Arms, legs, fingers, and toes must be exercised to maintain circulation. Wet clothing, socks, and shoes must be replaced with dry ones. Risk factors include underlying diseases or medications that decrease tissue perfusion and prolonged cold environmental exposure. Caution must be taken to avoid cramped positions; wet or constrictive clothing; prolonged dependency of the feet; use of tobacco, alcohol, and sedative medications; and exposure to wet, muddy ground and windy conditions.

Frostnip & Chilblain (Erythema Pernio)

Frostnip is a mild temporary form of cold-induced injury causing local paresthesias of the involved area that completely resolve with passive external rewarming.

Chilblains or erythema pernio are inflammatory skin changes caused by exposure to cold without actual freezing of the tissues. These skin lesions may be red or purple papular lesions, which are painful or pruritic, with burning or paresthesias. They may be associated with edema or blistering and aggravated by warmth. With continued exposure, ulcerative or hemorrhagic lesions may appear and progress to scarring, fibrosis, and atrophy. Treatment consists of elevating and passively externally rewarming the affected part.

Immersion Foot or Trench Foot

Immersion foot (or hand) is caused by prolonged immersion in cold water or mud, usually below 10°C. Prehyperemic stage is marked by early symptoms of cold and anesthesia of the affected area. Hyperemic stage follows with a hot sensation, intense burning, and shooting pains. Posthyperemic stage occurs with ongoing cold exposure; the affected part becomes pale or cyanotic with diminished pulsations due to vasospasm. This may result in blistering, swelling, redness, ecchymoses, hemorrhage, necrosis, peripheral nerve injury, or gangrene.

Treatment consists of air drying and gradual rewarming by exposure to air at room temperature. Affected parts are elevated to aid in removal of edema fluid. Pressure sites are protected with cushions. Bed rest is required until all ulcers have healed.

Frostbite

Frostbite is injury from tissue freezing and formation of ice crystals in the tissue. Most tissue destruction follows reperfusion of the frozen tissues resulting in further tissue damage. In mild cases, only the skin and subcutaneous tissues are involved. Symptoms include numbness, prickling, tingling, and pallor. With increasing severity, deeper structures become involved. The skin appears white or yellow, loses elasticity, and becomes immobile. Edema, hemorrhagic blisters, necrosis, gangrene, paresthesias, and stiffness may occur.

Treatment

A. Immediate Treatment

Evaluate and treat the patient for associated systemic hypothermia, concurrent conditions, and injury. Early use of systemic analgesics is recommended for nonfrozen injuries. Hydrate patients to avoid hypovolemia and to improve perfusion.

1. Rewarming—Rapid rewarming at temperatures slightly above normal body temperature may significantly decrease tissue necrosis and reverse the tissue crystallization. If there is any possibility of refreezing, the frostbitten part must not be thawed. Ideally, the frozen extremity must not be used. Rewarming is best accomplished by warm bath immersion. The frozen extremity is immersed for several minutes in a moving water bath heated to 40–42°C until the distal tip of the part being thawed flushes. Water in this temperature range feels warm but not hot to the normal
hand or wrist. If warm water is not available, then passive thawing in a warm environment must be allowed. Dry heat is not recommended because it is more difficult to regulate and increases the likelihood of accidental burns. Thawing may cause tenderness and burning pain. Once the frozen part has thawed and returned to normal temperature, discontinue external heat. In the early stage, rewarming by exercise, rubbing, or friction is contraindicated. The patient must be kept at bed rest with the affected parts elevated and uncovered at room temperature. Avoid application of casts, occlusive dressings, or bandages. Blisters must be left intact unless signs of infection supervene.

2. Anti-infective measures and wound care—Frostbite increases susceptibility to tetanus and infection. Tetanus prophylaxis status must be verified and updated as needed. Infection risk may be reduced by aseptic wound care. Non-adherent sterile gauze and fluffy dressing must be loosely applied to wounds and cushions used for all areas of pressure. Antibiotics should not be administered empirically.

B. Medical and Surgical Treatment Options

Telemedicine may be used so that specialists can provide advice on early field treatment of cold-injured patients in remote areas, thereby improving outcomes. Clinicians must watch for evidence of compartment syndrome and need for fasciotomy. Eschar formation without evidence of infection may be conservatively treated. The underlying skin may heal spontaneously with the eschar acting as a biologic dressing. Rates of amputation have been reduced with the use of intravenous infusions of synthetic prostaglandins and of a tissue plasminogen activators, and with intra-arterial administration of a thrombolytic within 24 hours of exposure. The rate of tissue salvage decreases with every hour of delay from rewarming to thrombolytic therapy.

C. Follow-Up Care

Patient education must include ongoing care of the cold injury and prevention of future hypothermia and cold injury. Gentle, progressive physical therapy to promote circulation should be instituted as tolerated.

Prognosis

Recovery from frostbite depends on the underlying comorbidities, the extent of initial tissue damage, the rewarming reperfusion injury, and the late sequelae. The involved extremity may be at increased susceptibility for discomfort and injury upon re-exposure to cold. Neuropathic sequelae include pain, numbness, tingling, hyperhidrosis, and cold sensitivity of the extremities. Nerve conduction abnormalities may persist for many years after a cold injury.

When to Admit

- Management of tissue damage, comorbidities, associated injuries.
- Need for hospital-based interventions.
- Psychosocial factors that could compromise patient safety or recovery.

DROWNING

ESSENTIALS OF DIAGNOSIS

- The first requirement of rescue is immediate rescue breathing and CPR.
- Clinical manifestations include hypoxemia, pulmonary edema, and hypoventilation.
- The patient must also be assessed for hypothermia, hypoglycemia, alcohol intake, concurrent injuries, and medical conditions.

General Considerations

Drowning, as defined by the World Health Organization, is the “process resulting in primary respiratory impairment from submersion in a liquid medium.” Drowning may result in asphyxiation (from fluid aspiration or laryngospasm), hypoxemia, hypothermia, and acidemia. Outcomes from drowning range from life without morbidity to death. Morbidity may be immediate or delayed. A patient may be deceptively asymptomatic during the initial recovery period only to deteriorate or die as a result of acute respiratory failure within the following 12–24 hours. Disseminated intravascular coagulation may also lead to bleeding after asphyxiation from drowning.

Drowning is a leading cause of death in children and highly preventable in all ages with implementation of educational and safety measures. Clinicians must provide patient education and guidance about drowning prevention.

Clinical Findings

A. Symptoms and Signs

The patient’s appearance may vary from asymptomatic to marked distress with abnormal vital signs. Symptoms and signs include respiratory difficulty, chest pain, dysrhythmia, hypotension, cyanosis, and hypothermia (from cold water or prolonged submersion). The patient may experience headache, neurologic deficits, and altered level of consciousness.

B. Laboratory Findings

Metabolic acidosis is common and arterial blood gas results may be helpful in determining the degree of injury.
since initial clinical findings may appear benign. PaO₂ is usually decreased; PaCO₂ may be increased or decreased; pH is decreased. Bedside blood sugar must be checked rapidly. Other testing is based on clinical scenario.

**Prevention**

Education and prevention are critical given the high burden of disease from drowning.

Preventive measures must be taken to reduce morbidity and mortality from drowning. Conditions that increase risk of submersion injury include the use of alcohol, psychotropic drugs, and other drugs, inadequate water safety skills, poor physical health, hyperventilation, sudden illness, acute trauma, decompression sickness, dangerous water conditions, and environmental exposures.

**Treatment**

**A. First Aid**

1. The first requirement of rescue is immediate basic life support treatment and CPR. At the scene, immediate airway management and measures to combat hypoxemia are critical to improve outcome.

2. Patient must be assessed for hypothermia, hypoglycemia, concurrent medical conditions, and associated trauma.

3. Rescuer must not attempt to drain water from the victim's lungs.

4. Resuscitation and basic life support efforts must be continued until core body temperature reaches 32°C.

**B. Subsequent Management**

1. **Ensure optimal ventilation and oxygenation**—The onset of hypoxemia exists even in the alert, conscious patient who appears to be breathing normally. Oxygen must be administered immediately at the highest available concentration. Oxygen saturation must be maintained at 90% or higher via some form of supplemental oxygen.

   Serial physical examinations and chest radiographs must be performed to detect possible pneumonitis, atelectasis, and pulmonary edema. Bronchodilators may be used to treat wheezing. Nasogastric suctioning may be necessary to decompress the stomach.

2. **Cardiovascular support**—Intravascular volume status must be monitored and supported by vascular fluid replacement, vasopressors, or diuretics as needed.

3. **Correction of blood pH and electrolyte abnormalities**—Metabolic acidosis is present in the majority of drowning victims, but this typically corrects through adequate ventilation and oxygenation. Glycemic control improves outcome.

4. **Cerebral and spinal cord injury**—Central nervous system damage may progress despite apparently adequate treatment of hypoxia and shock.

5. **Hypothermia**—Core body temperature must be measured and managed as appropriate (see Accidental Systemic Hypothermia, above).

**Course & Prognosis**

As the duration of submersion lengthens, the probability of worse outcome increases. Favorable prognosis is related to a duration of submersion of less than 5 minutes. Respiratory damage is often severe in the minutes to hours following a drowning. With respiratory supportive treatment, improvements typically occur quickly over the first few days following the drowning. Long-term complications of drowning may include neurologic impairment, seizure disorder, and pulmonary or cardiac damage. Prognosis is directly correlated with the patient’s age, submersion time, rapidity of prehospital resuscitation and subsequent transport to a medical facility, clinical status at time of arrival to hospital, Glasgow Coma Scale score, pupillary reactivity, and overall health assessment (APACHE II score).

**When to Admit**

Most patients with significant drowning or concurrent medical or traumatic conditions require inpatient monitoring following the event. This includes continuous monitoring of cardiorespiratory, neurologic, renal, and metabolic function. Pulmonary edema may not appear for 24 hours.

**Thermal Burns**

- Estimates of the burn location, size, and depth greatly determine treatment plan.
- The first 48 hours of burn care offer the greatest impact on morbidity and mortality of a burn victim.

Worldwide, burns are a common cause of injury and potential morbidity and mortality. Burn prognosis is affected by the type of environment where the burn occurred. Low-resource settings (wilderness or low-income areas) are associated with delays in and suboptimal access to standard burn treatments. The first 48 hours after thermal burn injury offer the greatest opportunity to impact the survival of the patient. Early surgical intervention, wound care, enteral feeding, glucose control and metabolic management, infection control, and prevention of hypothermia and compartment syndrome have contributed to significantly lower mortality.
rates and shorter hospitalizations. Research utilizing several different well-established burn severity scores has shown the importance of patient comorbidities to the prognosis of patients with severe burn injuries.

**General Considerations**

**A. Classification**

Burns are classified by extent, depth, patient age, and associated illness or injury. Accurate estimation of burn size and depth is necessary to quantify the parameters of resuscitation.

1. **Extent**—In adults, the "rule of nines" (Figure 37–2) is useful for rapidly assessing the extent of a burn. It is important to view the entire patient to make an accurate assessment of skin findings on initial and subsequent examinations. One rule of thumb is that the palm of an open hand in adult patients constitutes 1% of total body surface area (TBSA). TBSA is calculated for partial- and full-thickness burns.

2. **Depth**—Judgment of depth of injury is difficult. **Superficial burns** may appear red or gray but will demonstrate excellent capillary refill and are not blistered initially. If the wound is blistered and appears pink and wet, this represents a superficial partial-thickness burn. **Deep partial-thickness burns** appear white and wet, and bleed if poked; cutaneous sensation is maintained. **Full-thickness burns** result in a loss of adnexal structures and may appear white-yellow in color, or may have a black charred appearance. This stiff, dry skin does not bleed when poked and cutaneous sensation is lost.

Deep partial-thickness and full-thickness burns are treated in a similar fashion. Both require early debridement and grafting to heal appropriately, without which the skin becomes thin and scarred.

**B. Survival After Burn Injury**

Transfer to a burn unit is determined by large burn size, circumferential burn, or burn involving a joint or high-risk body part, and by comorbidities. Mortality rates have been significantly reduced due to treatment advances including improvements in wound care, treatment of infection, early burn excision, skin substitute usage, and early nutritional support.

**C. Associated Injuries or Illnesses**

Smoke inhalation, associated trauma, and electrical injuries are commonly associated with burns. Severe burns from any source may result in similar complications (ie, infections, respiratory compromise, multiorgan dysfunction, venous thromboembolism, and gastrointestinal complications).

**D. Systemic Reactions to Burn Injury**

Burns greater than approximately 20% of TBSA may lead to systemic metabolic derangements requiring intensive support. The inflammatory cascade can result in shock and coagulopathy.

**Treatment**

**A. Initial Resuscitation**

1. **Primary survey**—Burn patients require a full trauma assessment, starting with "ABCDE" (airway, breathing, circulation, disability, exposure).

   a. **Airway control**—Serial assessments of airway and breathing are necessary because airway compromise and ARDS may develop, particularly in those with inhalation injury.

   b. **Vascular access**—Vascular access must be obtained on all burn patients.

   c. **Fluid resuscitation**—Patients with burns greater than 15% of TBSA require intravascular fluid administration of large volumes of crystalloid. The most widely recognized guideline for fluid resuscitation is the Parkland formula (https://www.mdcalc.com/parkland-formula-burns/) in which the fluid requirement in the first 24 hours is estimated as 4 mL/kg × body weight per percent of body surface area burned. Half the calculated fluid is given in the first 8-hour period from the time of injury, not the time of arrival to medical care. The remaining fluid is delivered over the next 16 hours. An extremely large volume of fluid may be required. Crystalloid solutions alone may be insufficient to restore cardiac preload during the period of burn shock. Conversely, clinicians must watch for clinical signs of volume overload as it may lead to pulmonary complications or to a compartment syndrome from edema. Electrical burns and inhalation injury may increase the fluid requirement.

**B. Management**

1. **Pain control**—Pain control is critical in burn injury patients. Treatment is with (oral or intravenous) nonsteroidal anti-inflammatory drugs and opioids.
Monitoring includes vital signs, wound care, and observation. Abdominal compartment syndrome—Abdominal compartment syndrome is a potentially lethal condition that may develop in severely burned patients, with mortality rates of approximately 60% despite surgical intervention. Diagnosis is confirmed by bladder pressures greater than 30 mm Hg in at-risk patients. Surgical abdominal decompression may improve ventilation and oxygen delivery but may not impact survival.

2. Chemoprophylaxis—
   A. Tetanus Immunization—Verify and update tetanus prophylaxis status in all burn patients. (See Chapter 33.)
   B. Antibiotics—All nonsuperficial wounds need to be covered with topical antibiotics. Prophylaxis with systemic antibiotics is not indicated.

3. Surgical management—
   A. Escharotomy—As tissue swelling occurs, ischemia may develop under any constricting eschar of an extremity, neck, chest, or in circumferential full-thickness burns of the trunk. Escharotomy incisions can be life- and limb-saving.
   B. Fasciotomy—Fasciotomy is indicated for any compartment syndrome. Clinicians must frequently monitor patients for development of early signs of a compartment syndrome, particularly in those with circumferential burns.
   C. Debridement, dressings, and topical and systemic antibiotic therapy—Minor burn wounds must be debrided to determine the depth of the burn and then thoroughly cleansed. Thereafter, daily wound care must consist of debridements as needed, topical antibiotics, and wound dressings. Patient compliance and adequate pain control is essential for successful outpatient treatment. The wound must be reevaluated by the treating clinician within 24–72 hours to evaluate for signs of infection.

   The goal of burn wound management is to protect the wound from desiccation and avoid further injury or infection. Regular and thorough cleansing of burned areas is of critical importance. Topical antibiotics may be applied after wound cleansing. Silver sulfadiazine is no longer recommended.

   It is imperative to closely monitor for and treat systemic infection, since this remains a leading cause of morbidity among patients with major burn injuries. Health care-associated infections are increasingly common.

   D. Wound Management—The goal of therapy after fluid resuscitation is rapid and stable closure of the wound. Wounds that do not heal spontaneously in 7–10 days (ie, deep partial-thickness or full-thickness burns) are best treated by a specialist through excision and autograft to avoid development of granulation and infection. The quality of the skin in regenerated deep partial-thickness burns is marginal because of the very thin dermis that emerges.

   Cultured allogeneic keratinocyte grafts can provide rapid early coverage for superficial burn injuries. Skin substitution with cultured grafts may be life-saving for severe burns. Although the replaced dermis has nearly normal histologic dermal elements, there are no adnexal structures present, and very few, if any, elastic fibers.

   E. Abdominal Compartment Syndrome—Abdominal compartment syndrome is a potentially lethal condition that may develop in severely burned patients, with mortality rates of approximately 60% despite surgical intervention. Diagnosis is confirmed by bladder pressures greater than 30 mm Hg in at-risk patients. Surgical abdominal decompression may improve ventilation and oxygen delivery but may not impact survival.

C. Patient Support

Burn patients require extensive supportive care, both physiologically and psychologically. It is important to maintain normal core body temperature and avoid hypothermia, by maintaining environmental temperature at or above 30°C, in patients with burns over more than 20% of TBSA. Burn patients are at risk for many complications such as respiratory injury, ARDS or respiratory failure unresponsive to maximal ventilatory support, sepsis, multiorgan failure, and venous thromboembolism.

Burn patients have increased metabolic and energy needs for wound healing and require careful assessment and provision of optimal nutrition. Early aggressive nutrition (by parenteral or enteral routes) reduces infections, recovery time, noninfectious complications, length of hospital stay, long-term sequelae, and mortality.

Prevention of long-term scars remains a formidable problem in seriously burned patients.

Prognosis

Prognosis depends on the extent and location of the burn tissue damage, associated injuries, comorbidities, and complications. Hyperglycemia is a predictor of worse outcomes. Common complications include sepsis; gangrene requiring limb amputation; or neurologic, cardiac, cognitive, or psychiatric dysfunction. Psychiatric support may be necessary following burn injury.

When to Refer

Transfer to a burn unit is indicated for large burn size (for partial-thickness burns greater than 10% of TBSA or for full-thickness burns greater than 5% of TBSA), circumferential burn, inhalation injury, or burn involving a joint or high-risk body part (face, hands, feet, genitalia), and for patients with comorbidities.

When to Admit

• All severe burn patients require extensive supportive care, both physiologically and psychologically.
• Significant burns (based on location and extent).
• Patients with significant comorbidities and suboptimal home situations.
• Burn center consultation can advise which patients require transfer and which can be managed via telemedicine/telephone consultation.
• Monitoring includes vital signs, wound care, and observation for potential complications of electrolyte abnormalities, acute kidney injury, hepatic failure, cardiopulmonary compromise, hyperglycemia, and infection.

Heng JS et al. Revised Baux score and updated Charlson comorbidity index are independently associated with mortality in burns intensive care patients. Burns. 2015 Nov;41(7):1420–7. [PMID: 26187055]
Clinical Findings

Electrical burns are of three distinct types: flash (arching) burns, flame (clothing) burns, and the direct heating effect of tissues by the electrical current.

*Skin damage does not correlate with the degree of injury.* Not all electrical injuries cause skin damage; very minor skin damage may be present with massive internal injuries. Symptoms and signs may range from very subtle to death. The presence of entrance and exit burns signifies an increased risk of deep tissue damage. Current passing through skeletal muscle can cause muscle necrosis and contractions severe enough to result in bone fracture. If the current passes through the heart or brainstem, death may be immediate due to ventricular fibrillation, asystole, or apnea.

Resuscitation must be initiated on all victims of electrical injury since clinical findings are deceptive and unreliable.

Complications

Complications include cardiac or respiratory arrest; dysrhythmias; neurologic dysfunction, such as autonomic dysfunction (resulting in pupils that are fixed, dilated, or asymmetric); altered mental status; seizures; paraplegia; headache; vascular injury; tissue edema and necrosis; compartment syndrome; associated traumatic injuries (ruptured ear drums, fractures); pneumothorax; rhabdomyolysis; acute kidney injury; hypovolemia; infections; ocular complications; sepsis; gangrene; and cognitive or psychiatric dysfunction. Psychiatric support may be necessary following electrical injury.

Treatment

A. Emergency Measures

The patient must be assessed and treated as a trauma victim. The victim must be safely separated from the electrical current prior to initiation of CPR or other treatments. *Resuscitation must then be initiated since clinical findings of death are unreliable.*

B. Hospital Measures

The initial assessment involves airway, breathing, and circulation followed by a full trauma protocol. Fluid resuscitation is important to maintain adequate urinary output. Initial evaluation includes cardiac monitoring and ECG, complete blood count, electrolytes, kidney function tests, liver chemistries, creatine phosphokinase or urine myoglobin, urinalysis, and cardiac enzymes. ECG does not show typical patterns of ischemia since the electrical damage is epicardial. Victims must be evaluated for hidden injury, organ injury, blunt trauma, dehydration, skin burns, hypertension, acid-base disturbances, and neurological as well as psychological damage.

Electrical burn wounds are an underrecognized and yet devastating form of burn injury with wide-ranging and significant complications. When electrical injury occurs, there must be a high suspicion for extensive deep tissue necrosis. Superficial skin may appear deceivingly benign, leading to a delayed or completely overlooked diagnosis of deep tissue injury.
Deep tissue necrosis leads to profound tissue swelling, which results in a high risk of a compartment syndrome. Early debridement of devitalized tissues and tetanus prophylaxis may reduce the risks of infection.

Pain management is important before, during, and after initial treatment and subsequent rehabilitation.

**Prognosis**

Prognosis depends on the degree and location of electrical injury, initial tissue damage, associated injuries, comorbidities, and complications.

**When to Refer**

- Specialists may be needed to perform fasciotomy for compartment syndrome, to perform debridement of devitalized tissue, or to perform microvascular reconstruction.
- Ophthalmologists should evaluate patients for possible ocular complications, and subsequent ENT physicians should evaluate for tympanic membrane rupture or hearing loss.

**When to Admit**

Indications for hospitalization include high-voltage exposure; dysrhythmia or ECG changes; large burn; neurologic, pulmonary, or cardiac symptoms; suspicion of significant deep tissue or organ damage; transmural current pathway; history of cardiac disease or other significant comorbidities or injuries; and need for surgery.

**RADIATION EXPOSURE**

**ESSENTIALS OF DIAGNOSIS**

- Damage from radiation is determined by the source, type, quantity, duration, bodily location, and susceptibility and accumulation of exposures of the person.
- Clinicians and patients must be educated regarding the risks of medical diagnostic radiation. These radiation risks must be weighed against the benefits of the medical imaging needed.

**General Considerations**

Radiation exposure may occur from environmental, occupational, medical care, accidental, or intentional causes. The extent of damage from radiation exposure depends on the type, quantity, and duration of radiation exposure; the organs exposed; the degree of disruption to DNA; metabolic and cellular function; and the age, underlying condition, susceptibility, comorbidities, and accumulative exposures of the victim.

Radiation occurs from both nonionizing and ionizing radiation sources. **Nonionizing radiation** is low energy, resulting in injuries related to local thermal damage (ie, microwave, ultraviolet, visible light, and radiowave). **Ionizing radiation** is high energy, causing bodily damage in several ways. Ionizing radiation is either electromagnetic (ie, x-rays and gamma rays) or particulate (ie, alpha or beta particles, neutrons, and protons). Exposure may be external, internal, or both.

The International Commission on Radiological Protection (ICRP) website provides the most up-to-date recommendations for protection against ionizing radiation (http://www.icrp.org/index.asp). The World Health Organization (WHO) has published a series of guidelines on radiation emergencies (eg, see https://www.who.int/ionizing_radiation/a_e/en/). These guidelines include recommended interventions during the early, intermediate, and late emergency phases and the management of their psychosocial impact.

**Clinical Findings**

Radiation exposure results in acute and delayed effects. Acute effects involve damage of the rapidly dividing cells (ie, the mucosa, skin, and bone marrow). This may be manifested as mucositis, nausea, vomiting, gastrointestinal edema and ulcers, skin burns, and bone marrow suppression over hours to days after exposure. Delayed effects include malignancy, reproduction abnormalities, and liver, kidney, and central nervous system and immune system dysfunction.

Clinicians must be educated to recognize and treat acute radiation sickness also referred to as **acute radiation syndrome**. Acute radiation syndrome is due to an exposure to high doses of ionizing radiation over a brief time course. The symptom onset is within hours to days depending on the dose. Symptoms include anorexia, nausea, vomiting, weakness, exhaustion, lassitude and, in some cases, prostration; these symptoms may occur singly or in combination. Dehydration, anemia, and infection may follow. The Centers for Disease Control and Prevention offers web-based information regarding acute radiation syndrome (https://www.cdc.gov/nceh/radiation/emergencies/arsphysicianfactsheet.htm).

In **acute radiation exposure**, medical care includes close monitoring of the gastrointestinal, cutaneous, hematologic, cardiopulmonary, and cerebrovascular symptoms and signs from initial exposure and over time.

**Therapeutic Radiation Exposure**

Radiation therapy has been a successful component in the treatment of many malignancies. These radiation-treated cancer survivors have a higher risk of development of a second malignancy; obesity; and pulmonary, cardiac and thyroid dysfunction as well as an increased overall risk for chronic health conditions and mortality.
Medical Imaging Radiation Exposure

Medical imaging with ionizing radiation exposure has dramatically increased over the past few decades. Medical imaging radiation exposure is a growing concern for health care professionals and the public. With the rising use of medical imaging, there are urgent safety needs for standardization and regulation of radiation dosing in medical diagnostics and for clinician and public education about this issue.

The American College of Radiology (ACR) offers “ACR Appropriateness Criteria,” which are evidence-based guidelines created by expert panels to serve as a reference for best practices for imaging decisions by health care providers (https://www.acr.org/Clinical-Resources/ACR- Appropriateness-Criteria). Clinicians and patients must carefully weigh the risks and benefits of radiation exposure when deciding on an imaging test.

Occupational & Environmental Radiation Exposure

The National Nuclear Security Administration’s Radiation Emergency Assistance Center provides 24-hour access to expert consultation services over the telephone or via email (telephone: 1-865-576-1005 or email: https://orise.orau.gov/reacts/). The Centers for Disease Control and Prevention “Radiation Emergencies” website (https://www.cdc.gov/nceh/radiation/emergencies/index.htm) is a useful resource for professionals.

Treatment

Treatment is focused on decontamination, symptomatic relief, supportive care, and psychosocial support. Specific treatments focus on the dose, route, and effects of exposure.

Prognosis

Prognosis is determined by the radiation dose, duration, and frequency as well as by the underlying condition of the victim. Death is usually due to hematopoietic failure, gastrointestinal mucosal damage, central nervous system damage, widespread vascular injury, or secondary infection. Carcinogenesis is related to the radiation type, total dose, duration, and accumulation of exposure, and to the susceptibility of the victim. The younger the victim’s age at the time of exposure, the greater the risk of acute and long-term damage from radiation. Radiation-related cancer risks persist throughout the exposed person’s life span.

With the increased use of ionizing radiation for medical diagnostics and treatments, there is a growing concern for the iatrogenic increase in radiation-induced cancer risks. There are age-related sensitivities to radiation; prenatal and younger age victims are more susceptible to carcinogenesis.

When to Admit

Most patients with significant ionizing radiation exposure require admission for close monitoring and supportive treatment.
Decompression illness occurs when the ascent is too rapid and gas bubbles form and cause damage depending on their location (ie, coronary, pulmonary, spinal or cerebral blood vessels, joints, soft tissue). Decompression illness symptoms depend on the size, number, and location of gas bubbles released (notably nitrogen). Risk of decompression illness depends on the dive details (depth, duration, number of dives, interval surface time between dives, and water conditions) as well as the diver’s age, weight, physical condition, physical exertion, the rate of ascent, and the length of time between the low altitude (scuba dive) and high altitude (air travel or ground ascent). Predisposing factors include obesity, injury, hypoxia, lung or cardiac disease, right to left cardiac shunt, diver’s overall health, dehydration, alcohol and medication effects, and panic attacks. Decompression illness may also occur in those who take hot showers after cold dives. There have been clinical case reports of delayed presentations of decompression illness following post-dive exercise.

Preventive measures include diver education; pre-dive medical screening and dive planning; strict adherence to dive course, timing, and depths; and a slow and controlled ascent plus proper control of buoyancy. Conservative recommendation is to avoid high altitudes (air travel or ground ascent) for at least 24 hours after surfacing from the dive, especially following multiple dives.

**Clinical Findings**

The range of clinical manifestations varies depending on the location of the gas bubble formation or the compressibility of gases in the body. Symptom onset may be immediate, within minutes or hours (in the majority), or present up to 48 hours later. Decompression illness symptoms include pain in the joints (“the bends”); skin pruritus or burning (skin bends); cardiac symptoms (acute coronary syndrome, conduction abnormalities); spinal cord or cerebral symptoms (focal neurologic dysfunction or “dissociation” symptoms that do not follow typical distribution neuroanatomy patterns); labyrinthine decompression illness (“the staggers,” central vertigo); pulmonary decompression illness (“the chokes,” inspiratory pain, cough, and respiratory distress); arterial gas embolism (cerebral, pulmonary); barotrauma of the lungs, ear, and sinus; and coma and death.

Decompression illness involving the brain and spinal cord may occur by different mechanisms due to air bubbles causing arterial occlusion, venous obstruction, or in situ toxicity.

The clinician must assess for associated conditions of hypothermia, hypoglycemia, hypovolemia, drowning, trauma, envenomations, or concurrent medical conditions.

**Treatment**

Early recognition and prompt treatment are extremely important. Decompression illness must be considered if symptoms are temporally related to recent diving or altitude or pressure changes within the past 48 hours. Continuous administration of 100% oxygen is indicated and beneficial for all patients. Hyperbaric oxygen treatment is commonly recommended for decompression illness symptoms. Immediate consultation with a diving medicine or hyperbaric oxygen specialist is indicated even if mild decompression illness symptoms resolve. Nonsteroidal anti-inflammatory drugs, acetaminophen, or aspirin may be given for pain control if there are no contraindications. Opioids must be used very cautiously, since these may obscure the response to recompression.

**When to Admit**

Rapid transportation to a hyperbaric treatment facility for recompression is imperative for decompression illness. The Divers Alert Network is an excellent worldwide resource for emergency advice 24 hours daily for the management of diving-related conditions (www.diversalertnetwork.org).

**HIGH-ALTITUDE ILLNESS**

**ESSENTIALS OF DIAGNOSIS**

- The severity of the high-altitude illness is affected by the rate and height of ascent and the individual’s susceptibility.
- Prompt recognition and medical treatment of early symptoms of high-altitude illness may prevent progression.
- Clinicians must assess other conditions that may coexist or mimic symptoms of high-altitude illness.
- Immediate descent is the definitive treatment for high-altitude cerebral edema and high-altitude pulmonary edema.

**General Considerations**

As altitude increases, hypobaric hypoxia results due to a decrease in both barometric pressure and oxygen partial pressure. High-altitude illnesses are due to hypobaric hypoxia at high altitudes (usually greater than 2000 meters or 6562 feet). High-altitude illness includes a spectrum of disorders categorized by end-organ effects (mostly cerebral and pulmonary) and exposure duration (acute and long-term). Acute high-altitude illnesses are acute hypoxia, acute mountain sickness (AMS), high-altitude cerebral edema (HACE), and high-altitude pulmonary edema (HAPE).
Acclimatization occurs as a physiologic response to the rise in altitude and increasing hypobaric hypoxia. High-altitude illness results when the hypoxic stress is greater than the individual’s ability to acclimatize. Risk factors for high-altitude illness include increased physical activity with insufficient acclimatization, inadequate education and preparation, individual susceptibility, and previous high-altitude illness. The key determinants of high-altitude illness risk and severity include both individual susceptibility factors and altitudinal factors (rapid rate and height of ascent and total change in altitude).

Individual susceptibility factors include underlying conditions such as cardiac and pulmonary dysfunction, patent foramen ovale, blood disorders, pregnancy, neurologic conditions, cigarette smoking, recent surgery, diabetes, and many other chronic medical conditions. Those with symptomatic cardiac or pulmonary disease must avoid high altitudes.

Patient assessment for high-altitude illness must also include evaluation for other conditions, which may coexist or may present in a similar manner.

1. High-Altitude–Associated Neurologic Conditions: AMS & HACE

There is a spectrum of neurologic conditions caused by high altitude, ranging from acute mountain sickness (AMS) to the more serious form, high-altitude cerebral edema (HACE). Clinicians may utilize various diagnostic tools to assess the level of cerebral impairment due to high altitude.

AMS includes symptoms such as headache (most severe and persistent symptom), lassitude, drowsiness, dizziness, chilliness, nausea and vomiting, and difficulty sleeping. Later symptoms include irritability, difficulty concentrating, anorexia, insomnia, and increased headaches.

HACE includes the severe symptoms of AMS and results from cerebral vasogenic edema and cerebral cellular hypoxia. It usually occurs at elevations above 2500 meters (8202 feet) but may occur at lower elevations. Hallmarks are altered mental status, ataxia, severe lassitude, and encephalopathy. Examination findings may include confusion, ataxia, urinary retention or incontinence, focal neurologic deficits, papilledema, and seizures. Symptoms may progress to obtundation, coma, and death.

Treatment

Definitive treatment is immediate descent of at least 610 meters (2001 feet), and descent must continue until symptoms improve. Descent is essential if the symptoms are persistent, severe, or worsening, or if HACE or HAPE are present. If immediate descent is not possible, portable hyperbaric chambers can provide symptomatic relief, but they must not delay descent.

Initial treatment involves oxygen administration to keep the pulse oximetry $S_O_2$ to greater than 90%.
Acetazolamide (250 mg twice daily) is an effective medication for both prophylaxis and treatment of mild symptoms of AMS.

Dexamethasone is given for moderate to severe AMS (4 mg orally every 6 hours). Dexamethasone is the primary treatment for HACE (8 mg once then 4 mg every 6 hours).

Acetazolamide can be added as an adjunct in severe HACE cases. In most individuals, symptoms clear within 24–48 hours. HACE treatment must continue until 24 hours after resolution of symptoms or until descent is completed. Dexamethasone should not be given for longer than 7 days.

It is imperative that the clinician also assess for other conditions that may mimic or coexist with AMS and HACE.

If HAPE symptoms and signs are present along with HACE, nifedipine or a selective phosphodiesterase inhibitor may be added for pulmonary vasodilation. The clinician must be cautious when using combinations of vasodilators.

2. Acute HAPE

HAPE is the leading cause of death from high-altitude illness. The hallmark is markedly elevated pulmonary artery pressure followed by pulmonary edema. It usually occurs at altitudes above 3000 meters (9840 feet), although it may occur at lower levels. Early symptoms may appear within 6–36 hours after arrival at a high-altitude area. These include incessant dry cough, shortness of breath disproportionate to exertion, headache, decreased exercise performance, fatigue, dyspnea at rest, and chest tightness. Recognition of the early symptoms may enable the patient to descend before incapacitating pulmonary edema develops. Strenuous exertion must be avoided. Later, wheezing, orthopnea, and hemoptysis may occur as pulmonary edema worsens.

Physical findings may include tachycardia, mild fever, tachypnea, cyanosis, prolonged respiration, rales, and rhonchi. The clinician must assess for other potential medical conditions because the clinical picture may resemble other entities. Diagnosis is usually clinical; ancillary tests are nonspecific or unavailable on site. Prompt recognition and medical attention of early symptoms of HAPE may prevent progression.

Treatment

Immediate descent (at least 610 meters [2000 feet]) is essential, although this may not be immediately possible and may not alone improve symptoms.

The patient must be placed at rest, reclined with head elevated. Supplemental oxygen must be administered to maintain pulse oximetry reading $S_O_2$ greater than 90%. Recompression in a portable hyperbaric bag will temporarily reduce symptoms if rapid or immediate descent is not possible, but must not delay descent.

Nifedipine (60 mg slow extended-release tablets daily, given in divided doses) can be used as an adjunct if the other therapies (descent, oxygen, or portable hyperbarics) are not successful or available. Selective phosphodiesterase inhibitors may be used for HAPE prevention but may also provide effective symptom relief as an alternative or if nifedipine is not available. Administering nifedipine plus a phosphodiesterase inhibitor as pulmonary vasodilators is not recommended because this combination may also lower the mean arterial pressure and decrease cerebral perfusion. Treatment for ARDS (see Chapter 9) is required for some patients. If neurologic symptoms are present concurrently with HAPE and do not resolve with improved oxygenation, dexamethasone may be added according to HACE treatment guidelines.
Disorders Related to Environmental Emergencies

3. Subacute Mountain Sickness

This occurs most frequently in unacclimatized individuals and at high altitudes (above 4500 meters) for a prolonged period of time. Treatment consists of rest, oxygen administration, diuretics, and return to lower altitudes.

4. Chronic Mountain Sickness (Monge Disease)

This uncommon condition is seen in residents of high-altitude communities who have lost their acclimatization to such a hypobaric hypoxia environment. It is difficult to differentiate from chronic pulmonary disease.

Prevention of High-Altitude Disorders

Pre-trip preventive measures include participant education, medical preparticipation evaluation, pre-trip planning, optimal physical conditioning before travel, and adequate rest and sleep the day before travel and during the trip. Preventive efforts during ascent include reduced food intake and avoidance of alcohol, tobacco, and unnecessary physical activity during travel.

Gradual ascent is the most effective way to allow acclimatization. Low-risk ascension rate is 2 or more days to arrive at 2500–3000 meters. The altitude reached during waking hours is not as important as the altitude at which the hiker sleeps. If the terrain does not allow a sleeping elevation increase below 500 meters, an extra rest day must be added before or after the increased sleep elevation more than 500 meters.

Drug prophylaxis may be prescribed for AMS and HACE if no contraindications exist. Prophylactic low-dose acetazolamide (125 mg twice daily orally) has been shown to reduce the incidence and severity of AMS and HACE when started 3 days prior to ascent and continued for 48–72 hours at high altitude. Dexamethasone is an alternative prophylactic medication for AMS and HACE.

Individuals with a past history of HAPE should use drug prophylaxis to reduce the risk of recurrence. Nifedipine started the day before ascent and continued through the fourth day at target elevation, or through the seventh day if the ascent rate was faster, is recommended. Salmeterol can be added beginning 24 hours prior to ascent. This can be used as an adjunct to nifedipine but not as monotherapy.

Phosphodiesterase inhibitors may be beneficial in the treatment of HAPE based on their physiologic effects of decreased pulmonary arterial pressures and pulmonary vasodilation.

When to Admit

- All patients with HACE or HAPE must be hospitalized for further observation.
- Hospitalization must also be considered for any patient who remains symptomatic after treatment and descent.
- Pulmonary symptoms and hypoxia may be worsened by complications such as pulmonary embolism, secondary respiratory infection, bronchospasm, mucous plugging, or acute coronary syndrome.

Safety of Air Travel & Selection of Patients for Air Travel

The medical safety of air travel depends on the nature and severity of the traveler's preflight condition and factors such as travel duration, frequency and use of inflight exercise, cabin altitude pressure, availability of medical supplies, infectious diseases of other travelers, and the presence of health care professionals on board. Air travel passengers are susceptible to a wide range of flight-related problems: pulmonary (hypoxemia, gas expansion), venous thromboembolism (VTE), infections, cardiac, gastrointestinal, ocular, immunologic, syncope, neuropsychiatric, metabolic, trauma, and illicit substance-related conditions. Air-travel risks are higher for those air travelers with preexisting medical conditions.

Hypobaric hypoxia is the underlying etiology of most serious medical emergencies in flight due to cabin altitude. Despite commercial aircraft pressurization requirements, there is significant hypoxemia, dyspnea, gas expansion, and stress in travelers.

Any form of prolonged travel involving immobilization has been associated with increased risk of VTE (referred to as “traveler’s thrombosis”), although air travel has been the main focus of medical review. Risks for VTE in long-distance travelers include the following: (1) travel involving immobilization for 4 or more hours, (2) hypercoagulable disorders, and (3) acquired risks.

Air travel is not advised for anyone who is “incapacitated” or has any “unstable conditions.” The Air Transport Association of America defines an incapacitated passenger as “one who is suffering from a physical or mental disability and who, because of such disability or the effect of the flight on the disability, is incapable of self-care; would endanger the health or safety of such person or other passengers or airline employees; or would cause discomfort or annoyance of other passengers.” Unstable conditions include active pneumothorax, advanced pulmonary hypertension, acute worsening of an underlying lung disease, poorly controlled hypertension, dysrhythmias, angina, valvular disease, heart failure, or acute psychiatric condition; severe anemia or symptomatic sickle cell disease; recent myocardial infarction; cerebrovascular accident; poorly controlled seizure disorder; deep venous thrombosis; postsurgery; especially heart surgery (unless approved by surgeon); and any active communicable disease. Public Health Travel Restrictions have shown efficacy in preventing commercial air or
international travel of persons with certain communicable diseases that pose public health threat.

**Pregnancy**

Traveling during pregnancy is becoming more common. Pregnant travelers have unique travel-related and location-specific risks. A clinician’s authorization is required if travel is essential during the ninth month of pregnancy or earlier in a complicated or high-risk pregnancy.

Long travel increases risk of VTE for the pregnant traveler. Pregnant travelers are at higher risk from infection transmission and air travel radiation exposure.

**Prevention**

Air travel complications may be reduced by the following preventive measures: passenger prescreening, passenger education, and in-flight positioning and activity. Prescreening evaluation is recommended for all high-risk patients including preexisting requirement for oxygen, continuous positive airway pressure or ventilator support, underlying restrictive or obstructive lung disease, comorbidities worsened by hypoxemia, previous respiratory distress during air travel, recent pneumothorax, and recent (within 6 weeks) acute respiratory illness. Patients at risk for hypoxia must be assessed prior to air travel to determine if there is a need for supplemental in-flight oxygen.

Air travel education must include risk reduction measures for VTE, infectious diseases, and exacerbations of underlying medical conditions. Patients and clinicians can check the World Health Organization website for the most updated information on travel health risks and infectious diseases (https://www.who.int/ith/en/).

All long-distance travelers can reduce VTE risk by avoiding constrictive clothing, staying well-hydrated, changing position frequently, avoiding cramped position, avoiding leg crossing, engaging in frequent (at least every hour) in-flight leg stretching exercises, and walking for 5 minutes every hour. Clinicians must assess those with high risk of VTE prior to air travel to determine whether anticoagulation is indicated (see Table 14–14).

Patients with drug overdoses or poisoning may initially have no symptoms or they may have varying degrees of overt intoxication. The asymptomatic patient may have been exposed to or may have ingested a lethal dose, but not yet exhibit any manifestations of toxicity. It is important to (1) quickly assess the potential danger, (2) consider gut and skin decontamination to prevent absorption, (3) treat complications if they occur, and (4) observe the asymptomatic patient for an appropriate interval.

Assess the Danger

If the drug or poison is known, its danger can be assessed by consulting a text or computerized information resource or by calling a regional poison control center. (In the United States, dialing 1-800-222-1222 will direct the call to the regional poison control center.) Assessment will usually take into account the dose ingested; the time since ingestion; the presence of any symptoms or clinical signs; preexisting cardiac, respiratory, kidney, or liver disease; and, occasionally, specific serum drug or toxin levels. Be aware that the history given by the patient or family may be incomplete or unreliable.

THE SYMPTOMATIC PATIENT

In symptomatic patients, treatment of life-threatening complications takes precedence over in-depth diagnostic evaluation. Patients with mild symptoms may deteriorate rapidly, which is why all potentially significant exposures should be observed in an acute care facility. The following complications may occur, depending on the type of poisoning.

COMA

Assessment & Complications

Coma is commonly associated with ingestion of large doses of antihistamines (eg, diphenhydramine), benzodiazepines and other sedative-hypnotic drugs, ethanol, opioids, antipsychotic drugs, or antidepressants. The most common cause of death in comatose patients is respiratory failure, which may occur abruptly. Pulmonary aspiration of gastric contents may also occur, especially in victims who are deeply obtunded or convulsing. Hypoxia and hypoventilation may cause or aggravate hypotension, arrhythmias, and seizures. Thus, protection of the airway and assisted ventilation are the most important treatment measures for any poisoned patient.

Treatment

A. Emergency Management

The initial emergency management of coma can be remembered by the mnemonic ABCD, for Airway, Breathing, Circulation, and Drugs (dextrose, thiamine, and naloxone or flumazenil), respectively.

1. Airway—Establish a patent airway by positioning, suction, or insertion of an artificial nasal or oropharyngeal airway. If the patient is deeply comatose or if airway reflexes are depressed, perform endotracheal intubation. These airway interventions may not be necessary if the patient is intoxicated by an opioid or a benzodiazepine and responds to intravenous naloxone or flumazenil.
2. Breathing—Clinically assess the quality and depth of respiration and provide assistance if necessary with a bag-valve-mask device or mechanical ventilator. Administer supplemental oxygen, if needed. The arterial or venous blood CO₂ tension is useful in determining the adequacy of ventilation. The arterial blood PO₂ determination may reveal hypoxemia, which may be caused by respiratory depression, bronchospasm, pulmonary aspiration, or non-cardiogenic pulmonary edema. Pulse oximetry provides an assessment of oxygenation, but is not reliable in patients with methemoglobinemia or carbon monoxide poisoning, unless a pulse oximetry device capable of detecting these forms of hemoglobin is used.

3. Circulation—Measure the pulse and blood pressure and estimate tissue perfusion (eg, by measurement of urinal output, skin signs, arterial blood pH). Place the patient on continuous ECG monitoring. Insert an intravenous line, and draw blood for glucose, electrolytes, serum creatinine and liver tests, and possible quantitative toxicologic testing.

4. Drugs—

A. Dextrose and Thiamine—Unless promptly treated, severe hypoglycemia can cause irreversible brain damage. Therefore, in all obtunded, comatose or convulsing patients, give 50% dextrose, 50–100 mL by intravenous bolus, unless a rapid point-of-care blood sugar test rules out hypoglycemia. In alcoholic or very malnourished patients who may have marginal thiamine stores, give thiamine, 100 mg intramuscularly or in the intravenous fluids.

B. Opioid Antagonists—Naloxone, 0.4–2 mg intravenously or 2–4 mg by intranasal spray, may reverse opioid-induced respiratory depression and coma. It is often given empirically to any comatose patient with depressed respirations. If opioid overdose is strongly suspected, give additional doses of naloxone (up to 5–10 mg may be required to reverse the effects of potent opioids). Note: Naloxone has a shorter duration of action (2–3 hours) than most common opioids; repeated doses may be required, and continuous observation for at least 3–4 hours after the last dose is mandatory.

C. Flumazenil—Flumazenil, 0.2–0.5 mg intravenously, repeated as needed up to a maximum of 3 mg, may reverse benzodiazepine-induced coma. Caution: In most circumstances, use of flumazenil is not advised as the potential risks outweigh its benefits. Flumazenil should not be given if the patient has coingested a potential convulsant drug, is a user of high-dose benzodiazepines, or has a seizure disorder because its use in these circumstances may precipitate seizures. Note: Flumazenil has a short duration of effect (2–3 hours), and reedation requiring additional doses may occur.

HYPOTHERMIA

Assessment & Complications

Hypothermia commonly accompanies coma due to opioids, ethanol, hypoglycemic agents, phenothiazines, barbiturates, benzodiazepines, and other sedative-hypnotics and central nervous system depressants. Hypothermic patients may have a barely perceptible pulse and blood pressure. Hypothermia may cause or aggravate hypotension, which will not reverse until the temperature is normalized.

Treatment

Treatment of hypothermia is discussed in Chapter 37. Gradual rewarming is preferred unless the patient is in cardiac arrest.

HYPOTENSION

Assessment & Complications

Hypotension may be due to poisoning by many different drugs, including antihypertensives, beta-blockers, calcium channel blockers, disulfiram (ethanol interaction), iron, trazodone, quetiapine, and other antipsychotic agents and antidepressants. Poisons causing hypotension include cyanide, carbon monoxide, hydrogen sulfide, aluminum or zinc phosphide, arsenic, and certain mushrooms.

Hypotension in the poisoned or drug-overdosed patient may be caused by venous or arteriolar vasodilation, hypovolemia, depressed cardiac contractility, or a combination of these effects.

Treatment

Most hypotensive poisoned patients respond to empiric treatment with repeated 200 mL intravenous boluses of 0.9% saline or other isotonic crystalloid up to a total of 1–2 L; much larger amounts may be needed if the victim is profoundly volume depleted (eg, as with massive diarrhea due to Amanita phalloides mushroom poisoning). Monitoring the central venous pressure (CVP) can help determine whether further fluid therapy is needed. Consider bedside cardiac ultrasound or pulmonary artery catheterization (or both) to assess CVP. If fluid therapy is not successful after adequate volume replacement, give dopamine or norepinephrine by intravenous infusion.

Hypotension caused by certain toxins may respond to specific treatment. For hypotension caused by overdoses of tricyclic antidepressants or other sodium channel blockers, administer sodium bicarbonate, 50–100 mEq by intravenous bolus injection. Norepinephrine 4–8 mcg/min by intravenous infusion is more effective than dopamine in some patients with overdoses of tricyclic antidepressants or of drugs with predominantly vasodilating effects. For beta-blocker overdose, glucagon (5–10 mg intravenously) may be of value. For calcium channel blocker overdose, administer calcium chloride, 1–2 g intravenously (repeated doses may be necessary; doses of 5–10 g and more have been given in some cases). High-dose insulin (0.5–1 unit/kg/h intravenously) euglycemic therapy may also be used (see the sections Beta-Adrenergic Blockers and Calcium Channel Blockers, below). Intralipid 20% lipid emulsion has been reported to improve hemodynamics in some cases of intoxication by highly lipid-soluble drugs such as bupivacaine, bupropion, clozapimine, and verapamil. Intravenous methylene blue and extracorporeal membrane oxygenation (ECMO) have been employed in a few refractory cases; ECMO may offer temporary hemodynamic stabilization while the offending drug is eliminated.
HYPERTENSION

Assessment & Complications

Hypertension may be due to poisoning with amphetamines and synthetic stimulants, anticholinergics, cocaine, performance-enhancing products (containing caffeine, phenylephrine, ephedrine, or yohimbine), monoamine oxidase (MAO) inhibitors, and other drugs.

Severe hypertension (eg, diastolic blood pressure greater than 105–110 mm Hg in a person who does not have chronic hypertension) can result in acute intracranial hemorrhage, myocardial infarction, or aortic dissection.

Treatment

Treat hypertension if the patient is symptomatic or if the diastolic pressure is higher than 105–110 mm Hg—especially if there is no prior history of hypertension.

Hypertensive patients who are agitated or anxious may benefit from a sedative (such as lorazepam, 2–3 mg intravenously) or an antipsychotic drug (eg, haloperidol or olanzapine). For persistent hypertension, administer phenolamine, 2–5 mg intravenously, or nitroprusside sodium, 0.25–8 mcg/kg/min intravenously. If excessive tachycardia is present, add esmolol, 25–100 mcg/kg/min intravenously, or labetalol, 0.2–0.3 mg/kg intravenously. Caution: Do not give beta-blockers alone, since doing so may paradoxically worsen hypertension in some cases as a result of unopposed alpha-adrenergic stimulation.

ARRHYTHMIAS

Assessment & Complications

Arrhythmias may occur with a variety of drugs or toxins (Table 38–1). They may also occur as a result of hypoxia, metabolic acidosis, or electrolyte imbalance (eg, hyperkalemia, hypokalemia, hypomagnesemia, or hypocalcemia), or following exposure to chlorinated solvents or chloral hydrate overdose. Atypical ventricular tachycardia (torsades de pointes) is often associated with drugs that prolong the QT interval.

Table 38–1. Common toxins or drugs causing arrhythmias.1

</tr>
</tbody>
</table>

1Arrhythmias may also occur as a result of hypoxia, metabolic acidosis, or electrolyte imbalance (eg, hyperkalemia or hypokalemia, hypocalcemia, hypomagnesemia).

2https://crediblemeds.org/

Treatment

Hypoxia or electrolyte imbalance should be sought and treated. If ventricular arrhythmias persist, administer lidocaine or amiodarone at usual antiarrhythmic doses. Note: Wide QRS complex tachycardia in the setting of tricyclic antidepressant overdose (or diphenhydramine or class la antiarrhythmic drugs) should be treated with sodium bicarbonate, 50–100 mEq intravenously by bolus infusion. Caution: In such cases, avoid class la antiarrhythmic agents (eg, procainamide, disopyramide) and amiodarone, which may aggravate arrhythmias caused by tricyclic antidepressants. Torsades de pointes associated with prolonged QT interval may respond to intravenous magnesium (2 g intravenously over 2 minutes) or overdrive pacing. Treat digitalis-induced arrhythmias with digoxin-specific antibodies.

For tachyarrhythmias induced by chlorinated solvents, chloral hydrate, Freons, or sympathomimetic agents, use propranolol or esmolol (see doses given above in Hypertension section).
**Assessment & Complications**

Seizures may be caused by many poisons and drugs, including amphetamines, antidepressants (especially tricyclic antidepressants, bupropion, and venlafaxine), antihistamines (especially diphenhydramine), antipsychotics, camphor, synthetic cannabinoids and cathinones, cocaine, isoniazid (INH), chlorinated insecticides, pipermazine, tramadol, and theophylline. The onset of seizures may be delayed for up to 18–24 hours after extended-released bupropion overdose.

Seizures may also be caused by hypoxia, hypoglycemia, hypocalcemia, hyponatremia, withdrawal from alcohol or sedative-hypnotics, head trauma, central nervous system infection, or idiopathic epilepsy.

Prolonged or repeated seizures may lead to hypoxia, metabolic acidosis, hyperthermia, and rhabdomyolysis.

**Treatment**

Administer lorazepam, 2–3 mg, or diazepam, 5–10 mg, intravenously, or—if intravenous access is not immediately available—midazolam, 5–10 mg intramuscularly. If convulsions continue, administer phenobarbital, 15–20 mg/kg slowly intravenously over no less than 30 minutes. (For drug-induced seizures, phenobarbital is preferred over phenytoin or levetiracetam.) Propofol infusion has also been reported effective for some resistant drug-induced seizures.

Seizures due to a few drugs and toxins may require antidotes or other specific therapies (as listed in Table 38–2).

**HYPERTHERMIA**

**Assessment & Complications**

Hyperthermia may be associated with poisoning by amphetamines and other synthetic stimulants (cathinones, pipermazine), atropine and other anticholinergic drugs, cocaine, salicylates, strychnine, tricyclic antidepressants, and various other medications. Overdoses of serotonin reuptake inhibitors (eg, fluoxetine, paroxetine, sertraline) or their use in a patient taking an MAO inhibitor may cause agitation, hyperactivity, myoclonus, and hyperthermia ("serotonin syndrome"). Antipsychotic agents can cause rigidity and hyperthermia (neuroleptic malignant syndrome [NMS]). (See Chapter 25.) Malignant hyperthermia is a rare disorder associated with general anesthetic agents.

Hyperthermia is a rapidly life-threatening complication. Severe hyperthermia (temperature higher than 40–41°C) can rapidly cause brain damage and multigorgan failure, including rhabdomyolysis, acute kidney injury, and coagulopathy (see Chapter 37).

**Treatment**

Treat hyperthermia aggressively by removing the patient’s clothing, spraying the skin with tepid water, and high-volume fanning. Alternatively, the patient can be placed in an ice water bath (not simply applying ice to selected surfaces). If external cooling is not rapidly effective, as shown by a normal rectal temperature within 30–40 minutes, or if there is significant muscle rigidity or hyperactivity, induce neuromuscular paralysis with a nondepolarizing neuromuscular blocker (eg, rocuronium, vecuronium). Once paralyzed, the patient must be intubated and mechanically ventilated and sedated. While the patient is paralyzed, the absence of visible muscular convulsive movements may give the false impression that brain seizure activity has ceased; bedside electroencephalography may be useful in recognizing continuing nonconvulsive seizures.

Dantrolene (2–5 mg/kg intravenously) may be effective for hyperthermia associated with muscle rigidity that does not respond to neuromuscular blockade (ie, malignant hyperthermia). Bromocriptine, 2.5–7.5 mg orally daily, has been recommended for neuroleptic malignant syndrome. Cyproheptadine, 4 mg orally every hour for three or four
The indications and dosages for specific antidotes are discussed in the respective sections for specific toxins.

### DECONTAMINATION OF THE SKIN

Corrosive agents rapidly injure the skin and eyes and must be removed immediately. In addition, many toxins are readily absorbed through the skin, and systemic absorption can be prevented only by rapid action.

Wash the affected areas with copious quantities of lukewarm water or saline, taking care to limit exposure to health care providers. Wash carefully behind the ears, under the nails, and in skin folds. For oily substances (eg, pesticides), wash the skin at least twice with plain soap and shampoo the hair. Specific decontaminating solutions or solvents (eg, alcohol) are rarely indicated and in some cases may paradoxically enhance absorption. For exposure to chemical warfare poisons such as nerve agents or vesicants, some authorities recommend use of a dilute hypochlorite solution (household bleach diluted 1:10 with water), but not in the eyes.

### DECONTAMINATION OF THE EYES

Act quickly to prevent serious damage. Flush the eyes with copious amounts of saline or water. (If available, instill local anesthetic drops in the eye before beginning irrigation.) Remove contact lenses if present. Lift the tarsal conjunctiva to look for undissolved particles and to facilitate irrigation. Continue irrigation for 15 minutes or until each eye has been irrigated with at least 1 L of solution. If the toxin is an acid or a base, check the pH of the tears after irrigation, and continue irrigation until the pH is between 6 and 8. An amphoteric decontamination solution (Diphoterine, Prevor) is used in some countries for treatment of alkali injuries to the eye.

After irrigation is complete, perform a careful examination of the eye, using fluorescein and a slit lamp or Wood lamp to identify areas of corneal injury. Patients with serious conjunctival or corneal injury should be immediately referred to an ophthalmologist.

### ANTIDOTES

Give an antidote (if available) when there is reasonable certainty of a specific diagnosis (Table 38–3). Be aware that some antidotes themselves may have serious side effects.

**Table 38–3.** Some toxic agents for which there are specific antidotes.¹

¹See text for indications and dosages.

²May induce seizures in patients with preexisting seizure disorder, benzodiazepine addiction, or concomitant tricyclic antidepressant or other convulsant overdose. If seizures occur, diazepam and other benzodiazepine anticonvulsants will not be effective. As with naloxone, the duration of action of flumazenil is short (2–3 hours) and resedation may occur, requiring repeated doses.
GASTROINTESTINAL DECONTAMINATION

Removal of ingested poisons by induced emesis or gastric lavage was a routine part of emergency treatment for decades. However, prospective randomized studies have failed to demonstrate improved clinical outcome after gastric emptying. For small or moderate ingestions of most substances, toxicologists generally recommend oral activated charcoal alone without prior gastric emptying; in some cases, when the interval after ingestion has been more than 1–2 hours and the ingestant is non–life-threatening, even charcoal is withheld (eg, if the estimated benefit is outweighed by the potential risk of pulmonary aspiration of charcoal). Exceptions are large ingestions of anticholinergic compounds and salicylates, which often delay gastric emptying, and ingestion of sustained-release or enteric-coated tablets, which may remain intact for several hours. In these cases, delayed gut decontamination may be indicated.

Gastric emptying is not generally used for ingestion of corrosive agents or petroleum distillates, because further esophageal injury or pulmonary aspiration may result. However, in certain cases, removal of the toxin may be more important than concern over possible complications. Consult a medical toxicologist or regional poison control center (1-800-222-1222) for advice.

A. Activated Charcoal

Activated charcoal effectively adsorbs almost all drugs and poisons. Poorly adsorbed substances include iron, lithium, potassium, sodium, mineral acids, and alcohols.

1. Indications—Activated charcoal can be used for prompt adsorption of drugs or toxins in the stomach and intestine. However, evidence of benefit in clinical studies is lacking. Administration of charcoal, especially if mixed with sorbitol, can provoke vomiting, which could lead to pulmonary aspiration in an obtunded patient.

2. Contraindications—Activated charcoal should not be used for comatose or convulsing patients unless it can be given by gastric tube and the airway is first protected by a cuffed endotracheal tube. It is also contraindicated for patients with ileus or intestinal obstruction or those who have ingested corrosives for whom endoscopy is planned.

3. Technique—Administer activated charcoal, 60–100 g orally or via gastric tube, mixed in aqueous slurry. Repeated doses may be given to ensure gastrointestinal adsorption or to enhance elimination of some drugs.

B. Whole Bowel Irrigation

Whole bowel irrigation uses large volumes of a balanced polyethylene glycol-electrolyte solution to mechanically cleanse the entire intestinal tract. Because of the composition of the irrigating solution, there is no significant gain or loss of systemic fluids or electrolytes.

1. Indications—Whole bowel irrigation is particularly effective for massive iron ingestion in which intact tablets are visible on abdominal radiographs. It has also been used for ingestions of lithium, sustained-release and enteric-coated tablets, and swallowed drug-filled packets.

2. Contraindications—Do not use in patients with suspected intestinal obstruction. Use with caution in patients who are obtunded or have depressed airway protective reflexes.

3. Technique—Administer a balanced polyethylene glycol-electrolyte solution (CoLyte, GoLYTELY) into the stomach via gastric tube at a rate of 1–2 L/h until the rectal effluent is clear. This may take several hours. It is most effective when patients are able to sit on a commode to pass the intestinal contents.

C. Increased Drug Removal

1. Urinary manipulation—Forced diuresis is hazardous; the risk of complications (fluid overload, electrolyte imbalance) usually outweighs its benefits. Some drugs (eg, salicylates, phenobarbital) are more rapidly excreted with an alkaline urine. To alkalize the urine, add 100 mEq (two ampules) of sodium bicarbonate to 1 L of 5% dextrose in 0.225% saline (¼ normal saline), and infuse this solution intravenously at a rate of about 150–200 mL/h. Acidification (sometimes promoted for amphetamines, phencyclidine) is not very effective and is contraindicated in the presence of rhabdomyolysis or myoglobinuria.

2. Hemodialysis—The indications for dialysis are as follows: (1) known or suspected potentially lethal amounts of a dialyzable drug (Table 38–4); (2) poisoning with deep coma, apnea, severe hypotension, fluid or electrolyte or acid-base disturbance, or extreme body temperature changes that cannot be corrected by conventional measures; or (3) poisoning in patients with severe kidney, cardiac, pulmonary, or hepatic disease who will not be able to eliminate toxin by the usual mechanisms.

Table 38–4. Recommended use of hemodialysis in poisoning.

1See text for further discussion of indications.

CNS, central nervous system; CVVHD, continuous venovenous hemodialysis.
Continuous renal replacement therapy (including continuous venovenous hemodialfiltration and similar techniques) is of uncertain benefit for elimination of most poisons but has the advantage of gradual removal of the toxin and correction of any accompanying acidosis. Its use has been reported in the management of a variety of poisonings, including lithium intoxication.

3. Repeat-dose charcoal—Repeated doses of activated charcoal, 20–30 g orally or via gastric tube every 3–4 hours, may hasten elimination of some drugs (eg, phenytoin, carbamazepine, dapsone) by absorbing drugs excreted into the gut lumen (“gut dialysis”). However, clinical studies have failed to prove better outcome using repeat dose charcoal. Sorbitol or other cathartics should not be used with each dose, or else the resulting large stool volumes may lead to dehydration or hyponatremia.

### DIAGNOSIS OF POISONING

The identity of the ingested substance or substances is usually known, but occasionally a comatose patient is found with an unlabeled container or the patient is unable or unwilling to give a coherent history. By performing a directed physical examination and ordering common clinical laboratory tests, the clinician can often make a tentative diagnosis that may allow empiric interventions or may suggest specific toxicologic tests.

#### Physical Examination

Important diagnostic variables in the physical examination include blood pressure, pulse rate, temperature, pupil size, sweating, muscle tone, level of consciousness, and the presence or absence of peristaltic activity. Poisonings may present with one or more of the following common syndromes.

A. **Sympathomimetic Syndrome**

The blood pressure and pulse rate are elevated, though with severe hypertension reflex bradycardia may occur. The temperature is often elevated, pupils are dilated, and the skin is sweaty, though mucous membranes are dry. Patients are usually agitated, anxious, or frankly psychotic.

**Examples:** Amphetamines, cocaine, ephedrine, pseudoephedrine, synthetic cathinones and cannabinoids.

B. **Sympatholytic Syndrome**

The blood pressure and pulse rate are decreased and body temperature is low. The pupils are small or even pinpoint. Patients are usually obtunded or comatose.

**Examples:** Barbiturates, benzodiazepines and other sedative hypnotics, gamma-hydroxybutyrate (GHB), clonidine and related antihypertensives, ethanol, opioids.

C. **Cholinergic Syndrome**

Stimulation of muscarinic receptors causes bradycardia, miosis (constricted pupils), sweating, and hyperperistalsis as well as bronchorrhea, wheezing, excessive salivation, and urinary incontinence. Nicotinic receptor stimulation may produce initial hypertension and tachycardia as well as fasciculations and muscle weakness. Patients are usually agitated and anxious.

**Examples:** Carbamates, nicotine, organophosphates (including nerve agents), physostigmine.

D. **Anticholinergic Syndrome**

Tachycardia with mild hypertension is common, and the body temperature is often elevated. Pupils are widely dilated. The skin is flushed, hot, and dry. Peristalsis is decreased, and urinary retention is common. Patients may have myoclonic jerking or choreoathetoid movements. Agitated delirium is frequently seen, and severe hyperthermia may occur.

**Examples:** Atropine, scopolamine, other naturally occurring and pharmaceutical anticholinergics, antihistamines, tricyclic antidepressants.

#### Laboratory Tests

The following clinical laboratory tests are recommended for screening of the overdosed patient: measured serum osmolality and calculated osmol gap, electrolytes and anion gap, glucose, creatinine, blood urea nitrogen (BUN), creatine kinase, urinalysis (eg, oxalate crystals with ethylene glycol poisoning, myoglobinuria with rhabdomyolysis), and electrocardiography. Quantitative serum acetaminophen and ethanol levels should be determined in all patients with drug overdoses.

A. **Osmol Gap**

The osmol gap (Table 38–5) is increased in the presence of large quantities of low-molecular-weight substances, most commonly ethanol. Other common poisons associated with increased osmol gap are acetone, ethanol, ethylene glycol, isopropyl alcohol, methanol, and propylene glycol. **Note:** Severe alcoholic ketoacidosis and diabetic ketoacidosis can also cause an elevated osmol gap resulting from the production of ketones and other low-molecular-weight substances.
On the basis of serum digoxin level and immediate hemodialysis or hemoperfusion, abdominal imaging, specific antidote (eg, Fab antibody fragments [eg, DigiFab] may be indicated based on the results. Consultation with a regional poison control center (1-800-222-1222) or a medical toxicologist is recommended when the diagnosis is uncertain; there are questions about what laboratory tests to order; when dialysis is being considered to remove the drug or poison; or when advice is needed regarding the indications, dose, and side effects of antidotes.

### When to Refer
Consultation with a regional poison control center (1-800-222-1222) or a medical toxicologist is recommended when the diagnosis is uncertain; there are questions about what laboratory tests to order; when dialysis is being considered to remove the drug or poison; or when advice is needed regarding the indications, dose, and side effects of antidotes.

### When to Admit
- The patient has symptoms and signs of intoxication that are not expected to clear within a 6- to 8-hour observation period.

---

---

Some drugs or toxins may have profound and irreversible toxicity unless rapid and specific management is provided outside of routine supportive care. For these agents, laboratory testing may provide the serum level or other evidence required for administering a specific antidote or arranging for hemodialysis.
• Delayed absorption of the drug might be predicted to cause a later onset of serious symptoms (eg, after ingestion of a sustained-release product).
• Continued administration of an antidote is required (eg, N-acetylcysteine for acetaminophen overdose).
• Psychiatric or social services evaluation is needed for suicide attempt or suspected drug abuse.

ACETAMINOPHEN

Acetaminophen (paracetamol in the United Kingdom, Europe) is a common analgesic found in many nonprescription and prescription products. After absorption, it is metabolized mainly by glucuronidation and sulfation, with a small fraction metabolized via the P450 mixed-function oxidase system (2E1) to a highly toxic reactive intermediate. This toxic intermediate is normally detoxified by cellular glutathione. With acute acetaminophen overdose (greater than 150–200 mg/kg, or 8–10 g in an average adult), hepatocellular glutathione is depleted and the reactive intermediate attacks other cell proteins, causing necrosis. Patients with enhanced P450 2E1 activity, such as those who chronically abuse alcohol and patients taking INH, are at increased risk for developing hepatotoxicity. Hepatic toxicity may also occur after overdose of acetaminophen—eg, as a result of taking two or three acetaminophen-containing products concurrently or exceeding the recommended maximum dose of 4 g/day for several days. The amount of acetaminophen in US oral prescription combination products (eg, hydrocodone/acetaminophen) is limited by the FDA to no more than 325 mg per tablet.

Clinical Findings

Shortly after ingestion, patients may have nausea or vomiting, but there are usually no other signs of toxicity until 24–48 hours after ingestion, when hepatic aminotransferase levels begin to increase. With severe poisoning, fulminant hepatic necrosis may occur, resulting in jaundice, hepatic encephalopathy, acute kidney injury, and death. Rarely, massive ingestion (eg, serum levels greater than 500–1000 mg/L [33–66 mmol/L]) can cause early onset of acute coma, seizures, hypotension, and metabolic acidosis unrelated to hepatic injury.

The diagnosis after acute overdose is based on measurement of the serum acetaminophen level. Plot the serum level versus the time since ingestion on the acetaminophen nomogram shown in Figure 38–1. Ingestion of
ACIDS, CORROSIVE

The strong mineral acids exert primarily a local corrosive effect on the skin and mucous membranes. Symptoms include severe pain in the throat and upper gastrointestinal tract; bloody vomitus; difficulty in swallowing, breathing, and speaking; discoloration and destruction of skin and mucous membranes in and around the mouth; and shock. Severe systemic metabolic acidosis may occur both as a result of cellular injury and from systemic absorption of the acid.

Severe deep destructive tissue damage may occur after exposure to hydrofluoric acid because of the penetrating and highly toxic fluoride ion. Systemic hypocalcemia and hyperkalemia may also occur after fluoride absorption, even following skin exposure.

Inhalation of volatile acids, fumes, or gases such as chlorine, fluorine, bromine, or iodine causes severe irritation of the throat and larynx and may cause upper airway obstruction and noncardiogenic pulmonary edema.

Treatment

A. Ingestion

Dilute immediately by giving a glass (4–8 oz) of water to drink. Do not give bicarbonate or other neutralizing agents, and do not induce vomiting. Some experts recommend immediate cautious placement of a small flexible gastric tube and removal of stomach contents followed by lavage, particularly if the corrosive is a liquid or has important systemic toxicity.

In symptomatic patients, perform flexible endoscopic esophagoscopy to determine the presence and extent of injury. CT scan or plain radiographs of the chest and abdomen may also reveal the extent of injury. Perforation, peritonitis, and major bleeding are indications for surgery.

B. Skin Contact

Flood with water for 15 minutes. Use no chemical antidotes; the heat of the reaction may cause additional injury.

For hydrofluoric acid burns, soak the affected area in benzalkonium chloride solution or apply 2.5% calcium gluconate gel (prepared by adding 3.5 g calcium gluconate to 5 oz of water-soluble surgical lubricant, eg, K-Y Jelly); then arrange immediate consultation with a plastic surgeon or other specialist. Binding of the fluoride ion may be achieved by injecting 0.5 mL of 5% calcium gluconate per square centimeter under the burned area. (Caution: Do not use calcium chloride.) Use of a Bier-block technique or intra-articular infusion of calcium is sometimes required for extensive burns or those involving the nail bed; consult with a hand surgeon or poison control center (1-800-222-1222).

C. Eye Contact

Anesthetize the conjunctiva and corneal surfaces with topical local anesthetic drops (eg, proparacaine). Flood with water for 15 minutes, holding the eyelids open. Check pH with pH 6.0–8.0 test paper, and repeat irrigation, using 0.9% saline, until pH is near 7.0. Check for corneal damage with fluorescein and slit-lamp examination; consult an ophthalmologist about further treatment.

D. Inhalation

Remove from further exposure to fumes or gas. Check skin and clothing. Observe for and treat chemical pneumonitis or pulmonary edema.
ALKALIES

The strong alkalies are common ingredients of some household cleaning compounds and may be suspected by their “soapy” texture. Those with alkalinity above pH 12.0 are particularly corrosive. Disk (or “button”) batteries are also a source. Alkalies cause liquefactive necrosis, which is deeply penetrating. Symptoms include burning pain in the upper gastrointestinal tract, nausea, vomiting, and difficulty in swallowing and breathing. Examination reveals destruction and edema of the affected skin and mucous membranes and bloody vomitus and stools. Radiographs may reveal evidence of perforation or the presence of radiopaque disk batteries in the esophagus or lower gastrointestinal tract.

Treatment

A. Ingestion

Dilute immediately with a glass of water. Do not induce emesis. Some gastroenterologists recommend immediate cautious placement of a small flexible gastric tube and removal of stomach contents followed by gastric lavage after ingestion of liquid caustic substances, in order to remove residual material. However, others argue that passage of a gastric tube is contraindicated due to the risk of perforation or reexposure of the esophagus to the corrosive material from vomiting around the tube.

Prompt endoscopy is recommended in symptomatic patients to evaluate the extent of damage; CT scanning may also aid in assessment. If a radiograph reveals ingested disk batteries lodged in the esophagus, immediate endoscopic removal is mandatory.

The use of corticosteroids to prevent stricture formation is of no proved benefit and is definitely contraindicated if there is evidence of esophageal perforation.

B. Skin Contact

Wash with running water until the skin no longer feels soapy. Relieve pain and treat shock.

C. Eye Contact

Anesthetize the conjunctival and corneal surfaces with topical anesthetic (eg, proparacaine). Irrigate with water or saline continuously for 20–30 minutes, holding the lids open. Amphoteric solutions may be more effective than water or saline and some are available in Europe (Diphoterine, Prevor). Check pH with pH test paper and repeat irrigation for additional 30-minute periods until the pH is near 7.0. Check for corneal damage with fluorescein and slit-lamp examination; consult an ophthalmologist for further treatment.

TREATMENT

A. Emergency and Supportive Measures

Maintain a patent airway and assist ventilation, if necessary. Treat seizures as described at the beginning of this chapter. Rapidly lower the body temperature in patients who are hyperthermic (temperature higher than 39–40°C). Give intravenous fluids to prevent myoglobinuric kidney injury in patients who have rhabdomyolysis.

B. Specific Treatment

Treat agitation, psychosis, or seizures with a benzodiazepine such as diazepam, 5–10 mg, or lorazepam, 2–3 mg intravenously. Add phenobarbital 15 mg/kg intravenously for persistent seizures. Treat hypertension with a vasodilator drug such as phentolamine (1–5 mg intravenously) or nitroprusside, or a combined alpha- and beta-adrenergic blocker such as labetalol (10–20 mg intravenously). Do not administer a pure beta-blocker such as propranolol alone, as this may result in paradoxical worsening of the hypertension as a result of unopposed alpha-adrenergic effects.

Treat tachycardia or tachyarrhythmias with a short-acting beta-blocker such as esmolol (25–100 mcg/kg/min by intravenous infusion). Treat hyperthermia as described above. Treat hyponatremia as outlined in Chapter 21.

ANTICOAGULANTS

Warfarin and related compounds (including ingredients of many commercial rodenticides, the so-called superwarfarins such as brodifacoum, difenacoum, and related compounds) inhibit the normal clotting system by blocking hepatic synthesis of vitamin K–dependent clotting factors. After ingestion of “superwarfarins,” inhibition of clotting factor synthesis may persist for several weeks or even months after a single dose. Newer oral anticoagulants include the direct thrombin inhibitor dabigatran and the factor Xa inhibitors apixaban, betrixaban, edoxaban, and rivaroxaban. Some of these, especially dabigatran, are largely eliminated by the kidney and may accumulate in patients with kidney dysfunction.

Excessive anticoagulation may cause hemoptysis, gross hematuria, bloody stools, hemorrhages into organs, widespread bruising, and bleeding into joint spaces.

TREATMENT

A. Emergency and Supportive Measures

Discontinue the drug at the first sign of gross bleeding, and determine the prothrombin time (international normalized ratio, INR). The prothrombin time is increased within 12–24 hours (peak 36–48 hours) after overdose of warfarin or “superwarfarins.” Note: The newer oral anticoagulants (dabigatran, apixaban, betrixaban, edoxaban, and rivaroxaban) do not predictably alter the prothrombin time; however, a normal INR suggests no significant toxicity.

If the patient has ingested an acute overdose, administer activated charcoal.

B. Specific Treatment

1. Warfarin—In cases of warfarin and “superwarfarin” overdose, do not treat prophylactically with vitamin K—wait for evidence of anticoagulation (elevated prothrombin time). See Table 14–21 for the management of INR above therapeutic range. Doses of vitamin K as high as 200 mg/day have been required after ingestion of “superwarfarins.” Give fresh-frozen plasma, prothrombin complex concentrate, or activated factor VII as needed to rapidly correct the coagulation factor deficit if there is serious bleeding. If the patient is chronically anticoagulated and has strong medical indications for being maintained in that status (eg, prosthetic heart valve), give much smaller doses of vitamin K (1 mg orally) and fresh-frozen plasma (or both) to titrate to the desired prothrombin time. If the patient has ingested brodifacoum or a related superwarfarin, prolonged observation (over weeks) and repeated administration of large doses of vitamin K may be required.

2. Direct-acting oral anticoagulants—Vitamin K does not reverse the anticoagulant effects of the direct-acting oral anticoagulants. Idarucizumab has been approved by the FDA for reversal of the thrombin inhibitor dabigatran; andexanet is approved for reversal of the factor Xa inhibitors apixaban, edoxaban, betrixaban, and rivaroxaban. The efficacy of fresh-frozen plasma and clotting factor concentrates is uncertain.
Anticonvulsants (carbamazepine, phenytoin, valproic acid, and many newer agents) are widely used in the management of seizure disorders and some are also used for treatment of mood disorders or pain. Phenytoin can be given orally or intravenously. Rapid intravenous injection of phenytoin can cause acute myocardial depression and cardiac arrest owing to the solvent propylene glycol (fosphenytoin does not contain this diluent). Chronic phenytoin intoxication can occur following only slightly increased doses because of zero-order kinetics and a small toxic-therapeutic window. Phenytoin intoxication can also occur following acute intentional or accidental overdose. The overdose syndrome is usually mild even with high serum levels. The most common manifestations are ataxia, nystagmus, and drowsiness. Choreaathetoid movements have been described.

Carbamazepine intoxication causes drowsiness, stupor and, with high levels, atioventricular block, coma, and seizures. Dilated pupils and tachycardia are common. Toxicity may be seen with serum levels over 20 mg/L (85 mcg/mL), although severe poisoning is usually associated with concentrations greater than 30–40 mg/L (127–169 mcg/mL). Because of erratic and slow absorption, intoxication may progress over several hours to days.

Valproic acid intoxication produces a unique syndrome consisting of hypernatremia (from the sodium component of the salt), metabolic acidosis, hypocalcemia, elevated serum ammonia, and mild liver aminotransferase elevation. Hypoglycemia may occur as a result of hepatic metabolic dysfunction. Coma with small pupils may be seen and can mimic opioid poisoning. Emphalopathy and cerebral edema can occur.

The newer anticonvulsants gabapentin, levetiracetam, vigabatrin, and zonisamide generally cause somnolence, confusion, and dizziness; there is one case report of hypertension and bradycardia after a large overdose of levetiracetam. Felbamate can cause crystalluria and kidney injury after overdose and may cause idiosyncratic aplastic anemia with therapeutic use. Lamotrigine, topiramate, and tiagabine have been reported to cause seizures after overdose; lamotrigine has sodium-channel blocking properties and may cause QRS prolongation and heart block.

**Treatment**

**A. Emergency and Supportive Measures**

For recent ingestions, give activated charcoal orally or by gastric tube. For large ingestions of carbamazepine or valproic acid—especially of sustained-release formulations—consider whole bowel irrigation. Combined multiple-dose activated charcoal and whole-bowel irrigation may be beneficial in ensuring gut decontamination for selected large ingestions.

**B. Specific Treatment**

There are no specific antidotes. Naloxone was reported to have reversed valproic acid overdose in one anecdotal case. Carnitine (and possibly L-arginine) may be useful in patients with valproic acid–induced hyperammonemia. Consider hemodialysis for massive intoxication with valproic acid or carbamazepine (eg, carbamazepine levels greater than 60 mg/L [254 mcg/mL] or valproic acid levels greater than 800 mg/L [5544 mcg/mL]).

**Antipsychotic Drugs**

Drugs in this group include “conventional” antipsychotics (eg, chlorpromazine, haloperidol, droperidol) and newer “atypical” antipsychotics (eg, risperidone, olanzapine, ziprasidone, quetiapine, aripiprazole). While conventional drugs act mainly on CNS dopamine receptors, atypical drugs also interact with serotonin receptors.

Therapeutic doses of conventional phenothiazines (particularly chlorpromazine) induce drowsiness and mild orthostatic hypotension in as many as 30% of patients. Larger doses can cause obtundation, miosis, severe hypotension, tachycardia, convulsions, and coma. Abnormal cardiac conduction may occur, resulting in prolongation of QRS or QT intervals (or both) and ventricular arrhythmias. Among the atypical agents, quetiapine is more likely to cause coma and hypotension. Hypotension is probably related to blockade of peripheral alpha-adrenergic receptors, causing vasodilatation.

With therapeutic or toxic doses, an acute extrapyramidal dystonic reaction may develop in some patients, with spasmodic contractions of the face and neck muscles, extensor rigidity of the back muscles, carpopedal spasm, and motor restlessness. This reaction is more common with haloperidol and other butyrophenones and less common with newer atypical antipsychotics. Severe rigidity accompanied by hyperthermia and metabolic acidosis (“neuroleptic malignant syndrome”) may occasionally occur and is life-threatening (see Chapter 25). Atypical antipsychotics have also been associated with weight gain and diabetes mellitus, including diabetic ketoacidosis.

**Treatment**

**A. Emergency and Supportive Measures**

Administer activated charcoal for large or recent ingestions. For severe hypotension, treatment with intravenous fluids and vasopressor agents may be necessary. Treat hyperthermia as outlined. Maintain cardiac monitoring.
B. Specific Treatment

Hypotension often responds to intravenous saline boluses; cardiac arrhythmias associated with widened QRS intervals on the ECG may respond to intravenous sodium bicarbonate as is given for tricyclic antidepressant overdoses. Prolongation of the QT interval and torsades de pointes is usually treated with intravenous magnesium or overdrive pacing.

For extrapyramidal signs, give diphenhydramine, 0.5–1 mg/kg intravenously, or benztprine mesylate, 0.01–0.02 mg/kg intramuscularly. Treatment with oral doses of these agents should be continued for 24–48 hours.

Bromocriptine (2.5–7.5 mg orally daily) may be effective for mild or moderate neuroleptic malignant syndrome. Dantrolene (2–5 mg/kg intravenously) has also been used for muscle rigidity but is not a true antidote. For severe hyperthermia, rapid neuromuscular paralysis is preferred.

---

ARSENIC

Arsenic is found in some pesticides and industrial chemicals and is used as a chemical medicinal agent. Chronic arsenic poisoning has been associated with contaminated aquifers used for drinking water. Symptoms of acute poisoning usually appear within 1 hour after ingestion but may be delayed as long as 12 hours. They include abdominal pain, vomiting, watery diarrhea, and skeletal muscle cramps. Profound dehydration and shock may occur. In chronic poisoning, symptoms can be vague but often include pancytopenia, painful peripheral sensory neuropathy, and skin changes including melanosis, keratosis, and desquamating rash. Cancers of the lung, bladder, and skin have been reported. Urinary arsenic levels may be falsely elevated after certain meals (eg, seafood) that contain large quantities of a nontoxic form of organic arsenic.

---

ATROPINE & ANTICHOLINERGICS

Atropine, scopolamine, belladonna, *Datura stramonium*, *Hyoscyamus niger*, some mushrooms, tricyclic antidepressants, and antihistamines are antimuscarinic agents with variable central nervous system effects. Symptoms of toxicity include dryness of the mouth, thirst, difficulty in swallowing, and blurring of vision. Physical signs include dilated pupils, flushed skin, tachycardia, fever, delirium, myoclonus, ileus, and flushed appearance. Antidepressants and antihistamines may also induce convulsions.

Antihistamines are commonly available with or without prescription. Diphenhydramine commonly causes delirium, tachycardia, and seizures. Massive diphenhydramine overdose may mimic tricyclic antidepressant cardiotoxic poisoning.

---

Treatment

A. Emergency and Supportive Measures

Administer activated charcoal. External cooling and sedation, or neuromuscular paralysis in rare cases, are indicated to control high temperatures.

B. Specific Treatment

For severe anticholinergic syndrome (eg, agitated delirium), give physostigmine salicylate, 0.5–1 mg slowly intravenously over 5 minutes, with ECG monitoring; repeat as needed to a total dose of no more than 2 mg. Caution: Bradyarrhythmias and convulsions are a hazard with physostigmine administration, and the drug should be avoided in patients with evidence of cardiotoxic effects (eg, QRS interval prolongation) from tricyclic antidepressants or other sodium channel blockers.
BETA-ADRENERGIC BLOCKERS

There are a wide variety of beta-adrenergic blocking drugs, with varying pharmacologic and pharmacokinetic properties (see Table 11–9). The most toxic beta-blocker is propranolol, which not only blocks beta-1 and beta-2 adrenoceptors but also has direct membrane-depressant and central nervous system effects.

Clinical Findings

The most common findings with mild or moderate intoxication are hypotension and bradycardia. Cardiac depression from more severe poisoning is often unresponsive to conventional therapy with beta-adrenergic stimulants such as dopamine and norepinephrine. In addition, with propranolol and other lipid-soluble drugs, seizures and coma may occur. Propranolol, oxprenolol, acebutolol, and alpranolol also have membrane-depressant effects and can cause conduction disturbance (wide QRS interval) similar to tricyclic antidepressant overdose.

The diagnosis is based on typical clinical findings. Routine toxicology screening does not usually include beta-blockers.

Treatment

A. Emergency and Supportive Measures

Attempts to treat bradycardia or heart block with atropine (0.5–2 mg intravenously), isoproterenol (2–20 mcg/min by intravenous infusion, titrated to the desired heart rate), or an external transcutaneous cardiac pacemaker are often ineffective, and specific antidotal treatment may be necessary.

For drugs ingested within an hour of presentation (or longer after ingestion of an extended-release formulation), administer activated charcoal.

B. Specific Treatment

For persistent bradycardia and hypotension, give glucagon, 5–10 mg intravenously, followed by an infusion of 1–5 mg/h. Glucagon is an inotropic agent that acts at a different receptor site and is therefore not affected by beta-blockade. High-dose insulin (0.5–1 unit/kg/h intravenously) along with glucose supplementation has also been used to reverse severe cardiotoxicity. Membrane-depressant effects (wide QRS interval) may respond to boluses of sodium bicarbonate (50–100 mEq intravenously) as for tricyclic antidepressant poisoning. Intravenous lipid emulsion (Intralipid 20%, 1.5 mL/kg) has been used successfully in severe propranolol overdose.

CALCIUM CHANNEL BLOCKERS

In therapeutic doses, nifedipine, nicardipine, amlodipine, felodipine, isradipine, nisoldipine, and nimodipine act mainly on blood vessels, while verapamil and diltiazem act mainly on cardiac contractility and conduction. However, these selective effects can be lost after acute overdose. Patients may present with bradycardia, atioventricular (AV) nodal block, hypotension, or a combination of these effects. Hyperglycemia is common due to blockade of insulin release. With severe poisoning, cardiac arrest may occur.

Treatment

A. Emergency and Supportive Measures

For ingested drugs, administer activated charcoal. In addition, whole bowel irrigation should be initiated as soon as possible if the patient has ingested a sustained-release product.

B. Specific Treatment

Treat symptomatic bradycardia with atropine (0.5–2 mg intravenously), isoproterenol (2–20 mcg/min by intravenous infusion), or a transcutaneous cardiac pacemaker. For hypotension, give calcium chloride 10%, 10 mL, or calcium gluconate 10%, 20 mL. Repeat the dose every 3–5 minutes. The optimum (or maximum) dose has not been established, but many toxicologists recommend raising the ionized serum calcium level to as much as twice the normal level. Calcium is most useful in reversing negative inotropic effects and is less effective for AV nodal blockade and bradycardia. High doses of insulin (0.5–1 unit/kg intravenous bolus followed by 0.5–1 unit/kg/h infusion) along with sufficient dextrose to maintain euglycemia have been reported to be beneficial, but there are no controlled studies. Infusion of Intralipid 20% lipid emulsion has been reported to improve hemodynamics in animal models and case reports of calcium channel blocker poisoning. Methylen blue (1–2 mg/kg) was reported to reverse refractory shock due to profound vasodilation in a patient with amiodipine poisoning. ECMO has been recommended for refractory shock.

CARBON MONOXIDE

Carbon monoxide is a colorless, odorless gas produced by the combustion of carbon-containing materials. Poisoning may occur as a result of suicidal or accidental exposure to automobile exhaust, smoke inhalation in a fire, or accidental exposure to an improperly vented gas heater, generator, or other appliance. Carbon monoxide can be generated during degradation of some anesthetic gases by carbon dioxide adsorbents. Carbon monoxide avidly binds to hemoglobin, with an affinity approximately 250 times that of oxygen. This results in reduced oxygen-carrying capacity and altered delivery of oxygen to cells (see also Smoke Inhalation in Chapter 9).

Clinical Findings

At low carbon monoxide levels (carboxyhemoglobin saturation 10–20%), victims may have headache, dizziness, abdominal pain, and nausea. With higher levels, confusion, dyspnea, and syncope may occur. Hypotension, coma, and seizures are common with levels greater than 50–60%. Survivors of acute severe poisoning may develop permanent obvious or subtle neurologic and neuropsychiatric deficits. The fetus and newborn may be more susceptible because of high carbon monoxide affinity for fetal hemoglobin.

Carbon monoxide poisoning should be suspected in any person with severe headache or acutely altered mental status, especially during cold weather, when improperly vented heating systems may have been used. Diagnosis depends on specific measurement of the arterial or venous carboxyhemoglobin saturation, although the level may have declined if high-flow oxygen therapy has already been administered, and levels do not always correlate with clinical symptoms. Routine arterial blood gas testing and pulse oximetry are not useful because they give falsely normal PaO₂ and oxyhemoglobin saturation determinations, respectively. (A specialized pulse oximetry device, the Masimo pulse CO-oximeter, is capable of distinguishing oxyhemoglobin from carboxyhemoglobin.)

Treatment

A. Emergency and Supportive Measures

Maintain a patent airway and assist ventilation, if necessary. Remove the victim from exposure. Treat patients with coma, hypotension, or seizures as described at the beginning of this chapter.

B. Specific Treatment

The half-life of the carboxyhemoglobin (CoHb) complex is about 4–5 hours in room air but is reduced dramatically by high concentrations of oxygen. Administer 100% oxygen by tight-fitting high-flow reservoir face mask or endotracheal tube. Hyperbaric oxygen (HBO) can provide 100% oxygen under higher than atmospheric pressures, further shortening the half-life; it may also reduce the incidence of subtle neuropsychiatric sequelae. Randomized controlled studies disagree about the benefit of HBO, but commonly recommended indications for HBO in patients with carbon monoxide poisoning include a history of loss of consciousness, CoHb greater than 25%, metabolic acidosis, age over 50 years, and cerebellar findings on neurologic examination.

CHEMICAL WARFARE: NERVE AGENTS

Nerve agents used in chemical warfare work by cholinesterase inhibition and are most commonly organophosphorus compounds. Agents such as tabun (GA), sarin (GB), soman (GD), and VX are similar to insecticides such as malathion but are vastly more potent. They may be inhaled or absorbed through the skin. Systemic effects due to unopposed action of acetylcholine include miosis, salivation, abdominal cramps, diarrhea, and muscle paralysis producing respiratory arrest. Inhalation also produces severe bronchoconstriction and copious nasal and tracheobronchial secretions.

Treatment

A. Emergency and Supportive Measures

Perform thorough decontamination of exposed areas with repeated soap and shampoo washing. Personnel caring for such patients must wear protective clothing and gloves, since cutaneous absorption may occur through normal skin.

B. Specific Treatment

Give atropine in an initial dose of 2 mg intravenously and repeat as needed to reverse signs of acetylcholine excess. (Some victims have required several hundred milligrams.) Treat also with the cholinesterase-reactivating agent pralidoxime, 1–2 g intravenously initially followed by an infusion at a rate of 200–400 mg/h.
CHEMICAL WARFARE: RICIN

Ricin is a naturally occurring toxin found in minute quantities in the castor bean (Ricinus communis). It can cause toxicity if castor beans are roughly chewed or blenderized, although the quantity of ricin is small and it is poorly absorbed from the gastrointestinal tract, so symptoms following castor bean ingestion are usually limited to diarrhea and abdominal pain. Less commonly, severe gastroenteritis can lead to volume depletion and advanced chronic kidney disease. On the other hand, purified ricin is extremely toxic if administered parenterally: the LD₅₀ for injected ricin in animals is as low as 0.1 mcg/kg. A fatal case of suspected ricin poisoning by homicidal injection of an estimated 0.28 mg of ricin was associated with diffuse organ damage and death from cardiac failure after 2 days. Inhalation of ricin powder has not been reported in humans, but animal studies suggest it could cause hemorrhagic tracheobronchitis and pneumonia.

Treatment

A. Emergency and Supportive Measures

After suspected ricin inhalation or exposure to powdered ricin, remove clothing and wash skin with water. Personnel caring for such patients should wear protective respiratory gear, clothing, and gloves.

B. Specific Treatment

There is no known antidote or other specific treatment. A vaccine (RiVax®) has been developed and has been granted an Orphan Drug designation by the FDA. Provide supportive care for volume loss due to gastroenteritis and cardiac and respiratory support as needed.

CLONIDINE & OTHER SYMPATHOLYTIC ANTIHYPERTENSIVES

Overdosage with these agents (clonidine, guanabenz, guanfacine, methyldopa) causes bradycardia, hypotension, miosis, respiratory depression, and coma. (Transient hypertension occasionally occurs after acute overdosage, a result of peripheral alpha-adrenergic effects in high doses.) Symptoms are usually resolved in less than 24 hours, and deaths are rare. Similar symptoms may occur after ingestion of topical nasal decongestants chemically similar to clonidine (oxymetazoline, tetrahydrozoline, naphazoline). Brimonidine and apraclonidine are used as ophthalmic preparations for glaucoma. Tizanidine is a centrally acting muscle relaxant structurally related to clonidine; it produces similar toxicity in overdose.

COCAINIE

See Amphetamines & Cocaine.

CYANIDE

Cyanide is a highly toxic chemical used widely in research and commercial laboratories and many industries. Its gaseous form, hydrogen cyanide, is an important component of smoke in fires. Cyanide-generating glycosides are also found in the pits of apricots and other related plants. Cyanide is generated by the breakdown of nitroprusside, and poisoning can result from rapid high-dose infusions. Cyanide is also formed by metabolism of acetonitrile, a solvent found in some over-the-counter fingernail glue removers. Cyanide is rapidly absorbed by inhalation, skin absorption, or ingestion. It disrupts cellular function by inhibiting cytochrome oxidase and preventing cellular oxygen utilization.

Clinical Findings

The onset of toxicity is nearly instantaneous after inhalation of hydrogen cyanide gas but may be delayed for minutes to hours after ingestion of cyanide salts or cyanogenic plants or chemicals. Effects include headache, dizziness, nausea, abdominal pain, and anxiety, followed by confusion, syncope, shock, seizures, coma, and death. The odor of “bitter almonds” may be detected on the victim’s breath or in vomitus, though this is not a reliable finding. The venous oxygen saturation may be elevated (greater than 90%) in severe poisonings because tissues have failed to take up arterial oxygen.

Treatment

A. Emergency and Supportive Measures

Remove the victim from exposure, taking care to avoid exposure to rescuers. For suspected cyanide poisoning due
to nitroprusside infusion, stop or slow the rate of infusion. (Metabolic acidosis and other signs of cyanide poisoning usually clear rapidly.)

For cyanide ingestion, administer activated charcoal. Although charcoal has a low affinity for cyanide, the usual doses of 60–100 g are adequate to bind typically ingested lethal doses (100–200 mg).

B. Specific Treatment

In the United States, there are two available cyanide antidote regimens. The conventional cyanide antidote package (Nithiodote) contains sodium nitrite (to induce methemoglobinemia, which binds free cyanide) and sodium thiosulfate (to promote conversion of cyanide to the less toxic thiocyanate). Administer 3% sodium nitrite solution, 10 mL intravenously followed by 25% sodium thiosulfate solution, 50 mL intravenously (12.5 g). **Caution:** Nitrites may induce hypotension and dangerous levels of methemoglobin.

The other approved cyanide treatment in the United States is hydroxocobalamin (Cyanokit, EMD Pharmaceuticals), a newer and potentially safer antidote. The adult dose of hydroxocobalamin is 5 g intravenously (children’s dose is 70 mg/kg). **Note:** Hydroxocobalamin causes red discoloration of skin and body fluids that may last several days and can interfere with some laboratory tests.

### DIETARY SUPPLEMENTS & HERBAL PRODUCTS

Unlike prescription and over-the-counter pharmaceuticals, dietary supplements do not require FDA approval, do not undergo the same premarketing evaluation of safety and efficacy as drugs, and purveyors may or may not adhere to good manufacturing practices and quality control standards. Supplements may cause illness as a result of intrinsic toxicity, misidentification or mislabeling, drug-herb reactions, or intentional adulteration with pharmaceuticals. If you suspect a dietary supplement or herbal product may be the cause of an otherwise unexplained illness, contact the FDA (1-888-463-6332) or the regional poison control center (1-800-222-1222), or consult the following online database: https://www.fda.gov/food/dietary-supplements.

Table 38–7 lists selected examples of clinical toxicity from some of these products.

### DIGITALIS & OTHER CARDIAC GLYCOSIDES

Cardiac glycosides paralyze the Na⁺-K⁺-ATPase pump and have potent vagotonic effects. Intracellular effects include enhancement of calcium-dependent contractility and shortening of the action potential duration. A number of...
plants (eg, olerander, foxglove, lily-of-the-valley) contain cardiac glycosides. Bufotenin, a cardiotoxic steroid found in certain toad secretions and used as an herbal medicine and a purported aphrodisiac, has pharmacologic properties similar to cardiac glycosides.

**Clinical Findings**

Intoxication may result from acute single exposure or chronic accidental overmedication, especially in patients with kidney dysfunction taking digoxin. After acute overdosage, nausea and vomiting, bradycardia, hyperkalemia, and AV block frequently occur. Patients in whom toxicity develops gradually during long-term therapy may be hypokalemic and hypomagnesemic owing to concurrent diuretic treatment and more commonly present with ventricular arrhythmias (eg, ectopy, bidirectional ventricular tachycardia, or ventricular fibrillation). Digoxin levels may be only slightly elevated in patients with intoxication from cardiac glycosides other than digoxin because of limited cross-reactivity of immunologic tests.

**Treatment**

**A. Emergency and Supportive Measures**

After acute ingestion, administer activated charcoal. Monitor potassium levels and cardiac rhythm closely. Treat bradycardia initially with atropine (0.5–2 mg intravenously) or a transcutaneous external cardiac pacemaker.

**B. Specific Treatment**

For patients with significant intoxication, administer digoxin-specific antibodies (digoxin immune Fab [ovine]; DigiFab). Estimation of the dose is based on the body burden of digoxin calculated from the ingested dose or the steady-state serum digoxin concentration, as described below. More effective binding of digoxin may be achieved if the dose is given partly as a bolus and the remainder as an infusion over a few hours.

1. From the ingested dose—Number of vials = approximately 1.5–2 × ingested dose (mg).
2. From the serum concentration—Number of vials = serum digoxin (ng/mL) × body weight (kg) × 10^{−2}. **Note:** This is based on the equilibrium digoxin level; after acute overdose, serum levels may be falsely high for several hours before tissue distribution is complete, and overestimation of the DigiFab dose is likely.
3. Empiric dosing—Empiric titration of DigiFab may be used if the patient’s condition is relatively stable and an underlying condition (eg, atrial fibrillation) favors retaining a residual level of digitalis activity. Start with one or two vials and reassess the patient’s clinical condition after 20–30 minutes. For cardiac glycosides other than digoxin or digitoxin, there is no formula for estimation of vials needed and treatment is entirely based on response to empiric dosing.

**Note:** After administration of digoxin-specific Fab antibody fragments, serum digoxin levels may be falsely elevated depending on the assay technique.

---

---

**ETHANOL, BENZODIAZEPINES, & OTHER SEDATIVE-HYPNOTIC AGENTS**

The group of agents known as sedative-hypnotic drugs includes a variety of products used for the treatment of anxiety, depression, insomnia, and epilepsy. Besides common benzodiazepines, such as lorazepam, alprazolam, clonazepam, diazepam, oxazepam, chlordiazepoxide, and triazolam, this group includes the newer benzodiazepine-like hypnotics zolpidem, zopiclone, and zaleplon, and the muscle relaxants baclofen and carisoprodol. Ethanol and other selected agents are also popular recreational drugs. All of these drugs depress the central nervous system reticular activating system, cerebral cortex, and cerebellum.

**Clinical Findings**

Mild intoxication produces euphoria, slurred speech, and ataxia. Ethanol intoxication may produce hypoglycemia, even at relatively low concentrations, in children and in fasting adults. With more severe intoxication, stupor, coma, and respiratory arrest may occur. Carisoprodol (Soma) commonly causes muscle jerking or myoclonus. Death or serious morbidity is usually the result of pulmonary aspiration of gastric contents. Bradycardia, hypotension, and hypothermia are common. Patients with massive intoxication may appear to be dead, with no reflex responses and even absent electroencephalographic activity. Diagnosis and assessment of severity of intoxication are usually based on clinical findings. Ethanol serum levels over 300 mg/dL (0.3 g/dL; 65 mmol/L) can produce coma in persons who are not using the drug long term, but regular users may remain awake at much higher levels.

**Treatment**

**A. Emergency and Supportive Measures**

Administer activated charcoal if the patient has ingested a massive dose and the airway is protected. Repeat-dose charcoal may enhance elimination of phenobarbital, but it has not been proved to improve clinical outcome. Hemodialysis may be necessary for patients with severe phenobarbital intoxication.

**B. Specific Treatment**

Flumazenil is a benzodiazepine receptor-specific antagonist; it has no effect on ethanol, barbiturates, or other sedative-hypnotic agents. If used, flumazenil is given slowly intravenously, 0.2 mg over 30–60 seconds, and repeated in
0.2–0.5 mg increments as needed up to a total dose of 3–5 mg. **Caution:** Flumazenil should rarely be used because it may induce seizures in patients with preexisting seizure disorder, benzodiazepine tolerance, or concomitant tricyclic antidepressant or other convulsant overdose. If seizures occur, diazepam and other benzodiazepine anticonvulsants will not be effective. As with naloxone, the duration of action of flumazenil is short (2–3 hours) and reseizure may occur, requiring repeated doses.

**HYPOGLYCEMIC DRUGS**

Medications used for diabetes mellitus include insulin, sulfonylureas and other insulin secretagogues, alpha-glucosidase inhibitors (acarbose, miglitol), biguanides (metformin), thiazolidinediones (pioglitazone, rosiglitazone), sodium glucose transporter (SGLT2) inhibitors, and peptide analogs (pramlintide, exenatide) or enhancers (sitagliptin) (see Chapter 27). Of these, insulin and the insulin secretagogues are the most likely to cause hypoglycemia. Metformin can cause lactic acidosis, especially in patients with impaired kidney function or after intentional drug overdose. Euglycemic diabetic ketoacidosis has been reported with SGLT2 use. Table 27–5 lists the duration of hypoglycemic effect of oral hypoglycemic agents and Table 27–6 the extent and duration of various types of insulins.

**Clinicla Findings**

Hypoglycemia may occur quickly after injection of short-acting insulins or may be delayed and prolonged, especially if a large amount has been injected into a single area, creating a “depot” effect. Hypoglycemia after sulfonylurea ingestion is usually apparent within a few hours but may be delayed several hours, especially if food or glucose-containing fluids have been given.

**Treatment**

Give sugar and carbohydrate-containing food or liquids by mouth, or intravenous dextrose if the patient is unable to swallow safely. For severe hypoglycemia, start with D50W, 50 ml intravenously (25 g dextrose); repeat, if needed. Follow up with dextrose-containing intravenous fluids (D5W or D10W) to maintain a blood glucose greater than 70–80 mg/dL.

For hypoglycemia caused by sulfonylureas and related insulin secretagogues, consider use of octreotide, a synthetic somatostatin analog that blocks pancreatic insulin release. A dose of 50–100 mcg octreotide subcutaneously every 6–12 hours can reduce the need for exogenous dextrose and prevent rebound hypoglycemia from excessive dextrose dosing.

Admit all patients with symptomatic hypoglycemia after sulfonylurea overdose. Observe asymptomatic overdose patients for at least 12 hours.

Consider hemodialysis for patients with metformin overdose accompanied by severe lactic acidosis (lactate greater than 20 mmol/L or pH < 7.0).

**ISONIAZID**

INH is an antibiotic used mainly in the treatment and prevention of tuberculosis. It may cause hepatitis with long-term use, especially in alcoholic patients and elderly persons. It produces acute toxic effects by competing with pyridoxal 5-phosphate, resulting in lowered brain gamma-aminobutyric acid (GABA) levels. Acute ingestion of as little as 1.5–2 g of INH can cause toxicity, and severe poisoning is likely to occur after ingestion of more than 80–100 mg/kg.
Clinical Findings

Confusion, slurred speech, and seizures may occur abruptly after acute overdose. Severe lactic acidosis—out of proportion to the severity of seizures—is probably due to inhibited metabolism of lactate. Peripheral neuropathy and acute hepatitis may occur with long-term use.

Diagnosis is based on a history of ingestion and the presence of severe acidosis associated with seizures. INH is not usually included in routine toxicologic screening, and serum levels are not readily available.

Treatment

A. Emergency and Supportive Measures

Seizures may require higher than usual doses of benzodiazepines (eg, lorazepam, 3–5 mg intravenously) or administration of pyridoxine as an antidote.

Administer activated charcoal after large recent ingestion, but with caution because of the risk of abrupt onset of seizures.

B. Specific Treatment

Pyridoxine (vitamin B6) is a specific antagonist of the acute toxic effects of INH and is usually successful in controlling convulsions that do not respond to benzodiazepines. Give 5 g intravenously over 1–2 minutes or, if the amount ingested is known, give a gram-for-gram equivalent amount of pyridoxine. Patients taking INH are usually given 25–50 mg of pyridoxine orally daily to help prevent neuropathy.

Lead is used in a variety of industrial and commercial products, such as firearms ammunition, storage batteries, solders, paints, pottery, plumbing, and gasoline and is found in some traditional Hispanic and Ayurvedic ethnic medicines. Lead toxicity usually results from chronic ingestion and is rare after a single ingestion. Lead produces a variety of adverse effects on cellular function and primarily affects the nervous system, gastrointestinal tract, and hematopoietic system.

Clinical Findings

Lead poisoning often goes undiagnosed initially because presenting symptoms and signs are nonspecific and exposure is not suspected. Common symptoms include colicky abdominal pain, constipation, headache, and irritability. Severe poisoning may cause coma and convulsions. Chronic intoxication may cause learning disorders (in children) and motor neuropathy (eg, wrist drop). Lead-containing bullet fragments in or near joint spaces can result in chronic lead toxicity.

Diagnosis is based on measurement of the blood lead level. Whole blood lead levels above 5 mcg/dL warrant public health investigation. Levels between 10 and 25 mcg/dL have been associated with impaired neurobehavioral development in children. Levels of 25–50 mcg/dL may be associated with headache, irritability, and subclinical neuropathy. Levels of 50–70 mcg/dL are associated with moderate toxicity, and levels greater than 70–100 mcg/dL are often associated with severe poisoning. Other laboratory findings of lead poisoning include microcytic anemia with basophilic stippling and elevated free erythrocyte protoporphyrin.

B. Specific Treatment

A. Emergency and Supportive Measures

The most critical intervention in the treatment of lead poisoning is identification of and removal from the source of exposure. For patients with encephalopathy, maintain a patent airway and treat coma and convulsions as described at the beginning of this chapter.

For recent acute ingestion, if a large lead-containing object (eg, fishing weight) is still visible in the stomach on abdominal radiograph, whole bowel irrigation, endoscopy, or even surgical removal may be necessary to prevent subacute lead poisoning. (The acidic gastric contents may corrode the metal surface, enhancing lead absorption. Once the object passes into the small intestine, the risk of toxicity declines.)

Workers with a single lead level over 60 mcg/dL (or three successive monthly levels greater than 50 mcg/dL) or construction workers with any single blood lead level above 50 mcg/dL must by federal law be removed from the site of exposure. Contact the regional office of the United States Occupational Safety and Health Administration (OSHA) for more information. Several states mandate reporting of cases of confirmed lead poisoning.

Note: It is impermissible under the law to treat asymptomatic workers with elevated blood lead levels in order to keep their levels under 50 mcg/dL rather than remove them from the exposure.

1. Severe toxicity—Patients with severe intoxication (encephalopathy or levels greater than 70–100 mcg/dL) should receive edetate calcium disodium (ethylenediaminetetraacetic acid, EDTA), 1500 mg/m2/kg/day (approximately 50 mg/kg/day) in four to six divided doses or as a
continuous intravenous infusion. Most clinicians also add dimercaprol (BAL), 4–5 mg/kg intramuscularly every 4 hours for 5 days, for patients with encephalopathy.

2. Less severe toxicity—Patients with less severe symptoms and asymptomatic patients with blood lead levels between 55 and 69 mcg/dL may be treated with edetate calcium disodium alone in dosages as above. An oral chelator, succimer (DMSA), is available for use in patients with mild to moderate intoxication. The usual dose is 10 mg/kg orally every 8 hours for 5 days, then every 12 hours for 2 weeks.

LITHIUM

Lithium is widely used for the treatment of bipolar depression and other psychiatric disorders. The only normal route of lithium elimination is via the kidney, so patients with acute or chronic kidney disorders are at risk for accumulation of lithium resulting in gradual onset (chronic) toxicity. Intoxication resulting from chronic accidental overdosage or kidney impairment is more common and usually more severe than that seen after acute oral overdose.

Clinical Findings

Mild to moderate toxicity causes lethargy, confusion, tremor, ataxia, and slurred speech. This may progress to myoclonic jerking, delirium, coma, and convulsions. Recovery may be slow and incomplete following severe intoxication. Laboratory studies in patients with chronic intoxication often reveal an elevated serum creatinine and an elevated BUN/creatinine ratio due to underlying volume contraction. The white blood cell count is often elevated. ECG findings include T-wave flattening or inversion, and sometimes bradycardia or sinus node arrest. Nephrogenic diabetes insipidus can occur with overdose or with therapeutic doses. Dysfunction of the thyroid and parathyroid glands has also been described as a result of prolonged lithium exposure.

Lithium levels may be difficult to interpret. Lithium has a low toxic:therapeutic ratio, and chronic intoxication can be seen with levels only slightly above the therapeutic range (0.8–1.2 mEq/L). In contrast, patients with acute ingestion may have transiently very high levels (up to 10 mEq/L reported) without any symptoms before the lithium fully distributes into tissues. Note: Falsely high lithium levels (as high as 6–8 mEq/L) can be measured if a green-top blood specimen tube (containing lithium heparin) is used for blood collection.

Treatment

After acute oral overdose, consider gastric lavage or whole bowel irrigation to prevent systemic absorption (Note: lithium is not adsorbed by activated charcoal). In all patients, evaluate kidney function and volume status, and give intravenous saline-containing fluids as needed. Monitor serum lithium levels and seek assistance with their interpretation and the need for dialysis from a medical toxicologist or regional poison control center (1-800-222-1222). Consider hemodialysis if the patient is markedly symptomatic or if the serum lithium level exceeds 4–5 mEq/L, especially if kidney function is impaired. Continuous renal replacement therapy may be an effective alternative to hemodialysis.

LSD & OTHER HALLUCINOGENS

A variety of substances—ranging from naturally occurring plants and mushrooms to synthetic substances such as phencyclidine (PCP), toluene and other solvents, dextromethorphan, and lysergic acid diethylamide (LSD)—are abused for their hallucinogenic properties. The mechanism of toxicity and the clinical effects vary for each substance.

Many hallucinogenic plants and mushrooms produce anticholinergic delirium, characterized by flushed skin, dry mucous membranes, dilated pupils, tachycardia, and urinary retention. Other plants and mushrooms may contain hallucinogenic indoles such as mescaline and LSD, which typically cause marked visual hallucinations and perceptual distortion, widely diluted pupils, and mild tachycardia. PCP, a dissociative anesthetic agent similar to ketamine, can produce fluctuating delirium and coma, often associated with vertical and horizontal nystagmus. Toluene and other hydrocarbon solvents (butane, trichloroethylene, “chemo,” etc) cause euphoria and delirium and may sensitizes the myocardiun to the effects of catecholamines, leading to fatal dysrhythmias. Other drugs used for their psychostimulant effects include synthetic cannabinoid receptor agonists, Salvia divinorum, synthetic tryptamines, and phenylethylamines, and mephedrone and related cathinone derivatives. See https://www.erowid.org/psychoactives/psychoactives.shtml for descriptions of various hallucinogenic substances.

Treatment

A. Emergency and Supportive Measures

Maintain a patent airway and assist respirations if necessary. Treat coma, hyperthermia, hypertension, and seizures as outlined at the beginning of this chapter. For recent large ingestions, consider giving activated charcoal orally or by gastric tube.
**B. Specific Treatment**

Patients with anticholinergic delirium may benefit from a dose of physostigmine, 0.5–1 mg intravenously, not to exceed 1 mg/min. Dysphoria, agitation, and psychosis associated with LSD or mescaline intoxication may respond to benzodiazepines (eg, lorazepam, 1–2 mg orally or intravenously) or haloperidol (2–5 mg intramuscularly or intravenously) or another antipsychotic drug (eg, olanzapine or ziprasidone). Monitor patients who have sniffed solvents for cardiac dysrhythmias (most commonly premature ventricular contractions, ventricular tachycardia, ventricular fibrillation); treatment with beta-blockers such as propranolol (1–5 mg intravenously) or esmolol (250–500 mcg/kg intravenously, then 50 mcg/kg/min by infusion) may be more effective than lidocaine or amiodarone.

---

**MERCURY**

Mercury poisoning may occur by ingestion of inorganic mercuric salts, organic mercury compounds, or inhalation of metallic mercury vapor. Ingestion of the mercuric salts causes a burning sensation in the throat, discoloration and edema of oral mucous membranes, abdominal pain, vomiting, bloody diarrhea, and shock. Direct nephrotoxicity causes acute kidney injury. Inhalation of high concentrations of metallic mercury vapor may cause acute fulminant chemical pneumonia. Chronic mercury poisoning causes weakness, ataxia, intention tremors, irritability, and depression. Exposure to alkyl (organic) mercury derivatives from highly contaminated fish or fungicides used on seeds has caused ataxia, tremors, convulsions, and catastrophic birth defects. Nearly all fish have some traces of mercury contamination; the US Environmental Protection Agency (EPA) advises consumers to avoid swordfish, shark, king mackerel, and tilefish because they contain higher levels. Fish and shellfish that are generally low in mercury content include shrimp, canned light tuna (not albacore “white” tuna), salmon, pollock, and catfish. Dental fillings composed of mercury amalgam pose a very small risk of chronic mercury poisoning and their removal is rarely justified. Some imported skin lightening creams contain toxic quantities of mercury.

**Treatment**

**A. Acute Poisoning**

There is no effective specific treatment for mercury vapor pneumonitis. Remove ingested mercuric salts by lavage and administer activated charcoal. For acute ingestion of mercuric salts, give dimercaprol (BAL) at once, as for arsenic poisoning. Unless the patient has severe gastroenteritis, consider succimer (DMSA), 10 mg/kg orally every 8 hours for 5 days and then every 12 hours for 2 weeks. Unithiol (DMPS) is a chelator that can be given orally or parenterally but is not commonly available in the United States; it can be obtained from some compounding pharmacies. Maintain urinary output. Treat oliguria and anuria if they occur.

**B. Chronic Poisoning**

Remove from exposure. Neurologic toxicity is not considered reversible with chelation, although some authors recommend a trial of succimer or unithiol (contact a regional poison center or medical toxicologist for advice).

Budnik LT et al. Alternative drugs go global: possible lead and/or mercury intoxication from imported natural health products and a need for scientifically evaluated poisoning monitoring from environmental exposures. J Occup Med Toxicol. 2016 Nov 8;11:49. [PMID: 27833648]

---

**METHANOL & ETHYLENE GLYCOL**

Methanol (wood alcohol) is commonly found in a variety of products, including solvents, duplicating fluids, record cleaning solutions, and paint removers. It is sometimes ingested intentionally by alcoholic patients as a substitute for ethanol and may also be found as a contaminant in bootleg whiskey. Ethylene glycol is the major constituent in most antifreeze compounds. The toxicity of both agents is caused by metabolism to highly toxic organic acids—methanol to formaldehyde; ethylene glycol to glycolic and oxalic acids. Diethylene glycol is a nephrotoxic solvent that has been improperly substituted for glycerine in various liquid medications (cough syrup, teething medicine, acetaminophen), causing numerous deaths in Haiti, Panama, and Nigeria.

**Clinical Findings**

Shortly after ingestion of methanol or ethylene glycol, patients usually appear “drunk.” The serum osmolality (measured with the freezing point device) is usually increased, but acidosis is often absent early. After several hours, metabolism to toxic organic acids leads to a severe anion gap metabolic acidosis, tachypnea, confusion, convulsions, and coma. Methanol intoxication frequently causes visual disturbances, while ethylene glycol often produces oxalate crystalluria and acute kidney injury. **Note:** Point-of-care analytical devices commonly used in the emergency department may falsely measure glycolic acid (a toxic metabolite of ethylene glycol) as lactic acid.

**Treatment**

**A. Emergency and Supportive Measures**

For patients presenting within 30–60 minutes after ingestion, empty the stomach by aspiration through a nasogastric tube. Charcoal is not very effective but should be administered if other poisons or drugs have also been ingested.
B. Specific Treatment

Patients with significant toxicity (manifested by severe metabolic acidosis, altered mental status, markedly elevated osmol gap, or evidence of end-organ toxicity) should undergo hemodialysis as soon as possible to remove the parent compound and the toxic metabolites. Treatment with folic acid, thiamine, and pyridoxine may enhance the breakdown of toxic metabolites.

Ethanol blocks metabolism of the parent compounds by competing for the enzyme alcohol dehydrogenase. Fomepizole (4-methylpyrazole; Antizol) blocks alcohol dehydrogenase and is much easier to use than ethanol. If started before onset of acidosis, fomepizole may be used as the sole treatment for ethylene glycol ingestion in some cases. A regional poison control center (1-800-222-1222) should be contacted for indications and dosing.

Treatment

A. Emergency and Supportive Measures

Administer high-flow oxygen. If the causative agent was recently ingested, administer activated charcoal. Repeat-dose activated charcoal may enhance dapsone elimination.

B. Specific Treatment

Methylene blue enhances the conversion of methemoglobin to hemoglobin by increasing the activity of the enzyme methemoglobin reductase. For symptomatic patients, administer 1–2 mg/kg (0.1–0.2 mL/kg of 1% solution) intravenously. The dose may be repeated once in 15–20 minutes if necessary. Patients with hereditary methemoglobin reductase deficiency or glucose-6-phosphate dehydrogenase deficiency may not respond to methylene blue treatment. In severe cases where methylene blue is not available or is not effective, exchange blood transfusion may be necessary.

METHEMOGLOBINEMIA-INDUCING AGENTS

A large number of chemical agents are capable of oxidizing ferrous hemoglobin to its ferric state (methemoglobin), a form that cannot carry oxygen. Drugs and chemicals known to cause methemoglobinemia include benzocaine (a local anesthetic found in some topical anesthetic sprays and a variety of nonprescription products), aniline, propadiene (an herbicide), nitrates, nitrogen oxide gases, nitrobenzene, dapsone, phenazopyridine (Pyridium), and many others. Dapsone has a long elimination half-life and may cause dizziness, nausea, headache, dyspnea, confusion, seizures, and coma. The severity of symptoms depends on the percentage of hemoglobin oxidized to methemoglobin; the reading is often between 85% and 90%. (A newer oximetry device [Masimo Pulse CO-oximeter] is capable of estimating the methemoglobin level.) Severe poisoning is usually present when methemoglobin fractions are greater than 40–50%. Even at low levels (15–20%), hemolysis may occur after a latent period of 8–12 hours.

Clinical Findings

Methemoglobinemia reduces oxygen-carrying capacity and may cause dizziness, nausea, headache, dyspnea, confusion, seizures, and coma. The severity of symptoms depends on the percentage of hemoglobin oxidized to methemoglobin; severe poisoning is usually present when methemoglobin fractions are greater than 40–50%. Even at low levels (15–20%), victims appear cyanotic because of the “chocolate brown” color of methemoglobin, but they have normal PO₂ results on arterial blood gas determinations. Conventional pulse oximetry gives inaccurate oxygen saturation measurements; the reading is often between 85% and 90%. (A newer pulse oximetry device [Masimo Pulse CO-oximeter] is capable of estimating the methemoglobin level.) Severe metabolic acidosis may be present. Hemolysis may occur, especially in patients susceptible to oxidant stress (ie, those with glucose-6-phosphate dehydrogenase deficiency).

A. Emergency Measures

After the onset of symptoms, efforts to remove the toxic agent are probably useless, especially in cases of amatoxin

MUSHROOMS

There are thousands of mushroom species that cause a variety of toxic effects. The most dangerous species of mushrooms are Amanita phalloides and related species, which contain potent cytotoxins (amatoxins). Ingestion of even a portion of one amatoxin-containing mushroom may be sufficient to cause death.

The characteristic pathologic finding in fatalities from amatoxin-containing mushroom poisoning is acute massive necrosis of the liver.

Clinical Findings

Amanotox-containing mushrooms typically cause a delayed onset (8–12 hours after ingestion) of severe abdominal cramps, vomiting and profuse diarrhea, followed in 1–2 days by acute kidney injury, hepatic necrosis, and hepatic encephalopathy. Cooking the mushrooms does not prevent poisoning.

Monomethylhydrazine poisoning (Gyromitra and Helvella species) is more common following ingestion of uncooked mushrooms, as the toxin is water-soluble. Vomiting, diarrhea, hepatic necrosis, convulsions, coma, and hemolysis may occur after a latent period of 8–12 hours.

Treatment

A. Emergency Measures

After the onset of symptoms, efforts to remove the toxic agent are probably useless, especially in cases of amatoxin
A variety of purported antidotes (eg, thioctic acid, penicillin, corticosteroids) have been suggested for amatoxin-type mushroom poisoning, but controlled studies are lacking and experimental data in animals are equivocal. Aggressive fluid replacement for diarrhea and intensive supportive care for hepatic failure are the mainstays of treatment. Silymarin (silibinin), a derivative of milk thistle, is commonly used in Europe, but is currently commercially available in the United States only as an oral nutritional supplement. The European intravenous product (Legalan-SIL) can be obtained in the United States under an emergency IND provided by the FDA. Contact the regional poison control center (1-800-222-1222) for more information.

Lever transplant may be the only hope for survival in gravely ill patients—contact a liver transplant center early.

OPIATES & OPIOIDS

Prescription and illicit opiates and opioids (morphine, heroin, codeine, oxycodone, fentanyl, hydromorphone, etc) are popular drugs of misuse and abuse and the cause of frequent hospitalizations for overdose. These drugs have widely varying potencies and durations of action; for example, some of the illicit fentanyl derivatives are up to 2000 times more potent than morphine. In recent years, poisonings and fatalities have been reported due to the presence of fentanyl and its derivatives in counterfeit medications and illicit drug use. All of these agents decrease central nervous system activity and sympathetic outflow by acting on opiate receptors in the brain. Tramadol is an analgesic that is unrelated chemically to the opioids but acts on opioid receptors. Buprenorphine is a partial agonist-antagonist opioid used for the outpatient treatment of opioid addiction (Table 5–8).

Clinical Findings

Mild intoxication is characterized by euphoria, drowsiness, and constricted pupils. More severe intoxication may cause hypotension, bradycardia, hypothermia, coma, and respiratory arrest. Pulmonary edema may occur. Death is usually due to apnea or pulmonary aspiration of gastric contents. Methadone may cause QT interval prolongation and torsades de pointes. While the duration of effect for heroin is usually 3–5 hours, methadone intoxication may last for 48–72 hours or longer. Tramadol, dextromethorphan, and meperidine also occasionally cause seizures. With meperidine, the metabolite normeperidine is probably the cause of seizures and is most likely to accumulate with repeated dosing in patients with chronic kidney disease. Propoxyphene prolongs the QRS interval and may cause seizures; it is no longer available in the United States. Wound botulism has been associated with skin-popping, especially involving “black tar” heroin. Buprenorphine added to an opioid regimen may produce acute narcotic withdrawal symptoms. Many opioids, including fentanyl, tramadol, oxycodone, and methadone, are not detected on routine urine toxicology “opiate” screening.

Treatment

A. Emergency and Supportive Measures

Protect the airway and assist ventilation. Administer activated charcoal for recent large ingestions.

B. Specific Treatment

Naloxone is a specific opioid antagonist that can rapidly reverse signs of narcotic intoxication. Although it is structurally related to the opioids, it has no agonist effects of its own. Administer 0.2–2 mg intravenously and repeat as needed to awaken the patient and maintain airway protective reflexes and spontaneous breathing. Very large doses (10–20 mg) may be required for patients intoxicated by some opioids (eg, codeine, fentanyl derivatives). Caution: The duration of effect of naloxone is only about 2–3 hours; repeated doses may be necessary for patients intoxicated by long-acting drugs such as methadone. Continuous observation for at least 3 hours after the last naloxone dose is mandatory.

PESTICIDES: CHOLINESTERASE INHIBITORS

Organophosphorus and carbamate insecticides (organophosphates: parathion, malathion, etc; carbamates: carbaryl, aldicarb, etc) are widely used in commercial agriculture and home gardening and have largely replaced older, more
environmentally persistent organochlorine compounds such as DDT and chlordane. The organophosphates and carbamates—also called anticholinesterases because they inhibit the enzyme acetylcholinesterase—cause an increase in acetylcholine activity at nicotinic and muscarinic receptors and in the peripheral and central nervous system. There are a variety of chemical agents in this group, with widely varying potencies. Most of them are poorly water-soluble, are often formulated with an aromatic hydrocarbon solvent such as xylene and are well absorbed through intact skin. Most chemical warfare “nerve agents” (such as GA [tabun], GB [sarin], GD [soman], and VX) are organophosphates.

Clinical Findings
Inhibition of cholinesterase results in abdominal cramps, diarrhea, vomiting, excessive salivation, sweating, lacrimation, miosis, wheezing and bronchorrhea, seizures, and skeletal muscle weakness. Initial tachycardia is usually followed by bradycardia. Profound skeletal muscle weakness, aggravated by excessive bronchial secretions and wheezing, may result in respiratory arrest and death. Symptoms and signs of poisoning may persist or recur over several days, especially with highly lipid-soluble agents such as fenthion or dimethoate.

The diagnosis should be suspected in patients who present with miosis, sweating, and hyperperistalsis. Serum and red blood cell cholinesterase activity is usually depressed at least 50% below baseline in those victims who have severe intoxication.

Treatment
A. Emergency and Supportive Measures
If the agent was recently ingested, consider gut decontamination by aspiration of the liquid using a nasogastric tube followed by administration of activated charcoal. If the agent is on the victim’s skin or hair, wash repeatedly with soap or shampoo and water. Providers should take care to avoid skin exposure by wearing gloves and waterproof aprons. Dilute hypochlorite solution (eg, household bleach diluted 1:10) is reported to help break down organophosphate pesticides and nerve agents on equipment or clothing.

B. Specific Treatment
Atropine reverses excessive muscarinic stimulation and is effective for treatment of salivation, bronchial hypersecretion, wheezing, abdominal cramping, and sweating. However, it does not interact with nicotinic receptors at autonomic ganglia and at the neuromuscular junction and has no direct effect on muscle weakness. Administer 2 mg intravenously, and if there is no response after 5 minutes, give repeated boluses in rapidly escalating doses (eg, doubling the dose each time) as needed to dry bronchial secretions and decrease wheezing; as much as several hundred milligrams of atropine has been given to treat severe poisoning.

Pralidoxime (2-PAM, Protopam) is a more specific antidote that reverses organophosphate binding to the cholinesterase enzyme; therefore, it should be effective at the neuromuscular junction as well as other nicotinic and muscarinic sites. It is most likely to be clinically effective if started very soon after poisoning, to prevent permanent binding of the organophosphate to cholinesterase. However, clinical studies have yielded conflicting results regarding the effectiveness of pralidoxime in reducing mortality. Administer 1–2 g intravenously as a loading dose and begin a continuous infusion (200–500 mg/h, titrated to clinical response). Continue to give pralidoxime as long as there is any evidence of acetylcholine excess. Pralidoxime is of questionable benefit for carbamate poisoning, because carbamates have only a transitory effect on the cholinesterase enzyme. Other, unproven therapies for organophosphate poisoning include magnesium, sodium bicarbonate, clonidine, and extracorporeal removal.

PETROLEUM DISTILLATES & SOLVENTS
Petroleum distillate toxicity may occur from inhalation of the vapor or as a result of pulmonary aspiration of the liquid during or after ingestion. Acute manifestations of aspiration pneumonitis are vomiting, coughing, and bronchopneumonia. Some hydrocarbons—ie, those with aromatic or halogenated subunits—can also cause severe systemic poisoning after oral ingestion. Hydrocarbons can also cause systemic intoxication by inhalation. Vertigo, muscular incoordination, irregular pulse, myoclonus, and seizures occur with serious poisoning and may be due to hypoxemia or the systemic effects of the agents. Chlorinated and fluorinated hydrocarbons (trichloroethylene, Freons, etc) and many other hydrocarbons can cause ventilicular arrhythmias due to increased sensitivity of the myocardium to the effects of endogenous catecholamines.

Treatment
Remove the patient to fresh air. For simple aliphatic hydrocarbon ingestion, gastric emptying and activated charcoal are not recommended, but these procedures may be indicated if the preparation contains toxic solutes (eg, an insecticide) or is an aromatic or halogenated product. Observe the victim for 6–8 hours for signs of aspiration pneumonitis (cough, localized crinkles or rhonchi, tachypnea, and infiltrates on chest radiograph). Corticosteroids are not recommended. If fever occurs, give a specific antibiotic only after identification of bacterial pathogens by laboratory studies. Because of the risk of arrhythmias, use bronchodilators with caution in patients with chlorinated or fluorinated solvent intoxication. If tachyarrhythmias occur, use esmolol intravenously 25–100 mcg/kg/min.

Salicylates (aspirin, methyl salicylate, bismuth subsalicylate, etc) are found in a variety of over-the-counter and prescription medications. Salicylates uncouple cellular oxidative phosphorylation, resulting in anaerobic metabolism and excessive production of lactic acid and heat, and they also interfere with several Krebs cycle enzymes. A single ingestion of more than 200 mg/kg of salicylate is likely to produce significant acute intoxication. Poisoning may also occur as a result of chronic excessive dosing over several days. Although the half-life of salicylate is 2–3 hours after small doses, it may increase to 20 hours or more in patients with intoxication.

**Clinical Findings**

Acute ingestion often causes nausea and vomiting, occasionally with gastritis. Moderate intoxication is characterized by hyperpnea (deep and rapid breathing), tachycardia, tinnitus, and elevated anion gap metabolic acidosis. (A normal anion gap sometimes occurs due to salicylate interference with the chemistry analyzer, falsely raising the measured chloride.) Serious intoxication may result in agitation, confusion, coma, seizures, cardiovascular collapse, pulmonary edema, hyperthermia, and death. The prothrombin time is often elevated owing to salicylate-induced hypoprothrombinemia. Central nervous system intracellular glucose depletion can occur despite normal measured serum glucose levels.

Diagnosis of salicylate poisoning is suspected in any patient with metabolic acidosis and is confirmed by measuring the serum salicylate level. Patients with levels greater than 100 mg/dL (1000 mg/L or 7.2–8.6 mmol/L) after acute overdose or greater than 60–70 mg/dL (600–700 mg/L or 4.3–5 mmol/L) with subacute or chronic intoxication.

**Treatment**

**A. Emergency and Supportive Measures**

Administer activated charcoal orally. Gastric lavage followed by administration of extra doses of activated charcoal may be needed in patients who ingest more than 10 g of aspirin. The desired ratio of charcoal to aspirin is about 10:1 by weight; while this cannot always be given as a single dose, it may be administered over the first 24 hours in divided doses every 2–4 hours along with whole bowel irrigation. Give glucose-containing fluids to reduce the risk of cerebral hypoglycemia. Treat metabolic acidosis with intravenous sodium bicarbonate. This is critical because acidosis (especially acidemia, pH < 7.40) promotes greater entry of salicylate into cells, worsening toxicity. **Warning:** Sudden and severe deterioration can occur after rapid sequence intubation and controlled ventilation if the pH is allowed to fall due to hypercarbia during the apneic period.

**B. Specific Treatment**

Alkalization of the urine enhances renal salicylate excretion by trapping the salicylate anion in the urine. Add 100 mEq (two ampules) of sodium bicarbonate to 1 L of 5% dextrose in 0.2% saline, and infuse this solution intravenously at a rate of about 150–200 mL/h. Unless the patient is oliguric or hyperkalemic, add 20–30 mEq of potassium chloride to each liter of intravenous fluid. Patients who are volume-depleted often fail to produce an alkaline urine (paradoxical aciduria) unless potassium is given.

Hemodialysis may be lifesaving and is indicated for patients with severe metabolic acidosis, markedly altered mental status, or significantly elevated salicylate levels (eg, greater than 100–120 mg/dL [1000–1200 mg/L or 7.2–8.6 mmol/L] after acute overdose or greater than 60–70 mg/dL [600–700 mg/L or 4.3–5 mmol/L] with subacute or chronic intoxication).

**SEAFOOD POISONINGS**

A variety of intoxications may occur after eating certain types of fish or other seafood. These include scombroid, ciguatera, paralytic shellfish, and puffer fish poisoning. The mechanisms of toxicity and clinical presentations are described in Table 38–8. In the majority of cases, the seafood has a normal appearance and taste (scombroid may have a peppery taste).

**Treatment**

**A. Emergency and Supportive Measures**

**Warning:** Abrupt respiratory arrest may occur in patients with acute paralytic shellfish and puffer fish poisoning. Observe patients for at least 4–6 hours. Replace fluid and electrolyte losses from gastroenteritis with intravenous saline or other crystalloid solution.

For recent ingestions, it may be possible to adsorb residual toxin in the gut with activated charcoal, 50–60 g orally.
Mechanism
Improper preservation of large fish results in bacteria. Clinical Presentation
Reef fish ingest toxic dinoflagellates, whose toxins accumulate in fish meat. Commonly implicated fish in the United States are barracuda, jack, snapper, and grouper.

<tbody>
<tr>
<td>Ciguatera</td>
<td>Reef fish ingest toxic dinoflagellates, whose toxins accumulate in fish meat. Commonly implicated fish in the United States are barracuda, jack, snapper, and grouper.</td>
<td>1–6 hours after ingestion, victims develop abdominal pain, vomiting, and diarrhea accompanied by a variety of neurologic symptoms, including paresthesia, reversal of hot and cold sensation, vertigo, headache, and intense itching. Autonomic disturbances, including hypotension and bradycardia, may occur.</td>
</tr>
<tr>
<td>Scombroid</td>
<td>Improper preservation of large fish results in bacterial degradation of histidine to histamine. Commonly implicated fish include tuna, mahimahi, bonita, mackerel, and kingfish.</td>
<td>Allergic-like (anaphylactoid) symptoms are due to histamine, usually begin within 15–90 minutes, and include skin flushing, itching, urticaria, angioedema, bronchospasm, and hypotension as well as abdominal pain, vomiting, and diarrhea.</td>
</tr>
<tr>
<td>Paralytic shellfish poisoning</td>
<td>Dinoflagellates produce saxitoxin, which is concentrated by filter-feeding mussels and clams. Saxitoxin blocks sodium conductance and neuronal transmission in skeletal muscles.</td>
<td>Onset is usually within 30–60 minutes. Initial symptoms include perioral and intraoral paresthesia. Other symptoms include nausea and vomiting, headache, dizziness, dysphagia, dysarthria, ataxia, and rapidly progressive muscle weakness that may result in respiratory arrest.</td>
</tr>
<tr>
<td>Puffer fish poisoning</td>
<td>Tetrodotoxin is concentrated in liver, gonads, intestine, and skin. Toxic effects are similar to those of saxitoxin. Tetrodotoxin is also found in some North American newts and Central American frogs.</td>
<td>Onset is usually within 30–40 minutes but may be as short as 10 minutes. Initial perioral paresthesias are followed by headache, diaphoresis, nausea, vomiting, ataxia, and rapidly progressive muscle weakness that may result in respiratory arrest.</td>
</tr>
</tbody>
</table>

Table 38–8. Common seafood poisonings.

B. Specific Treatment

There is no specific antidote for paralytic shellfish or puffer fish poisoning.

1. Ciguatera—There are anecdotal reports of successful treatment of acute neurologic symptoms with mannitol, 1 g/kg intravenously, but this approach is not widely accepted.

2. Scombroid—Antihistamines such as diphenhydramine, 25–50 mg intravenously, and the H2-blocker cimetidine, 300 mg intravenously, are usually effective.

A. Emergency Measures

Immobilize the patient and the bitten part in a neutral position. Avoid manipulation of the bitten area. Transport the patient to a medical facility for definitive treatment. Do not give alcoholic beverages or stimulants; do not apply ice; do not apply a tourniquet. The potential trauma to underlying tissues resulting from incision and suction performed by unskilled people is probably not justified in view of the small amount of venom that can be recovered.

B. Specific Antidote and General Measures

1. Pit viper (eg, rattlesnake) envenomation—There are two commercially available antivenins for rattlesnake envenomation (CroFab and Anavip). Depending on the severity of symptoms CroFab is administered in increments of 4–6 vials by slow intravenous drip in 250–500 mL saline. For more serious envenomation with marked local effects and systemic toxicity (eg, hypotension, coagulopathy), higher doses and additional vials may be required. The dosing of Anavip is 10 vials by slow intravenous infusion over 60 minutes initially followed by additional 10-vial increments as needed for more serious envenomations or for progression of symptoms. Monitor vital signs and the blood coagulation profile. Type and cross-match blood. The adequacy of venom neutralization is indicated by improvement in symptoms and signs, and the rate that swelling slows. Prophylactic antibiotics are not indicated after a rattlesnake bite.

2. Elapid (coral snake) envenomation—Give 1–2 vials of specific antivenom as soon as possible. Note: Pfizer/Wyeth no longer makes coral snake antivenom in the United States.

SNAKE BITES

The venom of poisonous snakes and lizards may be predominantly neurotoxic (coral snake) or predominantly cytolytic (rattlesnakes, other pit vipers). Neurotoxins cause respiratory paralysis; cytolytic venoms cause tissue destruction by digestion and hemorrhage due to hemolysis and destruction of the endothelial lining of the blood vessels. The manifestations of rattlesnake envenomation are mostly local pain, redness, swelling, and extravasation of blood. Perioral tingling, metallic taste, nausea and vomiting, hypotension, and coagulopathy may also occur. Thrombocytopenia can persist for several days after a rattlesnake bite. Neurotoxic envenomation may cause ptosis, dysphagia, diplopia, and respiratory arrest.

Table 38–8. Common seafood poisonings.
and remaining supplies are dwindling. To locate antisera for this or exotic snakes, call a regional poison control center (1-800-222-1222).

SPIDER BITES & SCORPION STINGS

Envenomation from most species of spiders in the United States causes only local pain, redness, and swelling. The more venomous brown widow spiders (Latrodectus mactans) cause generalized muscular pains, muscle spasms, and rigidity. The brown recluse spider (Loxosceles reclusa) causes progressive local necrosis as well as hemolytic reactions (rare).

Stings by most scorpions in the United States cause only local pain. Stings by the more toxic Centruroides species (found in the southwestern United States) may cause muscle cramps, twitching and jerking, and occasionally hypertension, convulsions, and pulmonary edema. Stings by scorpions from other parts of the world are not discussed here.

► Treatment

A. Black Widow Spider Bites

Pain may be relieved with parenteral opioids or muscle relaxants (eg, methocarbamol, 15 mg/kg). Calcium gluconate 10%, 0.1–0.2 mL/kg intravenously, may transiently relieve muscle rigidity, though its effectiveness is unproven. Latrodectus antivenom is possibly more effective, but because of concerns about acute hypersensitivity reactions (horse serum–derived), it is often reserved for very young or elderly patients or those who do not respond promptly to the above measures. Horse serum sensitivity testing is required. (Instruction and testing materials are included in the antivenin kit.)

B. Brown Recluse Spider Bites

Because bites occasionally progress to extensive local necrosis, some authorities recommend early excision of the bite site, whereas others use oral corticosteroids. Anecdotal reports have claimed success with dapsone and colchicine. All of these treatments remain of unproven.

C. Scorpion Stings

No specific treatment other than analgesics is required for envenomations by most scorpions found in the United States. An FDA-approved specific antivenom is available for Centruroides stings.

THEOPHYLLINE & CAFFEINE

Methylxanthines, including theophylline and caffeine, are nonselective adenosine receptor antagonists. In overdose, toxicity results from the release of endogenous catecholamines with beta-1- and beta-2-adrenergic stimulation. Theophylline may cause intoxication after an acute single overdose, or intoxication may occur as a result of chronic accidental repeated overdosage or reduced elimination resulting from hepatic dysfunction or interacting drug (eg, cimetidine, erythromycin). The usual serum half-life of theophylline is 4–6 hours, but this may increase to more than 20 hours after overdose. Caffeine in energy drinks or herbal or dietary supplement products can produce similar toxicity.

► Clinical Findings

Mild intoxication causes nausea, vomiting, tachycardia, and tremulousness. Severe intoxication is characterized by ventricular and supraventricular tachyarrhythmias, hypotension, and seizures. Status epilepticus is common and often intractable to the usual anticonvulsants. After acute overdose (but not chronic intoxication), hypokalemia, hyperglycemia, and metabolic acidosis are common. Seizures and other manifestations of toxicity may be delayed for several hours after acute ingestion, especially if a sustained-release preparation such as Theo-Dur was taken.

Diagnosis is based on measurement of the serum theophylline concentration. Seizures and hypotension are likely to develop in acute overdose patients with serum levels greater than 100 mg/L (555 mcg/mL). Serious toxicity may develop at lower levels (ie, 40–60 mg/L [222–333 mcg/mL/L]) in patients with chronic intoxication. Serum caffeine levels are not routinely available in clinical practice, but in a study of 51 fatal cases the median level was 180 mg/L (range 33–567 mg/L).

► Treatment

A. Emergency and Supportive Measures

After acute ingestion, administer activated charcoal. Repeated doses of activated charcoal may enhance theophylline elimination by “gut dialysis.” Addition of whole bowel irrigation should be considered for large ingestions resulting from hepatic dysfunction or interacting drug (eg, cimetidine, erythromycin). The usual serum half-life of theophylline is 4–6 hours, but this may increase to more than 20 hours after overdose. Caffeine in energy drinks or herbal or dietary supplement products can produce similar toxicity.

After acute ingestion, administer activated charcoal. Repeated doses of activated charcoal may enhance theophylline elimination by “gut dialysis.” Addition of whole bowel irrigation should be considered for large ingestions involving sustained-release preparations.

Hemodialysis is effective in removing theophylline and is indicated for patients with status epilepticus or markedly elevated serum theophylline levels (eg, greater than 100 mg/L [555 mcg/mL] after acute overdose or greater than 60 mg/L [333 mcg/mL] with chronic intoxication).
B. Specific Treatment

Treat seizures with benzodiazepines (lorazepam, 2–3 mg intravenously, or diazepam, 5–10 mg intravenously) or phenobarbital (10–15 mg/kg intravenously). Phenytoin is not effective. Hypotension and tachycardia—which are mediated through excessive beta-adrenergic stimulation—may respond to beta-blocker therapy even in low doses. Administer esmolol, 25–50 mcg/kg/min by intravenous infusion, or propranolol, 0.5–1 mg intravenously.

Newer-generation antidepressants such as trazodone, fluoxetine, citalopram, paroxetine, sertraline, bupropion, venlafaxine, and fluvoxamine are not chemically related to the tricyclic antidepressant agents and, with the exception of bupropion, do not generally produce quinidine-like cardiotoxic effects. However, they may cause seizures in overdoses and they may cause serotonin syndrome.

\[ \text{Figure 38–2.} \] Cardiac arrhythmias resulting from tricyclic antidepressant overdose. \( A \): Delayed intraventricular conduction results in prolonged QRS interval (0.18 s). \( B \) and \( C \): Supraventricular tachycardia with progressive widening of QRS complexes mimics ventricular tachycardia. (Reproduced, with permission, from Benowitz NL, Goldschlager N. Cardiac disturbances in the toxicologic patient. In: Haddad LM, Winchester JF [editors], Clinical Management of Poisoning and Drug Overdose, 3rd edition. Saunders/Elsevier, 1998. Copyright © Elsevier.)

TRICYCLIC & OTHER ANTIDEPRESSANTS

Tricyclic and related cyclic antidepressants are among the most dangerous drugs involved in suicidal overdose. These drugs have anticholinergic and cardiac depressant properties (“quinidine-like” sodium channel blockade). Tricyclic antidepressants produce more marked membrane-depressant cardiotoxic effects than the phenothiazines.

Signs of severe intoxication may occur abruptly and without warning within 30–60 minutes after acute tricyclic overdose. Anticholinergic effects include dilated pupils, tachycardia, dry mouth, flushed skin, muscle twitching, and decreased peristalsis. Quinidine-like cardiotoxic effects include QRS interval widening (greater than 0.12 s; Figure 38–2), ventricular arrhythmias, AV block, and hypotension. Rightward-axis deviation of the terminal 40 ms of the QRS has also been described. Prolongation of the QT interval and torsades de pointes have been reported with several of the newer antidepressants. Seizures and coma are common with severe intoxication. Life-threatening hyperthermia may result from status epilepticus and anticholinergic-induced impairment of sweating. Among newer agents, bupropion and venlafaxine have been associated with a greater risk of seizures.

The diagnosis should be suspected in any overdose patient with anticholinergic side effects, especially if there is widening of the QRS interval or seizures. For intoxication by most tricyclic antidepressants, the QRS interval correlates with the severity of intoxication more reliably than the serum drug level.

Serotonin syndrome should be suspected if agitation, delirium, diaphoresis, tremor, hyperreflexia, clonus (spontaneous, inducible, or ocular), and fever develop in a patient taking serotonin reuptake inhibitors.

\[ \text{Treatment} \]

A. Emergency and Supportive Measures

Observe patients for at least 6 hours and admit all patients with evidence of anticholinergic effects (eg, delirium, dilated pupils, tachycardia) or signs of cardiotoxicity.

Administer activated charcoal and consider gastric lavage after recent large ingestions. All of these drugs have large volumes of distribution and are not effectively removed by hemodialysis procedures.

B. Specific Treatment

Cardiotoxic sodium channel-depressant effects of tricyclic antidepressants may respond to boluses of sodium bicarbonate (50–100 mEq intravenously). Sodium bicarbonate provides a large sodium load that alleviates depression of the sodium-dependent channel. Reversal of acidosis may provide a large sodium load that alleviates depression of the sodium-dependent channel. Reversal of acidosis may also have beneficial effects at this site. Maintain the pH between 7.45 and 7.50. Alkalization does not promote excretion of tricyclic antidepressants. Prolongation of the QT interval or torsades de pointes is usually treated with intravenous magnesium or overdrive pacing. Severe cardiotoxicity in patients with overdoses of lipid-soluble drugs (eg, amitriptyline, bupropion) has reportedly responded to intravenous lipid emulsion (Intralipid). 1.5 mL/kg repeated one or two times if needed. Plasma exchange
using albumin and ECMO have been reported successful in several cases.

Mild serotonin syndrome may be treated with benzodiazepines and withdrawal of the antidepressant. Moderate cases may respond to cyproheptadine (4 mg orally or via gastric tube hourly for three or four doses) or chlorpromazine (25 mg intravenously). Severe hyperthermia should be treated with neuromuscular paralysis and endotracheal intubation in addition to external cooling measures.

INTRODUCTION TO CANCER

Patricia A. Cornett, MD
Tiffany O. Dea, PharmD, BCOP

Etiology

Cancer is the second most common cause of death in the United States. In 2018, an estimated 1,735,350 cases of cancer were diagnosed, and 609,640 persons died of cancer. Based on current statistics, almost 40% of Americans will be diagnosed with cancer at some point during their lifetime. Table 39–1 lists the 10 leading cancer types in men and women by site.

However, the death rates from cancer are decreasing. Compared to the 1991 cancer death rate of 215.1 per 100,000 population, the 2012 rate of 171.2 per 100,000 represents a 20% reduction in its death rate. Importantly, death rates have declined in the four most common cancer types (lung, colon-rectum, breast, and prostate). The largest declines in death rates in women have been in non-Hodgkin lymphoma and colorectal cancer and in men, in prostate and stomach cancers. Reductions in cancer mortality reflect successful implementation of a broad strategy of prevention, detection, and treatment. Due to these improvements, the number of cancer survivors is increasing. In 2015, an estimated 14.5 million people were alive in whom cancer had been previously diagnosed; that number is projected to grow to 18.9 million in 2024.

Modifiable Risk Factors

Tobacco is the most common preventable cause of cancer death; at least 30% of all cancer deaths in the United States are directly linked to tobacco. In 2014, an estimated 167,133 cancer deaths in the United States could be directly attributed to tobacco. Clear evidence links tobacco use to at least 15 cancers. The most dramatic link is with lung cancer; 80% of lung cancer cases occur in smokers. Remarkably, almost 10% of long-term survivors of a tobacco-related cancer continue to use tobacco products, increasing their risk of yet another cancer.

The prevalence of smoking for US adults based on the 2017 National Health Interview Survey is 16% for males and 12.4% for females, which is a remarkable reduction from the 1955 peak of 57% for males and the 1965 peak of 34% for females. Cigarettes are the most common form of tobacco used in the United States, though the use of non-cigarette forms of tobacco and of electronic cigarettes is increasing. The long-term risks of electronic cigarettes are not yet determined. The use of flavoring compounds increases the attractiveness of these devices to youth with the concern that these devices will encourage youth to transition to cigarettes. In 2016, 11% of high school students in the United States reported use of electronic cigarettes in the preceding month.

Tobacco cessation directed toward the individual should start with clinician counseling. Simple, concise advice from a clinician can yield cessation rates of 10–20%. Additive strategies include more intensive counseling; nicotine replacement therapy with patches, gum, lozenges, or inhalers; and prescription medication with bupropion or varenicline (see Chapter 1).

For those Americans who do not use tobacco, the most modifiable risk factors would be nutrition and physical activity. Prudent recommendations to reduce cancer risk are (1) avoid tobacco; (2) be physically active; (3) maintain a healthy weight; (4) consume a diet rich in fruits, vegetables, and whole grains; (5) lower consumption of saturated and trans dietary fats; (6) limit alcohol use; and (7) avoid excess sun exposure.

Another modifiable cancer risk factor is radiation from radiographic studies. A 2009 study reported that the use of computed tomography (CT) in diagnostic algorithms exposes individuals to significant radiation doses that may increase their lifetime risk of cancer. Both standardization of CT radiation doses and limiting testing have been important steps in minimizing this risk. The American Society of Hematology and American Society of Clinical Oncology have guidelines, inspired by the American Board of Internal Medicine Foundation’s “Choosing Wisely” campaign, for limiting radiographic testing, particularly when used in surveillance for treated cancer patients.

Data from the American Cancer Society, 2019.

Staging

The most commonly used staging system at the time of diagnosis is the TNM (Tumor, Nodes, Metastasis) system (see https://www.cancerstaging.org). Rules for staging for individual cancers are established and published by the American Joint Committee on Cancer (AJCC). The elements used for staging are tumor location, size and level of tumor invasion (T), absence or presence and extent of nodal metastases (N), and absence or presence of systemic metastases (M). Once the TNM designations have been determined, an overall stage is assigned, stage I, II, III, or IV. Clinical staging utilizes physical examination, laboratory and imaging tests as well as results from biopsies; pathologic staging relies on the results from surgery. In some instances, other classifications may be used for certain cancers such as the Ann Arbor staging system for lymphomas.

Other characteristics of cancers, not reflected in the TNM stage, may be used to indicate prognosis and guide treatment. Pathologic features seen on routine histologic examination for some cancers are very important; examples include the Gleason score for prostate cancer and the grade of sarcomas. Cancer specimens should also be sent for targeted molecular diagnostic testing, when appropriate. Examples include testing for HER2 in breast and gastric cancer; K-ras and BRAF mutations in colorectal cancer; BRAF mutations in melanoma; epidermal growth factor receptor (EGFR), K-ras mutations, and the ALK fusion gene in lung cancer; and programmed death-ligand 1 (PD-L1) expression testing in a variety of cancers.

Treatment

See Primary Cancer Treatment section below. Table 39–2 outlines treatment choices by cancer type for those responsive to systemic agents, and Table 39–3 provides a listing of common chemotherapeutic agents.

New cough or change in chronic cough. Dyspnea, hemoptysis, anorexia, weight loss. Enlarging nodule or mass; persistent opacity, atelectasis, or pleural effusion on chest radiograph or CT scan. Cytologic or histologic findings of lung cancer in sputum, pleural fluid, or biopsy specimen.

General Considerations
Lung cancer is the leading cause of cancer deaths in both men and women. The American Cancer Society estimates 234,030 new diagnoses and 154,050 deaths from lung cancer in the United States in 2018, accounting for approximately 13% of new cancer diagnoses and 25% of all cancer deaths.

Cigarette smoking causes 85–90% of cases of lung cancer. The causal connection between cigarettes and lung cancer is established not only epidemiologically but also through identification of carcinoens in tobacco smoke and analysis of the effect of these carcinogens on specific oncocenes expressed in lung cancer.

Other environmental risk factors for the development of lung cancer include exposure to environmental tobacco smoke, radon, asbestos, diesel exhaust, ionizing radiation, metals (arsenic, chromium, nickel, iron oxide), and industrial carcinogens. A familial predisposition to lung cancer is recognized. Certain diseases are associated with an increased risk of lung cancer, including pulmonary fibrosis, chronic obstructive pulmonary disease, and sarcoidosis.

The median age at diagnosis of lung cancer in the United States is 70; it is unusual under the age of 40. The combined relative 5-year survival rate for all stages of lung cancer is currently 19%.

There are five main histologic categories of bronchogenic carcinoma. Squamous cell carcinomas (23% of cases, based on US SEER data 2011–2015) arise from the bronchial epithelium and often present as intraluminal masses. They are usually centrally located and can present with hemoptysis. Squamous cell carcinomas stain for P63 and P40 on immunohistochemistry. Adenocarcinomas (48% of cases) arise from mucus glands or from any epithelial cell within or distal to the terminal bronchioles. They usually present as peripheral nodules or masses and stain for TTF-1 and Napsin-A on immunohistochemistry. Adenocarcinomas in situ (formerly bronchioloalveolar cell carcinomas) spread along preexisting alveolar structures (lepidic growth) without evidence of invasion. Large cell carcinomas (1.5% of cases) are a heterogeneous group of undifferentiated cancers that share large cells and do not fit into other categories. Large cell carcinomas are typically aggressive and have rapid doubling times. They present as central or peripheral masses. Cancers that are not better differentiated on pathologic review other than non–small cell carcinomas (NSCLC) or carcinomas not otherwise specified make up about 14% of cases. Small cell carcinomas (13% of cases) are tumors of bronchial origin that typically begin centrally, infiltrating submucosally to cause narrowing of the bronchus without a discrete luminal mass. They are aggressive cancers that often involve regional or distant metastasis on presentation.

For purposes of staging and treatment, bronchogenic carcinomas are divided into small cell lung cancer (SCLC) and the other four types, labeled NSCLC.

Clinical Findings
Lung cancer is symptomatic at diagnosis in a majority of patients. The clinical presentation depends on the type and location of the primary tumor, the extent of local spread, and the presence of distant metastases and any paraneoplastic syndromes.

A. Symptoms and Signs
Anorexia, weight loss, or asthenia occurs in 55–90% of patients presenting with a new diagnosis of lung cancer. Up to 60% of patients have a new cough or a change in a chronic cough; 6–31% have hemoptysis; and 25–40% complain of pain, either nonspecific chest pain or pain from bony metastases to the vertebrae, ribs, or pelvis. Local spread may cause endobronchial obstruction with atelectasis and postobstructive pneumonia, pleural effusion (12–33%), change in voice (compromise of the recurrent laryngeal nerve), superior vena cava syndrome (obstruction of the superior vena cava with supraclavicular venous engorge, ment), and Horner syndrome (ipsilateral ptosis, miosis, and anhidrosis from involvement of the inferior cervical ganglion and the paravertebral sympathetic chain). Distant metastases to the liver are associated with asthenia and weight loss. Brain metastases (10% in NSCLC, more common in adenocarcinoma, and 20–30% in SCLC) may present with headache, nausea, vomiting, seizures, dizziness, or altered mental status.

Paraneoplastic syndromes are patterns of organ dysfunction related to immune-mediated or secretory effects of neoplasms. These syndromes occur in 10–20% of lung cancer patients. They may precede, accompany, or follow the diagnosis of lung cancer. In patients with small cell carcinoma, the syndrome of inappropriate antidiuretic hormone (SIADH) can develop in 10–15%; in those with squamous cell carcinoma, hypercalcemia can develop in 10%. Digital clubbing is seen in up to 20% of patients at diagnosis (see Figure 6–41). Other common paraneoplastic syndromes include increased ACTH production, anemia, hypercoagulability, peripheral neuropathy, and the Lambert-Eaton myasthenic syndrome. Their recognition is important.
because treatment of the primary tumor may improve or resolve symptoms even when the cancer is not curable.

**B. Laboratory Findings**

The diagnosis of lung cancer rests on examination of a tissue or cytology specimen. **Sputum cytology** is highly specific but insensitive; the yield is highest when there are lesions in the central airways. While the diagnostic yield of **CT-guided biopsy** of peripheral nodules approaches 80–90%, the rates of pneumothorax are significant (15–30%), especially in those with emphysema. **Thoracentesis** (sensitivity 50–65%) can be used to establish a diagnosis of lung cancer in patients with malignant pleural effusions. Fine-needle aspiration (FNA) of palpable supraclavicular or cervical lymph nodes is frequently diagnostic.

**Fiberoptic bronchoscopy** allows visualization of the major airways, cytology brushing of visible lesions or lavage of lung segments with cytologic evaluation of specimens, direct biopsy of endobronchial abnormalities, blind transbronchial biopsy of the pulmonary parenchyma or peripheral nodules, and FNA biopsy of mediastinal lymph nodes. The use of fluorescence bronchoscopy improves the ability to identify early endobronchial lesions, and endobronchial and transesophageal endoscopic ultrasound enhance the direction and yield of FNA of mediastinal nodes. Electromagnetic navigational bronchoscopy allows bronchoscopic approaches to small peripheral nodules.

**C. Imaging**

Nearly all patients with lung cancer have abnormal findings on chest radiography or CT scan (Figure 39–1). These findings are rarely specific for a particular diagnosis. Interpretation of characteristic findings in isolated nodules is described in Chapter 9.

**D. Special Examinations**

1. **Staging**—Accurate staging is crucial (1) to provide the clinician with information to guide treatment, (2) to provide the patient with accurate information regarding prognosis, and (3) to standardize entry criteria for clinical trials to allow interpretation of results.

There are two essential principles of staging NSCLC. First, the more extensive the disease, the worse the prognosis; second, surgical resection offers the best chance for cure. Staging of NSCLC uses two integrated systems and is continuously updated. The eighth edition of the **AJCC/Union for International Cancer Control (UICC) stage classification** for lung cancer became effective in January 2017. The **TNM international staging system** attempts a physical description of the neoplasm: T describes the size and location of the primary tumor; N describes the presence and location of nodal metastases; and M refers to the presence or absence of distant metastases. These TNM stages are grouped into summary stages I–IV, and these are used to guide therapy. Many patients with stage I and stage II disease are cured through surgery. Patients with stage IIIIB and stage IV disease do not benefit from surgery.

SCLC is traditionally divided into two categories: **limited disease** (30%), when the tumor is limited to the unilateral hemithorax (including contralateral mediastinal nodes); or **extensive disease** (70%), when the tumor extends beyond the hemithorax (including pleural effusion). It is also recommended to stage SCLC according to the TNM staging system.

For both SCLC and NSCLC, staging begins with a thorough history and physical examination. A complete examination is essential to exclude obvious metastatic disease to lymph nodes, skin, and bone. A detailed history is essential because the patient’s performance status is a powerful predictor of disease course. All patients should have measurement of a complete blood count (CBC), serum electrolytes, calcium, creatinine, liver biochemical tests, lactate dehydrogenase, and albumin.

NSCLC patients being considered for surgery require meticulous evaluation to identify those with resectable disease. CT imaging is key for staging candidates for resection. The sensitivity and specificity of CT imaging for identifying lung cancer metastatic to the mediastinal
lymph nodes are 57% (49–66%) and 82% (77–86%), respectively. Therefore, chest CT imaging alone does not provide definitive staging information. CT imaging helps determine where to biopsy, and how the mediastinum should be sampled.

Positron emission tomography (PET) using 2-[\(^{18}\)F]fluoro-2-deoxyglucose (FDG) is an important modality for identifying metastatic foci in the mediastinum or distant sites. The sensitivity and specificity of PET for detecting mediastinal spread of primary lung cancer depend on the size of mediastinal nodes or masses. When mediastinal lymph nodes smaller than 1 cm are present, the sensitivity and specificity of PET for tumor involvement of nodes are 74% and 96%, respectively. When CT shows lymph nodes larger than 1 cm, the sensitivity and specificity are 95% and 76%, respectively.

The combination of PET and CT imaging has improved preoperative staging compared with CT or PET alone. Whole body fusion PET-CT imaging is most useful to confirm lack of regional or metastatic disease in NSCLC patients who are candidates for surgical resection.

Disadvantages of PET imaging include limited resolution below 1 cm and false-positive scans due to sarcoidosis, tuberculosis, or fungal infections. PET-CT scans are also inadequate for evaluating brain metastases due to normal physiologic FDG uptake in the brain. Obtaining an MRI of the brain is important to rule out brain metastases in patients with SCLC and in patients with NSCLC with at least stage II disease or poorly differentiated histologies.

3. Pulmonary function testing—Many patients with NSCLC have moderate to severe chronic lung disease that increases the risk of perioperative complications as well as long-term pulmonary insufficiency following lung resection. All patients considered for surgery require spirometry. In the absence of other comorbidities, patients with good lung function (preoperative FEV\(_1\) 2 L or more) are at low risk for complications from lobectomy or pneumonectomy. High-risk patients include those with a predicted postoperative FEV\(_1\) less than 700 mL (or less than 40% of predicted FEV\(_1\)).

4. Screening—Screening with low-dose helical CT scans has been shown to improve mortality rates for lung cancer. The National Lung Screening Trial, a multicenter randomized US trial involving over 53,000 current and former heavy smokers, showed that screening annually with low-dose helical CT for 3 years yielded a 20% relative reduction in lung cancer mortality and 6.7% reduction in all-cause mortality compared to chest radiography. Given these findings, US professional organizations, including the US Preventive Services Task Force (USPSTF), have recommended screening with low-dose helical CT for lung cancer. Smoking cessation policies and efforts should be integrated with any screening program.

### Treatment

**A. Non–Small Cell Lung Carcinoma**

Surgical resection offers the best chance for cure of NSCLC. Therefore, the initial approach to the patient is determined by answering two questions: (1) Is complete surgical resection technically feasible? (2) If yes, is the patient able to tolerate the surgery with acceptable morbidity and mortality? Clinical features that preclude complete resection include extrathoracic metastases or a malignant pleural effusion; or tumor involving the heart, pericardium, great vessels, esophagus, recurrent laryngeal or phrenic nerves, trachea, main carina, or contralateral mediastinal lymph nodes. Accordingly, stage I and stage II patients are treated with surgical resection where possible. Stage II and select cases of stage IB are additionally recommended to receive adjuvant chemotherapy. Stage IIIA patients have poor outcomes if treated with resection alone. They should undergo multimodality treatment that includes chemotherapy or radiotherapy, or both. Inoperable stage IIIA and stage IIIB patients treated with concurrent chemotherapy and radiation therapy have improved survival. Stage IV patients are treated with systemic therapy (targeted therapy, chemotherapy, or immunotherapy) or symptom-based palliative therapy, or both.

immunotherapy, and targeted therapy (NSCLC). Clinical trial evidence of efficacy with targeted therapy is now available, and the management of NSCLC can now be stratified into four categories: stage I (Table 39–2), stage II, stage III, and stage IV (Table 39–3).

Surgical approach affects outcome. In 1994, the North American Lung Cancer Study Group conducted a prospective trial of stage IA patients randomized to lobectomy versus limited resection. They reported a threefold increased rate of local recurrence in the limited resection group (\(P = 0.008\)) and a trend toward an increase in overall death rate (increase of 30%, \(P = 0.08\)) and increase in cancer-related death rate (increase of 50%, \(P = 0.09\)), compared with patients receiving lobectomy. However, for patients who cannot tolerate lobectomy, a sublobar resection (wedge resection or segmentectomy) may be considered.

Patients with clinical stage I primary NSCLC, who are not candidates for surgery because of significant comorbidity or other surgical contraindication, are candidates for stereotactic body radiotherapy. Stereotactic body radiotherapy, which is composed of multiple non-parallel radiation beams that converge, allows the delivery of a relatively large dose of radiation to a small, well-defined target. For clinical stage I NSCLC, 3-year local control rates with stereotactic body radiotherapy exceed 90%, and large meta-analyses of nonrandomized data have shown 2-year survival at 70% and 5-year survival at 40%. Patients with locally advanced disease (stages IIIA and IIIB) who are not surgical candidates have improved survival when treated with concurrent chemotherapy and radiation therapy compared with no therapy, radiation alone, or even sequential chemotherapy and radiation.

Neoadjuvant chemotherapy consists of giving antineoplastic drugs in advance of surgery or radiation therapy. Neoadjuvant therapy is more widely used in selected patients with stage IIIA or select stage IIIB disease. Some studies suggest a survival advantage.

Adjuvant chemotherapy consists of administering antineoplastic drugs following surgery or radiation therapy. Cisplatin-containing regimens have been shown to confer an overall survival benefit in at least stage II disease and a subset of stage IB disease where primary tumor size exceeds 4 cm. The Lung Adjuvant Cisplatin Evaluation Collaborative Group, a meta-analysis of the five largest cisplatin-based adjuvant trials, reported a 5% absolute benefit in 5-year overall survival with a cisplatin–containing doublet regimen following surgery (\(P = 0.005\)) in patients with at least stage II disease.

For stage IIIB and stage IV NSCLC, options for therapy include targeted therapy (Table 39–3), cytotoxic chemotherapy, and immunotherapy (checkpoint inhibitors) (Table 39–2). The approach to therapy is individualized based on molecular profiling and PD-L1 testing. Molecular profiling is offered as next-generation sequencing multi-gene assays. The key driver mutations in lung cancer currently include \(EGFR\), \(ALK\), \(BRAF\), and \(ROS1\), but only a minority of all lung cancer cases have these mutations. \(K\)-ras mutation is more commonly found among smokers but has not been targeted effectively. Difficulties in testing may arise when only small fine-needle aspirate biopsies are obtained; to have sufficient tissue for analysis, it is recommended that clinicians obtain core biopsies. PD-L1 expression is a flawed but currently actively used biomarker to assess possible response to checkpoint inhibitor therapy (specifically, programmed death-1 [PD-1] inhibitors).

Targeted therapy has played a pivotal role in advanced NSCLC (Tables 39–2 and 39–3). Activating \(EGFR\) mutations are found in approximately 10–20% of the white population and 30–48% in the Asian population and are usually found among nonsmokers to light smokers, females, and persons with nonsquamous histologies (particularly adenocarcinomas). For patients with \(EGFR\) mutations, an \(EGFR\) tyrosine kinase inhibitor (osimertinib, erlotinib, gefitinib, or afatinib) leads to a survival benefit in first-line treatment. Response rates with \(EGFR\) tyrosine kinase inhibitors in patients with \(EGFR\) mutation are at least 70%, and median overall survival is estimated to be 21–33 months. Recent phase III data show that osimertinib (third-generation irreversible \(EGFR\) tyrosine kinase inhibitor) leads to a longer duration of response, longer progression-free survival, and lower rates of severe adverse events compared to earlier generation \(EGFR\) tyrosine kinase inhibitors. Osimertinib is FDA approved as first-line treatment of \(EGFR\)-mutated lung cancers. Current resistance to therapy still develops for patients taking osimertinib, and options for second-line therapy include platinum-based chemotherapy or chemoimmunotherapy.

Approximately 5% of all patients with NSCLC carry translocations of \(ALK\) resulting in novel fusion gene products with oncogenic activity. This is usually found in a comparatively younger population, with adenocarcinoma histology, and nonsmoking to light-smoking history. In a phase III trial of \(ALK\)-rearranged lung cancer patients, crizotinib (an ALK, cMET and ROS1 tyrosine kinase inhibitor) showed a response rate over 70% compared with a rate of 45% among those treated with standard first-line chemotherapy, and an improvement in median progression-free survival of 10.9 vs 7 months, respectively. At 1 year, however, resistance develops in most patients taking crizotinib. Second-generation \(ALK\) inhibitors (ceritinib, alectinib, and brigatinib) are recommended for \(ALK\)-rearranged lung cancers resistant to crizotinib. Recent randomized trials have shown that alectinib compared to crizotinib in first-line treatment of \(ALK\)-rearranged lung cancers has superior response rates (83% vs 75%), longer progression-free survival, and longer time to CNS progression. Alectinib is now the recommended first-line agent in \(ALK\)-rearranged lung cancers.

Approximately 1–2% of NSCLC harbor \(ROS1\) rearrangements and are usually found among nonsmokers or light smokers with lung adenocarcinomas. \(ROS1\) rearranged lung cancers also respond to crizotinib with response rates over 70%. \(BRAF\) mutations have been found in 2% of NSCLC patients and often in smokers. The combination of dabrafenib (\(BRAF\) inhibitor) and trametinib (\(MEK\) inhibitor) has shown response rates of over 60% in patients with \(BRAF\) \(V600E\) mutations. Finally, \(K\)-ras mutations are found among 25% of patients with adenocarcinomas, are associated with smoking, and indicate a poor prognosis. Unfortunately, there is still no effective targeted approach to therapy for \(K\)-ras mutated lung cancers.

Immune checkpoint inhibition with \(PD\)-1 or \(PD\)-L1 inhibitors (nivolumab, pembrolizumab, atezolizumab, and durvalumab) are playing highly important roles in the treatment of NSCLC (Tables 39–2 and 39–3). Checkpoint
B. Small Cell Lung Carcinoma

Response rates of SCLC to cisplatin and etoposide (Table 39–2) are excellent with 80–90% response in limited-stage disease (50–60% complete response), and 60–80% response in extensive-stage disease (15–20% complete response). However, remissions tend to be short-lived (Table 39–2) are excellent with 80–90% response in limited-stage disease (50–60% complete response), and 60–80% response in extensive-stage disease (15–20% complete response). However, remissions tend to be short-lived compared with standard-second line chemotherapy. However, significant side effects and toxicity have been reported with PD-1 inhibitors, especially autoimmune manifestations such as hepatitis, thyroiditis, hypophysitis, colitis, pneumonitis, and type 1 diabetes mellitus. Recently, a randomized phase III trial has shown improved survival outcomes by adding durvalumab as consolidation therapy post-definitive chemoradiation for stage III NSCLCs.

If no targetable mutations are found and there is inadequate PD-L1 expression on tumor cells, patients are either offered combination immunotherapy with cytotoxic chemotherapy or cytotoxic chemotherapy alone (Table 39–2). Although not curative, chemotherapy has been shown in multiple clinical trials to provide a modest increase in overall survival in patients with stage IIIIB and stage IV NSCLC compared with supportive care alone, with the median survival increased from 5 months to a range of 8–12 months and 1-year survival rate to 30–40%. Palliative chemotherapy also leads to improved quality of life and symptom control, with first-line therapy involving a platinum-based regimen.

C. Palliative Therapy

Palliative therapy in extensive-stage disease. Thoracic radiation therapy improves survival in patients with limited SCLC and is given concurrently with chemotherapy. There is a high rate of brain metastasis in patients with SCLC, even following a good response to chemotherapy. Prophylactic cranial irradiation has been shown to decrease the incidence of central nervous system disease and improve survival in patients with limited-stage disease who respond to chemotherapy and a subset of patients with extensive-stage disease who have had an excellent response to chemotherapy.

Prognosis

The 5-year survival rate for lung cancer is approximately 19%. Predictors of survival include the type of tumor (SCLC versus NSCLC), molecular profiling, the stage of the tumor, the patient’s performance status, and weight loss in the past 6 months. Patients with targetable mutations have better overall survival when compared with those without mutations due to superior efficacy of targeted drug therapy.

PULMONARY METASTASIS

Pulmonary metastasis results from the spread of an extrapulmonary malignant tumor through vascular or lymphatic channels or by direct extension. Metastases usually occur via the pulmonary artery and typically present as multiple nodules or masses on chest radiography. The radiographic differential diagnosis of multiple pulmonary nodules also includes pulmonary arteriovenous malformation, infections (including abscesses, septic emboli, and atypical infections), sarcoidosis, rheumatoid nodules, and granulomatosis with polyangiitis. Metastases to the lungs are found in 20–55% of patients with various metastatic malignancies. Carcinomas of the kidney, breast, rectum, colon, and cervix and malignant melanoma are the most likely primary tumors.

Lymphangitic carcinomatosis denotes diffuse involvement of the pulmonary lymphatic network by primary or metastatic lung cancer, probably a result of extension of tumor from lung capillaries to the lymphatics. Tumor embolization from extrapulmonary cancer (renal cell carcinoma, hepatocellular carcinoma, choriocarcinoma) is an uncommon route for tumor spread to the lungs. Metastatic cancer may also present as a malignant pleural effusion.

Clinical Findings

A. Symptoms and Signs

Symptoms are uncommon but include cough, hemoptysis and, in advanced cases, dyspnea and hypoxemia. Symptoms are more often referable to the site of the primary tumor.

B. Laboratory Findings

The diagnosis of metastatic cancer involving the lungs is usually established by identifying a primary tumor. Appropriate studies should be ordered if there is a suspicion of any primary cancer, such as breast, thyroid, testis, colorectal, or prostate, for which specific treatment is available. If the history, physical examination, and initial studies fail to reveal the site of the primary tumor, attention is better focused on the lung, where tissue samples obtained by bronchoscopy, percutaneous needle biopsy, video-assisted thoracoscopic surgery (VATS), or thoracotomy may establish the histologic diagnosis and suggest the most likely primary cancer. Occasionally, cytologic studies of pleural fluid or pleural biopsy reveals the diagnosis.

To determine a primary diagnosis, immunohistochemical staining should be done on the biopsy specimen. For example, prostate-specific antigen (PSA) and thyroglobulin staining are highly specific for prostate and thyroid cancer, respectively. Thyroid transcription factor-1 (TTF-1) and napsin-A are relatively specific for primary lung adenocarcinoma, while the former can be positive in cases of SCLC and thyroid carcinoma and the latter can be positive in papillary and clear cell renal cell carcinomas. An adenocarcinoma that demonstrates negative TTF-1 and napsin-A staining strongly suggests a nonpulmonary primary cancer. Positive estrogen receptor (ER) and progesterone receptor (PR) stains suggest primary breast cancer.

C. Imaging

Chest radiographs usually show multiple spherical densities with sharp margins. The size of metastatic lesions varies from a few millimeters (miliary densities) to large masses. The lesions are usually bilateral, plural or subpleural in location, and more common in lower lung zones. Lymphangitic spread and solitary pulmonary nodule are less common radiographic presentations of pulmonary metastasis. CT imaging of the chest, abdomen, and pelvis may reveal the site of a primary tumor and will help determine feasibility of surgical resection of the metastatic lung tumors. PET-CT FDG scan is helpful in identifying the site of a primary cancer and identifying other areas of extrathoracic metastasis.

Treatment

Once the diagnosis has been established, management consists of treatment of the primary neoplasm and any pulmonary complications. Surgical resection of a solitary pulmonary nodule is often prudent in the patient with known current or previous extrapulmonary cancer. Local resection of one or more pulmonary metastases is feasible in a few carefully selected patients with various sarcomas and carcinomas (such as testis, colorectal, and kidney). About 15–25% of metastatic solid tumor patients have metastases limited to the lungs and are surgical candidates. Surgical resection should be considered only if (1) the primary tumor is under control, (2) the patient has adequate cardiopulmonary reserve to tolerate resection, (3) all metastatic tumor can be resected, (4) effective nonsurgical approaches are not available, and (5) there is no evidence of extrathoracic metastases that are not controlled. Unfavorable prognostic factors also include shorter disease-free interval from primary tumor treatment to presentation of metastases and a larger number of metastases. Retrospective data from the International Registry of Lung Metastases report an overall 5-year survival rate of 36% and 10-year survival rate of 26% after complete resection of pulmonary metastases. Patients who are not surgical candidates but have solitary or limited metastatic disease to the lungs may be candidates for stereotactic radiotherapy, radioablation, or cryotherapy. For patients with unresectable progressive disease, chemotherapy tailored to the primary cancer may be offered, and diligent attention to palliative care is essential (see Chapter 5).
MESOTHELIOMA

ESSENTIALS OF DIAGNOSIS

- Unilateral, nonpleuritic chest pain and dyspnea.
- Distant (more than 20 years earlier) history of exposure to asbestos.
- Pleural effusion or pleural thickening or both on chest radiographs.
- Malignant cells in pleural fluid or tissue biopsy.

General Considerations

Mesotheliomas are primary tumors arising from the surface lining of the pleura (80% of cases) or peritoneum (20% of cases). Numerous studies have confirmed the association of malignant pleural mesothelioma with exposure to asbestos. The lifetime risk to asbestos workers of developing malignant pleural mesothelioma is as high as 10%. The latent period between exposure and onset of symptoms ranges from 20 to 40 years. The clinician should inquire about asbestos exposure through mining, milling, manufacturing, shipyard work, insulation, brake linings, building construction and demolition, roofing materials, and other asbestos products (pipes, textiles, paints, tiles, gaskets, panels).

Clinical Findings

A. Symptoms and Signs

The average interval between onset of symptoms and diagnosis is 2–3 months; the median age at diagnosis is 72–74 years in Western countries. Symptoms include the insidious onset of shortness of breath, nonpleuritic chest pain, and weight loss. Physical findings include dullness to percussion, diminished breath sounds and, in some cases, digital clubbing.

B. Laboratory Findings

Pleural fluid is exudative and often hemorrhagic. Cytologic tests of pleural fluid are often negative. VATS biopsy is usually necessary to obtain an adequate specimen for histologic diagnosis. The histologic variants of malignant pleural mesothelioma are epithelial (50–60%), sarcomatoid (10%), and biphasic (30–40%). Since distinction from benign inflammatory conditions and metastatic adenocarcinoma may be difficult, immunohistochemical stains are important to confirm the diagnosis.

C. Imaging

Radiographic abnormalities consist of nodular, irregular, unilateral pleural thickening and varying degrees of unilateral pleural effusion. Sixty percent of patients have right-sided disease, while only 5% have bilateral involvement. CT scans demonstrate the extent of pleural involvement. PET-CT is used to help differentiate benign from malignant pleural disease, improve staging accuracy, and identify candidates for aggressive surgical approaches.

Complications

Malignant pleural mesothelioma progresses rapidly as the tumor spreads along the pleural surface to involve the pericardium, mediastinum, and contralateral pleura. The tumor may eventually extend beyond the thorax to involve abdominal lymph nodes and organs. Progressive pain and dyspnea are characteristic. Local invasion of thoracic structures may cause superior vena cava syndrome, hoarseness, Horner syndrome, arrhythmias, and dysphagia.

Treatment

Chemotherapy is the mainstay of treatment (Tables 39–2 and 39–3), with cytoreductive surgery included in multimodality treatment only if there is localized disease that is amenable to complete macroscopic surgical resection. The optimal surgical approach is still under debate. For localized disease, surgical options include pleurectomy and decortication (surgical stripping of the pleura and pericardium from apex of the lung to diaphragm) or extrapleural pneumonectomy (a radical surgical procedure involving removal of the ipsilateral lung, parietal and visceral pleura, pericardium, and most of the hemidiaphragm). Surgical cytoreduction alone is not sufficient, and either chemotherapy or radiation therapy (or both) should be included in a multimodality approach. In advanced unresectable disease, palliative chemotherapy with cisplatin and pemetrexed can achieve response rates of 30–40%, can extend median overall survival to 12 months, and can improve quality of life. Adding bevacizumab (a monoclonal antibody to vascular endothelial growth factor [VEGF]) to cisplatin and pemetrexed has been shown to further improve overall survival. Drainage of pleural effusions, pleurodesis, radiation therapy, and even surgical resection may offer palliative benefit to some patients.

Prognosis

Most patients die of respiratory failure and complications of local extension. Median survival time from diagnosis ranges from 7 months to 17 months. Five-year survival is 5–10%. Tumors that are predominantly sarcomatoid are more resistant to therapy and have a worse prognosis, with median survival times less than 1 year. Poor prognostic features include poor performance status, non-epithelioid histology, male gender, nodal involvement, elevated lactate dehydrogenase, high white blood cell count, low hemoglobin, and high platelet count.

HEPATOBILIARY CANCERS
Lawrence S. Friedman, MD

HEPATOCELLULAR CARCINOMA

ESSENTIALS OF DIAGNOSIS

- Usually a complication of cirrhosis.
- Characteristic CT and MRI features may obviate the need for a confirmatory biopsy.

**General Considerations**

Malignant neoplasms of the liver that arise from parenchymal cells are called hepatocellular carcinomas (accounting for 85% of liver cancers); those that originate in the ductular cells are called cholangiocarcinomas (15% or less). Rare tumors of the liver include angiosarcoma and lymphoma.

Hepatocellular carcinomas are associated with cirrhosis in 85% of cases. In Africa and most of Asia, hepatitis B virus (HBV) infection is a major etiologic factor, and a family history of hepatocellular carcinoma increases the risk synergistically. In the United States and other Western countries, incidence rates have risen rapidly (over twofold since 1978, with slowing of the rate increase since 2006 except in men ages 55–64), presumably because of the increasing prevalence of cirrhosis caused by chronic hepatitis C virus (HCV) infection and nonalcoholic fatty liver disease (NAFLD); however, incidence rates are projected to increase through 2030. In Western countries, risk factors for hepatocellular carcinoma in patients known to have cirrhosis are male gender, age greater than 55 years (although there has been an increase in the number of younger cases), Hispanic or Asian ethnicity, family history in a first-degree relative, overweight, obesity (especially in early adulthood), alcohol use (especially in combination with obesity), tobacco use, diabetes mellitus, hypothyroidism (in women), a prolonged prothrombin time, a low platelet count, and an elevated serum transferrin saturation. The risk of hepatocellular carcinoma is higher in persons with a viral rather than nonviral cause of cirrhosis and may be increased in persons with autoimmune diseases. Other associations include high levels of HBV replication; HBV genotype C; hepatitis C coinfection; elevated serum ALT levels in persons with chronic hepatitis B (in whom antiviral therapy to suppress HBV replication appears to reduce the risk); HCV genotypes 1b and 3; lack of response to antiviral therapy for HCV infection; hemochromatosis (and possibly the C282Y carrier state); aflatoxin exposure (associated with mutation of the TP53 gene); alpha-1-antitrypsin (alpha-1-antitrypsin) deficiency; tyrosinemia; and radiation exposure. In patients with the metabolic syndrome and NAFLD, hepatocellular carcinoma may arise from a hepatocellular adenoma in the absence of cirrhosis. Evidence for an association with long-term use of oral contraceptives is inconclusive. Whereas sulfonlurea and insulin use may increase the risk of hepatocellular carcinoma, consumption of coffee, vegetables, white meat, fish, and n-3 polyunsaturated fatty acids; aspirin use; and statin and metformin use in diabetic patients appear to be protective.

The fibrolamellar variant of hepatocellular carcinoma generally occurs in young women and is characterized by a distinctive histologic picture, absence of risk factors, unique genomic profiles, and indolent course. Vinyl chloride exposure is associated with angiosarcoma of the liver. Hepatoblastoma, the most common malignant liver tumor in infants and young children, occurs rarely in adults.

**Clinical Findings**

A. **Symptoms and Signs**

The presence of a hepatocellular carcinoma may be unsuspected until there is deterioration in the condition of a cirrhotic patient who was formerly stable. Cachexia, weakness, and weight loss are associated symptoms. The sudden appearance of ascites, which may be bloody, suggests portal or hepatic vein thrombosis by tumor or bleeding from a necrotic tumor.

Physical examination may show tender enlargement of the liver, occasionally with a palpable mass. In Africa, the typical presentation in young patients is a rapidly expanding abdominal mass. Auscultation may reveal a bruit over the tumor or a friction rub when the tumor has extended to the surface of the liver.

B. **Laboratory Findings**

Laboratory tests may reveal leukocytosis, as opposed to the leukopenia that is frequently encountered in cirrhotic patients. Anemia is common, but a normal or elevated hematocrit value may be found in up to one-third of patients owing to elaboration of erythropoietin by the tumor. Sudden and sustained elevation of the serum alkaline phosphatase in a patient who was formerly stable is a common finding. HBsAg is present in a majority of cases in endemic areas, whereas in the United States anti-HCV is found in up to 40% of cases. Alpha-fetoprotein levels are elevated in up to 70% of patients with hepatocellular carcinoma in Western countries (although the sensitivity is lower in blacks and levels are not elevated in patients with fibrolamellar hepatocellular carcinoma); however, mild elevations (10–200 ng/mL [10–200 mcg/L]) are also often seen in patients with chronic hepatitis. Serum levels of des-gamma-carboxy prothrombin are elevated in up to 90% of patients with hepatocellular carcinoma, but they may also be elevated in patients with vitamin K deficiency, chronic hepatitis, and metastatic cancer. Cytologic study of ascitic fluid rarely reveals malignant cells.
C. Imaging

Multiphasic helical CT and MRI with contrast enhancement are the preferred imaging studies for determining the location and vascularity of the tumor; MRI may be more sensitive than CT, and imaging with gadoxetic acid increases sensitivity. Lesions smaller than 1 cm in diameter may be difficult to characterize. Arterial phase enhancement of the lesion followed by delayed hypointensity (“washout”) is most specific for hepatocellular carcinoma based on stringent imaging criteria with a high specificity for hepatocellular carcinoma greater than or equal to 1 cm in diameter developed by the American College of Radiology through its Liver Imaging Reporting and Data System, the Organ Procurement and Transplantation Network, and the American Association for the Study of Liver Diseases. Ultrasoundography is less sensitive and more operator dependent but is used to screen for hepatic nodules in high-risk patients. Contrast-enhanced ultrasoundography has a sensitivity and specificity approaching those of arterial phase helical CT but, unlike CT and MRI, cannot image the entire liver during the short duration of the arterial phase and is thus associated with false-positive results. In selected cases, endoscopic ultrasoundography (EUS) may be useful. PET is under study.

D. Liver Biopsy and Staging

Liver biopsy is diagnostic, although seeding of the needle tract by tumor is a potential risk (1–3%). For lesions smaller than 1 cm, ultrasonography may be repeated every 3 months followed by further investigation of enlarging lesions. For lesions 1 cm or larger, biopsy can be deferred when characteristic arterial hypervascularity and delayed washout are demonstrated on either multiphasic helical CT or MRI with contrast enhancement (or both) in a patient with cirrhosis or if surgical resection is planned. Staging in the TNM classification includes the following definitions: T0: no evidence of primary tumor; T1a: solitary tumor less than or equal to 2 cm; T1b: solitary tumor more than 2 cm without vascular invasion; T2: solitary tumor more than 2 cm with vascular invasion or multiple tumors none more than 5 cm; T3: multiple tumors with at least one more than 5 cm; T4: single or multiple tumors of any size involving a major branch of the portal or hepatic vein or with direct invasion of adjacent organs other than the gallbladder or with perforation of the visceral peritoneum; N1: regional lymph node metastasis; M1: distant metastasis; F0: no to moderate hepatic fibrosis; F1: severe hepatic fibrosis to cirrhosis. The Barcelona Clinic Liver Cancer (BCLC) staging system is preferred and includes the Child-Pugh class, tumor stage, and liver function and has the advantage of linking overall stage with preferred treatment modalities and with an estimation of life expectancy.

Treatment

Surgical resection of a solitary hepatocellular carcinoma may result in cure if liver function is preserved (Child-Pugh class A or possibly B) and portal vein thrombosis is not present. Laparoscopic liver resection has been performed in selected cases. Treatment of underlying chronic viral hepatitis, adjuvant chemotherapy, and adaptive immunotherapy may lower postsurgical recurrence rates. Liver transplantation may be appropriate for small unresectable tumors in a patient with advanced cirrhosis, with reported 5-year survival rates of up to 75%. The recurrence-free survival may be better for liver transplantation than for resection in patients with well-compensated cirrhosis and small tumors (one tumor less than 5 cm or three or fewer tumors each less than 3 cm in diameter [Milan criteria]) and in those with expanded (University of California, San Francisco) criteria of one tumor less than or equal to 6.5 cm or three or fewer tumors less than or equal to 4.5 cm. The Extended Toronto criteria include tumor differentiation, cancer-related symptoms, confinement of tumor to the liver, and absence of vascular invasion, without regard to tumor number or size, to determine candidacy for liver transplantation, and appear to predict outcomes as well as the Milan criteria. Patients with stage 2 hepatocellular carcinoma meeting the Milan criteria receive an additional 28 points on their Model for End-Stage Liver Disease (MELD) score after 6 months on the waiting list (see Chapter 16), markedly increasing their chances of undergoing transplantation. However, liver transplantation is often impractical because of the donor organ shortage, and living donor liver transplantation may be considered in these cases. Patients with larger tumors (3–5 cm), a serum alpha-fetoprotein level of 1000 ng/mL (1000 mcg/L) or higher, or a MELD score of 20 or more...
have poor posttransplantation survival. In patients with a serum alpha-fetoprotein level greater than 1000 ng/mL (1000 mcg/L), downstaging by locoregional therapy to an alpha-fetoprotein level less than 500 ng/mL (500 mcg/L) improves survival following subsequent liver transplantation. Chemotherapy, hormonal therapy with tamoxifen, and long-acting octreotide have not been shown to prolong life, but transarterial chemoembolization (TACE), TACE with drug-eluting beads, transarterial chemoinfusion (TACI), and transarterial radioembolization (TARE) via the hepatic artery are palliative and may prolong survival in patients with a large or multifocal tumor in the absence of extrahepatic spread. TACI and TARE are suitable for patients with portal vein thrombosis. TARE with yttrium-90 has been shown to result in a longer time to progression than TACE. Microwave ablation, radiofrequency ablation, cryotherapy, or injection of absolute ethanol into tumors smaller than 2 cm may prolong survival in patients who are not candidates for resection and have tumors that are accessible; these interventions, as well as stereotactic body radiation therapy, may also provide a “bridge” to liver transplantation. Microwave ablation is becoming the preferred approach because it allows shorter treatment times and, like radiofrequency ablation, can be performed after TACE in select cases. Cryoablation may result in slower tumor progression than radiofrequency ablation for tumors that are 3.1–4 cm in diameter. Stereotactic body radiation therapy is also being used to treat unresectable hepatocellular carcinoma and may be effective in treating lesions larger than those treated with ablation techniques. Sorafenib (an oral multikinase inhibitor of Raf kinase, the VEGF receptor, and the platelet-derived growth factor receptor [and others]) prolongs median survival as well as the time to radiologic progression by 3 months in patients with advanced hepatocellular carcinoma; sorafenib is standard care in these patients. Lenvatinib is another oral multikinase inhibitor that is FDA approved for the same indications as sorafenib. Regorafenib is an oral multikinase inhibitor that provides a survival benefit for patients whose disease progresses despite sorafenib therapy, and nivolumab is an immune checkpoint inhibitor that has been approved for advanced hepatocellular carcinoma. Cabozantinib, another multikinase inhibitor, has been approved by the FDA for the treatment of hepatocellular carcinoma, and ramucirumab, an antibody to the VEGF receptor, is still in phase III trials. The modified Response Evaluation Criteria in Solid Tumors (mRECIST) are used to assess treatment response based on tumor shrinkage and viability after locoregional and antiangiogenic treatment. Meticulous efforts at palliative care are essential for patients in whom disease progresses despite treatment or in whom advanced tumors, vascular invasion, or extrahepatic spread are present. Severe pain may develop in such patients due to expansion of the liver capsule by the tumor and requires concerted efforts at pain management, including the use of opioids (see Chapter 5).

Prognosis

In the United States, overall 1- and 5-year survival rates for patients with hepatocellular carcinoma are 23% and 5%, respectively. Five-year survival rates rise to 56% for patients with localized resectable disease (T1, T2, selected T3 and T4; N0; M0) but are virtually nil for those with locally unresectable or advanced disease. In patients with HCV-related hepatocellular carcinoma, the serum alpha-fetoprotein level at the time of diagnosis of cancer has been reported to be an independent predictor of mortality. Some, but not all, studies have reported an unexpectedly high rate of early tumor recurrence in patients who were cured of HCV infection with oral direct-acting antiviral agents, rather than interferon-based therapy. A serum alpha-fetoprotein level greater than or equal to 200 ng/mL (200 milli-international units/mL) or increases of greater than 15 ng/mL/month predict worse outcomes in patients awaiting liver transplantation. In patients who are not eligible for surgery, an elevated serum C-reactive protein level is associated with poor survival. Contrary to traditional opinion, the fibrolamellar variant does not have a better prognosis than conventional hepatocellular carcinoma without cirrhosis.

When to Refer

All patients with hepatocellular carcinoma should be referred to a specialist.

When to Admit

- Complications of cirrhosis.
- Severe pain.
- For surgery and other interventions.

General Considerations

Carcinoma of the gallbladder occurs in approximately 2% of all people operated on for biliary tract disease; the incidence, like that of carcinoma of the bile ducts, has been decreasing in the United States but may be increasing again in some Western countries because of lifestyle changes. It is notoriously insidious, and the diagnosis is often made unexpectedly at surgery. Cholecystitis (often large, symptomatic stones) is usually present. Other risk factors are chronic infection of the gallbladder with *Salmonella typhi*, gallbladder polyps over 1 cm in diameter (particularly with hypoechoic foci on EUS), mucosal calcification of the gallbladder (porcelain gallbladder), anomalous pancreatico-biliary ductal junction, and aflatoxin exposure. Genetic factors include *K-ras* and *TP53* mutations. Spread of the cancer—by direct extension into the liver or to the peritoneal surface—may be seen on initial presentation. The TNM classification includes the following stages: Tis, carcinoma in situ; T1a, tumor invades lamina propria, and T1b, tumor invades muscle layer; T2, tumor invades perimuscular connective tissue with no extension beyond serosa (visceral peritoneum) (T2a) or into liver (T2b); T3, tumor perforates the serosa or directly invades the liver or adjacent organ or structure; T4, tumor invades the main portal vein or hepatic artery or invades two or more extrahepatic organs or structures; N1, metastasis to one to three regional lymph nodes; N2, metastasis to four or more regional lymph nodes; and M1, distant metastasis. Staging for intrahepatic cholangiocarcinoma is as follows: T1a, solitary tumor less than or equal to 5 cm without vascular invasion; T1b, solitary tumor more than 5 cm without vascular invasion; T2, solitary tumor with intrahepatic vascular invasion or multiple tumors 5 cm or smaller with or without vascular invasion; T3, tumor perforating the visceral peritoneum; T4, tumor invades adjacent organ (except gallbladder); N1, regional lymph node metastasis; and M1, distant metastasis. Additional staging is available for distal bile duct tumors. Other staging systems consider the patient’s age, performance status, tumor extent and form, perineural invasion, vascular encasement, hepatic lobe atrophy, underlying liver disease, and peritoneal metastasis.

Clinical Findings

A. Symptoms and Signs

Progressive jaundice is the most common and usually the first sign of obstruction of the extrahepatic biliary system. Pain in the right upper abdomen with radiation into the back is usually present early in the course of gallbladder carcinoma but occurs later in the course of bile duct carcinoma. Anorexia and weight loss are common and may be associated with fever and chills due to cholangitis. Rarely, hematemesis or melena results from erosion of tumor into a blood vessel (hemobilia). Fistula formation between the biliary system and adjacent organs may also occur. The course is usually one of rapid deterioration, with death occurring within a few months.

Physical examination reveals profound jaundice. Pruritus and skin excoriations are common. A palpable gallbladder with obstructive jaundice usually is said to signify malignant disease (Courvoisier sign); however, this clinical generalization has been proven to be accurate only about 50% of the time. Hepatomegaly due to hypertrophy of the unobstructed liver lobe is usually present and is associated with liver tenderness. Ascites may occur with peritoneal implants.

B. Laboratory Findings

With biliary obstruction, laboratory examination reveals predominantly conjugated hyperbilirubinemia, with total serum bilirubin values ranging from 5 to 30 mg/dL. There is usually concomitant elevation of the alkaline phosphatase and serum cholesterol. AST is normal or minimally elevated. The serum CA 19-9 level is elevated in up to 85% of patients and may help distinguish cholangiocarcinoma from a benign
biliary stricture (in the absence of cholangitis) but is neither sensitive nor specific.

C. Imaging

Ultrasoundography and contrast-enhanced, triple-phase, helical CT may show a gallbladder mass in gallbladder carcinoma and intrahepatic mass or biliary dilatation in carcinoma of the bile ducts. CT may also show involved regional lymph nodes and atrophy of a hepatic lobe because of vascular encasement with compensatory hypertrophy of the unaffected lobe. MRI with magnetic resonance cholangiopancreatography (MRCP) and gadolinium enhancement permits visualization of the entire biliary tract and detection of vascular invasion and obviates the need for angiography and, in some cases, direct cholangiography; it is the imaging procedure of choice but may understage malignant hilar strictures. The sensitivity and image quality can be increased with use of ferumoxide enhancement. The features of intrahepatic cholangiocarcinoma on MRI appear to differ from those of hepatocellular carcinoma, with contrast washout in the latter but not the former. In indeterminate cases, PET can detect cholangiocarcinomas as small as 1 cm and lymph node and distant metastases, but false-positive results occur. The most helpful diagnostic studies before surgery are either endoscopic retrograde or percutaneous transhepatic cholangiography with biopsy and cytologic specimens, although false-negative biopsy and cytology results are common. Digital image analysis and fluorescent in situ hybridization of cytologic specimens for polysomy improve sensitivity. EUS with FNA of tumors, peroral cholangioscopy, confocal laser endomicroscopy, and intraductal ultrasonography may confirm a diagnosis of cholangiocarcinoma in a patient with bile duct stricture and an otherwise indeterminate evaluation, but FNA can result in tumor seeding and is often avoided if the tumor is potentially resectable.

Treatment

In young and fit patients, curative surgery for gallbladder carcinoma may be attempted if the tumor is well localized. The 5-year survival rate for carcinoma of the gallbladder invading the lamina propria or muscularis (stage 1, T1a or 1b, N0, M0) is as high as 85% with laparoscopic cholecystectomy but drops to 60%, even with a more extended open resection, if there is perimuscular invasion (T2). The role of radical surgery for T3 and T4 tumors is debatable. If the tumor is unresectable at laparotomy, biliary-enteric bypass (eg, Roux-en-Y hepaticojejunostomy) can be performed. Carcinoma of the bile ducts is curable by surgery in less than 10% of cases. If resection margins are negative, the 5-year survival rate has been reported in patients with stage I and II perihepatic cholangiocarcinoma being 75% 5-year survival rate has been reported in patients with stage I and II perihepatic cholangiocarcinoma undergoing chemoradiation and exploratory laparotomy followed by liver transplantation. For those patients whose disease progresses despite treatment, meticulous efforts at palliative care are essential (see Chapter 5).

When to Refer

All patients with carcinoma of the biliary tract should be referred to a specialist.

When to Admit

- Biliary obstruction.
- Cholangitis.

CARCINOMA OF THE PANCREAS & AMPOULLA OF VATER

ESSENTIALS OF DIAGNOSIS

- Obstructive jaundice (may be painless).
- Enlarged gallbladder (may be painful).
- Upper abdominal pain with radiation to back, weight loss, and thrombophlebitis are usually late manifestations.

General Considerations

Carcinoma is the most common neoplasm of the pancreas. About 75% are in the head and 25% in the body and tail of the organ. Pancreatic carcinomas account for 2% of all cancers and 5% of cancer deaths. Ampullary carcinomas are much less common. Risk factors for pancreatic cancer include age, tobacco use (which is thought to cause 20–25% of cases), heavy alcohol use, obesity, chronic pancreatitis, diabetes mellitus, prior abdominal radiation, family history, and possibly gastric ulcer and exposure to arsenic and cadmium. New-onset diabetes mellitus after age 45 years occasionally heralds the onset of pancreatic cancer. In diabetic patients, metformin use and possibly aspirin use may reduce the risk of pancreatic cancer slightly, but insulin use and glucagon-like peptide-1-based therapy (eg, sitagliptin) may increase the risk. About 7% of patients with pancreatic cancer have a family history of pancreatic cancer in a first-degree relative, compared with 0.6% of control subjects. In 5–10% of cases, pancreatic cancer occurs as part of a hereditary syndrome, including familial breast cancer (carriers of BRCA-2 have a 7% lifetime risk of pancreatic cancer), hereditary pancreatitis (PSS1 mutation), familial atypical multiple mole melanoma (p16/CDKN2A mutation), Peutz-Jeghers syndrome (STK11/LKB1 mutation), ataxia-telangiectasia (ATM mutation), and Lynch syndrome (hereditary nonpolyposis colorectal cancer [MLH1, MSH2, MSH6 mutations]). Neuroendocrine tumors account for 1–2% of pancreatic neoplasms and may be functional (producing gastrin, insulin, glucagon, vasoactive intestinal peptide, somatostatin, growth hormone–releasing hormone, adrenocorticotropic hormone, and others) or nonfunctional. Cystic neoplasms account for only 1% of pancreatic cancers, but they are important because pancreatic cysts are common and may be mistaken for pseudocysts. A cystic neoplasm should be suspected when a cystic lesion in the pancreas is found in the absence of a history of pancreatitis. At least 15% of all pancreatic cysts are neoplasms. Serous cystadenomas (which account for 32–39% of cystic pancreatic neoplasms and also occur in patients with von Hippel-Lindau disease) are benign. However, mucinous cystic neoplasms (defined by the presence of ovarian stroma and accounting for 10–45% of cystic pancreatic neoplasms), intraductal papillary mucinous neoplasms (21–33% of cystic pancreatic neoplasms), solid pseudopapillary tumors (less than 5%, primarily in young women), and cystic islet cell tumors (3–5%) may be malignant. Their prognoses are better than the prognosis of pancreatic adenocarcinoma, unless the cystic neoplasm is at least locally advanced.

Clinical Findings

A. Symptoms and Signs

Pain is present in over 70% of cases and is often vague, diffuse, and located in the epigastrium or, when the lesion is in the tail, located in the left upper quadrant of the abdomen. Radiation of pain into the back is common and sometimes predominate. Sitting up and leaning forward may afford some relief, and this usually indicates that the lesion has spread beyond the pancreas and is inoperable. Diarrhea, perhaps due to malabsorption, is an occasional early symptom. Migratory thrombophlebitis is a rare sign. Weight loss is a common but late finding and may be associated with depression. Occasional patients (often aged 40 years or older) present with acute pancreatitis in the absence of an alternative cause. Jaundice is usually due to biliary obstruction by a cancer in the pancreatic head. A palpable gallbladder is also indicative of obstruction by a neoplasm (Courvoisier sign), but there are frequent exceptions. A hard, fixed, occasionally tender mass may be present. In advanced cases, a hard periumbilical (Sister Mary Joseph’s) nodule may be palpable.

B. Laboratory Findings

There may be mild anemia. Glycosuria, hyperglycemia, and impaired glucose tolerance or true diabetes mellitus are found in 10–20% of cases. The serum amylase or lipase level is occasionally elevated. Liver biochemical tests may suggest obstructive jaundice. Steatorrhea in the absence of jaundice is uncommon. Occult blood in the stool is suggestive of carcinoma of the ampulla of Vater (the combination of biliary obstruction and bleeding may give the stools a distinctive silver appearance). CA 19-9, with a sensitivity of 70% and a specificity of 87%, has not proven useful for early detection of pancreatic cancer; increased values are also found in acute and chronic pancreatitis and cholangitis. Plasma chromogranin A levels are elevated in 88–100% of patients with pancreatic neuroendocrine tumors (NETs).

C. Imaging

Multiphase thin-cut helical CT is generally the initial diagnostic procedure and detects a mass in over 80% of cases. CT identifies metastases, delineates the extent of the tumor, and allows percutaneous FNA for cytologic studies and tumor markers. MRI is an alternative to CT. Ultrasonography is not reliable because of interference by intestinal gas. PET is a sensitive technique for detecting pancreatic cancer and metastases, but PET-CT is not a routine staging procedure. Selective celiac and superior mesenteric arteriography may demonstrate vessel invasion by tumor, a finding that would preclude attempts at surgical resection, but it is used less commonly since the advent of multiphase helical CT. EUS is more sensitive than CT for detecting pancreatic cancer and equivalent to CT for determining
nodal involvement and resectability. A normal EUS excludes pancreatic cancer. EUS may also be used to guide FNA or biopsy for tissue diagnosis, tumor markers, and DNA analysis. ERCP may clarify an ambiguous CT or MRI study by delineating the pancreatic duct system or confirming an ampullary or biliary neoplasm. MRCP appears to be at least as sensitive as ERCP in diagnosing pancreatic cancer. In some centers, pancreatoscopy or intraductal ultrasonography is used to evaluate filling defects in the pancreatic duct and assess resectability of intraductal papillary mucinous tumors. With obstruction of the splenic vein, splenomegaly or gastric varices are present, the latter detected by endoscopy, EUS, or angiography.

Cystic neoplasms can be distinguished by their appearance on CT, EUS, and ERCP and features of the cyst fluid on gross, cytologic, and genetic analysis. For example, serous cystadenomas may have a central scar or honeycomb appearance; mucinous cystadenomas are unicellular or multilocular and contain mucin-rich fluid with high carcinoembryonic antigen levels (greater than 200 ng/mL [200 mcg/L]) and K-ras mutations; and intraductal papillary mucinous neoplasms are associated with a dilated pancreatic duct and extrusion of gelatinous material from the ampulla.

▶ Staging

Staging of pancreatic cancer by the TNM classification includes the following definitions: Tis: carcinoma in situ; T1a: tumor limited to the pancreas, 0.5 cm or less in greatest dimension; T1b: tumor more than 0.5 cm and less than or equal to 1 cm; T1c: tumor 1–2 cm; T2: tumor limited to the pancreas, more than 2 cm and less than or equal to 4 cm in greatest dimension; T3: tumor more than 4 cm in greatest dimension; T4: tumor involves the celiac axis, superior mesenteric artery, or common hepatic artery regardless of dimension; T4a: tumor invades the portal vein; T4b: tumor invades the SMV or PV; T4c: tumor invades the superior mesenteric or SMA; T4d: tumor invades the portal vein, SMV, or SMA through the pancreatic parenchyma. Nodal metastasis N0: no nodal metastasis, N1: metastasis to one to three regional lymph nodes, N2: metastasis to four or more regional lymph nodes; M1: distant metastasis.

▶ Treatment

Abdominal exploration is usually necessary when cytologic diagnosis cannot be made or if resection is to be attempted, which includes up to 30% of patients with pancreatic carcinoma. In a patient with a localized mass in the head of the pancreas and without jaundice, laparoscopy may detect tiny peritoneal or liver metastases and thereby avoid resection in 4–13% of patients. Radical pancreatoduodenal (Whipple) resection is indicated for cancers strictly limited to the head of the pancreas, periampullary area, and duodenum (T1, N0, M0). Five-year survival rates are 20–25% in this group and as high as 40% in those with negative resection margins and without lymph node involvement. Preoperative endoscopic decompression of an obstructed bile duct is often achieved with a plastic stent or short metal stent but does not reduce operative mortality and is associated with complications. The best surgical results are achieved at centers that specialize in the multidisciplinary treatment of pancreatic cancer. Adjuvant chemotherapy with gemcitabine, 5-fluorouracil, or gemcitabine with capecitabine is superior to no adjuvant therapy. Gemcitabine with capecitabine has been found to be superior to gemcitabine alone. The role of adjuvant chemoradiation is controversial but often used in the United States. Neoadjuvant chemotherapy with or without radiation is increasingly being used to downstage patients and in those with resectable cancer. Common chemotherapy regimens for this purpose include FOLFIRINOX (5-fluorouracil, leucovorin, irinotecan, oxaliplatin) and gemcitabine with nanoparticle albumin-bound (nab)-paclitaxel. Chemoradiotherapy downstages about 30% of patients with locally advanced disease to allow resection. When resection is not feasible, endoscopic stenting of the bile duct is performed to relieve jaundice. A plastic stent is generally placed if the patient’s anticipated survival is less than 6 months (or surgery is planned). A metal stent is preferred when anticipated survival is 6 months or greater. Whether covered metal stents designed to prevent tumor ingrowth offer an advantage over uncovered stents is uncertain because covered stents are associated with higher rates of migration and acute cholecystitis due to occlusion of the cystic duct. Surgical biliary bypass may be considered in patients expected to survive at least 6 months. Surgical duodenal bypass may be considered in patients in whom duodenal obstruction is expected to develop; alternatively, endoscopic placement of a self-expandable duodenal stent may be feasible. Chemoradiation may be used for palliation of unresectable cancer confined to the pancreas. Chemotherapy has been disappointing in metastatic pancreatic cancer, although improved response rates have been reported with FOLFIRINOX and with the combination of gemcitabine and nab-paclitaxel. In patients who have received prior chemotherapy, 5-fluorouracil and leucovorin in combination with nanoliposomal irinotecan has resulted in improved survival compared with 5-fluorouracil and leucovorin alone. Celiac plexus nerve block (under CT or endoscopic ultrasound guidance) or thoracoscopic splanchnicectomy may improve pain control.

Surgical resection is the treatment of choice for NETs, when feasible. Metastatic disease may be controlled with long-acting somatostatin analogs, interferon, chemotherapy, peptide-receptor radionuclide therapy, and chemoeembolization. For potentially neoplastic cystic lesions, there is a consensus that asymptomatic incidental pancreatic cysts 2 cm or smaller are at low risk for harboring invasive carcinoma. The cysts may be monitored by imaging tests (MRI) in 1 year and then every 2 years for 5 years and perhaps longer if no changes are observed, with EUS and FNA if a cyst enlarges to 3 cm and another high-risk feature (dilated main pancreatic duct, presence of a solid component) develops. The optimal approach is uncertain, however, and other guidelines have been proposed.

Surgical resection is indicated for mucinous cystic neoplasms, symptomatic serous cystadenomas, solid pseudopapillary tumors (which have a 15% risk of malignant transformation), and cystic tumors larger than 2 cm in diameter that remain undefined after helical CT, EUS, and diagnostic aspiration. All intraductal papillary mucinous neoplasms of the main pancreatic duct should be resected, but those of branch ducts may be monitored with serial
imaging if they (1) are asymptomatic and exhibit benign features; (2) have a diameter less than 3 cm (some authorities recommend a diameter 1.5 cm or smaller, but even lesions 3 cm or larger may be monitored in elderly persons with no other worrisome cyst features); and (3) lack non-enhancing mural nodules, a thick wall, an abrupt change in the caliber of the pancreatic duct with distal pancreatic atrophy, or possibly bile duct dilatation and gallbladder adenomyomatosis. Most such lesions with benign features remain stable on follow-up, but the risk of malignancy persists for at least 10 years. Moreover, the risk of pancreatic ductal carcinoma and of nonpancreatic cancers may also be increased in this group of patients. In the absence of locally advanced disease, survival is higher for malignant cystic neoplasms than for adenocarcinoma. Endoscopic resection or ablation, with temporary placement of a pancreatic duct stent, may be feasible for ampullary adenomas, but patients must be followed for recurrence.

**Prognosis**

Carcinoma of the pancreas, especially in the body or tail, has a poor prognosis; 80–85% of patients present with advanced unresectable disease, and reported 5-year survival rates range from 2% to 5%. From 1980 to 2010, mortality from pancreatic cancer did not decrease, but it may now be starting to improve. Obesity may adversely affect mortality in Western countries. Metformin may improve survival in diabetic patients with pancreatic adenocarcinoma, and use of HMG-CoA reductase inhibitors (statins) preceding a diagnosis of pancreatic cancer may improve survival. Tumors of the ampulla have a better prognosis, with reported 5-year survival rates of 20–40% after resection; jaundice and lymph node involvement are adverse prognostic factors. In carefully selected patients, resection of cancer of the pancreatic head is feasible and results in reasonable survival. In persons with a family history of pancreatic cancer in at least two first-degree relatives, or with a genetic syndrome associated with an increased risk of pancreatic cancer, screening with EUS and helical CT or MRI/MRCP should be considered beginning at age 40–45 or 10 years before the age at which pancreatic cancer was first diagnosed in a family member.

For those patients whose disease progresses despite treatment, meticulous efforts at palliative care are essential (see Chapter 5).

**When to Refer**

All patients with carcinoma involving the pancreas and the ampulla of Vater should be referred to a specialist.

**When to Admit**

Patients who require surgery and other interventions should be hospitalized.

Khalaf N et al. Regular use of aspirin or non-aspirin nonsteroidal anti-inflammatory drugs is not associated with risk of incident pancreatic cancer in two large cohort studies. Gastroenterology. 2018 Apr;154(5):1380–90. [PMID: 29229401]

**ALIMENTARY TRACT CANCERS**

Carling Ursem, MD
Kenneth R. McQuaid, MD

**ESOPHAGEAL CANCER**

**ESSENTIALS OF DIAGNOSIS**

- Progressive dysphagia to solid food.
- Weight loss common.
- Endoscopy with biopsy establishes diagnosis.

**General Considerations**

Esophageal cancer usually develops in persons between 50 and 70 years of age. There were an estimated 17,920 new cases of esophageal cancer in 2018. The overall ratio of men to women is 3:1. There are two histologic types: squamous cell carcinoma and adenocarcinoma. Squamous cell carcinoma is common in Eastern Europe and Asia while adenocarcinoma is more common in North America and most Western European countries. In the United States, squamous cell carcinoma is much more common in blacks than in whites. Chronic alcohol and tobacco use are strongly associated with an increased risk of squamous cell carcinoma. Adenocarcinoma is more common in whites. Its incidence is increasing dramatically, and it is now more common than squamous cell carcinoma in the United States. The majority of adenocarcinomas develop as a complication of Barrett metaplasia due to chronic gastroesophageal reflux. Thus, most adenocarcinomas arise near the gastroesophageal junction. Obesity also is strongly associated with adenocarcinoma, even after controlling for gastroesophageal reflux.

**Clinical Findings**

A. Symptoms and Signs

The majority (50–60%) of patients with esophageal cancer present with advanced, incurable disease. While early symptoms are nonspecific and subtle, over 90% eventually have solid food dysphagia, which progresses over weeks to months. Odynophagia is sometimes present. Significant weight loss is common. Local tumor extension into the
tracheobronchial tree may result in a tracheo-esophageal fistula, characterized by coughing on swallowing or by pneumonia. Chest or back pain suggests mediastinal extension. Recurrent laryngeal nerve involvement may produce hoarseness. Physical examination is often unrevealing. The presence of supraclavicular or cervical lymphadenopathy or of hepatomegaly implies metastatic disease.

B. Laboratory Findings

Laboratory findings are nonspecific. Anemia related to chronic disease or occult blood loss is common. Elevated aminotransferase or alkaline phosphatase concentrations suggest hepatic or bony metastases. Hypoalbuminemia may result from malnutrition.

C. Imaging

A barium esophagogram may be the first study obtained to evaluate dysphagia. The appearance of a polyloid, obstructive, or ulcerative lesion is suggestive of carcinoma and requires endoscopic evaluation. However, even lesions believed to be benign by radiography warrant endoscopic evaluation. Chest radiographs may show adenopathy, a widened mediastinum, pulmonary or bony metastases, or signs of tracheo-esophageal fistula such as pneumonia.

D. Upper Endoscopy

Endoscopy with biopsy establishes the diagnosis of esophageal carcinoma with a high degree of reliability. In some cases, significant submucosal spread of the tumor may yield nondiagnostic mucosal biopsies. Repeat biopsy may be necessary.

Staging

After confirmation of the diagnosis of esophageal carcinoma, the stage of the disease should be determined since doing so influences the choice of therapy. Patients should undergo evaluation with contrast CT of the chest and abdomen to look for evidence of pulmonary or hepatic metastases, lymphadenopathy, and local tumor extension. If there is no evidence of distant metastases or extensive local spread on CT, then EUS with guided FNA biopsy of suspicious lymph nodes should be performed to evaluate the locoregional stage. EUS is superior to CT in demonstrating the level of local mediastinal extension and local lymph node involvement. PET with fluorodeoxyglucose or integrated PET-CT imaging is indicated to look for regional or distant spread in patients thought to have localized disease after other diagnostic studies, prior to invasive surgery. Bronchoscopy is sometimes required in esophageal cancers above the carina to exclude tracheobronchial extension. Laparoscopy to exclude occult peritoneal carcinomatosis should be considered in patients with tumors at or near the gastroesophageal junction (see Gastric Adenocarcinoma).

Differential Diagnosis

Esophageal carcinoma must be distinguished from other causes of progressive dysphagia, including peptic stricture, achalasia, and adenocarcinoma of the gastric cardia with esophageal involvement. Benign-appearing peptic strictures should be biopsied at presentation to exclude occult malignancy.

Treatment

The approach to esophageal cancer depends on the tumor stage, tumor location, patient preference and functional status, and the expertise of the gastroenterologists, surgeons, oncologists, and radiation oncologists. It is helpful to classify patients into two general categories: those with early stage (curable) disease and those with advanced stage ( incurable) disease.

A. Therapy for “Curable” Disease

Superficial esophageal cancers confined to the epithelium (high-grade dysplasia or carcinoma in situ [Tis]), lamina propria (T1a), or submucosal (T1b) are increasingly recognized in endoscopic screening and surveillance programs. Esophagectomy achieves high cure rates for superficial tumors but is associated with mortality (2%) and morbidity. If performed by experienced clinicians, endoscopic mucosal resection of Tis and T1a cancers achieves equivalent long-term survival with less morbidity (see Barrett Esophagus, Chapter 15). Patients with larger tumors or deeper tumors invasive to the submucosa (T1b) have higher rates of lymph node metastasis. For this reason, an esophagectomy is recommended for those with T1b tumors. If only endoscopic mucosal resection is performed, then frequent posttreatment endoscopic surveillance is required to ensure there is no residual or recurrent tumor.

1. Surgery with or without neoadjuvant chemoradiation therapy—There are multiple surgical approaches to the resection of invasive (non-superficial) but potentially “curable” esophageal cancers (stage Ib, II, IIIa, or IIIb). Accepted techniques include en bloc transthoracic excision of the esophagus with extended lymph node dissection, transhiatal esophagectomy (entailing laparotomy with cervical anastomosis), and minimally invasive esophagectomy techniques. Meta-analysis data suggest equivalent oncologic outcomes from minimally invasive esophagectomy and conventional open techniques, although there are fewer postoperative complications and shorter hospital stays with the laparoscopic approach. There is general consensus that at least a D1 lymphadenectomy should be performed. However, there is much debate about whether the D2 lymphadenectomy typically performed in higher-incidence countries (such as Japan and South Korea) is superior to the D1 lymphadenectomy more commonly performed in the United States where the incidence of esophageal cancers is lower. Multiple meta-analyses have shown that regardless of surgery type, surgery at a high-volume hospital is associated with decreased perioperative mortality.

Patients with stage I tumors have high cure rates with surgery alone and do not require radiation or chemotherapy. If regional lymph node metastases have occurred (stage IIb and III), the rate of cure with surgery alone is reduced to less than 20%. Meta-analysis of trials comparing neoadjuvant (preoperative) therapy followed by surgery with surgery alone suggests a 13% absolute improvement
in 2-year survival with combined therapy. Preoperative (neoadjuvant) chemoradiation therapy is recommended for stage IIA, IIB, and III tumors in fit patients. The preferred neoadjuvant chemotheraphy regimen used with radiation is weekly carboplatin plus paclitaxel (Table 39–2). As an alternative, a combination of cisplatin plus 5-fluorouracil may be used along with radiation. When radiation therapy is considered, techniques that are less toxic such as intensity-modulated radiation therapy (IMRT) or proton beam therapy may be considered. Perioperative chemotherapy without radiation may also be considered for tumors of the gastroesophageal junction based on the randomized, multicenter, phase III MAGIC trial.

2. Chemotherapy plus radiation therapy without surgery—Combined treatment with chemotherapy and radiation is superior to radiation alone and has achieved long-term survival rates in up to 25% of patients. Chemoradiation alone should be considered in patients with localized disease (stage II or IIA) who are poor surgical candidates due to serious medical illness or poor functional status (Eastern Cooperative Oncology Group score greater than 2). Chemoradiation alone as definitive, nonsurgical therapy is more likely to achieve short-term and long-term survival in patients with squamous cell carcinoma than in patients with adenocarcinoma. This is especially true for patients with cervical esophageal cancers, which appear similar biologically to head and neck cancers.

3. Supportive care during definitive therapy—Patients with significant tumor obstruction may require local measures such as esophageal stent placement or percutaneous gastric or jejunal tube placement to maintain adequate hydration and nutrition during neoadjuvant chemoradiation or chemotherapy. Multidisciplinary consultation is required to determine the optimal procedure. Consultation with a nutritionist also is appropriate to optimize nutrition perioperatively.

B. Therapy for Incurable Disease

More than half of patients have either locally extensive tumor spread (T4b) that is unresectable or distant metastases (M1) (stage IIIIC and stage IV). Surgery is not warranted in these patients. Since prolonged survival can be achieved in few patients, the primary goal is to provide relief from dysphagia and pain, optimize quality of life, and minimize treatment side effects. The optimal palliative approach depends on the presence or absence of metastatic disease, expected survival, patient preference, and institutional experience.

1. Chemotherapy or chemoradiation—Combined radiation therapy and chemotherapy may achieve palliation in two-thirds of patients but is associated with significant side effects. It should be considered for patients with locally advanced tumors without distant metastases (stage IIIIC) who have good functional status and no significant medical problems, in whom prolonged survival may be achieved. Improvement in dysphagia occurs within 2–4 weeks in almost 90% of patients.

It should be noted that the systemic therapy treatment options are the same for metastatic esophageal, gastroesophageal junction, and gastric cancers. This is true regardless of squamous cell or adenocarcinoma histology, with the exceptions noted below (Table 39–2). Combination chemotherapy may be considered in patients with metastatic disease who still have good functional status and expected survival of at least several months. Because of the decreased toxicity of two-drug regimens, they are preferred over three-drug regimens. For patients with poor functional status, single-agent therapy with a fluoropyrimidine, a taxane, or irinotecan may be used. In patients with metastatic distal esophageal and gastroesophageal junction adenocarcinomas positive for amplification of the HER2 gene (approximately 15% of cases), addition of the monoclonal antibody trastuzumab (see Chapter 17) to chemotherapy is associated with prolonged survival. In addition, ramucirumab, a monoclonal antibody targeting the VEGF receptor-2, demonstrated a survival advantage in patients with adenocarcinoma of the gastroesophageal junction after progression on first-line therapy when used both as monotherapy and in combination with paclitaxel (Tables 39–2 and 39–3). As with all metastatic solid tumors, immunotherapy with pembrolizumab should be considered if the tumor is either microsatellite instability-high (MSI-H) or has deficient mismatch repair protein expression (dMMR). For the remainder of metastatic esophageal cancers, a PD-1 or PD-L1 targeted agent should be considered in the second-line or later setting.

2. Local therapy for esophageal obstruction—Patients with advanced esophageal cancer often have a poor functional and nutritional status. Radiation therapy alone to the area of esophageal obstruction may afford short-term relief of pain and dysphagia. Rapid palliation of dysphagia may be achieved by peroral placement of permanent expandable wire stents (alone or followed by radiation). However, placement of these stents is complicated by perforation, migration, or tumor ingrowth in up to 40% of cases. Palliative feeding tube placement may be considered for hydration and nutrition in selected cases when aligned with the patient’s goals of care and overall prognosis.

Prognosis

The overall 5-year survival rate of esophageal carcinoma is less than 20%. Apart from distant metastasis (M1b), the two most important predictors of poor survival are adjacent mediastinal spread (T4) and lymph node involvement. Whereas cure may be achieved in patients with regional lymph node involvement (stages IIIB and III), involvement of nodes outside the chest (M1a) is indicative of metastatic disease (stage IV) that is incurable. For those patients whose disease progresses despite chemotherapy, meticulous efforts at palliative care are essential (see Chapter 5).

When to Refer

- Patients should be referred to a gastroenterologist for evaluation and staging (endoscopy with biopsy, EUS) and palliative endoscopic antitumor therapy (stent).
- Patients with curable and resectable disease for whom neoadjuvant therapy may be appropriate (stage IIB or IIIA) should be referred to medical, radiation, and sur-
General Considerations

Gastric adenocarcinoma remains the second most common cause of cancer death worldwide. However, its incidence has declined rapidly over the past 70 years, especially in Western countries, which may be attributable to changes in diet (more fruits and vegetables), food refrigeration (allowing more fresh foods and reduced salted, smoked, and preserved foods), reduced toxic environmental exposures, and a decline in Helicobacter pylori. The incidence of gastric cancer remains high (70/100,000) in Japan and many developing regions, including eastern Asia, Eastern Europe, Chile, Colombia, and Central America. In the United States, there were an estimated 26,240 new cases and 10,800 deaths in 2018. The incidence is higher in Asian Americans, Hispanics, African Americans, and American Indian/Alaska Natives.

There are two main histologic variants of gastric cancer: “intestinal-type” (which resembles intestinal cancers in forming glandular structures) and “diffuse” (which is poorly differentiated, has signet-ring cells, and lacks glandular formation). The incidence of intestinal-type gastric cancer has declined significantly, but it is still the more common type (70–80%); it occurs twice as often in men as women, primarily affects older people (mean age 63 years), and is more strongly associated with environmental factors. It is believed to arise through a gradual, multi-step progression from inflammation (most commonly due to H pylori), to atrophic gastritis, to intestinal metaplasia, and finally dysplasia or cancer. Chronic H pylori gastritis is the strongest risk factor for gastric carcinoma, increasing the relative risk 3.5- to 20-fold. It is estimated that 60–90% of cases of gastric carcinomas may be attributable to H pylori. Other risk factors for intestinal-type gastric cancer include pernicious anemia, a history of partial gastric resection more than 15 years previously, smoking, and diets that are high in nitrates or salt and low in vitamin C. Diffuse gastric cancer accounts for 20–30% of gastric cancer cases. In contrast to intestinal-type cancer, it affects men and women equally, occurs more commonly in young people, is not as strongly related to H pylori infection, and has a worse prognosis than intestinal-type cancer. Most diffuse gastric cancers are attributable to acquired or hereditary mutations in the genes regulating the E-cadherin cell adhesion protein. Hereditary diffuse gastric cancer accounts for 1–3% of gastric cancers. The cancer may arise at a young age, is often multifocal and infiltrating with signet ring cell histology, and confers poor prognosis. Many of these families have a germline mutation of E-cadherin (CDH1), which is inherited in an autosomal dominant pattern and carries a greater than 60% lifetime risk of gastric cancer. Prophylactic gastrectomy should be considered in patients known to carry this mutation.

Most gastric cancers arise in the body and antrum. These may occur in a variety of morphologic types: (1) polyoid or fungating intraluminal masses; (2) ulcerating masses; (3) diffusely spreading (limitis plastica), in which the tumor spreads through the submucosa, resulting in a rigid, atonic stomach with thickened folds (prognosis dismal); and (4) superficially spreading or “early” gastric cancer—confined to the mucosa or submucosa (with or without lymph node metastases) and associated with a...
favorable prognosis. HER2 amplification and overexpression is seen in 10–25% of gastric adenocarcinoma cases and is more commonly observed in intestinal histology and moderately differentiated disease. The prognostic significance of HER2 status is uncertain. Testing for microsatellite instability (MSI), deficiency in mismatch repair proteins (dMMR), and PD-L1 is recommended in advanced disease to identify tumors that may respond to immunotherapy. For gastric adenocarcinoma, MSI-H/dMMR is found in 8–16% of cases.

In contrast to the dramatic decline in cancers of the distal stomach, a rise in incidence of tumors of the gastric cardia has been noted. These tumors have demographic and pathologic features that resemble Barrett-associated esophageal adenocarcinomas (see Esophageal Cancer).

► Clinical Findings

A. Symptoms and Signs

Gastric carcinoma is generally asymptomatic until the disease is quite advanced. Symptoms are nonspecific and are determined in part by the location of the tumor. Dyspepsia, vague epigastric pain, anorexia, early satiety, and weight loss are the presenting symptoms in most patients. Patients may derive initial symptomatic relief from over-the-counter remedies, further delaying diagnosis. Ulcerating lesions can lead to acute gastrointestinal bleeding with hematemesis or melena. Pyloric obstruction results in postprandial vomiting. Lower esophageal obstruction causes progressive dysphagia. Physical examination is rarely helpful. Signs of metastatic spread include a left supraclavicular lymph node (Virchow node), an umbilical nodule (Sister Mary Joseph nodule), a rigid rectal shelf (Blumer shelf), and ovarian metastases (Krukenberg tumor). Guaiac-positive stools may be detectable.

B. Laboratory Findings

Iron deficiency anemia due to chronic blood loss or anemia of chronic disease is common. Liver test abnormalities, particularly elevation of alkaline phosphatase, may be present if there is metastasis to the liver. Circulating tumor markers do not have established clinical validity in screening or diagnosis of gastric cancer. However, when checked serially, tumor markers can assist in monitoring treatment response.

C. Endoscopy

Upper endoscopy should be obtained in all patients over age 60 years with new onset of epigastric symptoms (dyspepsia) and young patients with “alarm” symptoms (dysphagia, recurrent vomiting, significant weight loss), especially in immigrants from countries with a high prevalence of gastric cancer. Endoscopy with biopsies of suspicious lesions is highly sensitive for detecting gastric carcinoma. It can be difficult to obtain adequate biopsy specimens in linitis plastica lesions.

D. Imaging

Once a gastric cancer is diagnosed, preoperative evaluation with contrast CT of chest, abdomen, and pelvis and EUS is indicated to delineate the local extent of the primary tumor as well as to evaluate for nodal or distant metastases. EUS is superior to CT in determining the depth of tumor penetration and is useful for evaluation of early gastric cancers that may be removed by endoscopic mucosal resection. PET or combined PET-CT imaging is recommended for detection of distant metastasis.

► Screening

Because of its unproven efficacy and cost-effectiveness, screening for _H pylori_ infection and treating it to prevent gastric cancer is not recommended for asymptomatic adults in the general population but may be considered in patients who have immigrated from regions with a high incidence of gastric cancer or who have a family history of gastric cancer. Because of the high incidence of gastric carcinoma in Japan, screening upper endoscopy is performed there to detect early gastric carcinoma. Approximately 40% of tumors detected by screening are early, with a 5-year survival rate of almost 90%. Screening is not recommended in the United States.

► Staging

Staging is defined according to the TNM system, in which T1 tumors invade the lamina propria or muscularis mucosa (T1a) or submucosa (T1b), T2 invade the muscularis propria, T3 penetrate the subserosal connective tissue, and T4 invade serosa or adjacent structures. Lymph nodes are graded as N0 if there is no involvement, and N1, N2, or N3 if there is involvement of 1–2, 3–6, or more than 7 regional nodes. M0 signifies the absence of metastatic disease and M1, its presence. Sampling of at least 15 lymph nodes is recommended during surgical staging (see Curative Surgical Resection below). A staging laparoscopy prior to definitive surgery to exclude peritoneal carcinomatosis should be considered in patients with stage T1b or greater disease without radiographic evidence of distant metastases. Pathologic review should include (1) grade of tumor, (2) histologic subtype, (3) depth of invasion, (4) whether lymphatic or vascular invasion is present, and (5) if there is known metastatic disease, the status of HER2 protein expression by immunohistochemistry or fluorescent in situ hybridization or both, along with MMR or MSI testing and possibly PD-L1 protein expression.

► Differential Diagnosis

Ulcerating gastric adenocarcinomas are distinguished from benign gastric ulcers by biopsies. Approximately 3% of gastric ulcers initially believed to be benign later prove to be malignant. All gastric ulcers identified at endoscopy should be biopsied to exclude malignancy. Ulcers that are suspicious for malignancy to the endoscopist or that have atypia or dysplasia on histologic examination warrant repeat endoscopy in 2–3 months to verify healing and exclude malignancy. Nonhealing ulcers should be considered for resection. Infiltrative carcinoma with thickened gastric folds must be distinguished from lymphoma and other hypertrophic gastropathies.
Treatment

A. Curative Surgical Resection

Surgical resection is the only therapy with curative potential. Laparoscopic techniques achieve similar outcomes and lower overall complication rates as open gastrectomy. After preoperative staging, about two-thirds of patients will be found to have localized disease (i.e., stages I–III). In Japan and in specialized centers in the United States, endoscopic mucosal resection is performed in select patients with small (less than 1–2 cm), early (intramucosal or T1aN0) gastric cancers after careful staging with EUS. In a 2018 randomized trial in Korean patients who had endoscopic resection of early gastric cancer, there was a 50% reduction in metachronous gastric cancers over a 5-year period among patients who received treatment for *H pylori* compared with those who received a placebo. Approximately 25% of patients undergoing surgery will be found to have locally unresectable tumors or peritoneal, hepatic, or distant lymph node metastases that are incurable. The remaining patients with confirmed localized disease should undergo radical surgical resection. For adenocarcinoma localized to the distal two-thirds of the stomach, a subtotal gastrectomy should be performed. For proximal gastric cancer or diffusely infiltrating disease, total gastrectomy is necessary. The ultimate goal of surgery is obtaining negative surgical margins. Vitamin **B**₁₂ supplementation is required after gastrectomy. For patients with localized gastric cancer that is resectable, current National Comprehensive Cancer Network (NCCN) treatment guidelines recommend gastrectomy with extended (D1), or modified regional (D2), lymph node dissection and sampling of 15 or more lymph nodes. D2 lymphadenectomy has been shown to improve disease-specific survival but is associated with increased postoperative mortality.

B. Perioperative Chemotherapy or Chemoradiation

The use of perioperative chemotherapy or adjuvant chemoradiation is associated with improved survival in patients with localized or locoregional gastric adenocarcinoma who undergo surgical resection. The choice of treatment depends on the location and extent of tumor, type of surgery, patient comorbidities and performance status, and institutional experience. Tumors arising in the gastroesophageal junction may be treated following algorithms for esophageal primary tumors. Multidisciplinary treatment decision making involving the surgeon, radiation oncologist, and medical oncologist is imperative.

C. Palliative Modalities

Many patients will be found either preoperatively or at the time of surgical exploration to have advanced disease that is not amenable to curative intent surgery due to peritoneal or distant metastases or local invasion of other organs. In some of these cases, palliative resection of the tumor nonetheless may be indicated to alleviate pain, bleeding, or obstruction. For patients with unresectable disease, a surgical diversion with gastrojejunalostomy may be indicated to prevent obstruction. Alternatively, unresected tumors may be treated with endoscopic laser or stent therapy, radiation therapy, or angiographic embolization to relieve bleeding or obstruction. Chemotherapy may be considered in patients with metastatic disease who still have good functional status and expected survival of at least several months. The regimens used are the same as those discussed for esophageal and gastroesophageal junction tumors discussed above (Table 39–2).

Prognosis

The 5-year survival of gastric carcinoma is approximately 30%. However, 5-year survival in patients who undergo successful curative resection exceeds 45%. Survival is related to tumor stage, location, and histologic features. Stage I and stage II tumors resected for cure have a greater than 60% long-term survival. Patients with stage III tumors have a poor prognosis (less than 30% long-term survival) and should be considered for enrollment in clinical trials. Even with apparently localized disease, proximal tumors have a 5-year survival of less than 15%. For those whose disease progresses despite therapy, meticulous efforts at palliative care are essential (see Chapter 5).

When to Refer

- Patients with dysphagia, weight loss, protracted vomiting, iron deficiency anemia, melena, or new-onset of dyspepsia (especially if aged 55 years or older or associated with other alarm symptoms) in whom gastric cancer is suspected should be referred for endoscopy.
- Patients should be referred to a surgeon for attempt at curative resection in stage I, II, or III cancer, including staging laparoscopy if indicated.
- Prior to surgery, patients should be referred to an oncologist to determine the role for perioperative chemotherapy or adjuvant chemoradiation or chemotherapy.
- Patients who have undergone gastrectomy require consultation with a nutritionist due to propensity for malnutrition and complications, such as dumping syndrome and vitamin **B**₁₂ deficiency, postoperatively.
- Patients with unresectable or metastatic disease should be referred to an oncologist for consideration of palliative chemotherapy or chemoradiation. Early referral to palliative care services may also be considered for symptom management in patients with advanced and metastatic disease.

When to Admit

Patients with protracted vomiting, inability to maintain hydration or nutrition, or acute bleeding.
GASTRIC LYMPHOMA

ESSENTIALS OF DIAGNOSIS

- Symptoms of dyspepsia, weight loss, or anemia.
- Variable abnormalities on upper gastrointestinal series or endoscopy including thickened folds, ulcer, mass, or infiltrating lesions; diagnosis established by endoscopic biopsy.
- Abdominal CT and EUS required for staging.

General Considerations

Gastric lymphomas may be primary (arising from the gastric mucosa) or may represent a site of secondary involvement in patients with nodal lymphomas. Distinguishing advanced primary gastric lymphoma with adjacent nodal spread from advanced nodal lymphoma with secondary gastric spread is essential because the prognosis and treatment of primary and secondary gastric lymphomas are different. Primary gastric lymphoma is the second most common gastric malignancy, accounting for 3–5% of gastric cancers. More than 95% of these are non-Hodgkin B-cell lymphomas mainly consisting of either mucosa-associated lymphoid tissue (MALT)-type lymphoma and diffuse large B-cell lymphoma. Gastric T-cell lymphoma, which is associated with HTLV-1 infection, is rare and makes up 7% of primary gastric lymphomas.

Infection with H pylori is an important risk factor for the development of primary gastric lymphoma. Chronic infection with H pylori causes an intense lymphocytic inflammatory response that may lead to the development of lymphoid follicles. Over 90% of low-grade primary gastric MALT-type lymphomas are associated with H pylori infection.

Clinical Findings & Staging

The clinical presentation and endoscopic appearance of gastric lymphoma are similar to those of adenocarcinoma. Most patients have abdominal pain, weight loss, or bleeding. Patients with diffuse large B-cell lymphoma are more likely to have systemic symptoms and advanced tumor stage. At endoscopy, lymphoma may appear as an ulcer, mass, or diffusely infiltrating lesion. It tends to have horizontal infiltration as opposed to the vertical extension seen in adenocarcinoma. The diagnosis is established with endoscopic biopsy; FNA is not adequate. Since the disease can be multifocal, biopsies of both suspicious and normal-appearing areas are recommended. Biopsy specimens should be tested for H pylori and, if positive, for t(11;18) via PCR or FISH. EUS is the most sensitive test for determining the level of invasion and presence of perigastric lymphadenopathy and should be performed for accurate staging, if available. All patients should undergo staging with CT scanning of chest, abdomen, and pelvis. For patients with diffuse large B-cell lymphomas involving the stomach, combination PET-CT imaging, bone marrow biopsy with aspirate, tumor lysis laboratory tests, and hepatitis B and HIV serologies also may be required for staging and treatment planning (see Chapter 13).

Treatment

Treatment of primary gastric lymphomas depends on the tumor histology, grade, and stage. Marginal B-cell lymphomas of the MALT type that are low-grade and localized to the stomach wall (stage IE) or perigastric lymph nodes (stage IIE) have an excellent prognosis. Patients with primary gastric MALT-lymphoma should be tested for H pylori infection and treated if positive. Complete lymphoma regression after successful H pylori eradication occurs in approximately 75% of cases of stage IE and approximately 55% with stage IIE low-grade lymphoma. However, 95% of cancers positive for t(11;18) do not respond to antibiotics. Remission may take as long as a year, and relapse occurs in about 2% of cases per year. Restaging with endoscopy and biopsy is recommended 3 months after antibiotic treatment and 3–6 months following radiation therapy. Ultimately, endoscopic surveillance after treatment is recommended every 3–6 months for 5 years to evaluate for recurrence.

In patients whose tumors harbor specific gene translocations, including t(11;18) (API2-MALT1), t(1;14), or t(14;18), rates of remission after H pylori eradication are lower, and treatment with radiation may be required. Patients with localized marginal zone MALT-type lymphomas who either are not infected with H pylori or do not respond to eradication therapy may be treated with radiation therapy or rituximab, if not a candidate for radiation. Many patients with minimal disease after successful H pylori eradication may be observed closely without further therapy.

The long-term survival of low-grade MALT lymphoma for stage I is over 90% and for stage II is 35–65%. Because of a low risk of perforation with either radiation therapy or chemotherapy, surgical resection is no longer recommended. Diffuse large B-cell or other higher-grade lymphomas with secondary gastrointestinal involvement usually present at an advanced stage with widely disseminated disease and are treated according to stage and subtype of lymphoma (see Chapter 13).
GASTRIC NETS make up less than 1% of gastric neoplasms. They may occur sporadically or secondary to chronic hypergastrinemia that results in hyperplasia and transformation of enterochromaffin cells in the gastric fundus. The majority of NETs are caused by hypergastrinemia and occur in association with either pernicious anemia (75%) (type 1) or Zollinger-Ellison syndrome (5%) (type 2). Type 1 tumors are associated with chronic atrophic gastritis, gastric achlorhydria, and secondary hypergastrinemia. Initial diagnostic workup includes serum gastrin level, upper endoscopy, and EUS. Gastrin level should be obtained 1 week after the patient has stopped taking protein pump inhibitors. For low-grade tumors (Ki-67 less than 3% or less than 2 mitoses/10 high-power fields [HPF]), somatostatin receptor–based imaging (somatostatin receptor scintigraphy or gallium-68 dotatate PET/CT) should be considered. For high-grade tumors (Ki-67 greater than 20% or greater than 20 mitoses/10 HPF), PET/CT is preferred to evaluate the extent of disease.

For patients with hypergastrinemia (suspected of type 1 or type 2 carcinoid), serum vitamin B12 and intrinsic factor antibody levels should be obtained to exclude pernicious anemia. Gastric NETs associated with Zollinger-Ellison syndrome occur almost exclusively in patients with multiple endocrine neoplasia type 1 (MEN 1), in which chromosomal loss of 11q13 has been reported. Gastric NETs caused by hypergastrinemia tend to be multifocal, be smaller than 1 cm, have a low potential for metastatic spread, and thus are unlikely to cause development of the carcinoid syndrome. Small lesions may be successfully treated with endoscopic resection followed by endoscopic surveillance every 6–12 months, or with observation. Antrectomy reduces serum gastrin levels and may lead to regression of small tumors. It can be considered in patients with type 1 gastric NETs to reduce recurrence risk and frequency of post-therapy monitoring. Ocreotide therapy may be appropriate for patients with underlying gastrinoma and Zollinger-Ellison syndrome. Patients with tumors larger than 2 cm should undergo endoscopic or surgical resection (see Small Intestinal Adenocarcinomas below).

Type 3 gastric NETs arise sporadically, independent of gastrin production, and account for up to 20% of gastric NETs. Most sporadic gastric NETs are solitary, larger than 2 cm, and have a strong propensity for hepatic or pulmonary metastases and thus the carcinoid syndrome at initial presentation. CT or MRI should be obtained to evaluate for metastatic disease. Localized sporadic NETs should be treated with partial or total gastrectomy and regional lymphadenectomy. Advanced, low-grade gastric NETs can be monitored with serial scans, if asymptomatic. Somatostatin analogs may provide symptomatic relief for patients with functional gastric NETs. Advanced high-grade gastric neuroendocrine carcinomas are treated in a fashion similar to SCLCs.

GASTROINTESTINAL MESENCHYMAL TUMORS

Gastrointestinal mesenchymal tumors (which include stromal tumors, leiomyomas, and schwannomas) derive from mesenchymal stem cells and have an epithelioid or spindle cell histologic pattern, resembling smooth muscle. The most common stromal tumors are gastrointestinal stromal tumors (“GISTs”), which originate from interstitial cells of Cajal. GISTs occur throughout the gastrointestinal tract, but most commonly in the stomach (60%) and small intestine (30%). Approximately 85–90% of GISTs have mutations in KIT. Mesenchymal tumors may be discovered incidentally on imaging studies or endoscopy or may cause symptoms (most commonly bleeding, pain, or obstruction). At endoscopy, they appear as a submucosal mass that may have central umbilication or ulceration. EUS with guided FNA biopsy is the optimal study for diagnosing gastric mesenchymal tumors and distinguishing them from other submucosal lesions. Percutaneous biopsy may confer risk of bleeding or intra-abdominal seeding. CT of the abdomen and pelvis with contrast, MRI, and PET imaging are useful in the diagnosis and staging. PET imaging also may be useful to monitor response to treatment.

While almost all GISTs have malignant potential, the risk of developing metastasis is increased with tumor size greater than 2 cm, nongastric location, and mitotic index greater than 5 mitoses per 50 HPF. It is difficult to distinguish benign from malignant tumors by EUS appearance or by FNA. But, in general, lesions are more likely benign if they are smaller than 2 cm, have a smooth border, and have a homogeneous echo pattern on EUS. Resection settles the issue.

Surgery is recommended for all patients with tumors that are 2 cm or larger, increasing in size, have an EUS appearance suspicious for malignancy, or are symptomatic. The management of asymptomatic gastric lesions 2 cm or smaller in size depends on the EUS features. Tumors with high-risk EUS features can be surgically resected. If no high-risk features are noted, endoscopic surveillance can be performed. Because of the low but real long-term risk of malignancy, surgical resection should be considered in younger, otherwise healthy patients. However, other patients may be monitored with serial endoscopic ultrasonographic examinations or, in select cases, endoscopic resections. After complete surgical resection, GISTs recur within 5 years in over half of patients. The majority of recurrences are within the first 3 years. Adjuvant therapy with imatinib delays recurrence and prolongs survival, but it is not likely to be curative. Adjuvant imatinib is recommended for all high-risk patients for at least 1 year, though...
MALIGNANCIES OF THE SMALL INTESTINE

1. Small Intestinal Adenocarcinomas

These are aggressive tumors that occur most commonly in the duodenum or proximal jejunum. The incidence is rare, with 10,470 new diagnoses estimated in 2018 in the United States. Overall, prognosis is poor, with 5-year survival of 85% for localized disease, 75% for regional disease, and 42% for distant disease (overall, 27% of patients are stage IV at diagnosis). The management of small intestinal adenocarcinoma is extrapolated from data available for the management of colon adenocarcinoma. The ampulla of Vater is the most common site of small bowel carcinoma. The incidence of ampullary carcinoma is increased more than 200-fold in patients with familial adenomatous polyposis. Periodic endoscopic surveillance to detect early ampullary neoplasms is therefore recommended. Ampullary carcinoma may present with jaundice due to bile duct obstruction or bleeding. Surgical resection of early lesions is curative in up to 40% of patients.

2. Small Intestinal Lymphomas

Lymphomas may arise primarily in the gastrointestinal tract or may involve it secondarily in patients with disseminated disease. In Western countries, primary gastrointestinal lymphomas account for 5% of lymphomas and 20% of small bowel malignancies. They occur most commonly in the small intestine. There is an increased incidence of small intestinal lymphomas in patients with AIDS, Crohn disease, and those receiving immunosuppressive therapy. The most common histologic subtype is non-Hodgkin extranodal marginal zone (MALT) B-cell lymphoma. Enteropathy-associated T-cell lymphomas appear to be increasing in incidence in the United States. They are associated with the diagnosis of celiac disease. In the Middle East, lymphomas may arise in the setting of immunoproliferative small intestinal disease. Other types of intestinal lymphomas include primary intestinal follicular cell lymphoma, mantle cell lymphoma, and Burkitt lymphoma (see Chapter 13).

Presenting symptoms or signs of primary small bowel lymphoma include abdominal pain, weight loss, nausea and vomiting, distention, anemia, and occult blood in the stool. Fevers are unusual. Protein-losing enteropathy may result in hypoalbuminemia, but other signs of malabsorption are unusual. Barium radiography or CT enterography helps localize the site of the lesion. The diagnosis requires endoscopic, percutaneous, or laparoscopic biopsy. Imaging and possibly bone marrow biopsy are required to determine stage. Treatment depends on the tumor histologic subtype and stage of disease (see Chapter 13). Surgical resection of primary intestinal lymphoma, if feasible, may be appropriate for localized tumors. In patients with limited disease (stage IE) in whom resection is performed with negative margins, the role of adjuvant chemotherapy is unclear. Locoregional radiation should be considered if surgical margins are positive. Patients with more extensive disease generally are treated according to the tumor histology.

3. Intestinal Neuroendocrine Tumors

ESSENTIALS OF DIAGNOSIS

- Majority are asymptomatic and discovered incidentally at endoscopy or surgery.
- Carcinoid syndrome occurs in less than 10%; hepatic metastases are generally present.
- Risk of metastasis is related to tumor size and location.

General Considerations

Neuroendocrine tumors account for approximately one-third of tumors arising in the small bowel. Gastrointestinal NETs most commonly occur in the small intestine (45%) but are also found in the rectum (20%), appendix (17%),

CMDT 2020 CHAPTER 39
and colon (11%), with the remainder occurring in the stomach (less than 10%; see Gastric Neuroendocrine Tumors above). Carcinoid tumors are well-differentiated tumors that may secrete a variety of hormones, including serotonin, somatostatin, gastrin, and substance P.

Small intestinal carcinoids most commonly arise in the distal ileum within 60 cm of the ileocecal valve. Up to 30% are multicentric. Although many carcinoids behave in an indolent fashion, the overall 5-year survival rates for patients with locoregional and metastatic small bowel carcinoids are approximately 65% and 35%, respectively. The risk of metastatic spread increases when the tumor is 1 cm or larger and when it is larger than 2 cm with invasion beyond muscularis propria. Appendiceal carcinoids are identified in 0.3% of appendectomies, usually as an incidental finding. Almost 80% of these tumors are smaller than 1 cm, and 90% are smaller than 2 cm. However, in patients with appendiceal carcinoid tumors larger than 2 cm, approximately 90% develop nodal and distant metastases; right hemicolectomy is recommended in these cases.

Rectal carcinoids are usually detected incidentally as submucosal nodules during proctoscopic examination and often locally excised by biopsy or snare polypectomy before the histologic diagnosis is known. Endorectal ultrasound is usually recommended to assess the size, presence, and depth of invasion, and presence of lymph node metastases. Rectal carcinoids smaller than 1 cm virtually never metastasize and are treated effectively with local endoscopic or transanal excision. Larger tumors are associated with the development of metastasis in 10%. Hence, a more extensive cancer resection operation is warranted in fit patients with rectal carcinoid tumors larger than 1–2 cm or with high-risk features (such as invasion of muscularis propria or evidence of nodal involvement), or both.

Clinical Findings

A. Symptoms and Signs

Most lesions smaller than 1–2 cm are asymptomatic and difficult to detect by endoscopy or imaging studies. Small intestinal carcinoids may present with abdominal pain, bowel obstruction, bleeding, or bowel infarction. Appendiceal and rectal carcinoids usually are small and asymptomatic, but large lesions can cause bleeding, obstruction, or altered bowel habits. Carcinoid syndrome occurs in less than 10% of patients. More than 90% of patients with carcinoid syndrome have hepatic metastases, usually from carcinoids of small bowel origin. About 10% of patients with carcinoid syndrome have primary bronchial or ovarian tumors without hepatic metastases. Carcinoid syndrome is caused by tumor secretion of hormonal mediators. The manifestations include facial flushing, edema of the head and neck (especially with bronchial carcinoid), abdominal cramps and diarrhea, bronchospasm, cardiac lesions (pulmonary or tricuspid stenosis or regurgitation in 10–30%), and telangiectases.

B. Laboratory Findings

Serum chromogranin A (CgA) is elevated in the majority of NETs, although its sensitivity for small, localized carcinoid tumors is unknown. CgA is elevated in almost 90% of patients with advanced small bowel carcinoid. Urinary 5-hydroxyindoleacetic acid (5-HIAA) and platelet serotonin levels are also elevated in patients with metastatic carcinoid; however, these tests are less sensitive than CgA. There is increased urinary 5-HIAA in carcinoid syndrome; symptomatic patients usually excrete more than 25 mg of 5-HIAA per day in the urine. Because certain foods and medications can interfere with 5-HIAA levels, these should be withheld for 48 hours prior to a 24-hour urine collection.

C. Imaging

Abdominal CT may demonstrate a mesenteric mass with tethering of the bowel, lymphadenopathy, and hepatic metastasis. Abdominal CT or enterography may reveal kinking of the bowel, but because the lesion is extraluminal, the diagnosis may be overlooked for several years. Somatostatin receptor scintigraphy (OctreoScan) and gallium Ga-68 DOTATATE PET scan are routinely used in staging and can help identify diseases that may benefit from treatment with somatostatin analogs.

Treatment & Outcomes

Small intestinal carcinoids generally are indolent tumors with slow spread. Patients with disease confined to the small intestine should be treated with surgical excision. There is no proven role for adjuvant therapy after complete resection. Five-year survival rates for patients with stage I and II disease are 96% and 87%, respectively. In patients with resectable disease who have lymph node involvement (stage III), the 5-year survival is 74%; however, by 25 years, less than 25% remain disease free. Even patients with metastatic disease may have an indolent course with a 5-year survival of 43%.

In patients with advanced disease, therapy historically has been deferred until the patient is symptomatic. Conventional cytotoxic chemotherapy agents do not achieve significant responses in carcinoid tumors and have not been associated with improved outcomes. For patients who are symptomatic either from tumor bulk or carcinoid syndrome, the cornerstone of therapy is typically a long-acting somatostatin analog, which inhibits hormone secretion from the carcinoid tumor. In 90% of patients, this results in dramatic relief of symptoms of carcinoid syndrome, including diarrhea or flushing, for a median period of 1 year. Thereafter, many patients stop responding to octreotide. Options at disease progression include octreotide dose escalation, or addition of everolimus, the mammalian target of rapamycin (mTOR) inhibitor. For patients with somatostatin receptor–positive disease based on imaging, another option after progression on standard dose somatostatin analog therapy is treatment with peptide receptor radionuclide therapy. Peptide receptor radionuclide therapy consists of a somatostatin analog conjugated to a radioactive isotope such as yttrium-90 or lutetium-177. In the United States, peptide receptor radionuclide therapy is specifically approved for gastroenteropancreatic NETs. Additionally, in selected patients with hepatic-dominant disease, resection of hepatic metastases may provide dramatic improvement in carcinoid syndrome symptoms.
Tumor debulking with liver-directed therapy (chemoembolization or radioembolization) may also provide symptomatic improvement in some of these patients.

Patients with advanced, poorly differentiated intestinal NETs are treated in a similar fashion to those with small cell cancers. They have a poor prognosis.

4. Small Intestine Sarcoma

Sarcomas constitute approximately 10% of small bowel neoplasms and are commonly found in the jejunum and ileum (and in a Meckel diverticulum, if present). Most arise from stromal tumors (GISTs) that stain positive for CD117; a minority arise from smooth muscle tumors (leiomyosarcomas) (see Gastrointestinal Mesenchymal Tumors above). Common symptoms of small intestine sarcoma include pain, weight loss, bleeding, and perforation. As the lesions tend to enlarge extraluminally, obstruction is rare.

Kaposi sarcoma was at one time a common complication in AIDS, but the incidence is declining with antiretroviral therapy. It can also occur in the setting of immunosuppression after organ transplant. Lesions may be present anywhere in the intestinal tract. Visceral involvement usually is associated with cutaneous disease. Most lesions are clinically silent; however, large lesions may be symptomatic. Widespread involvement may be best treated by systemic chemotherapy using single-agent therapy or combinations of pegylated-doxorubicin, paclitaxel, vincristine, bleomycin, or etoposide. Surgery or radiation may be indicated for isolated high-risk lesions.

Colorectal cancer is the second leading cause of death due to malignancy in the United States. Colorectal cancer will develop in approximately 4.2% of Americans and has a 5-year survival rate of 65%. In 2018, there were an estimated 140,250 new cases of colorectal cancer in the United States, with an estimated 50,630 deaths. Between 1996 and 2010, its mortality rate decreased by 46%. During this same period, the percentage of patients 50 years or older who were screened for colorectal cancer increased to 66%. On average, new cases have been falling 3.2% each year over the last 10 years. The colorectal cancer mortality in adults aged 20–54 years increased by 1% annually from 2004 to 2014, although the same trend was not observed in black patients.

Colorectal cancers are almost all adenocarcinomas, which tend to form bulky exophytic masses or annular constricting lesions. The majority of colorectal cancers are thought to arise from malignant transformation of an adenomatous poly (tubular, tubulovillous, or villous adenoma) or serrated poly (hyperplastic poly, traditional serrated adenoma, or sessile serrated adenoma). Polyps that are “advanced” (ie, polyps at least 1 cm in size, adenomas with villous features or high-grade dysplasia, or serrated polyps with dysplasia) are associated with a greater risk of cancer. Approximately 85% of sporadic colorectal cancers arise from adenomatous polyps and have loss of function of one or more tumor suppressor genes (eg, p53, APC, or DCC) due to a combination of spontaneous mutation of one allele combined with chromosomal instability and aneuploidy (abnormal DNA content) that leads to deletion and loss of heterozygosity of the other allele (eg, 5q, 17q, or 18p deletion). Activation of oncogenes such as KRAS and BRAF is present in a subset of colorectal cancers with prognostic and therapeutic implications discussed further below.

Approximately 10–20% of colorectal cancers arise from serrated polyps, most of which have hypermethylation of CpG-rich promoter regions that leads to inactivation of the DNA mismatch repair gene MLH1, resulting in microsatellite instability, and activation of mutations of the BRAF gene. Serrated colon cancers have distinct clinical and pathologic characteristics, including diploid DNA content, predominance in the proximal colon, poor differentiation, and more favorable prognosis.
Up to 5% of colorectal cancers are caused by inherited germline mutations resulting in polyposis syndromes (eg, familial adenomatous polyposis) or hereditary nonpolyposis colorectal cancer (HNPCC or Lynch syndrome). These conditions are discussed further in Chapter 15.

## Risk Factors

A number of factors increase the risk of developing colorectal cancer. Some of these factors include smoking, consumption of red and processed meats, alcohol intake, diabetes mellitus, physical inactivity, obesity, and history of inflammatory bowel disease. Recognition of these factors has had an impact on screening strategies. However, 75% of all cases occur in people with no known predisposing factors.

### A. Age

The incidence of colorectal cancer rises sharply after age 45 years, and 90% of cases occur in persons over the age of 50 years with a median age of 68 years at the time of diagnosis. For unknown reasons, over the past two decades there has been a 50% increase in incidence among adults under age 50, although the risk remains substantially lower than in those over age 50.

### B. Family History of Neoplasia

A family history of colorectal cancer is present in approximately 20% of patients with colon cancer. Hereditary factors are believed to contribute to 20–30% of colorectal cancers; however, the genes responsible for most of these cases have not yet been identified. (See Chapter 15 for discussion of inherited polyposis syndromes.) Approximately 6% of the Ashkenazi Jewish population has a missense mutation in the APC (APC H1307K) that confers a modestly increased lifetime risk of developing colorectal cancer (OR 1.4–1.9) but phenotypically resembles sporadic colorectal cancer rather than familial adenomatous polyposis. Genetic screening is available, and patients harboring the mutation merit more intensive screening.

A family history of colorectal cancer or adenomatous polyps is one of the most important risk factors for colorectal cancer. The risk of colon cancer is proportionate to the number and age of affected first-degree family members with colon neoplasia. People with one first-degree family member with colorectal cancer have an increased risk approximately two times that of the general population; however, the risk is almost four times if the family member was younger than 45 years when the cancer was diagnosed. Patients with two first-degree relatives have a fourfold increase, or 25–30% lifetime, risk of developing colon cancer. First-degree relatives of patients with adenomatous polyps also have a twofold increased risk for colorectal neoplasia, especially if they were younger than 60 years when the polyp was detected or if the polyp was 10 mm or larger.

### C. Inflammatory Bowel Disease

The risk of adenocarcinoma of the colon begins to rise 8 years after disease onset in patients with ulcerative colitis and Crohn colitis (see Chapter 15). For this reason, initiation of surveillance with colonoscopy is recommended at 8–10 years after onset of inflammatory bowel disease symptoms.

## D. Dietary and Lifestyle Factors and Chemoprevention in Colorectal Cancer Risk

In epidemiologic studies, diets rich in fats and red meat are associated with an increased risk of colorectal adenomas and cancer, whereas diets high in fruits, vegetables, and fiber are associated with a decreased risk. However, prospective studies have not shown a reduction in colon cancer or recurrence of adenomatous polyps with diets that are low in fat; are high in fiber, fruits or vegetables; or that include calcium, folate, beta-carotene, or vitamin A, C, D, or E supplements.

Low-dose aspirin has been associated with a reduced risk of colorectal adenomas and cancer in multiple studies. A 2016 USPSTF systematic review of controlled trials concluded that prolonged regular use of low-dose aspirin (81 mg/day) is associated with a 40% reduction in colorectal cancer incidence after 10 years and a 33% reduction in colorectal cancer mortality after 20 years. Because long-term aspirin use is associated with a low incidence of serious complications (gastrointestinal hemorrhage, stroke), low-dose aspirin should not be routinely administered as a chemopreventive agent without other medical indications. Persons who are not at increased risk for bleeding, have a life expectancy of at least 10 years, and are willing to take low-dose aspirin daily for at least 10 years are more likely to benefit; persons who place a higher value on its potential benefits than its potential harms may choose to take low-dose aspirin (grade C recommendation). Low-dose aspirin may also be considered in patients with a personal or family history of colorectal cancer or advanced adenomas; however, its administration does not obviate the need for colonoscopy screening and surveillance.

Retrospective analysis of randomized phase III trial data and a meta-analysis have shown that patients with higher levels of pre- and post-diagnosis physical activity experience reduced colorectal cancer–specific mortality and all-cause mortality. Maintaining a healthy body weight, a healthy diet, and a physically active lifestyle are recommended in colorectal cancer survivors.

### E. Other Factors

The incidence and mortality of colon adenocarcinoma is higher in blacks than in whites. It is unclear whether this is due to genetic or socioeconomic factors (eg, diet or reduced access to medical care).

## Clinical Findings

### A. Symptoms and Signs

Adenocarcinomas grow slowly and may be present for several years before symptoms appear. However, some asymptomatic tumors may be detected by the presence of fecal occult blood (see Screening for Colorectal Neoplasms, below). Symptoms depend on the location of the carcinoma. Chronic blood loss from right-sided colonic cancers may cause iron deficiency anemia, manifested by...
fatigue and weakness. Obstruction, however, is uncommon because of the large diameter of the right colon and the liquid consistency of the fecal material. Lesions of the left colon often involve the bowel circumferentially. Because the left colon has a smaller diameter and the fecal matter is solid, obstructive symptoms may develop with colicky abdominal pain and a change in bowel habits. Constipation may alternate with periods of increased frequency and loose stools. The stool may be streaked with blood, though marked bleeding is unusual. With rectal cancers, patients note tenesmus, urgency, and recurrent hematochezia. Physical examination is usually normal except in advanced disease. The liver should be examined for hepatomegaly, suggesting metastatic spread. For cancers of the distal rectum, digital examination is necessary to determine whether there is extension into the anal sphincter or fixation, suggesting extension to the pelvic floor.

B. Laboratory Findings
A CBC should be obtained to look for anemia. Elevated liver biochemical tests, particularly the serum alkaline phosphatase, raise suspicion of metastatic disease. The serum carcinoembryonic antigen (CEA) should be measured in all patients with proven colorectal cancer but is not appropriate for screening. The CEA is not elevated in many patients with confirmed colorectal cancer; conversely, the CEA may be elevated in active smokers and those with a variety of other nonmalignant conditions. A preoperative CEA level greater than 5 ng/mL is a poor prognostic indicator. After complete surgical resection, CEA levels should normalize; persistently elevated levels suggest the presence of persistent disease and warrant further evaluation. The sensitivity of CEA for detection of recurrence ranges from 68% to 82% and its specificity from 80% to 97%. For this reason, CEA is routinely monitored at the time of adjuvant therapy and during postoperative surveillance for patients who had elevated levels before resection.

C. Colonoscopy
Colonoscopy is the required diagnostic procedure in patients with a clinical history suggestive of colon cancer or in patients with an abnormality suspicious for cancer detected on radiographic imaging. Colonoscopy permits biopsy for pathologic confirmation of malignancy.

D. Imaging
Chest, abdominal, and pelvic CT scans with contrast are required for preoperative staging. CT scans may demonstrate distal metastases but are less accurate in the determination of the level of local tumor extension (T stage) or lymphatic spread (N stage). Intraoperative assessment of the liver by direct palpation and ultrasonography can be performed to detect hepatic metastases (M stage). For rectal cancers (generally defined as tumors arising 12 cm or less proximal to the anal verge), pelvic MRI or endorectal ultrasonography is required to determine the depth of penetration of the cancer through the rectal wall (T stage) and perirectal lymph nodes (N stage), informing decisions about preoperative (neoadjuvant) chemoradiotherapy and operative management. PET is not routinely used for staging or surveillance in colorectal cancers.

Staging
The TNM system is the commonly used classification to stage colorectal cancer. Staging is important not only because it correlates with the patient's long-term survival but also because it is used to determine which patients should receive adjuvant or neoadjuvant therapy.

Differential Diagnosis
The nonspecific symptoms of colorectal cancer may be confused with those of irritable bowel syndrome, diverticular disease, ischemic colitis, inflammatory bowel disease, infectious colitis, and hemorrhoids. Neoplasm must be excluded in any patient over age 40 years who reports a change in bowel habits or hematochezia or who has an unexplained iron deficiency anemia or occult blood in stool samples.

Treatment
A. Surgery
Resection of the primary colonic or rectal cancer is the treatment of choice for almost all patients who have resectable lesions and can tolerate general anesthesia. For colon cancer, multiple studies demonstrate that minimally invasive, laparoscopically assisted colectomy results in similar outcomes and rates of recurrence to open colectomy. Regional dissection of at least 12 lymph nodes should be performed to determine staging, which guides decisions about adjuvant therapy.

For rectal carcinoma, preoperative (neoadjuvant) chemoradiation with 5-fluorouracil is recommended in all node-positive tumors, and in T3 and greater tumors, due to increased risk of local recurrence (see below). After neoadjuvant therapy, the operative approach depends on the level of the tumor above the anal verge, the size and depth of penetration, and the patient's overall condition. Clinical staging by endorectal ultrasound or MRI with endorectal coil is important in guiding the treatment approach. In carefully selected patients with small, mobile (less than 4 cm), well-differentiated T1 or T2 rectal tumors that are less than 8 cm from the anal verge, transanal excision may be considered. This approach avoids laparotomy and spares the rectum and anal sphincter, preserving normal bowel continence. All other patients will require either a low anterior resection with a colorectal anastomosis or an abdominopereineal resection with a colostomy, depending on how far above the anal verge the tumor is located and the extent of local tumor spread. Careful dissection of the entire mesorectum by either open or laparoscopic surgery reduces local recurrence to 5%. Although low anterior resections obviate a colostomy, they are associated with increased immediate postsurgical complications (eg, leak, dehiscence, stricture) and long-term defecatory complaints (eg, increased stool frequency, and incontinence). With unresectable rectal cancer, the patient may be palliated with a diverting colostomy. Pathology review of colorectal cancers should include testing for mismatch repair proteins for all patients. Tumors of
patients with metastatic colorectal cancer should also be tested for extended RAS and BRAF mutations.

### B. Systemic Chemotherapy for Colon Cancer

Chemotherapy has been demonstrated to improve overall and tumor-free survival in select patients with colon cancer depending on stage (Table 39–2).

1. **Stage I**—Because of the excellent 5-year survival rate (approximately 92%), no adjuvant therapy is recommended for stage I colon cancer. The 5-year survival rate of stage I rectal cancer is approximately 87%.

2. **Stage II (node-negative disease)**—The 5-year survival rate is approximately 87% for stage II A disease and 63% for stage II B disease. A significant survival benefit from adjuvant chemotherapy has not been demonstrated in most randomized clinical trials for stage II colon cancer (see discussion for stage III disease). However, otherwise healthy patients with stage II disease who are at higher risk for recurrence (perforation; obstruction; close or indeterminate margins; poorly differentiated histology; lymphatic, vascular, or perineural invasion; T4 tumors; or fewer than 12 lymph nodes sampled) may benefit from adjuvant chemotherapy. Patients whose tumors reveal microsatellite instability have a more favorable prognosis and do not benefit from 5-fluorouracil-based adjuvant therapy.

3. **Stage III (node-positive disease)**—With surgical resection alone, the expected 5-year survival rate is 30–50%. Postoperative adjuvant chemotherapy significantly increases disease-free survival as well as overall survival by up to 30% and is recommended for all fit patients (Table 39–2). Multiple large, well-designed studies of adjuvant chemotherapy for stage III colorectal cancer reported a higher rate of disease-free survival at 5 years for patients treated for 6 months postoperatively with a combination of oxaliplatin, 5-fluorouracil, and leucovorin (FOLFOX) (73.3%) than with 5-fluorouracil and leucovorin (FL) alone (67.4%). Similar benefit was reported for patients treated with oxaliplatin and capecitabine (orally active fluoropyrimidine). The benefit of adding oxaliplatin to 5-fluorouracil has not been demonstrated in patients who are 70 years of age or older. A large international randomized controlled trial comparing 3 months with 6 months of adjuvant therapy found that 3 months of therapy resulted in equivalent disease-free survival for patients with earlier stage T1, T2, or T3, and N1 disease but not with more advanced T4 or N2 disease. Additionally, similar disease-free survival was seen with use of 3 months vs 6 months of capecitabine and oxaliplatin but not when infusional 5-fluorouracil plus oxaliplatin was used. The reason for the difference between regimens is currently unknown; the shorter treatment duration did result in significantly less neuropathy across regimens.

For patients with high-risk disease (T4 or N2), 6 months of adjuvant chemotherapy are still recommended. The addition of a biologic agent (bevacizumab or cetuximab) to adjuvant chemotherapy improves response rates and overall survival and is recommended in the first-line treatment of suitable patients. Bevacizumab is a monoclonal antibody targeting VEGF. Combination therapy with bevacizumab and FOLFOX or FOLFIRI prolongs mean survival by 2–5 months compared with either regimen alone. Cetuximab and panitumumab are monoclonal antibodies targeting EGFR. Activating codon 12 and 13 K-ras gene mutations downstream of EGFR are present in approximately 35% of patients with metastatic colorectal cancer and are a biomarker for nonresponse to cetuximab and panitumumab, for which reason the use of these agents is restricted to patients with tumors wild-type for K-ras. In stage IV patients with K-ras wild-type tumors, the addition of panitumumab or cetuximab to FOLFOX or FOLFIRI prolongs survival by approximately 4 months. Bevacizumab may cause serious side effects, including arterial thromboembolic events, bowel perforation, or serious bleeding, in up to 5% of patients. EGFR-targeted agents cause an acneiform rash in the majority of patients. Cetuximab is associated with severe infusion reactions in approximately 2–5%.

When disease progresses despite treatment either with FOLFOX or with FOLFIRI (often in conjunction with bevacizumab or an EGFR-targeted antibody), therapy is switched to the alternate regimen. The novel anti-angiogenic agent, aflibercept, is FDA approved for second-line treatment of colorectal cancer in combination with FOLFIRI. Palliative therapy with cetuximab or panitumumab alone or in combination with irinotecan can benefit patients with K-ras wild-type tumors whose disease has progressed after first-line and second-line chemotherapies. Both trifluridine/tipiracil and
the multi-targeted kinase inhibitor regorafenib are FDA approved for patients with metastatic, refractory colorectal cancer after progression on standard regimens. Clinical trial participation should be considered for eligible patients who are intolerant of or ineligible for standard therapies or in whom disease has progressed.

C. Neoadjuvant and Adjuvant Therapy for Rectal Cancer

Compared with colon cancer, rectal cancer has lower long-term survival rates and significantly higher rates of local tumor recurrence with surgery alone (approximately 25%) attributed in part to the difficulty of achieving adequate surgical resection margins and to lack of serosal ence- ment of the rectum. When initial imaging studies suggest stage I disease, surgery may be performed first (see Surgery above). For stage II and III tumors by clinical staging (including endorectal ultrasound or pelvic MRI), preoperative chemoradiation with 5-fluorouracil or capecitabine as a radiation-sensitizing agent improves disease-free survival and decreases pelvic recurrence rate. Preoperative chemoradiation has been shown to be superior to postoperative chemoradiation with lower local recurrence and toxicity rates in the randomized, phase III CAO/ARO/AIO-94 trial. Following surgical resection with total mesorectal excision (see Surgery above), adjuvant 5-fluorouracil–based therapy (generally with the FOLFOX regimen extrapolating from its benefit in patients with similarly-staged colon cancers) is recommended for a total of approximately 6 months of perioperative therapy inclusive of neoadjuvant chemoradia- tion. Due to its better tolerability and potentially decreased risk of distant metastatic spread, the majority (or even the entirety) of the adjuvant FOLFOX chemotherapy can be given up-front prior to chemoradiation as “total neoadjuvant therapy,” per NCCN guidelines.

Follow-Up After Surgery

Patients who have undergone resections for cure are monitored closely to look for evidence of symptomatic or asymptomatic tumor recurrence that may be amenable to curative resection in a small number of patients. Patients should be evaluated every 3–6 months for 2 years and then every 6 months for a total of 5 years with history, physical examination, and laboratory surveillance, including serum CEA levels if baseline levels are elevated. The NCCN and ASCO guidelines recommend surveillance contrast CT scans of chest, abdomen, and pelvis up to every 6 months for up to 5 years post-resection in high-risk stage II and all stage III patients. Patients who had a complete preoperative colonoscopy should undergo another colonoscopy 1 year after surgical resection. Patients who did not undergo full colonoscopy preoperatively also should undergo a full colonoscopy after completion of all adjuvant therapy to exclude other synchronous colorectal neoplasms. If a colo- noscopy does not detect new adenomatous polyps 1 year postoperatively, surveillance colonoscopy should be performed every 3–5 years thereafter to look for metachronous polyps or cancer. Because of the high incidence of local tumor recurrence in patients with rectal cancer, proctoscopy surveillance of the low anterior resection anastomotic site may also be performed periodically. New onset of symptoms or a rising CEA warrants investigation with chest, abdominal, and pelvic CT and colonoscopy to look for a new primary tumor or recurrence, or metachro- nous metastatic disease that may be amenable to curative or palliative therapy. For patients with a rising CEA level with unrevealing CT imaging, a PET scan may be more sensitive for the detection of occult metastatic disease.

Prognosis

The stage of disease at presentation is the most important determinant of 5-year survival in colon cancer: stage I, greater than 90%; stage II, 70–85%; stage III with fewer than 4 positive lymph nodes, 67%; stage III with more than 4 positive lymph nodes, 33%; and stage IV, 5–7%. For each stage, rectal cancers have a worse prognosis. For those patients whose disease progresses despite therapy, meticulous efforts at palliative care are essential (see Chapter 5).

Screening for Colorectal Neoplasms

Colorectal cancer is ideal for screening because it is a common disease that is fatal in almost 50% of cases and yet is curable if detected at an earlier stage. Furthermore, most cases arise from benign adenomatous or serrated polyps that progress over many years to cancer, and removal of these polyps has been shown to prevent the majority of cancers. Colorectal cancer screening is endorsed by the USPSTF, the Agency for Health Care Policy and Research, the American Cancer Society, and every professional gastroenterology and colorectal surgery society. Although there is continued debate about the optimal cost-effective means of providing population screening, there is unanimous consent that screening of some kind should be offered to every patient over the age of 50 years. Several analyses suggest that screening is cost-effective. It is important for primary care providers to understand the relative merits of various options and to discuss them with their patients. Only 62.6% of adults over age 50 are up-to-date with colorectal screening. Discussion and encouragement by the primary care provider are the most important factors in achieving patient compliance with screening programs. A 2018 Kaiser Permanente study reported increased participation to 82.5% through an organized screening program. Currently in the United States, the two most widely used strategies are colonoscopy every 10 years or fecal immunochemical testing (FIT) testing annually.

Recommendations for screening from the 2016 USPSTF and 2008 US Multi-Society Task Force (USMSTF) are listed in Table 39–6. Screening is recommended for all men and women 50 through 75 years of age who are at average risk for cancer. Many guidelines recommend screening for African Americans and Alaska Natives beginning at age 45. In 2018, the American Cancer Society provided a qualified recommendation for starting screening at age 45 for average-risk adults; however, other agencies do not feel that available evidence yet supports this recommendation. The potential for harm from screening must be weighed against the likelihood of benefit, especially in elderly patients with...
comorbid illnesses and shorter life expectancy. Although routine screening is not recommended in adults above age 75, it may be considered on a case-by-case basis in adults age 76 through 85 years who have excellent health and functional status. In 2017, the USMSTF issued revised, simplified recommendations in which screening tests were placed into three tiers (Table 39–7). For average-risk patients, colonoscopy every 10 years or FIT testing is preferred (Tier 1). Tier 2 tests (CT colonography every 5 years, flexible sigmoidoscopy every 5 years, or fecal FIT-fecal DNA testing every 3 years) and Tier 3 tests (colon capsule every 5 years) may be offered but are considered less suitable due to various disadvantages (discussed below).

Patients with first-degree relatives with colorectal neoplasia (cancer or adenomatous polyps) are at increased risk. Therefore, most guidelines recommend initiating screening at age 40–50 years (or 10 years younger than the familial diagnosis) in individuals with first-degree relatives with colorectal cancer or with advanced adenomas. Recommendations for screening in families with inherited cancer syndromes or inflammatory bowel disease are provided in Chapter 15. For patients at average risk for colorectal cancer, the recommendations of the USPSTF and USMSTF are discussed below.

**Table 39–6.** Recommendations for colorectal cancer screening,1 including the US Preventive Services Task Force (2016) recommendations2 and the US Multi-Society Task Force on Colorectal Cancer (2008) recommendations.2

**Table 39–7.** Revised recommendations for colorectal cancer screening for average-risk individuals from the US Multi-Society Task Force on Colorectal Cancer (2017).1

| Tier 12 | Colonoscopy every 10 years, or Fecal immunochemical test (FIT) every 1 year |  
| Tier 2 | CT colonography every 5 years, or Flexible sigmoidoscopy every 5–10 years, or Fecal FIT-fecal DNA testing every 3 years |  
| Tier 3 | Colon capsule every 5 years |  

1Screening of individuals considered to be at “average risk” for colorectal cancer is recommended beginning at 50 years of age, except in African-Americans for whom beginning at 45 years of age is supported by some limited data. Since the incidence of colorectal cancer is rising in persons under age 50 years, a thorough diagnostic evaluation is recommended for younger individuals with rectal bleeding. Colonoscopy screening can be discontinued at 75 years of age in persons who are up-to-date with screening and who have had consistently negative screening tests (especially prior negative colonoscopy), or in individuals who have life expectancies of less than 10 years. Conversely, in persons who have no prior screening, colorectal screening can be initiated and continued to 85 years of age, depending on health and life expectancy.

2Colonoscopy and FIT are recommended as the cornerstones of colorectal cancer screening. In a sequential approach in which colonoscopy every 10 years is offered first, FIT done annually should be offered to patients who decline colonoscopy. “Tier 1” designation indicates that colonoscopy and FIT are recommended as the tests of choice even when multiple other options are available. A risk-stratified approach is also considered appropriate with FIT screening in patient populations estimated to have a low prevalence of advanced colonic neoplasia and colonoscopy considered more appropriate in patient populations estimated to have a high prevalence of colonic neoplasia.

3Tier 2 and Tier 3 tests may be offered but are considered less suitable due to various disadvantages (see text).

Note: USMSTF screening recommendations vary for individuals considered to be at “high risk” for colorectal cancer. Specifically, for individuals with a family history of colorectal cancer or advanced adenoma in a first-degree relative at age < 60 years or with these findings in two first-degree relatives at any age, screening by colonoscopy every 5 years is recommended, beginning 10 years before the age at diagnosis of the youngest relative or at age 40 years, whichever is earlier. Individuals with a single first-degree relative diagnosed with colorectal cancer or advanced adenoma at age > 60 years are recommended to undertake the “average-risk” screening options shown above but beginning at 40 years of age. Modified, with permission, from Rex DK et al. Colorectal cancer screening: recommendations for physicians and patients from the US Multi-Society Task Force on Colorectal Cancer. Am J Gastroenterol. 2017 Jul;112(7):1016–30. By permission from Springer Nature.
A. Stool-Based Tests

1. Fecal occult blood test—Most colorectal cancers and some large adenomas result in increased chronic blood loss. A variety of tests for fecal occult blood are commercially available that have varying sensitivities and specificities for colorectal neoplasia. These include guaiac-based fecal occult blood tests (gFOBT) (eg, Hemoccult I and II and Hemoccult SENSA) that detect the pseudoperoxidase activity of heme or hemoglobin and FITs that detect human globin. In clinical trials, FITs have proven superior to gFOBT in sensitivity for detection of colorectal cancer and advanced adenomas with similar specificity. Because FITs are not affected by diet or medications and have superior accuracy, the USMSTF now recommends their use instead of gFOBT.

Several FIT kits are commercially available. These tests are highly specific for detecting human globin and therefore eliminate the need for pretest dietary restrictions. In 19 clinical studies, the pooled sensitivity and specificity of FIT for colorectal cancer in average-risk patients were 79% and 94%, respectively. The optimal interval (yearly or every 2 years) and number of stool samples (one or two) required for optimal FIT testing is as yet undetermined. Currently, annual testing of a single stool sample is recommended.

FIT testing is the preferred option for population-based screening in various European and Australian programs. In the United States, it is offered as the preferred option by many healthcare plans. For healthcare systems in which screening colonoscopy is readily available, FIT is a suitable option for patients seeking a noninvasive screening test who are willing to undertake annual fecal testing. Patients with a positive FIT test must undergo further evaluation with colonoscopy.

2. Multitarget DNA assay—Stool DNA tests measure a variety of mutated genes and methylated gene markers from exfoliated tumor cells. A newer-generation assay (Cologuard) combines a fecal DNA panel with a FIT. In a prospective comparative trial conducted in persons at average risk for colorectal cancer undergoing colonoscopy, the sensitivity for colorectal cancer for Cologuard was 92.3% vs 73.8% for FIT alone and the sensitivity for adenomas larger than 1 cm or serrated polyps for Cologuard was 42.4% vs 23.8% for FIT alone. A positive stool DNA test requires colonoscopy evaluation. Compared with FIT testing alone, FIT-fecal DNA testing has disadvantages including higher cost, lower specificity, lower cost-effectiveness, and cumbersome requirements for stool collection and mailing. Hence, the 2017 USMSTF relegated it to Tier 2, noting that it may be recommended in patients age 50–65 years who seek a noninvasive test with high-sensitivity, due to acceptable specificity in this age group.

B. Endoscopic Examinations of the Colon

1. Colonoscopy—Colonoscopy permits examination of the entire colon. In addition to detecting early cancers, colonoscopy allows removal of adenomatous polyps by biopsy or polypectomy, which is believed to reduce the risk of subsequent cancer. Over the past decade, there has been a dramatic increase in screening colonoscopy, with over 60% of US adults screened in the past 10 years. In asymptomatic individuals between 50 and 75 years of age undergoing screening colonoscopy, the prevalence of advanced colonic neoplasia is 4–11% and of colon cancer is 0.1–1%.

Although colonoscopy is believed to be the most sensitive test for detecting adenomas and cancer, it has several disadvantages. To allow adequate visualization of the entire colonic mucosa, it requires thorough bowel cleansing the evening and morning prior to the examination. To alleviate discomfort during the procedure, intravenous sedation is used for most patients, necessitating a companion to transport the patient home post-procedure. Serious complications occur uncommonly; they include perforation (0.1%), bleeding (0.25%), and death (2.9/100,000).

The skill of the operator has a major impact upon the quality of the colonoscopy examination. In several studies, the rate of colorectal cancer within 3 years of a screening colonoscopy was 0.7–0.9%, ie, approximately 1 in 110 patients. This may be attributable to polyps and early cancers that were overlooked during the colonoscopy. Polyps that are small, flat, or located behind folds are easily missed, especially if the bowel preparation is poor. Population-based case-control and cohort studies suggest that colonoscopy is associated with greater reduction in colorectal cancer incidence and mortality in the distal colon (80%) than the proximal colon (40–60%). This may be attributable to incomplete examination of the proximal colon, and differences between the proximal and distal colon that include worse bowel preparation, suboptimal colonoscopic technique, and a higher prevalence of serrated polyps and flat adenomas. To optimize diagnostic accuracy as well as patient safety and comfort, colonoscopy should be performed after optimal bowel preparation by a well-trained endoscopist who spends sufficient time (at least 7 minutes) carefully examining the colon (especially the proximal colon) while withdrawing the endoscope.

2. Flexible sigmoidoscopy—Use of a 60-cm flexible sigmoidoscope permits visualization of the rectosigmoid and descending colon. Adenomatous polyps are identified in 10–20% and colorectal cancers in 1% of patients. The finding at sigmoidoscopy of an adenomatous polyp in the distal colon increases the likelihood at least twofold that an advanced neoplasm is present in the proximal colon.

The chief disadvantage of screening with flexible sigmoidoscopy is that it requires some bowel cleansing, it may be associated with some discomfort (since intravenous sedation is not used), and it does not examine the proximal colon. The prevalence of proximal versus distal neoplasia is higher in persons older than age 65 years, in African Americans, and in women. For these reasons, the 2017 USMSTF recommendations have placed flexible sigmoidoscopy among Tier 2 tests. If chosen, flexible sigmoidoscopy should be performed every 5–10 years.

C. Radiographic and Other Imaging of the Colon

1. CT colonography—Using helical CT with computer-assisted image reconstruction, two- and three-dimensional views can be generated of the colon lumen that simulate the view of colonoscopy (virtual colonoscopy). CT
Imaging of the colon can be performed by a variety of techniques, including colonoscopy, double-contrast barium enema, capsule colonoscopy, and CT colonography. Colonoscopy requires a similar bowel cleansing regimen as colonoscopy as well as insufflation of air into the colon through a rectal tube, which may be associated with discomfort. Nonetheless, this examination is performed rapidly and requires no sedation or intravenous contrast. Several large studies have compared the accuracy of virtual colonoscopy with colonoscopy for colorectal screening. Using current imaging software with multidetector helical scanners, the sensitivity is greater than 95% for the detection of cancer and greater than 84–92% for the detection of polyps 10 mm or larger. CT colonography is less sensitive than colonoscopy for the detection of polyps smaller than 1 cm, flat adenomas, and serrated polyps. Patients undergoing screening with CT colonography should be managed appropriately. If no polyps are found, the interval for repeat screening examination is uncertain; however, 5 years may be reasonable. All patients with polyps 10 mm or larger should be referred for colonoscopy with polypectomy because of the high prevalence (30%) of advanced pathology (cancer, high-grade dysplasia, or vil lous features) within these polyps. The optimal management of patients with polyps less than 10 mm in size is controversial. The USMSTF currently recommends that colonoscopy with polypectomy be offered to patients with one or more 6–9 mm polyps. Patients who refuse or who have increased risk of carcinoma should undergo surveillance CT colonography in 3–5 years. At the present time, there is no consensus on the management of patients with polyps smaller than 6 mm; however, some radiologists choose not even to report these findings.

The chief disadvantages of CT colonography are the need for a bowel preparation, limited availability in many health care systems, a possible increased risk of neoplasia due to radiation exposure, and the potential for finding incidental extracolonic findings that may lead to further evaluations. The 2017 USMSTF has therefore classified this as a Tier 2 screening option (Table 39–7). CT colonography is an excellent screening option in patients who do not wish to undergo or are unsuitable for colonoscopy and in patients in whom colonoscopy could not be completed.

2. Capsule colonoscopy—Imaging of the colon can be accomplished by oral ingestion of a capsule that captures video images of the colon. Compared with colonoscopy, the colon capsule has reduced sensitivity for polyps greater than 6 mm (64% vs 84%) and for colo rectal cancers (74% vs 100%). At present, it is approved by the FDA for evaluation in patients who are not suitable candidates for colonoscopy or in whom colonoscopy could not evaluate the proximal colon. In addition to its suboptimal sensitivity for neoplasia, the main disadvantages of capsule colonoscopy are its cost, need for extensive bowel preparation, lack of reimbursement by most insurance carriers, and small risk of small bowel obstruction. For these reasons, the 2017 USMSTF recommendations classified it a Tier 3 screening test, suitable for highly selected patients (Table 39–7).

3. Barium enema—Double-contrast barium enema was previously used as a screening technique because it was widely available, relatively inexpensive, and safe. However, compared to CT colonography, it is more time-consuming and difficult to perform, less comfortable, and less accurate. It can no longer be recommended for routine screening.

When to Refer

- Patients with symptoms (change in bowel habits, hema tochezia), signs (mass on abdominal examination or digital rectal examination [DRE]), or laboratory tests (iron deficiency anemia) suggestive of colorectal neoplasmia should be referred for colonoscopy.
- Patients with suspected colorectal cancer or adenomatous polyps of any size should be referred for colonoscopy.
- Virtually all patients with proven colorectal cancer should be referred to a surgeon for resection. Patients with clinical stage T3 or node-positive rectal tumors (or both) also should be referred to medical and radiation oncologists preoperatively for neoadjuvant therapy. Patients with stage II, III, or IV colorectal tumors should be referred to a medical oncologist.

When to Admit

- Patients with complications of colorectal cancer (obstruction, acute bleeding) requiring urgent evaluation and intervention.
- Patients with severe complications of chemotherapy.
- Patients with advanced metastatic disease requiring palliative care.

CHAPTER 39

PROSTATE CANCER

ESSENTIALS OF DIAGNOSIS

- Prostatic induration on DRE or elevation of PSA.
- Most often asymptomatic.
- Rarely: systemic symptoms (weight loss, bone pain).

General Considerations

Prostate cancer is the most common noncutaneous cancer detected in American men and the second leading cause of cancer-related death in men. In 2018, an estimated 164,690 new cases of prostate cancer were diagnosed and 29,420 associated deaths.
Clinical Findings

A. Symptoms and Signs

Prostate cancer may manifest as discrete nodules or areas of induration within the prostate on a DRE. However, currently most prostate cancers are detected because of elevations in serum PSA (not DRE findings).

Patients rarely present with signs of urinary retention or neurologic symptoms from epidural metastases and cord compression. Obstructive voiding symptoms are most often due to benign prostatic hyperplasia, which occurs in the same age group. Nevertheless, large or locally extensive prostatic cancers can cause obstructive voiding symptoms. Lymph node metastases can lead to lower extremity lymphedema. Because the axial skeleton is the most common site of metastases, patients may present with back pain or pathologic fractures.

B. Laboratory Findings

1. Serum tumor markers—PSA is a glycoprotein produced only by cells, either benign or malignant, of the prostate gland. The serum level is typically low and correlates with the total volume of prostate tissue and tends to increase with age. Measurement of serum PSA is useful in detecting and staging prostate cancer, monitoring response to treatment, and identifying recurrence before it becomes clinically evident. As a screening test, PSA is elevated (greater than 4.0 ng/mL [4.0 mcg/L]) in 10–15% of men. Prostate cancer will be diagnosed in approximately 18–30% of men with PSA 4.1–10 ng/mL (4.1–10 mcg/L) and 50–70% of men with PSA greater than 10 ng/mL (10 mcg/L). Patients with PSA less than 10 ng/mL usually have localized and therefore potentially curable cancers. Interestingly, approximately 20% of patients who undergo radical prostatectomy for localized prostate cancers have normal levels of PSA.

In untreated patients with prostate cancer, the level of PSA correlates with the volume and stage of disease. Whereas most organ-confined cancers are associated with PSA levels below 10 ng/mL (10 mcg/L), advanced disease (seminal vesicle invasion, lymph node involvement, or occult distant metastases) is more common in patients with PSA levels in excess of 40 ng/mL (40 mcg/L). Approximately 98% of patients with metastatic prostate cancer will have elevated PSA. However, there are rare cancers that are localized despite substantial elevations in PSA. Therefore, initial treatment decisions cannot be made on the basis of PSA testing alone. A rising PSA after therapy is usually consistent with progressive disease, either locally recurrent or metastatic.

2. Miscellaneous laboratory testing—Patients with urinary retention or with ureteral obstruction due to locally advanced prostate cancers may present with elevations in blood urea nitrogen or serum creatinine. Patients with bony metastases may have elevations in serum alkaline phosphatase or calcium. Laboratory and clinical evidence of disseminated intravascular coagulation can occur in patients with advanced prostate cancers.

3. Prostate biopsy—Transrectal ultrasound-guided biopsy is the standard method for detection of prostate cancer. The use of a spring-loaded, 18-gauge biopsy needle has allowed transrectal biopsy to be performed with minimal patient discomfort and morbidity. Local anesthesia is routinely used and increases the tolerability of the procedure. The specimen preserves glandular architecture and permits accurate grading. Prostate biopsy specimens are taken from the apex, mid-portions, and base in men who have an abnormal DRE or an elevated serum PSA, or both. Extended-pattern biopsies, including a total of at least 10 biopsies, are associated with improved cancer detection and risk stratification of patients with newly diagnosed disease. In addition, suspicious hypoechoic prostatic lesions seen on transrectal ultrasound may be targeted for biopsy. Patients with abnormalities of the seminal vesicles can have these structures specifically biopsied to identify local tumor invasion.

C. Imaging

Use of imaging should be tailored to the likelihood of advanced disease in newly diagnosed cases. Asymptomatic patients with well-differentiated to moderately differentiated cancers, thought to be localized to the prostate on DRE and transrectal ultrasonography and associated with modest elevations of PSA (ie, less than 10 ng/mL [10 mcg/L]), need no further imaging.

MRI allows for evaluation of the prostate as well as regional lymph nodes. The positive predictive value for detection of both capsular penetration and seminal vesicle invasion is similar for transrectal ultrasound and MRI, although newer multi-parametric MRI techniques may better stage patients considering treatment or, alternatively, active surveillance. Additionally, there is a growing role for multi-parametric MRI in prostate cancer diagnosis, particularly among men with previous negative prostate biopsies, to evaluate for suspicious prostatic lesions. Such lesions may then be sampled via MR-Fusion or MRI-guided biopsy. Such an approach may improve not only overall cancer detection but discovery of clinically relevant disease, and its use in routine clinical practice has increased and continues to evolve. CT plays little role in assessing local disease because of its inability to accurately identify or
stage prostate lymphatic cancers, but it is routinely used to detect regional lymphatic metastases in patients with greater than 10% risk of nodal involvement.

Conventional radionuclide (99-technetium) bone scans are superior to conventional plain skeletal radiographs in detecting bony metastases. Prostate cancer bone metastases tend to be multiple and most commonly occur in the axial skeleton. Men with more advanced local lesions, symptoms of metastases (eg, bone pain), high-grade disease, or elevations in PSA greater than 20 ng/mL (20 mcg/L) should undergo radionuclide bone scan. PET (eg, 18F-sodium fluoride [18F-NaF] PET) and 18F-NaF PET/CT hybrid imaging appear to be more sensitive than conventional bone scans. A high frequency of abnormal scans with 18F-NaF PET/CT resulting from degenerative joint disease, however, has resulted in a reduced enthusiasm for their use. PET imaging using fluciclovine (Axumin) has been approved for suspected cancer recurrence based on elevated PSA after prior treatment. Small molecules targeting PSMA (prostate-specific membrane antigen) also show significant promise as next-generation imaging agents (eg, 18F-DCFBC [N-[(S)-1,3-dicarboxypropyl]carbamoyl]-4-[18F-fluorobenzyl-L-cysteine], a low-molecular-weight radiotracer that targets PSMA). Intravenous urography and cystoscopy are not routinely needed to evaluate patients with prostate cancer.

Despite application of modern, sophisticated techniques, understaging of prostate cancer occurs in at least 20% of patients.

### Screening for Prostate Cancer

Whether screening for prostate cancer results in a decrease in its mortality rate is controversial. The screening tests currently available include DRE, PSA testing, and transrectal ultrasound. Prostate cancer detection rates using DRE alone vary from 1.5% to 7%, but unfortunately, most of these cancers are advanced (stage T3 or greater). Transrectal ultrasound should not be used as a first-line screening tool because of its expense, low specificity (and therefore high biopsy rate), and minimal improvement in detection rate when compared with the combined use of DRE and PSA testing.

PSA testing increases the detection rate of prostate cancers compared with DRE. Approximately 2–2.5% of men older than 50 years of age will be found to have prostate cancer using PSA testing compared with a rate of approximately 1.5% using DRE alone. The sensitivity, specificity, and positive predictive value of PSA and DRE are listed in Table 39–8. PSA-detected cancers are more likely to be localized compared with those detected by DRE alone. The Prostate Cancer Prevention Trial provided data demonstrating a significant risk of prostate cancer even in men with PSA less than 4.0 ng/mL (4.0 mcg/L) (Table 39–9) and a web-based calculator has been developed to estimate the risk of harboring both prostate cancer and high-grade cancer (http://riskcalc.org/PBCG).

To improve the performance of PSA as a screening test, several investigators have developed alternative methods for its use. These include establishment of age- and race-specific reference ranges, measurement of free serum and protein-bound levels of PSA (percent free PSA), and calculation of changes in PSA over time (PSA velocity).

Modified, with permission, from Kramer BS et al. Prostate cancer screening: what we know and what we need to know. Ann Intern Med. 1993 Nov 1;119(9):914–23. Copyright © 1993 American College of Physicians. All rights reserved.

Generally, men with PSA free fractions exceeding 25% are unlikely to have prostate cancer, whereas those with free fractions less than 10% have an approximately 50% chance of having prostate cancer. Newer tests, including the Prostate Health Index (PHI) and 4kscore (https://4kscore.com), may better identify not only men at greater risk for prostate cancer but those with more aggressive disease. The frequency of PSA testing also remains a matter of debate. The traditional yearly screening approach may not be the most efficient; rather, earlier PSA testing at younger age may allow less frequent testing later as well as provide information regarding PSA velocity. Studies from the Baltimore Longitudinal Study of Aging suggest that men with PSA above the age-based median when tested between 40 and 60 years are at significantly increased risk for subsequent cancer detection over 25 years. Men with lower PSA (0.6 ng/mL [0.6 mcg/L] aged 40–50 and 0.71 ng/mL [0.71 mcg/L] aged 50–60) may require less frequent PSA tests. In addition, men with PSA velocity greater than

<sup>1</sup>High-grade cancer was defined as Gleason score ≥ 7.

0.35 ng/mL (0.35 mcg/L) per year measured 10–15 years before diagnosis had significantly worse cancer-specific survival compared with those with lower PSA velocity. The NCCN guidelines (https://www.nccn.org/professionals/physician_gls/f_guidelines.asp) for prostate cancer early detection incorporate many of these factors (Figure 39–2). The European Association of Urology (EAU) recommends offering a baseline serum PSA to all men aged 40–45 years and subsequently initiating a risk-adapted strategy.

Two large, randomized trials question the benefit of screening men for prostate cancer. In the US Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial, no mortality benefit was observed after combined screening with PSA testing and DRE during 13-year follow-up. Although screening resulted in a 12% increase in prostate cancer detection, the cancer-specific mortality rate was similar in the screening and control arms (3.7 and 3.4 deaths per 10,000 person-years, respectively). Similarly, in the

![Figure 39–2. An algorithm for prostate cancer early detection. DRE, digital rectal examination; 5-ARI, 5-alpha-reductase inhibitor; PSAV, PSA velocity (ng/mL/year) calculated on at least three consecutive values over at least an 18- to 24-month period. (Based on NCCN guidelines, data from the Baltimore Longitudinal Study on Aging, and Prostate Cancer Prevention Trial.)](image-url)
European Randomized Study of Screening for Prostate Cancer (ERSPC) trial, the benefit of PSA screening was minimal with an absolute reduction of 1.28 prostate cancer deaths per 1000 men screened at 13-year follow-up. In 2018, the USPSTF issued a revised (Grade C) recommendation for men aged 55 to 69 years that the decision to undergo periodic PSA-based screening should be an individual one. Before deciding about screening, men should discuss its potential benefits and harms with their clinician, incorporating their own values and preferences in the decision. The revised recommendation acknowledges that, while screening offers some men a small potential benefit of reducing the chance of dying from prostate cancer, many other men will experience potential harms from screening. These include false-positive results that require additional testing and possible prostate biopsy; overdiagnosis and overtreatment; and treatment complications, such as incontinence and erectile dysfunction. In determining whether screening is appropriate in individual cases, the individual patient's family history, race/ethnicity, comorbid medical conditions, values about the benefits and harms of screening and treatment-specific outcomes, and other health needs should be considered. Clinicians should not screen men who do not express a preference for screening. For men age 70 years and older, the USPSTF recommends against PSA-based screening (Grade D recommendation).

**Staging**

The majority of prostate cancers are adenocarcinomas. Most arise in the peripheral zone of the prostate, though a small percentage arise in the central (5–10%) and transition zones (20%) of the gland. Pathologists utilize the Gleason grading system whereby a “primary” grade is applied to the architectural pattern of malignant glands occupying the largest area of the specimen and a “secondary” grade is assigned to the next largest area of cancer. Grading is based on architectural rather than histologic criteria, and five “grades” are possible. Adding the score of the primary and secondary grades gives a Gleason score from 2 to 10. Gleason score correlates with tumor volume, pathologic stage, and prognosis. A simplified five-grade group system has been introduced by the International Society of Urological Pathologists.

**Treatment**

**A. Active Surveillance**

The optimal treatment for patients with clinically localized prostate cancers remains controversial. A survival benefit of treating localized prostate cancer has not been conclusively demonstrated. Patients need to be advised of all treatment options, including active surveillance, with the specific benefits, risks, and limitations. The goal of active surveillance is to avoid treatment in men who may never require treatment while recognizing and definitively treating men harboring higher risk disease in order to balance cancer risk with the morbidity of treatment. Treatment decisions are made based on stage, PSA, and cancer grade (Gleason score) as well as the age and health of the patient. Active surveillance alone may be effective management for appropriately selected patients, typically those with low PSA, small volume, well-differentiated cancers, and life expectancy less than 10–15 years. For such patients, active surveillance involves serial PSA levels, DREs, and periodic prostate biopsies to reassess grade and extent of cancer. Endpoints for intervention in patients on active surveillance, particularly PSA changes, have not been clearly defined and surveillance regimens remain an active area of research. Nonetheless, they are increasingly accepted by patients and clinicians with contemporary series demonstrating freedom from definitive treatment in greater than half of patients at 5 years, and risk of developing metastases and suffering cancer-specific death in less than 3% and 2%, respectively, at 10 years. Active surveillance, which is distinguished from mere observation (watchful waiting), is featured prominently in the 2018 NCCN guidelines and may be the preferred management in most men with very low risk prostate cancer. This approach is increasingly accepted and incorporated in routine clinical practice.

**B. Radical Prostatectomy**

During radical prostatectomy, the seminal vesicles, prostate, and ampullae of the vas deferens are removed. Refinements in technique have allowed preservation of urinary continence in most patients and erectile function in selected patients. Radical prostatectomy can be performed via open retropubic, transperineal, or laparoscopic (with or without robotic assistance) surgery. Local recurrence is uncommon after radical prostatectomy and related to pathologic stage. Organ-confined cancers rarely recur; however, cancers with adverse pathologic features (capsular penetration, seminal vesicle invasion) are associated with higher local (10–25%) and distant (20–50%) relapse rates.

Ideal candidates for radical prostatectomy include healthy patients with stages T1 and T2 prostate cancers. Patients with advanced local tumors (T4) or lymph node metastases are rarely candidates for prostatectomy alone, although the surgery is sometimes used in combination with hormonal therapy and postoperative radiation therapy for select high-risk patients.

**C. Radiation Therapy**

Radiation can be delivered by a variety of techniques including use of external beam radiotherapy and transperineal implantation of radioisotopes. Morbidity is limited, and the survival of patients with localized cancers (T1, T2, and selected T3) approaches 65% at 10 years. As with surgery, the likelihood of local failure correlates with technique and cancer characteristics. The likelihood of a positive prostate biopsy more than 16 months after radiation varies between 20% and 60%. Patients with local recurrence are at an increased risk of cancer progression and cancer death compared with those who have negative biopsies. Ambiguous target definitions, inadequate radiation doses, and understaging of the cancer may be responsible for the failure noted in some series. Newer techniques of radiation (implantation, conformal therapy using three-dimensional reconstruction of CT-based tumor volumes, heavy particle, charged particle,
and heavy charged particle) may improve local control rates. **Three-dimensional conformal radiation** delivers a higher dose because of improved targeting and appears to be associated with greater efficacy as well as lower likelihood of adverse side effects compared with previous techniques. **Brachytherapy**—the implantation of permanent or temporary radioactive sources (palladium, iodine, or iridium) into the prostate—can be used as monotherapy in those with low-grade or low-volume malignancies or combined with external beam radiation in patients with higher-grade or higher-volume disease. The PSA may rise after brachytherapy because of prostate inflammation and necrosis. This transient elevation (PSA bounce) should not be mistaken for recurrence and may occur up to 20 months after treatment.

**D. Cryosurgery**

In cryosurgery, liquid nitrogen is circulated through small hollow-core needles inserted into the prostate under ultrasound guidance. The freezing process results in tissue destruction. The positive biopsy rate after cryosublation ranges between 7% and 23%.

**E. Localized Disease**

Although selected patients may be candidates for active surveillance based on age or health and evidence of small-volume or well-differentiated cancers, most men with an anticipated life expectancy of longer than 10 years should be considered for treatment. Newly introduced genomic tests may provide novel information to help guide treatment decisions. Both radiation therapy and radical prostatectomy result in acceptable levels of local control. A large, prospective, randomized trial compared watchful waiting with radical prostatectomy in 695 men with clinically localized and well-differentiated to moderately differentiated cancers. Radical prostatectomy significantly reduced disease-specific mortality, overall mortality, and risks of metastasis and local progression. The relative reduction in the risk of death at 23 years was 0.56 in the prostatectomy group, with the number needed to treat to avert one death (NNT) = 8 patients; the benefit was largest in men younger than age 65 years (relative risk [RR] = 0.45) and with intermediate-risk prostate cancer (RR = 0.38). Surgery also reduced the risk of metastases in older men (RR = 0.68).

**F. Locally and Regionally Advanced Disease**

Patients with advanced pathologic stage or positive surgical margins are at an increased risk for local and distant tumor relapse. Such patients are candidates for adjuvant therapy (radiation for positive margins and seminal vesicle invasion or androgen deprivation for lymph node metastases). Two randomized clinical trials (EORTC 22911 and SWOG 8794) have demonstrated improved progression-free and metastasis-free survival with early radiotherapy in these men, and subsequent analysis of SWOG 8794 showed improved overall survival in men receiving adjuvant radiation therapy. Evidence suggests that salvage radiotherapy after radical prostatectomy, within 2 years of PSA relapse, increases prostate cancer-specific survival in men with shorter PSA doubling time (less than 6 months).

Those with locally extensive cancers, including seminal vesicle and bladder neck invasion, are at increased risk for both local and distant relapse despite conventional therapy. A variety of investigational regimens are being tested in an effort to improve cancer outcomes in such patients. Combination therapy (androgen deprivation combined with surgery or irradiation), newer forms of irradiation, and hormonal therapy alone are being tested, as is neoadjuvant and adjuvant chemotherapy. Neoadjuvant and adjuvant androgen deprivation therapy combined with external beam radiation therapy have demonstrated improved survival compared with external beam radiation therapy alone for patients with intermediate- and high-risk disease.

**G. Metastatic Disease**

Since death due to prostate carcinoma is almost invariably the result of failure to control metastatic disease, research has emphasized efforts to improve control of distant disease. Most prostate carcinomas are hormone dependent and approximately 70–80% of men with metastatic prostate carcinoma will respond to various forms of androgen deprivation. **Androgen deprivation therapy** may be effective at several levels along the pituitary–gonadal axis using a variety of methods or agents (Table 39–10). Use of luteinizing hormone-releasing hormone (LHRH) agonists (leuprolide, goserelin) achieves medical castration without orchietomy and is the most common method of reducing testosterone levels. A single LHRH antagonist (degarelix) is FDA approved and has no short-term testosterone “flare” associated with LHRH agonists. Because of its rapid onset of action, ketoprofen should be considered in patients with advanced prostate cancer who present with spinal cord compression, bilateral ureteral obstruction, or disseminated intravascular coagulation. Although testosterone is the major circulating androgen, the adrenal gland secretes the androgens dehydroepiandrosterone, dehydroepiandrosterone sulfate, and androstenedione. This has led to attempts to suppress both testicular and adrenal androgens in an effort to achieve better initial and longer response. Accordingly, in patients with hormone-sensitive metastatic disease, complete androgen blockade, combining oral **abiraterone acetate** plus prednisone with use of an LHRH agonist/antagonist or orchiectomy, results in superior survival compared to LHRH agonist/antagonist therapy alone. Additionally, cytotoxic chemotherapy with docetaxel plus prednisone and androgen deprivation improves survival in patients with untreated high-volume hormone-sensitive metastatic disease. Nonsteroidal antiandrogen agents may be useful in the setting of the initial treatment of non-metastatic (PSA only) disease. They act by competitively binding the receptor for dihydrotestosterone, the intracellular androgen responsible for prostate cell growth and development. A meta-analysis of trials comparing the use of either an LHRH agonist or orchietomy alone with either in combination with an antiandrogen agent showed little benefit of combination therapy. However, patients at risk for disease-related symptoms (bone pain, obstructive voiding symptoms) should receive concurrent antiandrogens due to the initial elevation of serum testosterone that accompanies LHRH agonists. In addition to immediate side effects of androgen deprivation (sexual dysfunction and hot flashes),

LHRH, luteinizing hormone-releasing hormone.

The chronic suppression of testosterone leads to osteoporosis and risk of fractures, cardiovascular disease and diabetes mellitus, and decreased muscle and increased fat. Bisphosphonates can prevent osteoporosis associated with androgen deprivation, decrease bone pain from metastases, and reduce skeletal-related events. Denosumab, a RANK ligand inhibitor, is approved for the prevention of skeletal-related events in patients with bone metastases from prostate cancer and also appears to delay the development of these metastases in patients with castration-resistant prostate cancer. In addition, enzalutamide definitively improves metastasis-free survival in men with nonmetastatic castrate-resistant prostate cancer and rapidly rising PSA.

Docetaxel is the first cytotoxic chemotherapy agent to improve survival in patients with metastatic castration-resistant prostate cancer, which is defined as progressing disease despite a castrate level of serum testosterone of less than 50 ng/dL. Abiraterone (which targets CYP17, a key enzyme in androgen synthesis) and enzalutamide (a potent androgen receptor antagonist) have both demonstrated improvement in survival in metastatic castration-resistant prostate cancer patients and can be used prior to or following docetaxel. Sipuleucel-T, an autologous cellular immunotherapy, is FDA approved in asymptomatic or minimally symptomatic men with metastatic castration-resistant prostate cancer. Cabazitaxel is a second-line taxane chemotherapy used in men who have already received docetaxel. Radium-223 dichloride is approved for the treatment of men with castration-resistant, symptomatic bone metastases, with significant improvements in both overall survival and time to skeletal-related events (eg, fractures and spinal cord compression).
Prognosis

The likelihood of success of active surveillance or treatment can be predicted using risk assessment tools that usually combine stage, grade, PSA level, and number and extent of positive prostate biopsies. Several web-based tools are available (eg, https://www.mskcc.org/nomograms/prostate). One of the most widely used is the Kattan nomogram; it incorporates cancer stage, grade, and PSA level to predict the likelihood that a patient will be disease-free after radical prostatectomy or radiation therapy.

The University of California San Francisco CAPRA nomogram (https://urology.ucsf.edu/research/cancer/prostate-cancer-risk-assessment-and-the-ucsf-capra-score) uses serum PSA, Gleason score, clinical stage, percent positive biopsies, and patient age in a point system to risk stratify and predict the likelihood of PSA recurrence 3 and 5 years after radical prostatectomy (Tables 39–11 and 39–12) as well as metastasis and prostate cancer-specific and overall survival. The CAPRA nomogram has been validated on large multicenter and international radical prostatectomy and radiation-treated cohorts.

The patterns of prostate cancer progression have been well defined. Small and well-differentiated cancers (Gleason grade 3) are usually confined within the prostate, whereas large-volume (greater than 4 mL) or poorly differentiated (Gleason grades 4 and 5) cancers are more often locally extensive or metastatic to regional lymph nodes or bone. Penetration of the prostate capsule by cancer is common and occurs along perineural spaces. Seminal vesicle invasion is associated with a high likelihood of regional or distant disease and disease recurrence. The most common sites of lymph node metastases are the obturator and internal iliac lymph node chains and of distant metastases, the axial skeleton.

### General Considerations

Bladder cancer is the second most common urologic cancer; it occurs more commonly in men than women (3:1:1), and the mean age at diagnosis is 73 years. Cigarette smoking and exposure to industrial dyes or solvents are risk factors for the disease and account for approximately 60% and 15% of new cases, respectively. In the United States, almost all primary bladder cancers (98%) are epithelial malignancies, usually urothelial cell carcinomas (90%). Adenocarcinomas and squamous cell carcinomas account for approximately 2% and 7%, respectively. The latter is often associated with schistosomiasis, vesical calculi, or prolonged catheter use.

### Clinical Findings

#### A. Symptoms and Signs

Hematuria—gross or microscopic, chronic or intermittent—is the presenting symptom in 85–90% of patients with bladder cancer. Irritative voiding symptoms (urinary frequency and urgency) occur in a small percentage of patients as a result of the location or size of the cancer. Most patients with bladder cancer do not have signs of the disease because of its superficial nature. Abdominal masses detected on bimanual examination may be present in patients with large-volume or deeply infiltrating cancers. Hematuria or palpable lymphadenopathy may be present in patients with metastatic disease, and lymphedema of the lower extremities results from locally advanced cancers or metastases to pelvic lymph nodes.

### B. Laboratory Findings

Urinalysis reveals microscopic or gross hematuria in the majority of cases. On occasion, hematuria is accompanied by pyuria. Anemia may be present in a small number of cases associated with ureteral obstruction. Anemia may occasionally be due to chronic blood loss or to bone marrow metastases. Exfoliated cells from normal and abnormal urothelium can readily be detected in voided urine specimens. Cytology can be useful to detect the disease initially or to detect its recurrence. Cytology is sensitive in detecting cancers of higher grade and stage (80–90%), but less so in detecting superficial or well-differentiated lesions (50%). There are numerous urinary tumor markers under investigation for screening, assessing recurrence, progression, prognosis, or response to therapy.

### C. Imaging

Bladder cancers may be identified as masses within the bladder using ultrasound, CT, or MRI. However, the presence of cancer is confirmed by cystoscopy and biopsy, with imaging primarily used to evaluate the upper urinary tract and to stage more advanced lesions.

### D. Cystourethroscopy and Biopsy

The diagnosis and staging of bladder cancers are made by cystoscopy and transurethral resection. If cystoscopy—performed usually under local anesthesia—confirms the presence of a bladder tumor, the patient is scheduled for transurethral resection under general or regional anesthesia. Random bladder and, on occasion, transurethral prostate biopsies are performed to detect occult disease in the bladder or elsewhere and potentially identify patients at greater risk for cancer recurrence and progression.

### Pathology & Staging

Grading is based on cellular features: size, pleomorphism, mitotic rate, and hyperchromatism. Bladder cancer staging is based on the extent (depth) of bladder wall penetration and the presence of regional or distant metastases.

The natural history of bladder cancer is based on two separate but related processes: cancer recurrence within the bladder and progression to higher-stage disease. Both are correlated with cancer grade and stage.

### Treatment

Patients with superficial cancers (Tis, Ta, T1) are treated with complete transurethral resection with selective use of a single dose intravesical chemotherapy immediately following resection. The subset of patients with carcinoma in situ (Tis) and those undergoing resection of large, high-grade, recurrent Ta lesions or T1 cancers are good candidates for additional intravesical therapy.
Patients with invasive (T2, T3) but still localized cancers are at risk for both nodal metastases and progression and require radical cystectomy or the combination of chemotherapy and selective surgery or irradiation due to the much higher risk of progression compared with patients with lower-stage lesions.

For patients with muscle invasive (T2 or greater) urothelial cell carcinoma, neoadjuvant systemic chemotherapy prior to radical cystectomy is superior to radical cystectomy alone. This is particularly important for higher-stage or bulky tumors in order to improve their surgical resectability.

A. Intravesical Chemotherapy

Immunotherapeutic or chemotherapeutic agents delivered directly into the bladder via a urethral catheter can reduce the likelihood of recurrence in those who have undergone complete transurethral resection. Most agents are administered weekly for 6–12 weeks. Efficacy may be increased by prolonging contact time to 2 hours. The use of maintenance therapy after the initial induction regimen is beneficial. Common agents include thiotepa, mitomycin, doxorubicin, valrubicin, and bacillus Calmette–Guérin (BCG), with the last being the only agent effective in reducing disease progression. Side effects of intravesical chemotherapy include irritative voiding symptoms and hemorrhagic cystitis. Patients in whom symptoms or infection develop from BCG may require antituberculous therapy.

B. Surgical Treatment

Although transurethral resection is the initial form of treatment for all bladder tumors since it is diagnostic, allows for proper staging, and controls superficial cancers, muscle-infiltrating cancers require more aggressive treatment. Partial cystectomy is indicated in selected patients with solitary lesions or those with cancer in a bladder diverticulum. Radical cystectomy entails removal of the bladder, prostate, seminal vesicles, and surrounding fat and peritoneal attachments in men and the bladder, uterus, cervix, urethra, anterior vaginal vault, and usually the ovaries in women. Bilateral pelvic lymph node dissection is performed in all patients.

Urinary diversion can be performed using a conduit of small or large bowel. However, continent forms of diversion avoid the necessity of an external appliance and can be considered in a significant number of patients.

C. Radiotherapy

External beam radiotherapy delivered in fractions over a 6- to 8-week period is generally well tolerated, but approximately 10–15% of patients will develop bladder, bowel, or rectal complications. Local recurrence is common after radiotherapy alone (30–70%) and it is therefore combined with systemic chemotherapy in an effort to reduce the need for radical cystectomy or to treat patients who are poor candidates for radical cystectomy.

D. Chemotherapy

Metastatic disease is present in 15% of patients with newly diagnosed bladder cancer, and metastases develop within 2 years in up to 40% of patients who were believed to have localized disease at the time of cystectomy or definitive radiotherapy. Cisplatin-based combination chemotherapy results in partial or complete responses in 15–45% of patients (see Table 39–2).

Combination chemotherapy has been used to decrease recurrence rates with both surgery and radiotherapy and to attempt bladder preservation in those treated with radiation. Neoadjuvant chemotherapy appears to benefit all patients with muscle-invasive disease prior to planned cystectomy. Chemotherapy should also be considered before surgery in those with bulky lesions or those suspected of having regional disease. Chemoradiation is best suited for those with T2 or limited T3 disease without ureteral obstruction. Alternatively, adjuvant chemotherapy has been used after cystectomy in patients at high risk for recurrence, such as those who have lymph node involvement or local invasion.

E. Immunotherapy

Anti–PD-L1 immunotherapy with atezolizumab is associated with response rates of 25–30% in locally advanced and metastatic bladder cancer. In many cases, however, the responses to therapy are durable. Atezolizumab has been approved as second-line therapy for urothelial cancer. Additional checkpoint inhibitors have since been approved, including the anti-PD-1 agents pembrolizumab and nivolumab and the anti-PD-L1 agents durvalumab and avelumab (Table 39–2) for patients with chemotherapy-refractory disease. Additionally, atezolizumab and pembrolizumab are approved as first-line therapy in patients with metastatic disease (PD-L1 positive tumors) or cisplatin ineligible patients (regardless of PD-L1 status).

Prognosis

The frequency of recurrence and progression are correlated with grade. Whereas progression may be noted in few low-grade cancers (19–37%), it is common with poorly differentiated lesions (33–67%). Carcinoma in situ is most often found in association with papillary bladder cancers. Its presence identifies patients at increased risk for recurrence and progression.

At initial presentation, approximately 50–80% of bladder cancers are superficial: stage Ta, Tis, or T1. When properly treated, lymph node metastases and progression are uncommon in such patients and survival is excellent (81%). Five-year survival of patients with T2 and T3 disease ranges from 50% to 75% after radical cystectomy. Long-term survival for patients with metastatic disease at presentation is rare.

When to Refer

- Refer all patients to a urologist. Hematuria often deserves evaluation with both upper urinary tract imaging and cystoscopy, particularly in a high-risk group (eg, older men).
- Refer when histologic diagnosis and staging require endoscopic resection of cancer.
- Metastatic urothelial cancer should be managed by a medical oncologist.
CANCERS OF THE URETER & RENAL PELVIS

Cancers of the ureter and renal pelvis are rare and occur more commonly in patients who have bladder cancer, Balkan nephropathy, or Lynch syndrome, who smoke, who were exposed to Thorotrast (a contrast agent with radioactive thorium in use until the 1960s), and who have a long history of analgesic abuse. The majority are urothelial cell carcinomas. Gross or microscopic hematuria is present in most patients; flank pain secondary to bleeding and obstruction occurs less commonly. As with bladder cancers, urinary cytology is often positive. The most common signs identified at the time of CT or intravenous urography include an intraluminal filling defect, unilateral nonvisualization of the collecting system, and hydronephrosis. Ureteral and renal pelvic tumors must be differentiated from calculi, blood clots, papillary necrosis, or inflammatory and infectious lesions. On occasion, upper urinary tract lesions are accessible for biopsy, fulguration, or resection using a ureteroscope. Treatment is based on the site, size, grade, depth of penetration, and number of cancers present. Most are excised with laparoscopic or open nephroureterectomy (renal pelvic and upper ureteral lesions) or segmental excision of the ureter (distal ureteral lesions). Endoscopic resection may be indicated in patients with limited renal function or focal, low-grade, cancers. Similar to urothelial bladder cancers, use of chemotherapy prior to surgery may improve outcomes.

B. Laboratory Findings
Contemporary studies suggest hematuria is present in less than 50% of patients. Erythrocytosis from increased erythropoietin production occurs in 5%, though anemia is more common; hypercalcemia may be present in up to 10% of patients. Staufer syndrome is a reversible syndrome of hepatic dysfunction (with elevated liver tests) in the absence of metastatic disease.

C. Imaging
Solid renal masses are often first identified by abdominal ultrasonography or CT. CT and MRI scanning are the most valuable imaging tests for renal cell carcinoma. These scans confirm the character of the mass and provide valuable staging information with respect to regional lymph nodes, renal vein or vena cava tumor thrombus, and adrenal or liver metastases. CT and MRI also provide valuable information regarding the contralateral kidney (function, bilaterality of neoplasm). Chest radiographs or CT exclude pulmonary metastases. Bone scans should be performed for large tumors and in patients with bone pain or elevated serum alkaline phosphatase levels. Brain imaging should be obtained in patients with high metastatic burden or in those with neurologic deficits.

Differential Diagnosis
Solid renal masses are renal cell carcinoma until proven otherwise. Other solid masses include renal angiomyolipomas (fat density usually visible by CT), renal pelvis urothelial cancers (more central location, involvement of the collecting system, positive urinary cytology), renal oncocytomas (indistinguishable from renal cell carcinoma preoperatively), renal abscesses, and adrenal tumors (superoanterior to the kidney).

Treatment
Surgical extirpation is the primary treatment for localized renal cell carcinoma. Patients with a single kidney, bilateral lesions, or significant medical renal disease should be considered for partial nephrectomy. Patients harboring a small tumor with a normal contralateral kidney and good kidney function are also candidates for partial nephrectomy, while radical nephrectomy is indicated in patients with cancers larger than 7 cm and those in whom partial nephrectomy is not technically feasible. Radiofrequency and cryosurgical ablation are alternative options instead of surgery in select patients with tumors less than 3–4 cm with similar risk of metastatic progression but higher risk of local recurrence. Active surveillance is warranted in select patients (significant comorbidity, short life-expectancy) and appears safe with low risk of 5-year systemic progression. Percutaneous biopsy can provide tumor histology and grade to help guide treatment decisions.

Cytotoxic chemotherapy has no role in the treatment of metastatic renal cell carcinoma. Historically, biologic response modifiers, such as interferon-alpha and interleukin-2 produced partial response rates of 15–20% and 15–35%, respectively (Table 39–2). Responders tend to have lower tumor burdens, metastatic disease confined to the lung, and a high-performance status. Two randomized trials demonstrating a survival benefit of cytoreductive nephrectomy followed by the use of systemic therapy—specifically, interferon-alpha—compared with the use of systemic therapy alone have led to the widespread adoption of cytoreductive nephrectomy. Patients most likely to benefit from cytoreduction are those with good performance status, lung only metastases, and good prognostic features. Presently, management strategies are based on tumor histology and patient risk (favorable, intermediate, and poor). Several targeted medications, specifically VEGF, Raf-kinase, and mTOR inhibitors, are effective (40–60% response rates) in patients with advanced kidney cancer (Table 39–2). These oral agents, which include sunitinib, pazopanib, cabozantinib, axitinib, and sorafenib, are generally well tolerated and particularly active for clear cell carcinoma. The appropriate timing and combination of these agents, with and without surgery and cytokine therapy, remain to be determined. Sunitinib is approved for adjuvant use after complete surgical resection in patients with adverse pathologic features. The mTOR inhibitors everolimus and temsirolimus are approved for use in patients with prior anti-VEGF therapy, as is the combination of lenvatinib and everolimus. Nivolumab is an approved immunotherapy for treating metastatic disease that has progressed despite antiangiogenic therapy, and the combination with ipilimumab proved superior to sunitinib in previously untreated intermediate- and poor-risk metastatic renal cell carcinoma. In 2017, the FDA granted breakthrough therapy designation to the combination of the PD-L1 inhibitor avelumab with the VEGF inhibitor axitinib (Table 39–2).

Prognosis
After radical or partial nephrectomy, tumors confined to the renal capsule (T1–T2) demonstrate 5-year disease-free survivals of 90–100%. Tumors extending beyond the renal capsule (T3 or T4) and node-positive tumors have 5-year disease-free survivals of 50–60% and 0–15%, respectively. One subgroup of patients with nonlocalized disease has reasonable long-term survival, namely, those with solitary resectable metastases. In this setting, radical nephrectomy with resection of the solitary metastasis results in 5-year disease-free survival rates of 15–30%.

When to Refer
- Refer patients with solid renal masses or complex cysts to a urologist for further evaluation.
- Refer patients with renal cell carcinoma to a urologic surgeon for surgical excision.
- Refer patients with metastatic disease to an oncologist and urologist.

OTHER PRIMARY TUMORS OF THE KIDNEY

Oncocytomas account for 3–5% of renal tumors, are usually benign, and are indistinguishable from renal cell carcinoma on preoperative imaging. These tumors are seen in other organs, including the adrenals, salivary glands, and thyroid and parathyroid glands.

Angiomyolipomas are rare benign tumors composed of fat, smooth muscle, and blood vessels. They are most commonly seen in patients with tuberous sclerosis (often multiple and bilateral) or in young to middle-aged women. CT scanning may identify the fat component, which is diagnostic for angiomyolipoma. Asymptomatic lesions less than 5 cm in diameter usually do not require intervention; large lesions can spontaneously bleed. Acute bleeding can be treated by angiographic embolization or, in rare cases, nephrectomy. Lesions over 5 cm are often prophylactically treated with angiembolization to reduce the risk of bleeding.

SECONDARY CANCERS OF THE KIDNEY

The kidney is not an infrequent site for metastatic disease. Of the solid tumors, lung cancer is the most common (20%), followed by breast (10%), stomach (10%), and the contralateral kidney (10%). Lymphoma, both Hodgkin and non-Hodgkin, may also involve the kidney, although it tends to appear as a diffusely infiltrative process resulting in renal enlargement rather than a discrete mass.

TESTICULAR CANCERS (Germ Cell Tumors)

Most common neoplasm in men aged 20–35 years. Patient typically discovers a painless nodule. Orchiectomy necessary for diagnosis.

General Considerations

Malignant tumors of the testis are rare, with approximately five to six cases per 100,000 males reported in the United States each year. Ninety to 95 percent of all primary testicular tumors are germ cell tumors and can be divided into two major categories: nonseminomas, including embryonal cell carcinoma (20%), teratoma (5%), choriocarcinoma (less than 1%), and mixed cell types (40%); and seminomas (35%). The lifetime probability of developing testicular cancer is 0.3% for an American male.

Approximately 5% of testicular cancers develop in a patient with a history of cryptorchism, with seminoma being the most common. However, 5–10% of these tumors occur in the contralateral, normally descended testis. The relative risk of development of malignancy is higher for the intra-abdominal testsis (1:20) and lower for the inguinal testsis (1:80). Placement of the cryptorchid testsis into the scrotum (orchidopexy) does not alter its malignant potential but does facilitate routine examination and cancer detection.

Testicular cancer is slightly more common on the right than the left, paralleling the increased incidence of cryptorchidism on the right side. One to 2 percent of primary testicular cancers are bilateral and up to 50% of these men have a history of unilateral or bilateral cryptorchidism. Primary bilateral testicular cancers may occur synchronously or asynchronously but tend to be of the same histology. Seminoma is the most common histologic finding in bilateral primary testicular cancers, while malignant lymphoma is the most common bilateral testicular tumor overall.

Clinical Findings

A. Symptoms and Signs

The most common symptom of testicular cancer is painless enlargement of the testis. Sensations of heaviness are not unusual. Patients are usually the first to recognize an abnormality, yet typical delay in seeking medical attention ranges from 3 to 6 months. Acute testicular pain resulting from intratesticular hemorrhage occurs in approximately 10% of cases. Ten percent of patients are asymptomatic at presentation, and 10% manifest symptoms relating to metastatic disease such as back pain (retroperitoneal metastases), cough (pulmonary metastases), or lower extremity edema (vena cava obstruction).

A discrete mass or diffuse testicular enlargement is noted in most cases. Secondary hydroceles may be present in 5–10% of cases. In advanced disease, supraclavicular adenopathy may be present, and abdominal examination may reveal a mass. Gynecomastia is seen in 5% of germ cell tumors.

B. Laboratory Findings

Several serum markers are important in the diagnosis and monitoring of testicular carcinoma, including human chorionic gonadotropin (hCG), alpha-fetoprotein, and lactate dehydrogenase. Alpha-fetoprotein is never elevated with pure seminomas, and while hCG is occasionally elevated in seminomas, levels tend to be lower than those seen with nonseminomas. Lactate dehydrogenase may be elevated with either type of tumor and is a marker for disease burden. Liver tests may be elevated in the presence of hepatic metastases, and anemia may be present in advanced disease.
C. Imaging

Scrotal ultrasound can readily determine whether a mass is intratesticular or extratesticular. Once the diagnosis of testicular cancer has been established by inguinal orchectomy, clinical staging of the disease is accomplished by chest, abdominal, and pelvic CT scanning.

Staging

Testicular cancer is staged using the TNM system created based on extent of cancer in the testis, status of regional lymph nodes, the presence of metastases in distant lymph nodes or other viscera, and serum levels of tumor markers. Based on these features, germ cell tumors can be grouped to assign an overall stage: stage I lesion is confined to the testis; stage II demonstrates regional lymph node involvement in the retroperitoneum; and stage III indicates distant metastasis.

Differential Diagnosis

An incorrect diagnosis is made at the initial examination in up to 25% of patients with testicular tumors. Scrotal ultrasonography should be performed if any uncertainty exists with respect to the diagnosis. Although most intratesticular masses are malignant, a benign lesion—epidermoid cyst—may rarely be seen. Epidermoid cysts are usually very small benign nodules located just underneath the tunica albuginea; occasionally, however, they can be large. Testicular lymphoma is discussed below.

Treatment

Inguinal exploration with early vascular control of the spermatic cord structures is the initial intervention. If cancer cannot be excluded by examination of the testis, radical orchectomy is warranted. Scrotal approaches and open testicular biopsies should be avoided. Further therapy depends on the histology of the tumor as well as the clinical stage.

Patients with clinical stage I seminomas are candidates for surveillance, single-agent carboplatin, or adjuvant radiotherapy. Stage IIA and IIB seminomas (retroperitoneal disease less than 2 cm diameter in IIA and 2–5 cm in IIB) are treated by radical orchectomy and retroperitoneal irradiation. Retroperitoneal lymph node dissection is being studied as an alternative to radiation for stage IIA and IIB seminoma. Seminomas of stage IIC (greater than 5-cm-diameter retroperitoneal nodes) and stage III receive primary chemotherapy (etoposide and cisplatin or cisplatin, etoposide, and bleomycin) (Table 39–2). After chemotherapy, surgical resection of residual retroperitoneal nodes is warranted if the node is greater than 3 cm in diameter and positive on PET scan, since 40% will harbor residual carcinoma.

Up to 75% of clinical stage I nonseminomas are cured by orchectomy alone. Selected patients who meet specific criteria may be offered surveillance after orchectomy. These criteria are as follows: (1) cancer is confined within the tunica albuginea; (2) cancer does not demonstrate vascular invasion; (3) tumor markers normalize after orchectomy; (4) radiographic imaging of the chest and abdomen shows no evidence of disease; and (5) the patient is reliable. Patients most likely to experience relapse on a surveillance regimen include those with predominantly embryonal cancer and those with vascular or lymphatic invasion identified in the orchietomy specimen. Alternatives to surveillance for clinical stage I nonseminomas include adjuvant chemotherapy (bleomycin, etoposide, cisplatin) (see Table 39–2) or retroperitoneal lymph node dissection.

Following orchectomy, patients with bulky retroperitoneal disease (greater than 5-cm nodes) or metastatic nonseminomas are treated with combination chemotherapy (cisplatin and etoposide or cisplatin, etoposide, and bleomycin) (Table 39–2). If tumor markers normalize and a residual mass greater than 1 cm persists on imaging studies, it is resected because 15–20% will harbor residual cancer and 40% will harbor teratomas. Even if patients have a complete response to chemotherapy, some clinicians advocate retroperitoneal lymphadenectomy since 10% of patients may harbor residual carcinoma and 10%, retroperitoneal teratoma. If tumor markers fail to normalize following primary chemotherapy, salvage chemotherapy is required (cisplatin, etoposide, and ifosfamide).

Postoperative active surveillance by the clinician and patient means patients are followed up every 2–6 months for the first 2 years and every 4–6 months in the third year. For nonseminomas, tumor markers are obtained at each visit, and chest radiographs and abdominal and pelvic CT scans are obtained every 4–6 months. For seminomas, serum tumor markers may be obtained (optional), chest imaging is obtained only as clinically indicated, and abdominal and pelvic CT scans are performed every 3–6 months. Follow-up continues beyond the initial 3 years; however, 80% of relapses will occur within the first 2 years. With rare exceptions, patients who relapse can be cured by chemotherapy or surgery.

Prognosis

The 5-year disease-free survival rates for stage I and IIA seminomas (retroperitoneal disease less than 2 cm in diameter) treated by radical orchectomy and retroperitoneal irradiation are 98% and 92–94%, respectively. Ninety-five percent of patients with stage III disease attain a complete response following orchectomy and chemotherapy. The 5-year disease-free survival for patients with stage I nonseminomas (includes all treatments) ranges from 96% to 100%. For low-volume stage II disease, a 5-year disease-free survival of 90% is expected. Patients with bulky retroperitoneal or disseminated disease treated with primary chemotherapy followed by surgery have a 5-year disease-free survival rate of 55–80%.

When to Refer

Refer all patients with solid masses of the testis to a urologist and a medical oncologist if metastatic disease is suspected.

Clinical Findings

A. Symptoms and Signs

Back pain at the level of the tumor mass occurs in over 80% of cases and may be aggravated by lying down, weight bearing, sneezing, or coughing; it usually precedes the development of neurologic symptoms or signs. Since involvement is usually epidural, a mixture of nerve root and spinal cord symptoms often develops. Progressive weakness and sensory changes commonly occur. Bowel and bladder symptoms progressing to incontinence are late findings.

The initial findings of impending cord compression may be quite subtle, and there should be a high index of suspicion when back pain or weakness of the lower extremities develops in a cancer patient.

B. Imaging

MRI is usually the initial imaging procedure of choice in a cancer patient with new-onset back pain. If the back pain symptom is nonspecific, a whole-body PET scan with \(^{18}\)F-2-deoxyglucose may be a useful screening procedure. Bone radiographs are neither sensitive nor specific for the evaluation of a cancer patient with back pain. When neurologic findings suggest spinal cord compression, an emergent MRI should be obtained; the MRI should survey the entire spine to define all areas of tumor involvement for treatment planning purposes.

Treatment

Patients with a known cancer diagnosis found to have epidural impingement of the spinal cord should be given corticosteroids immediately. The initial dexamethasone dose is 10–100 mg intravenously followed by 4–6 mg every 6 hours intravenously or orally. Patients without a known diagnosis of cancer should have emergent surgery to relieve the impingement and obtain a pathologic specimen; preoperative corticosteroids should not be given since they might induce a tumor response and compromise the pathology results. Patients with solid tumors who have a single area of compression and who are considered candidates for surgery are best treated first with surgical decompression followed by radiation therapy. Better outcomes (ie, improved ability to ambulate and improved bladder and bowel function) occur in patients who undergo surgery followed by radiation therapy than in those who receive radiation alone. If multiple vertebral body levels are involved with cancer, fractionated radiation therapy is the preferred treatment option. Corticosteroids are generally tapered toward the end of radiation therapy. A scoring system exists for patients presenting with spinal cord metastases to identify those with poor survival times who would be best managed with supportive care or single fraction palliative radiation.

ESSENTIALS OF DIAGNOSIS

- Complication of metastatic solid tumor, lymphoma, or plasma cell myeloma.
- Back pain is most common presenting symptom.
- Prompt diagnosis is essential because once a severe neurologic deficit develops, it is often irreversible.
- Emergent treatment may prevent or potentially reverse paresis and urinary and bowel incontinence.

General Considerations

Cancers that cause spinal cord compression most commonly metastasize to the vertebral bodies, resulting in physical damage to the spinal cord from edema, hemorrhage, and pressure-induced ischemia to its vasculature. Persistent compression can result in irreversible changes to the myelin sheaths resulting in permanent neurologic impairment.

Prompt diagnosis and therapeutic intervention are essential, since the probability of reversing neurologic symptoms largely depends on the duration of symptoms. Patients who are treated promptly after symptoms appear may have partial or complete return of function and, depending on tumor sensitivity to specific treatment, may respond favorably to subsequent anticancer therapy.

MALIGNANT EFFUSIONS

ESSENTIALS OF DIAGNOSIS

- Occur in pleural, pericardial, and peritoneal spaces.
- Caused by direct neoplastic involvement of serous surface or obstruction of lymphatic drainage.
- Half of undiagnosed effusions in patients not known to have cancer are malignant.

General Considerations

The development of an effusion in the pleural, pericardial, or peritoneal space may be the initial finding in a patient with cancer, or an effusion may appear during the course of disease progression. Direct involvement of the serous surface with tumor is the most frequent initiating cause of the accumulation of fluid. The most common malignancies causing pleural and pericardial effusions are lung and breast cancers; the most common malignancies associated with malignant ascites are ovarian, colorectal, stomach, and pancreatic cancers.

Clinical Findings

A. Symptoms and Signs

Patients with pleural and pericardial effusions complain of shortness of breath and orthopnea. Patients with ascites complain of abdominal distention and discomfort. Cardiac tamponade causing pressure equalization in the chambers impairs both filling and cardiac output and can be life-threatening. Signs of tamponade include tachycardia, muffled heart sounds, pulsus paradoxus, and hypotension. Signs of pleural effusions include decreased breath sounds, egophony, and percussion dullness.

B. Laboratory Findings

Malignancy is confirmed as the cause of an effusion when analysis of the fluid specimen shows malignant cells in either the cytology or cell block specimen.

C. Imaging

The presence of effusions can be confirmed with radiographic studies or ultrasonography.

Differential Diagnosis

The differential diagnosis of a malignant exudative pleural or pericardial effusion includes nonmalignant processes, such as infection, pulmonary embolism, heart failure, and trauma.

Cancer

MALIGNANT EFFUSIONS

The differential diagnosis of malignant ascites includes similar benign processes, such as heart failure, cirrhosis, peritonitis, and pancreatic ascites.

Bloody effusions are usually due to cancer, but a bloody pleural effusion can also be due to pulmonary embolism, trauma and, occasionally, infection. Chylous pleural or ascitic fluid is generally associated with obstruction of lymphatic drainage as might occur in lymphomas.

Treatment

In some cases, treatment of the underlying cancer with chemotherapy can cause regression of the effusions; however, not uncommonly, the development of an effusion is an end-stage manifestation of the cancer. In this situation, decisions regarding management are in large part dictated by the patient's symptoms and goals of care.

A. Pleural Effusion

A pleural effusion that is symptomatic may be managed initially with a large volume thoracentesis. With some patients, the effusion slowly reaccumulates, which allows for periodic thoracentesis when the patient becomes symptomatic. However, in many patients, the effusion reaccumulates quickly, causing rapid return of shortness of breath. For those patients, two other management options exist. Chest tube drainage followed by pleurodesis involves placement of a chest tube that is connected to closed water seal drainage. After lung expansion is confirmed on a chest radiograph, a sclerosing agent (such as talc slurry or doxycycline) is injected into the catheter. Patients should be premedicated with analgesics and placed in a variety of positions in order to distribute the agent throughout the pleural spaces. Occasionally, spontaneous pleurodesis will occur with drainage ceasing and the chest tube can be removed. Pleurodesis will not be successful if the lung cannot be reexpanded. These patients are better managed with the second option of placement of an indwelling catheter that can be drained by a family member or a visiting nurse. This procedure may also be preferable for patients with short life expectancies or for those who do not respond to pleurodesis. Chest tube drainage followed by pleurodesis or placement of an indwelling catheter have essentially equivalent outcomes in terms of cost, relief of symptoms, and other measures of quality of life.

B. Pericardial Effusion

Fluid may be removed by a needle aspiration or by placement of a catheter for more thorough drainage. As with pleural effusions, most pericardial effusions will reaccumulate. Management options for recurrent, symptomatic effusions include prolonged catheter drainage (for several days until drainage has decreased to 20–30 mL/day) or surgical intervention such as a pericardiectomy.

C. Malignant Ascites

Patients with malignant ascites not responsive to chemotherapy are generally treated with repeated large-volume therapy are generally treated with repeated large-volume
paracenteses. As the frequency of drainage to maintain comfort can compromise the patient’s quality of life, other alternatives include placement of a catheter or port so that the patient, family member, or visiting nurse can drain fluid as needed at home. For patients with portal hypertension from large hepatic masses, diuretics (such as spironolactone 100 mg with furosemide 20–40 mg orally daily) may be useful to decrease the need for repeated paracenteses.

HYPERCALCEMIA

ESSENTIALS OF DIAGNOSIS

- Usually symptomatic and severe (15 mg/dL [3.75 mmol/L] or more).
- Most common paraneoplastic endocrine syndrome; accounts for most inpatients with hypercalcemia.
- The neoplasm is clinically apparent in nearly all cases when hypercalcemia is detected.

General Considerations

Hypercalcemia affects 20–30% of cancer patients at some point during their illness. The most common cancers causing hypercalcemia are myeloma, breast carcinoma, and NSCLC. Hypercalcemia is caused by one of three mechanisms: systemic effects of tumor-released proteins, direct osteolysis of bone by tumor, or vitamin D–mediated osteoabsorption.

Clinical Findings

A. Symptoms and Signs

Symptoms and signs of hypercalcemia can be subtle; more severe symptoms occur with higher levels of hypercalcemia and with a rapid rate at which the calcium level rises. Early symptoms typically include anorexia, nausea, fatigue, constipation, and polyuria; later findings may include muscular weakness and hyporeflexia, confusion, psychosis, tremor, and lethargy.

B. Laboratory Findings

Symptoms and signs are caused by free calcium; as calcium is bound by protein in the serum, the measured serum calcium will underestimate the free or ionized calcium in patients with low albumin levels. In the setting of hypoalbuminemia, the corrected serum calcium should be calculated by one of several available formulas (eg, corrected calcium = measured calcium – measured albumin + 4). Alternatively, the free ionized calcium can be measured. When the corrected serum calcium rises above 12 mg/dL (3 mmol/L), especially if the rise occurs rapidly, sudden death due to cardiac arrhythmia or asystole may occur. The presence of hypercalcemia does not invariably indicate a dismal prognosis, especially in patients with breast cancer, myeloma, or lymphoma.

In the absence of symptoms or signs of hypercalcemia, a laboratory finding of elevated serum calcium should be retested immediately to exclude the possibility of error.

C. ECG

Electrocardiography in hypercalcemia often shows a shortening of the QT interval.

Treatment

Emergency management should begin with the initiation of intravenous fluids with 0.9% saline at 100–300 mL/h to ensure rehydration with brisk urinary output of the often volume-depleted patient. If kidney function is normal or only marginally impaired, a bisphosphonate should be given. Choices include pamidronate, 60–90 mg intravenously over 2–4 hours, zoledronic acid, 4 mg intravenously over 15 minutes, or ibandronate, 2–4 mg intravenously over 2 hours. Zoledronic acid is more potent than pamidronate and has the advantage of a shorter administration time as well as a longer duration of effect, but with repeated dosing, it is more often associated with the very uncommon but serious side effect of osteonecrosis of the jaw. Once hypercalcemia is controlled, treatment directed at the cancer should be initiated if possible. However, hypercalcemia can occur in patients with cancers that are unresponsive to treatment. In the event that the hypercalcemia becomes refractory to repeated doses of bisphosphonates, other agents that can help control hypercalcemia (at least temporarily) include calcitonin and denosumab; corticosteroids can be useful in patients with myeloma and lymphoma. Salmon calcitonin, 4–8 international units/kg given subcutaneously or intramuscularly every 12 hours, can be used in patients with severe, symptomatic hypercalcemia; its onset of action is within hours but its hypocalcemic effect wanes in 2–3 days. Denosumab, 120 mg given subcutaneously weekly for 4 weeks followed by monthly administration, is a choice for long-term management of bisphosphonate-refractory hypercalcemia or for patients with kidney dysfunction that precludes use of a bisphosphonate.

HYPERURICEMIA & TUMOR LYSIS SYNDROME

ESSENTIALS OF DIAGNOSIS

- Complication of treatment-associated tumor lysis of hematologic and rapidly proliferating malignancies.
- May be worsened by thiazide diuretics.
- Rapid increase in serum uric acid can cause acute urate nephropathy from uric acid crystallization.
- Reducing pre-chemotherapy serum uric acid is fundamental to preventing urate nephropathy.

General Considerations

Tumor lysis syndrome (TLS) is seen most commonly following treatment of hematologic malignancies, such as acute lymphoblastic leukemia and Burkitt lymphoma. However, TLS can develop from any tumor highly sensitive to chemotherapy. TLS is caused by the massive release of cellular material including nucleic acids, proteins, phosphorus, and potassium. If both the metabolism and excretion of these breakdown products are impaired, hyperuricemia, hyperphosphatemia, and hyperkalemia will develop abruptly. Acute kidney injury may then develop from the crystallization and deposition of uric acid and calcium phosphate within the renal tubules further exacerbating the hyperphosphatemia and hyperkalemia.

Clinical Findings

Symptoms of hyperphosphatemia include nausea and vomiting as well as seizures. Also, with high levels of phosphorus, co-precipitation with calcium can cause renal tubule blockage, further exacerbating the kidney injury. Hyperkalemia, due to release of intracellular potassium and impaired kidney excretion, can cause arrhythmias and sudden death.

Treatment

Prevention is the most important factor in the management of TLS. Aggressive hydration prior to initiation of chemotherapy as well as during and after completion of the chemotherapy helps keep urine flowing and facilitates excretion of uric acid and phosphorus. In addition, for patients at moderate risk for developing TLS, eg, those with intermediate-grade lymphomas and acute leukemias, allopurinol should be given before starting chemotherapy at an oral dose of 200 mg/m² every 8 hours (maximum 800 mg/day) with dose reductions for impaired kidney function. Rasburicase 0.1–0.2 mg/kg/day is given intravenously for 1–7 days to patients at high risk for developing TLS, eg, those with high-grade lymphomas or acute leukemias with markedly elevated white blood cell counts (acute myeloid leukemia, white blood cell count greater than 50,000/mcL [50,000/10⁹/L]; acute lymphoblastic leukemia, white blood cell count greater than 100,000/mcL [100,000/10⁹/L]; or chronic lymphocytic leukemia with large lymph nodes [10 cm or larger] or nodes 5 cm or larger accompanied by white blood cell counts greater than 25,000/mcL [25,000/10⁹/L] and treated with venetoclax; or in any patient in whom hyperuricemia develops despite treatment with allopurinol). Rasburicase cannot be given to patients with known glucose 6-phosphate dehydrogenase (G6PD) deficiency nor can it be given to pregnant or lactating women. Systemic bicarbonate infusions to alkalinize the urine are not routinely recommended unless there is accompanying metabolic acidosis. In addition to the hyperuricemia, laboratory values should be monitored following initiation of chemotherapy; elevated potassium or phosphorus levels need to be promptly managed.

When to Refer

Should urinary output drop, serum creatinine or potassium levels rise, or hyperphosphatemia persist, a nephrologist should be immediately consulted to evaluate the need for dialysis.

INFECTIONS

Chapters 30 and 31 provide more detailed discussions of infections in the immunocompromised patient.

General Considerations

Many patients with disseminated neoplasms have increased susceptibility to infection. In some patients, this results from impaired defense mechanisms (eg, acute leukemia, Hodgkin lymphoma, plasma cell myeloma, chronic lymphocytic leukemia); in others, it results from the myelosuppressive and immunosuppressive effects of cancer chemotherapy or a combination of these factors. Complicating impaired defense mechanisms are the frequent presence of indwelling catheters, impaired mucosal surfaces, and colonization with more virulent hospital-acquired pathogens. The source of a neutropenic febrile episode is determined in about 30% of cases through blood, urine, or sputum cultures. The bacterial organisms accounting for
the majority of infections in cancer patients include gram-positive bacteria (coagulase-negative Staphylococcus, Staphylococcus aureus, Streptococcus pneumoniae, Corynebacterium, and streptococci) and gram-negative bacteria (Escherichia coli, Klebsiella, Pseudomonas, Enterobacter). Gram-positive organism infections are more common, but gram-negative infections are more serious and life-threatening. The risk of bacterial infections rises when the neutrophil count is below 500/mcL (0.5 × 10^9/L); the risk markedly increases when the count falls below 100/mcL (0.1 × 10^9/L) or when there is a prolonged duration of neutropenia, typically greater than 7 days.

**Clinical Findings**

A thorough physical examination should be performed. Routine DREs are generally avoided unless symptoms suggest a rectal abscess or prostatitis. If a DRE is necessary, antibiotics should be administered first. Appropriate cultures (eg, blood, sputum, urine and, if indicated, cerebrospinal fluid) should always be obtained. Two sets of blood cultures should be drawn before starting antibiotics; if the patient has an indwelling catheter, one of the cultures should be drawn from the line. A chest radiograph should also be obtained.

**Treatment**

Empiric antibiotic therapy needs to be initiated within 1 hour of presentation and following the collection of blood cultures in the febrile, neutropenic patient. The choice of antibiotics depends on a number of different factors including the patient’s clinical status and any localizing source of infection. If the patient is clinically well, monotherapy with an intravenous beta-lactam antibiotic (cefepime, ceftazidime, imipenem/cilastatin, piperacillin/tazobactam) should be started (see Infections in the Immunocompromised Patient, Chapter 30). If the patient is clinically ill with hypotension or hypoxia, an intravenous aminoglycoside or fluoroquinolone should be added for “double” gram-negative bacteria coverage. If there is a strong suspicion of a gram-positive organism, such as from S aureus catheter infection, intravenous vancomycin can be given empirically. Low-risk patients may be treated with oral antibiotics and even in the outpatient setting. The Infectious Diseases Society of America (IDSA) has published recommendations for such antibiotic use. These patients must have an expected neutropenic time frame of 7 days or less and have no comorbidities or signs of hemodynamic instability, gastrointestinal symptoms, altered mental status, pulmonary problems (infiltrate, hypoxia, or underlying chronic obstructive pulmonary disease), or liver or kidney disease or impairment. Patients should receive initial doses of empiric antibacterial therapy within 1 hour of being seen and monitored for at least 4 hours before discharge. If a patient is to be treated as an outpatient, he or she must also have good support at home and easy access to returning to the hospital if the clinical status worsens. If the patient does not defervesce with the broad-spectrum oral antibiotics, then the patient should be reevaluated for inpatient management.

Antibiotics should be continued until the neutrophil count is rising and greater than 500/mcL (0.5 × 10^9/L) for at least 1 day and the patient has been afebrile for 2 days. If an organism is identified through the cultures, the antibiotics should be adjusted to the antibiotic sensitivities of the isolate; treatment should be continued for the appropriate period of time and at least until the neutrophil count recovers and fever resolves.

For the neutropenic patient who is persistently febrile despite broad-spectrum antibiotics, an empiric antifungal drug should be added (amphotericin B, caspofungin, itraconazole, voriconazole, or liposomal amphotericin B).

**Clinical Findings**

A thorough physical examination should be performed. Routine DREs are generally avoided unless symptoms suggest a rectal abscess or prostatitis. If a DRE is necessary, antibiotics should be administered first. Appropriate cultures (eg, blood, sputum, urine and, if indicated, cerebrospinal fluid) should always be obtained. Two sets of blood cultures should be drawn before starting antibiotics; if the patient has an indwelling catheter, one of the cultures should be drawn from the line. A chest radiograph should also be obtained.

**Treatment**

Empiric antibiotic therapy needs to be initiated within 1 hour of presentation and following the collection of blood cultures in the febrile, neutropenic patient. The choice of antibiotics depends on a number of different factors including the patient’s clinical status and any localizing source of infection. If the patient is clinically well, monotherapy with an intravenous beta-lactam antibiotic (cefepime, ceftazidime, imipenem/cilastatin, piperacillin/tazobactam) should be started (see Infections in the Immunocompromised Patient, Chapter 30). If the patient is clinically ill with hypotension or hypoxia, an intravenous aminoglycoside or fluoroquinolone should be added for “double” gram-negative bacteria coverage. If there is a strong suspicion of a gram-positive organism, such as from *S. aureus* catheter infection, intravenous vancomycin can be given empirically. Low-risk patients may be treated with oral antibiotics and even in the outpatient setting. The Infectious Diseases Society of America (IDSA) has published recommendations for such antibiotic use. These patients must have an expected neutropenic time frame of 7 days or less and have no comorbidities or signs of hemodynamic instability, gastrointestinal symptoms, altered mental status, pulmonary problems (infiltrate, hypoxia, or underlying chronic obstructive pulmonary disease), or liver or kidney disease or impairment. Patients should receive initial doses of empiric antibacterial therapy within 1 hour of being seen and monitored for at least 4 hours before discharge. If a patient is to be treated as an outpatient, he or she must also have good support at home and easy access to returning to the hospital if the clinical status worsens. If the patient does not defervesce with the broad-spectrum oral antibiotics, then the patient should be reevaluated for inpatient management.

Antibiotics should be continued until the neutrophil count is rising and greater than 500/mcL (0.5 × 10^9/L) for at least 1 day and the patient has been afebrile for 2 days. If an organism is identified through the cultures, the antibiotics should be adjusted to the antibiotic sensitivities of the isolate; treatment should be continued for the appropriate period of time and at least until the neutrophil count recovers and fever resolves.

For the neutropenic patient who is persistently febrile despite broad-spectrum antibiotics, an empiric antifungal drug should be added (amphotericin B, caspofungin, itraconazole, voriconazole, or liposomal amphotericin B).

(continued)
therapy is to improve symptoms and quality of life, lowering doses to minimize toxicity is commonly done. However, when the goal of treatment is cure, dosing frequency and intensity should be maintained whenever possible.

A CBC including a differential count, with absolute neutrophil count and platelet count, and liver and kidney tests should be obtained before the initiation of chemotherapy. In patients with normal CBCs as well as normal liver and kidney function, drugs are started at their full dose. When the intent of chemotherapy is cure, including treatment in the adjuvant setting, every attempt should be made to schedule chemotherapy on time and at full dose. A CBC with differential may be checked at mid cycle (to determine the nadir of the absolute neutrophil and platelet counts), and liver and kidney function tests should be obtained immediately before the next cycle of chemotherapy.

Dose reductions may be necessary for patients with impaired kidney or liver function depending on the clearance mechanism of the drug. For patients receiving chemotherapy for palliation, bone marrow toxicity can be managed with dose reductions or delaying the next treatment cycle. A schema for dose modification is shown in Table 39–14.

1. Bone Marrow Toxicity

A. Neutropenia

Granulocyte colony-stimulating factor (G-CSF), given as either daily subcutaneous injections (eg, filgrastim, 300 mcg or 480 mcg) or as a one-time dose (pegfilgrastim, 6 mg) beginning 24 hours after cytotoxic chemotherapy is completed, reduces the duration and severity of granulocytopenia following cytotoxic chemotherapy (Table 39–13). The American Society of Clinical Oncology and NCCN guidelines recommend primary prophylaxis with G-CSF when there is at least a 20% risk of febrile neutropenia or when age, medical history, and disease characteristics put the patient at high risk for complications related to myelosuppression.

B. Anemia

Erythropoiesis-stimulating agents (ESAs) ameliorate the anemia and its associated symptoms caused by cancer chemotherapy but these drugs have untoward effects, including an increased risk of thromboembolism, and possibly decreased survival due to cancer-related deaths as well as a shortened time to tumor progression. The FDA recommends that these drugs should not be used when the intent of chemotherapy is curative. Administration of red blood cell transfusions is the alternative to managing symptomatic anemia in such patients.

ESAs can be an option in cancer patients with symptomatic anemia undergoing palliative treatment; patient preference is important in determining when to use ESAs or transfusions. When using ESAs, treatment should not be initiated until the hemoglobin is less than 10 g/dL (100 g/L) and the ESA held when the hemoglobin is greater than 12 g/dL (120 g/L). Epoetin alfa can be given subcutaneously at a dose of 40,000 units weekly or 150 units/kg three times weekly with a target hemoglobin of 11–12 g/dL (110–120 g/L). Darbepoetin alfa is given subcutaneously at a dose of 300–500 mcg every 3 weeks or 2.25 mcg weekly with the same target hemoglobin (see Table 39–13). To have maximum therapeutic effect, patients need to be iron replete. Uncontrolled hypertension is a contraindication to the use of ESAs; blood pressure must be controlled prior to initiation of this therapy.

C. Thrombocytopenia

Drug management of chemotherapy-induced thrombocytopenia is more limited. The only available drug, oprelvekin or recombinant interleukin-11, has modest activity in improving chemotherapy-related thrombocytopenia; however, it is rarely used due to the side effects of fluid retention, heart failure, and arrhythmias. Two drugs that activate the thrombopoietin receptor, romiplostim and eltrombopag, are FDA approved for use in idiopathic thrombocytopenia. Romiplostim is also approved for patients with thrombocytopenia related to interferon therapy of hepatitis C and for patients with aplastic anemia. While these agents have been used in

selected cases of refractory chemotherapy-related thrombocytopenia with some reports of success, trials to date have not demonstrated convincing efficacy in patients with chemotherapy-induced thrombocytopenia and neither agent is FDA approved for this indication.

2. Chemotherapy-Induced Nausea & Vomiting

A number of cytotoxic anticancer drugs can induce nausea and vomiting, which can be the most anticipated and stressful side effects for patients. Chemotherapy-induced nausea and vomiting is mediated in part by the stimulation of at least two central nervous system receptors, 5-hydroxytryptamine subtype 3 (5HT3) and neurokinin subtype 1 (NK1). Chemotherapy-induced nausea and vomiting can be anticipatory, occurring even before chemotherapy administration; acute, occurring within minutes to hours of chemotherapy administration; or delayed until the second day and lasting up to 7 days. Chemotherapy drugs are classified into high, moderate, low, and minimal likelihoods of causing emesis (90%, 30–90%, 10–30%, less than 10%, respectively). Highly emetogenic chemotherapy drugs include carboplatin, cisplatin, cyclophosphamide (at doses over 1.5 g/m2), dacarbazine, mechlorethamine, and streptozocin, or a combination of regularly dosed anthracyclines and cyclophosphamide. Moderately emetogenic chemotherapy drugs include alectumizumab, azacitadine, bendamustine, carboblatin, clofarabine, crizotinib, cyclophosphamide, cytarabine, daunomycin, doxorubicin, epirubicin, idarubicin, ifosfamide, irinotecan, mitotane, oxaliplatin, romidepsin, temozolomide, and vismodegib. Low emetogenic drugs include bortezomib, brenuximab, capcetabine, cabozantinib, dabrafenib, dasatinib, docetaxel, erlotinib, etoposide, fludarabine, fluorouracil, gemcitabine, hydroxyurea, ipilimumab, ixabepilone, lenalidomide, methotrexate, mitomycin, mitoxantrone, omacetaxine, paclitaxel, pemetrexed, pomalidomide, ponatinib, temsirilimus, trastuzumab, tremitamib, and topotecan. Drugs with minimal risk of emesis include bevacizumab, bleomycin, cetuximab, cladribine, decitabine, fludarabine, nivolumab, panitumumab, pembrolizumab, rituximab, temsirilimus, trastuzumab, vinblatine, vincristine, and vinorelbine.

Major advances have occurred in the development of highly effective antiemetic drugs. **Antagonists to the 5HT3-receptor** include alosetron, ondansetron, granisetron, dolasetron, and palonosetron, as well as tropisetron and ramosetron (neither yet available in the United States). Ondansetron can be given either intravenously (8 mg or 0.15 mg/kg) or orally (24 mg once before highly emetogenic chemotherapy, 8 mg twice daily for moderately emetogenic chemotherapy). Doses of 8 mg can be repeated parenterally or orally every 8 hours. Dosing of granisetron is 1 mg or 0.01 mg/kg intravenously or 1–2 mg orally. Dolasetron is given once as an oral 100-mg dose. Palonosetron, a long-acting 5HT3, with high affinity for the 5HT3-receptor, is given once at a dose of 0.25 mg intravenously, both for acute and delayed emesis. Where available, tropisetron is given at a dose of 5 mg either orally or intravenously and ramosetron, as a one-time 300-mcg dose intravenously. The efficacy of the 5HT3-blockers is improved by adding dexamethasone 10 mg once intravenously, then 4 mg orally or intravenously every 6 hours. As a class of drugs, the 5HT3-receptor antagonists have the potential to cause electrocardiogram changes, including QT prolongation. Before using these agents, hypokalemia or hypomagnesemia should be corrected. In addition, clinicians should be cautious when using these agents in patients who are elderly, who have preexisting bradycardias or heart failure, or who are taking medications known to prolong the QT interval.

Aprepitant, fosaprepitant, netupitant, palonosetron, and rolapitant are **antagonists to the NK1-receptor**. Aprepitant is given as a 125-mg oral dose followed by an 80-mg dose on the second and third day along with a 5HT3-receptor antagonist (such as ondansetron or granisetron) and dexamethasone to increase its immediate and delayed protective effect for highly emetogenic chemotherapy. Fosaprepitant, the intravenous formulation of the prodrug to aprepitant, can be given at a dose of 115 mg if followed by 2 days of apreptiant or at a dose of 150 mg if given alone. NEPA is a single-dose capsule consisting of a combination of netupitant and palonosetron. Rolapitant, a potent selective NK1-receptor antagonist, has a 7-day half-life; it is given as a one-time oral dose of 180 mg 1–2 hours before the start of moderately or highly emetogenic chemotherapy.

For highly emetogenic chemotherapy (eg, cisplatin), patients should be offered a four-drug regimen (a 5HT3-antagonist, dexamethasone, neurokinin-1 receptor antagonist, and olanzapine), all given on the first day (and if used, apreptiant given again on the second and third days with decadron and olanzapine continued on days 2–4. For moderately emetogenic chemotherapy, standard regimens include both three-drug regimens (an NK1-receptor antagonist, a 5HT3-antagonist, and dexamethasone) or a two-drug combination (5HT3-antagonist and dexamethasone). Palonosetron is the preferred 5HT3-blocker due to its greater affinity for the 5HT3-receptor and its longer half-life. For low emetogenic chemotherapy drugs, a single agent such as a 5HT3-antagonist or prochlorperazine or dexamethasone can be given. A 25-mg suppository form of prochlorperazine may be used for patients unable to swallow oral medications. Another medication that is helpful for anticipatory or refractory nausea and vomiting is olanzapine, 10 mg given orally once.

The importance of treating chemotherapy-induced nausea and vomiting expectantly and aggressively beginning with the first course of chemotherapy cannot be overemphasized. Patients being treated in the clinic setting should always be given antiemetics for home use with written instructions as well as contact numbers to call for advice.

3. Gastrointestinal Toxicity

Untoward effects of cancer chemotherapy include damage to the more rapidly growing cells of the body such as the mucosal lining from the mouth through the gastrointestinal tract. Oral symptoms range from mild mouth soreness to frank ulcerations. Not uncommonly, mouth ulcerations will have superimposed candida or herpes simplex infections. In addition to receiving cytotoxic chemotherapy, a significant risk factor for development of oral mucositis is poor oral hygiene and existing caries or periodontal disease. Toxicity in the gastrointestinal tract usually manifests as diarrhea. Gastrointestinal symptoms can range from
mild symptoms of loose stools to life-threatening diarrhea leading to dehydration and electrolyte imbalances. Drugs most commonly associated with causing mucositis in the mouth and the gastrointestinal tract are cytarabine, 5-fluorouracil, and methotrexate.

Patients undergoing treatment for head and neck cancer with concurrent chemotherapy and radiation therapy have a very high risk of developing severe mucositis.

Preventive strategies for oral mucositis include pretreatment dental care, particularly for all head and neck cancer patients and any cancer patient with poor dental hygiene who will be receiving chemotherapy. For patients receiving fluorouracil, simple measures such as ice chips in the mouth for 30 minutes during infusion can reduce the incidence and severity of mucositis. Once mucositis is encountered, superimposed fungal infections should be treated with topical antifungal medications (oral nystatin mouth suspensions, or clotrimazole troches) or systemic therapy (fluconazole 100–400 mg orally daily). Suspected herpetic infections can be treated with acyclovir (up to 800 mg orally five times daily) or valacyclovir (1 g orally twice daily). Mucositis may also be managed with mouthwashes; it is also important to provide adequate pain medication.

Other strategies for prevention of oral mucositis include the use of palifermin, the recombinant keratinocyte growth factor inhibitor. Prophylaxis with intravenous palifermin (60 mcg/kg/day) for patients receiving high-dose chemotherapy can reduce the incidence and duration of mucositis (Table 39–13).

Diarrhea is most associated with fluorouracil, capecitabine, and irinotecan as well as the tyrosine kinase inhibitors (dasatinib, imatinib, nilotinib, regorafenib, sorafenib, sunitinib) and epithelial growth factor inhibitors (cetuximab, erlotinib, panitumumab). Mild to moderate diarrhea can be managed with oral anti diarrheal medication (loperamide, 4 mg initially followed by 2 mg every 2–4 hours until bowel movements are formed). Occasionally, severe diarrhea will cause dehydration, electrolyte imbalances, and acute kidney injury; these patients require inpatient management with aggressive intravenous hydration and electrolyte replacement. Octreotide, 100–150 mcg subcutaneously three times daily, can be useful.

4. Skin Toxicity
Dermatologic complications from cancer chemotherapy can include hyperpigmentation (busulfan, hydroxyurea, liposomal doxorubicin), alopecia, photosensitivity, nail changes, acral erythema, and generalized rashes. Acral erythema (hand–foot syndrome), most commonly associated with administration of capecitabine, fluorouracil, and liposomal doxorubicin, manifests as painful palms or soles accompanied by erythema, progressing to blistering, desquamation, and ulceration in its worst forms. Strategies for prevention of acral erythema include oral pyridoxine, 200 mg daily, and applying cold packs to the extremities during chemotherapy administration. Agents targeting the epidermal growth factor pathway can cause an acne-like rash; the development of the rash may identify those who will respond to the drug. Inhibitors of the tyrosine kinase pathway are also associated with a high incidence of dermatologic complications, such as rash and acral erythema.

5. Miscellaneous Drug-Specific Toxicities
The toxicities of individual drugs are summarized in Tables 39–3 and 39–13; however, several of these toxicities warrant additional mention, since they occur with frequently administered agents, and special measures are often indicated.

A. Hemorrhagic Cystitis Induced by Cyclophosphamide or Ifosfamide
Patients receiving cyclophosphamide must maintain a high fluid intake prior to and following the administration of the drug and be counseled to empty their bladders frequently. Early symptoms suggesting bladder toxicity include dysuria and increased frequency of urination. Should microscopic hematuria develop, it is advisable to stop the drug temporarily or switch to a different alkylating agent, to increase fluid intake, and to administer a urinary analgesic such as phenazopyridine. The neutralizing agent, mesna, can be used for patients in whom cystitis develops. With severe cystitis, large segments of bladder mucosa may be shed, resulting in prolonged gross hematuria. Such patients should be observed for signs of urinary obstruction and may require cystoscopy for removal of obstructing blood clots. The cyclophosphamide analog ifosfamide can cause severe hemorrhagic cystitis when used alone. However, when its use is followed by a series of doses of the neutralizing agent mesna, bladder toxicity can be prevented (Table 39–13).

B. Neuropathy Due to Vinca Alkaloids and Other Chemotherapy Drugs
Neuropathy is caused by a number of different chemotherapy drugs, the most common being vincristine. The peripheral neuropathy can be sensory, motor, autonomic, or a combination of these types. In its mildest form, it consists of paresthesias of the fingers and toes. Occasionally, acute jaw or throat pain can develop as a form of trigeminal or glossopharyngeal neuralgia. With continued vincristine therapy, the paresthesias extend to the proximal interphalangeal joints, hyporeflexia appears in the lower extremities, and significant weakness can develop. Other drugs in the vinca alkaloid class as well as the taxane drugs (docetaxel and paclitaxel) and agents to treat myeloma (bortezomib and thalidomide) cause similar toxicity. The presence of neurologic symptoms is not in itself a reason to stop therapy; the severity of the symptoms must be balanced against the goals of therapy. Usually, though, the development of moderate to severe paresthesias or motor impairment results in the decision to discontinue the drug.

Constipation is the most common symptom of autonomic neuropathy associated with the vinca alkaloids. Patients receiving these drugs should be started on mild cathartics and other agents (Table 15–4); otherwise, severe impaction may result from an atomic bowel. More serious autonomic involvement can lead to acute intestinal obstruction with signs indistinguishable from those of an acute abdomen. Bladder neuropathies are uncommon but
may be severe. These two complications are absolute contraindications to continued vincristine therapy.

C. Methotrexate Toxicity

Methotrexate, a folate antagonist, is a commonly used component of regimens to treat patients with leptomeningeal disease, acute lymphoblastic leukemia, and sarcomas. Methotrexate is almost entirely eliminated by the kidney. Methotrexate toxicity affects cells with rapid turnover, including the bone marrow and mucosa resulting in myelosuppression and mucositis. Methotrexate can also damage the liver and kidney manifesting as elevated serum liver enzymes and creatinine. High-dose methotrexate, usually defined as a dose of 500 mg/m² or more given over 4–36 hours, would be lethal without “rescue” of the normal tissues. Leucovorin, a form of folate, will reverse the toxic effects of methotrexate and is given until serum methotrexate levels are in the safe range (less than 0.05 mmol/L). It is crucial that high-dose methotrexate and leucovorin are given precisely according to protocol as deviations of the timing of methotrexate delivery or delay in rescue can result in patient death. The dose used in intrathecal therapy is 12 mg. Lower doses of methotrexate can be problematic in patients with kidney disease who cannot clear the drug normally or in patients with effusions in which the drug distributes itself and leaks out continuously, exposing normal tissue to the drug. In a patient with kidney disease or an effusion, prolonged rescue with leucovorin is necessary.

Vigorous hydration and bicarbonate loading can help prevent crystallization of high-dose methotrexate in the renal tubular epithelium and consequent nephrotoxicity. Daily monitoring of the serum creatinine is mandatory. If possible, drugs impairing methotrexate excretion, such as aspirin, nonsteroidal anti-inflammatory drugs, amiodarone, omeprazole, penicillin, phenytoin, and sulfa, should be stopped before methotrexate administration.

D. Cardiotoxicity from Anthracyclines and Other Chemotherapy Drugs

A number of cancer chemotherapy drugs are associated with cardiovascular complications including traditional drugs such as anthracyclines as well as new targeted agents. The anthracycline drugs, including doxorubicin, daunorubicin, epirubicin, and idarubicin, can produce acute (during administration), subacute (days to months following administration), and delayed (years following administration) cardiac toxicity. The most feared complication is the delayed development of heart failure. Risk factors for this debilitating toxicity include the anthracycline cumulative dose, age over 70, previous or concurrent irradiation of the chest, preexisting cardiac disease, and concurrent administration of chemotherapy drugs such as trastuzumab. The problem is greatest with doxorubicin because it is the most commonly administered anthracycline due to its major role in the treatment of lymphomas, sarcomas, breast cancer, and certain other solid tumors. Patients receiving anthracyclines should have a baseline multiple-gated (MUGA) radionuclide cardiac scan to calculate the left ventricular-ejection fraction (LVEF). If the LVEF is greater than 50%, anthracyclines can be administered; if the LVEF is less than 30%, these drugs should not be given. For patients with intermediate values, anthracyclines can be cautiously given, if necessary, at lower doses with LVEF monitoring between doses. Changes in cardiac dynamics occur in most patients by the time they have received a total dose of 300 mg/m² of doxorubicin. In general, patients should not receive doses in excess of 450 mg/m²; the dose should be lower if prior chest radiotherapy has been given. The appearance of a high resting pulse may herald the appearance of overt cardiac toxicity. Unfortunately, toxicity may be irreversible and frequently fatal at total dosage levels above 550 mg/m². At lower doses (eg, 350 mg/m²), the symptoms and signs of cardiac failure generally respond well to medical therapy and discontinuation of the anthracycline. Doxorubicin and daunomycin have been formulated as liposomal products; these drugs, approved for use in patients with Kaposi sarcoma and sometimes in other cancers as a substitute for the conventional anthracyclines, appear to have minimal potential for cardiac toxicity.

As molecular mechanisms for cancer have been increasingly delineated, therapies have been developed that better target these mechanisms. Therapies targeting oncogenesis pathways include (1) HER2 inhibitors (lapatinib, pertuzumab, trastuzumab); (2) VEGF signaling pathway inhibitors (aliflurcept, axitinib, bevacizumab, cabozantinib, lenvatinib, pazopanib, ramucirumab, regorafenib, sorafenib, sunitinib, vandetanib); (3) multitargeted tyrosine kinase inhibitors (dasatinib, nilotinib, ponatinib); (4) protease inhibitors (bortezomib, carfilzomib); and (5) immune checkpoint inhibitors (ipilimumab, nivolumab, pembrolizumab). Many of the pathways targeted by these drugs share a common biologic pathway in cardiac tissue. Untoward cardiac events are being increasingly reported with these agents, including arrhythmias, cardiac ischemia, myocarditis, thrombosis, and heart failure. It is important to carefully monitor patients on these drugs and aggressively manage any modifiable cardiac risk factors (smoking, hyperlipidemia, diabetes mellitus, sedentary lifestyle).

E. Cisplatin Nephrotoxicity and Neurotoxicity

Cisplatin is effective in treating testicular, bladder, head and neck, lung, and ovarian cancers. With cisplatin, the serious side effects of nephrotoxicity and neurotoxicity must be anticipated and aggressively managed. Patients must be vigorously hydrated prior to, during, and after cisplatin administration. Both kidney function and electrolytes must be monitored. Low serum magnesium, potassium, and sodium levels can develop. The neurotoxicity is usually manifested as a peripheral neuropathy of mixed sensorimotor type and may be associated with painful paresthesias. Development of neuropathy typically occurs after cumulative doses of 300 mg/m². Ototoxicity is a potentially serious manifestation of neurotoxicity and can progress to deafness. Amifostine, given intravenously at a dose of 910 mg/m² over 15 minutes prior to cisplatin, is used to protect against nephrotoxicity and neuropathy. Use of amifostine does not
appear to compromise its antineoplastic effect. The second-generation platinum analog, carboplatin, is non-nephrotoxic, although it is myelosuppressive. In the setting of preexisting kidney disease or neuropathy, carboplatin is occasionally substituted for cisplatin.

F. Bleomycin Toxicity

See online text at www.accessmedicine.com/cmdt.

PROGNOSIS

Patients receiving chemotherapy for curative intent will often tolerate side effects with the knowledge that the treatment may result in eradication of their cancer. Patients receiving therapy for palliative intent often have their therapy tailored to improve quality of life while minimizing major side effects. A valuable sign of clinical improvement is the general well-being of the patient. Although general well-being is a combination of subjective (possibly partly a placebo effect) and objective factors, it nonetheless serves as a sign of clinical improvement along with improved appetite and weight gain and increased “performance status” (eg, ambulatory versus bedridden). Evaluation of factors such as activity status enables the clinician to judge whether the net effect of chemotherapy is worthwhile palliation (see Chapter 5).

ACUTE INTERMITTENT PORPHYRIA

ESSENTIALS OF DIAGNOSIS

- Unexplained abdominal crisis, generally in young women.
- Acute peripheral or central nervous system dysfunction; recurrent psychiatric illnesses.
- Hyponatremia.
- Porphobilinogen in the urine during an attack.

General Considerations

Though there are several different types of porphyrias, the one with the most serious consequences and the one that usually presents in adulthood is acute intermittent porphyria (AIP), which is inherited as an autosomal dominant condition, though it remains clinically silent in most patients who carry a mutation in HMBS. Clinical illness usually develops in women. Symptoms begin in the teens or 20s, but onset can begin after menopause in rare cases. The disorder is caused by partial deficiency of hydroxymethylbilane synthase activity, leading to increased excretion of aminolevulinic acid and porphobilinogen in the urine. The diagnosis may be elusive if not specifically considered. The characteristic abdominal pain may be due to abnormalities in autonomic innervation in the gut. In contrast to other forms of porphyria, cutaneous photosensitivity is absent in AIP. Attacks are precipitated by numerous factors, including drugs and intercurrent infections. Harmful and relatively safe drugs for use in treatment are listed in Table 40–1. Hyponatremia may be seen, due in part to inappropriate release of antidiuretic hormone, although gastrointestinal loss of sodium in some patients may be a contributing factor.

Clinical Findings

A. Symptoms and Signs

Patients show intermittent abdominal pain of varying severity, and in some instances, it may so simulate acute abdomen as to lead to exploratory laparotomy. Because the origin of the abdominal pain is neurologic, there is an absence of fever and leukocytosis. Complete recovery between attacks is usual. Any part of the nervous system may be involved, with evidence for autonomic and peripheral neuropathy. Peripheral neuropathy may be symmetric or asymmetric and mild or profound; in the latter instance, it can even lead to quadriplegia with respiratory paralysis. Other central nervous system manifestations include seizures, altered consciousness, psychosis, and abnormalities of the basal ganglia. Hyponatremia may further cause or exacerbate central nervous system manifestations.

B. Laboratory Findings

Often there is profound hyponatremia. The diagnosis can be confirmed by demonstrating an increased amount of porphobilinogen in the urine during an acute attack. Freshly voided urine is of normal color but may turn dark upon standing in light and air. Most families have different mutations in HMBS causing AIP. Mutations can be detected in 90% of patients and used for presymptomatic and prenatal diagnosis.

Prevention

Avoidance of factors known to precipitate attacks of AIP—especially drugs—can reduce morbidity. Sulfonamides and barbiturates are the most common culprits; others are listed in Table 40–1 and on the Internet (www.drugs-porphyria.org). Starvation diets or prolonged fasting also cause attacks and so must be avoided. Hormonal changes during pregnancy can precipitate crises.

### When to Admit

The patient should be hospitalized for an acute attack when accompanied by mental status changes, seizure, or hyponatremia.

### DOWN SYNDROME

**Essentials of Diagnosis**

- Typical craniofacial features (flat occiput, epicanthal folds, large tongue).
- Intellectual disability.
- Congenital heart disease (eg, atrioventricular canal defects) in 50% of patients.
- Alzheimer dementia in early-to-mid adulthood.
- Three copies of chromosome 21 (trisomy 21) or a chromosome rearrangement that results in three copies of a region of the long arm of chromosome 21.

### General Considerations

Nearly 0.5% of all human conceptions are trisomic for chromosome 21. Because of increased fetal mortality, birth incidence of Down syndrome is 1 per 700 but varies from 1 per 1000 in young mothers to more than three times as frequent in women of advanced maternal age. The presence of a fetus with Down syndrome can be detected in many pregnancies in the first or early second trimester through screening maternal serum for alpha-fetoprotein and other biomarkers (“multiple marker screening”) and by detecting increased nuchal thickness and underdevelopment of the nasal bone on ultrasonography. Prenatal diagnosis with high sensitivity and specificity can be achieved by assaying fetal DNA that is circulating in maternal blood. The chance of bearing a child with Down syndrome increases exponentially with the age of the mother at conception and begins a marked rise after age 35. By age 45 years, the odds of having an affected child are as high as 1 in 40. The risk of other conditions associated with trisomy also increases, because of the predisposition of older oocytes to nondisjunction during meiosis. There is little risk of trisomy associated with increased paternal age. However, older men do have an increased risk of fathering a child with a new autosomal dominant condition. Because there are so many distinct conditions, though, the chance of fathering an offspring with any given one is extremely small.

### Treatment

Treatment with a high-carbohydrate diet diminishes the number of attacks in some patients and is a reasonable empiric gesture considering its benignity. Acute attacks may be life-threatening and require prompt diagnosis, withdrawal of the inciting agent (if possible), and treatment with analgesics and intravenous glucose in saline and hematin. A minimum of 300 g of carbohydrate per day should be provided orally or intravenously. Electrolyte balance requires close attention. Hematin therapy should be undertaken with full recognition of adverse consequences, especially phlebitis and coagulopathy. The intravenous dosage is up to 4 mg/kg once or twice daily. Liver transplantation may provide an option for patients with disease poorly controlled by medical therapy.

### When to Refer

- For management of severe abdominal pain, seizures, or psychosis.
- For preventive management when a patient with porphyria contemplates pregnancy.
- For genetic counseling and molecular diagnosis.
**Clinical Findings**

**A. Symptoms and Signs**

Down syndrome is usually diagnosed at birth based on the typical craniofacial features, hypotonia, and single palmar crease. Several serious problems that may be evident at birth or may develop in early childhood include duodenal atresia, congenital heart disease (especially atrioventricular canal defects), and hematologic malignancy. The intestinal and cardiac anomalies usually respond to surgery. A transient neonatal leukemia generally responds to conservative management. The incidences of both acute lymphoblastic and myeloid leukemias are increased in childhood. Intelligence varies across a wide spectrum. Many people with Down syndrome do well in sheltered workshops and group homes, but few achieve full independence in adulthood. Other frequent complications include atlanto-axial instability, celiac disease, frequent infections due to immune deficiency, and hypothyroidism. An Alzheimer-like dementia usually becomes evident in the fourth or fifth decade. Patients with Down syndrome who survive childhood and who develop dementia have a reduced life expectancy; on average, they live to about age 55 years.

**B. Laboratory Findings**

Cytogenomic analysis should always be performed—even though most patients will have simple trisomy for chromosome 21—to detect unbalanced translocations; such patients may have a parent with a balanced translocation, and there will be a substantial recurrence risk of Down syndrome in future offspring of that parent and potentially that parent’s relatives.

**Treatment**

Duodenal atresia should be treated surgically. Congenital heart disease should be treated as in any other patient. Effective treatment does no long-term harm to neurodevelopment. As yet, no medical treatment has been proven to affect the neurodevelopmental or the neurodegenerative aspects. Based on the glutamatergic hypothesis for Alzheimer disease, studies have been initiated examining the potential benefit of the N-methyl-D-aspartate receptor antagonist memantine.

**When to Refer**

- For comprehensive evaluation of infants to investigate congenital heart disease, hematologic malignancy, and duodenal atresia.
- For genetic counseling of the parents.
- For signs of dementia in an adult patient.

**When to Admit**

A young patient should be hospitalized for failure to thrive, regurgitation, or breathlessness.

**ESSENTIALS OF DIAGNOSIS**

- Elevated serum total cholesterol and LDL cholesterol.
- Autosomal dominant inheritance.
- Mutation in *LRL*, *PCSK9*, or *APOB*.

**General Considerations**

Familial hypercholesterolemia (FH) is a group of autosomal dominant conditions that result in elevated low-density lipoprotein (LDL) levels in the blood. High LDL predisposes to atherosclerosis, which in turn leads to premature myocardial infarction or stroke. The incidence of these serious complications increases with age and when associated with the other common predispositions to atherosclerosis, such as smoking and hypertension. About 1 in 500 people in the United States have FH; worldwide, the prevalence is about 10 million. Only about 15% percent of people with FH are diagnosed and even fewer are treated effectively.

**Clinical Findings**

**A. Symptoms and Signs**

Yellow lipid deposits appear on tendons, especially the Achilles (tendon xanthoma).

**B. Laboratory Findings**

Total serum cholesterol with the LDL component is particularly high. A detailed family history and genetic testing should be obtained when individuals are younger than 40 years with an LDL level greater than 200 mg/mL and for individuals older than 40 years with a level greater than 250 mg/mL.
**Prevention**

In most instances, the elevated LDL is inherited as an autosomal dominant trait. An affected individual in all likelihood inherited FH from one parent, and each of his or her children has a 50/50 chance of inheriting FH. In uncommon cases, both parents have a mutation in the LDL receptor and one-quarter of their children, on average, will inherit two mutant alleles and have homozygous FH, which is a much more serious disease with manifestations in childhood.

Mutations in the following four genes can cause FH: (1) \( LDLR \), which encodes the LDL receptor located on the surface of cells and responsible for moving LDL into the cell for metabolism; the most common mutant gene in FH; (2) \( APOB \), which encodes a component of LDL and mutations inhibit binding to LDL receptor; (3) \( PCSK9 \), which encodes a protein that normally reduces production of LDL receptors, so mutations actually protect from hypercholesterolemia; and (4) \( ARH \), which requires mutations in both alleles (autosomal recessive inheritance) to cause FH.

DNA analysis for mutations in all of these genes is readily available.

**Treatment**

Statins, usually at high doses, can reduce LDL levels, occasionally to acceptable levels. If LDL levels remain elevated, other standard medications are required. The earlier in life that treatment is begun, the better the outcome in reducing mortality from atherosclerosis. In homozygous FH, if high-dose statins do not reduce LDL sufficiently, an inhibitor of PCSK9 is a recent option. If all else fails, then plasmapheresis is needed to reduce LDL.

Another important need in effective management is to screen relatives who are at risk, certainly by measuring LDL levels, but increasingly by identifying the mutation in the family and utilizing that for screening.

If these measures are not effective enough, treatment with an antibody that actually inhibits the product of the \( PCSK9 \) gene can be a quite expensive adjunct to standard therapy.

**When to Refer**

- For comprehensive evaluation of infants for their lipid profile.
- For genetic counseling of the patient, his or her parents, siblings, and offspring.
- For signs of atherosclerotic cardiovascular disease.

**When to Admit**

For signs or symptoms of acute arterial occlusive events.

**Clinical Findings**

**A. Symptoms and Signs**

This X-linked condition accounts for more cases of mental retardation in males than any condition except Down syndrome; about 1 in 4000 males is affected. The central nervous system phenotype includes autism spectrum, impulsivity and aggressiveness, and repetitive behaviors. The condition also affects intellectual function in females, although less severely and about 50% less frequently than in males. Affected (heterozygous) young women show no physical signs other than early menopause, but they may have learning difficulties, anxiety, sensory issues, or frank retardation. Affected males show macro-orchidism (enlarged testes) after puberty, large ears and a prominent jaw, a high-pitched voice, autistic characteristics, and mental retardation. Some males show evidence of a mild connective tissue defect, with joint hypermobility and mitral valve prolapse.

Women who are premutation carriers (55–200 CGG repeats) are at increased risk for premature ovarian failure and mild cognitive abnormalities. Male and female premutation carriers are at risk for mood and anxiety disorders and the development of tremor and ataxia beyond middle age (fragile-X tremor-ataxia syndrome, FXTAS). Changes in the cerebellar white matter may be evident on MRI before symptoms appear. Because of the relatively high prevalence of premutation carriers in the general population (1/130–1/600), older people in whom any of these behavioral or neurologic problems develop should undergo testing of the \( FMRI \) locus.

**B. Laboratory Findings**

The first marker for this condition was a small gap, or fragile site, evident near the tip of the long arm of the X chromosome.
Subsequently, the condition was found to be due to expansion of a trinucleotide repeat (CGG) near a gene called FMR1. All individuals have some CGG repeats in this location, but as the number increases beyond 52, the chances of further expansion during spermatogenesis or oogenesis increase.

Being born with one FMR1 allele with 200 or more repeats results in mental retardation in most men, and in about 60% of women. The more repeats, the greater the likelihood that further expansion will occur during gametogenesis; this results in anticipation, in which the disorder can worsen from one generation to the next.

Prevention

DNA diagnosis for the number of repeats has supplanted cytogenetic analysis for both clinical and prenatal diagnosis. This should be done on any male or female who has unexplained mental retardation. Newborn screening based on hypermethylation of the FMR1 gene is being considered as a means of early detection and intervention.

Treatment

Several treatments that address the imbalances in neurotransmission have been developed based on the mouse model and are in clinical trials. Valproic acid may reduce symptoms of hyperactivity and attention deficit, but standard therapies should be tried first.

When to Refer

- For otherwise unexplained mental retardation or learning difficulties in boys and girls.
- For otherwise unexplained tremor or ataxia in middle-aged individuals.
- For premature ovarian failure.
- For genetic counseling.

Clinical Findings

A. Symptoms and Signs

Gaucher disease has an autosomal recessive pattern of inheritance. A deficiency of beta-glucocerebrosidase causes an accumulation of sphingolipid within phagocytic cells throughout the body. Anemia and thrombocytopenia are common and may be symptomatic; both are due primarily to hypersplenism, but marrow infiltration with Gaucher cells may be a contributing factor. The abdomen can become painfully distended due to enlargement of the liver and spleen. Cortical erosions of bones, especially the vertebrae and femur, are due to local infarctions, but the mechanism is unclear. Episodes of bone pain (termed “crises”) are reminiscent of those in sickle cell disease. A hip fracture in a patient of any age with a palpable spleen—especially in a Jewish person of Eastern European origin—suggests the possibility of Gaucher disease. Peripheral neuropathy may develop in patients.

Two uncommon forms of Gaucher disease, called type II and type III, involve neurologic accumulation of sphingolipid and a variety of neurologic problems. Type II is of infantile onset and has a poor prognosis. Heterozygotes for Gaucher disease are at increased risk for developing Parkinson disease.

B. Laboratory Findings

Bone marrow aspirates reveal typical Gaucher cells, which have an eccentric nucleus and periodic acid–Schiff (PAS)-positive inclusions, along with wrinkled cytoplasm and inclusion bodies of a fibrillar type. In addition, the serum acid phosphatase is elevated. Definitive diagnosis requires the demonstration of deficient glucocerebrosidase activity in leukocytes. Hundreds of mutations have been found to cause Gaucher disease and some are highly predictive of the neuronopathic forms. Thus, mutation detection, especially in a young person, is of potential value. Only four mutations in glucocerebrosidase account for more than 90% of the disease among Ashkenazi Jews, in whom the carrier frequency is 1:15.

Prevention

Gaucher disease is the most common lysosomal storage disorder. Most clinical complications can be prevented by early institution of enzyme replacement therapy. Carrier screening, especially among Ashkenazi Jews, detects those couples at 25% risk of having an affected child. Prenatal diagnosis through mutation analysis is feasible. Because of an increased risk of malignancy, especially plasma cell myeloma and other hematologic cancers, regular screening of adults with Gaucher disease is warranted.

Treatment

A recombinant form of the enzyme glucocerebrosidase (imiglucerase) for intravenous administration on a regular basis reduces total body stores of glycolipid and improves orthopedic and hematologic manifestations. Unfortunately, the neurologic manifestations of types II and III have not improved with enzyme replacement therapy. The major drawback is the exceptional cost of imiglucerase, which can
exceed $300,000 per year for a severely affected adult patient. Eliglustat tartrate is an oral inhibitor of glucosylceramide synthase and reduces the compound that accumulates; while still quite expensive, this approach eliminates the need for frequent intravenous infusions. Early treatment of affected children normalizes growth and bone mineral density and improves liver and spleen size, anemia, and thrombocytopenia. In adults with thrombocytopenia due to sequestration, enzyme replacement often obviates the need for splenectomy.

**DISORDERS OF HOMOCYSTEINE METABOLISM**

**ESSENTIALS OF DIAGNOSIS**

- **Hyperhomocysteinemia:** more vascular disease but lowering homocysteine levels is not helpful.
- **Homocystinuria:** Marfan-like habitus, ectopia lentis, mental retardation, thromboses.
- **Elevated homocysteine in the urine or plasma.**

**General Considerations**

Patients with clinical and angiographic evidence of coronary artery disease and cerebrovascular and peripheral vascular diseases tend to have higher levels of plasma homocysteine than persons without these vascular diseases. Although this effect was initially thought to be due at least in part to heterozygotes for cystathionine beta-synthase deficiency (see below), there is little supporting evidence. Rather, an important factor leading to hyperhomocysteinemia is folate deficiency. Pyridoxine (vitamin B<sub>6</sub>) and vitamin B<sub>12</sub> are also important in the metabolism of methionine, and deficiency of any of these vitamins can lead to accumulation of homocysteine. A number of genes influence utilization of these vitamins and can predispose to deficiency. For example, having one—and especially two—copy of an allele that causes thermolability of methylene tetrahydrofolate reductase predisposes people to elevated fasting homocysteine levels. Both nutritional and most genetic deficiencies of these vitamins can be corrected by dietary supplementation of folic acid and, if serum levels are low, vitamins B<sub>6</sub> and B<sub>12</sub>. In the United States, cereal grains are fortified with folic acid. However, therapy with B vitamins and folate lowers homocysteine levels significantly but does not reduce the risk of either venous thromboembolism or complications of coronary artery disease. The role of lowering homocysteine as primary prevention for cardiovascular disease has received modest direct support in clinical trials. Hyperhomocysteinemia occurs with end-stage chronic kidney disease. In the general population, elevated homocysteine correlates with cognitive impairment.

**Clinical Findings**

**A. Symptoms and Signs**

Homocystinuria in its classic form is caused by cystathionine beta-synthase deficiency and exhibits autosomal recessive inheritance. This results in extreme elevations of plasma and urinary homocystine levels, a basis for diagnosis of this disorder. Homocystinuria is similar in certain superficial aspects to Marfan syndrome, since patients may have a similar body habitus and ectopia lentis is almost always present. However, mental retardation is often present in homocystinuria, and the cardiovascular events are those of repeated venous and arterial thromboses whose precise cause remains obscure. Thus, the diagnosis should be suspected in patients in the second and third decades of life who have arterial or venous thromboses without other risk factors. Bone mineral density is reduced in untreated patients. Life expectancy is reduced, especially in untreated and pyridoxine-unresponsive patients; myocardial infarction, stroke, and pulmonary embolism are the most common causes of death. This condition is diagnosed by newborn screening for hypermethioninemia; however, pyridoxine-responsive infants may not be detected. In addition, homozygotes for a common mutant allele, p.I278T, show marked clinical variability, with some unaffected as adults.

**B. Laboratory Findings**

Although many mutations have been identified in the cystathionine beta-synthase gene (CBS), amino acid analysis of plasma remains the most appropriate diagnostic test. Patients should be studied after they have been off folate or pyridoxine supplementation for at least 1 week. Relatively few laboratories currently provide highly reliable assays for homocysteine. Processing of the specimen is crucial to obtain accurate results. The plasma must be separated within 30 minutes; otherwise, blood cells release the amino acid and the measurement will then be artificially elevated.

**Prevention**

About 50% of patients have a form of cystathionine beta-synthase deficiency that improves biochemically and clinically through pharmacologic doses of pyridoxine
(50–500 mg/day) and folate (5–10 mg/day). For these patients, treatment from infancy can prevent retardation and the other clinical problems. Patients who are pyridoxine nonresponders must be treated with a dietary reduction in methionine and supplementation of cysteine, also from infancy. The vitamin betaine is also useful in reducing plasma methionine levels by facilitating a metabolic pathway that bypasses the defective enzyme.

**Treatment**

Patients with classic homocystinuria who have suffered venous thrombosis receive anticoagulation therapy, but there are no studies to support prophylactic use of warfarin or antiplatelet agents.

**KLINEFELTER SYNDROME**

**Clinical Findings**

**A. Symptoms and Signs**

Boys with an extra X chromosome are normal in appearance before puberty; thereafter, they have disproportionately long legs and arms, sparse body hair, a female escutcheon, gynecomastia, and small testes. Infertility is due to azoospermia; the seminiferous tubules are hyalinized. The incidence is 1 in 660 newborn males, but the diagnosis is often not made until a man is evaluated for inability to conceive. Intellectual disability is somewhat more common than in the general population. Many men with Klinefelter syndrome have language-based learning problems. However, their intelligence usually tests within the broad range of normal. As adults, detailed psychometric testing may reveal a deficiency in executive skills. The risk of osteoporosis, breast cancer, and diabetes mellitus is much higher in men with Klinefelter syndrome than in 46,XY men.

**B. Laboratory Findings**

Low serum testosterone is common. The karyotype is typically 47,XXY, but other sex chromosome anomalies cause variations of Klinefelter syndrome.

**Prevention**

Screening for cancer (especially of the breast), deep venous thrombosis, and glucose intolerance is indicated.

**Treatment**

Treatment with testosterone after puberty is advisable but will not restore fertility. However, men with Klinefelter syndrome have had mature sperm aspirated from their testes and injected into oocytes, resulting in fertilization. After the blastocysts have been implanted into the uterus of a partner, conception has resulted. But, men with Klinefelter syndrome do have an increased risk for aneuploidy in sperm, and therefore genomic analysis of a blastocyst should be considered before implantation.

**MARFAN SYNDROME**

**General Considerations**

Marfan syndrome, a systemic connective tissue disease, has an autosomal dominant pattern of inheritance. It is characterized by abnormalities of the skeletal, ocular, and cardiovascular systems; spontaneous pneumothorax; dural
ectasia; and striae atrophicae. Of most concern is disease of the ascending aorta, which begins as a dilated aortic root. Histology of the aorta shows diffuse medial degeneration. Mitral valve leaflets are also abnormal and mitral prolapse and regurgitation may be present, often with elongated chordae tendineae, which on occasion may rupture.

Clinical Findings

A. Symptoms and Signs

Affected patients are typically tall, with particularly long arms, legs, and digits (arachniodactyly). However, there can be wide variability in the clinical presentation. Commonly, scoliosis and anterior chest deformity, such as pectus excavatum, are found. Ectopia lentis is present in about half of patients; severe myopia is common and retinal detachment can occur. Mitral valve prolapse is seen in about 85% of patients. Aortic root dilation is common and leads to aortic regurgitation or dissection with rupture. To diagnose Marfan syndrome, people with an affected relative need features in at least two systems. People with no family history need features in the skeletal system, two other systems, and one of the major criteria of ectopia lentis, dilation of the aortic root, or aortic dissection. Patients with homocystinuria due to cystathionine beta-synthase deficiency also have dislocated lenses, tall, disproportionate stature, and thoracic deformity. They tend to have below normal intelligence, stiff joints, and a predisposition to arterial and venous occlusive disease. Males with Klinefelter syndrome do not show the typical ocular or cardiovascular features of Marfan syndrome and are generally sporadic occurrences in the family.

B. Laboratory Findings

Mutations in the fibrillin gene (FBN1) on chromosome 15 cause Marfan syndrome. Nonetheless, no simple laboratory test is available to support the diagnosis in questionable cases because related conditions may also be due to defects in fibrillin. The nature of the FBN1 mutation has little predictive value in terms of prognosis. The pathogenesis of Marfan syndrome involves aberrant regulation of transforming growth factor (TGF)-beta activity. Mutations in either of two receptors for TGF-beta (TGFBR1 and TGFBR2) can cause conditions that resemble Marfan syndrome in terms of aortic aneurysm and dissection and autosomal dominant inheritance. Mutations in more than two dozen other genes can predispose adults to thoracic aortic aneurysm and dissection.

Prevention

There is prenatal and presymptomatic diagnosis for patients in whom the molecular defect in FBN1 has been found.

Treatment

Children with Marfan syndrome require regular ophthalmologic surveillance to correct visual acuity and thus prevent amblyopia, and annual orthopedic consultation for diagnosis of scoliosis at an early enough stage so that bracing might delay progression. Patients of all ages require echocardiography at least annually to monitor aortic root diameter and mitral valve function. Long-term beta-adrenergic blockade, titrated to individual tolerance but enough to produce a negative inotropic effect (atenolol, 1–2 mg/kg orally daily), retards the rate of aortic dilation. While inhibition of the TGF-beta signaling pathway through angiotensin receptor blockade (ARB) in mice with Marfan syndrome is highly effective, ARB treatment in humans is no more effective than beta-adrenergic blockade. Calcium channel blockers, once used as a substitute for beta-blockade, are detrimental to the aorta. Restriction from vigorous physical exertion protects from aortic dissection. Prophylactic replacement of the aortic root with a composite graft when the diameter reaches 45–50 mm in an adult (normal: less than 40 mm) prolongs life. Earlier prophylactic surgery should be considered when there is a strong family history of aortic dissection or when the diameter of the aortic root increases more than 3–4 mm per year. A valve-sparing procedure resuspends the patient’s native aortic valve inside a graft that replaces the aneurysmal sinuses of Valsalva and ascending aorta, thus avoiding the need for lifelong anticoagulation. Women with Marfan syndrome are at heightened risk for aortic dissection in the peripartum and postpartum periods. Having an aortic root dimension greater than 40 mm should prompt consideration for prophylactic, valve-sparing aortic repair before undertaking a pregnancy.

Prognosis

People with Marfan syndrome who are untreated commonly die in the fourth or fifth decade from aortic dissection or heart failure secondary to aortic or mitral regurgitation. However, because of earlier diagnosis, lifestyle modifications, beta-adrenergic blockade, and prophylactic aortic and mitral valve surgery, life expectancy has increased by several decades.

When to Refer

- For detailed ophthalmologic examination.
- For at least annual cardioligic evaluation.
- For moderate scoliosis.
- For pregnancy in a woman with Marfan syndrome.
- For genetic counseling.

When to Admit

Any patient with Marfan syndrome in whom severe or unusual chest pain develops should be hospitalized to exclude pneumothorax and aortic dissection.

—

**HEREDITARY HEMORRHAGIC TELANGIECTASIA**

**ESSENTIALS OF DIAGNOSIS**

- Recurrent epistaxis.
- Mucocutaneous telangiectases.
- Visceral arteriovenous malformations (especially lung, liver, brain, bowel).

**Clinical Findings**

**A. Symptoms and Signs**

Hereditary hemorrhagic telangiectasia (HHT), formerly termed "Osler-Weber-Rendu syndrome," is an autosomal dominant disorder of development of the vasculature. Epistaxis may begin in childhood or later in adolescence. Punctate telangiectases of the lips, tongue, fingers, and skin generally appear in later childhood and adolescence. Arteriovenous malformations (AVMs) can occur at any age in the brain, lungs, and liver. Bleeding from the gastrointestinal tract is due to mucosal vascular malformations and usually is not a problem until mid-adult years or later. Pulmonary AVMs can cause hypoxemia (with peripheral cyanosis, dyspnea, and clubbing) and right-to-left shunting (with embolic stroke or brain abscess). The criteria for diagnosis require presence of three of the following four features: (1) recurrent epistaxis, (2) visceral AVMs, (3) mucocutaneous telangiectases, and (4) being the near relative of a clearly affected individual. Mutation analysis can be used for presymptomatic diagnosis or exclusion of the worry of HHT.

**B. Laboratory Findings**

MR or CT arteriography detects AVMs. Mutations in at least five genes can cause HHT. Three have been identified, and molecular analysis to identify them is available; these mutations in ENG, ALK1, and SMAD4 account for about 87% of families with HHT. When the familial mutation is known, molecular testing is far more cost effective than repeated clinical screening of relatives who are at risk.

**Prevention**

Embolization of pulmonary AVMs with wire coils or other occlusive devices reduces the risk of stroke and brain abscess. Treatment of brain AVMs reduces the risk of hemorrhagic stroke. All patients with HHT with evidence of a pulmonary shunt should practice routine endocarditis prophylaxis (see Table 33–3). All intravenous lines (except those for transfusion of red blood cells and radiographic contrast) should have an air-filter to prevent embolization of an air bubble. Prenatal diagnosis through mutation detection is possible.

**Treatment**

All patients in whom the diagnosis of HHT is considered should have an MRI of the brain with contrast. A contrast echocardiogram will detect most pulmonary AVMs when "bubbles" appear on the left side of the heart after 3–6 cardiac cycles. A positive contrast echocardiogram should be followed by a high-resolution CT angiogram for localization of pulmonary AVMs. Patients who have AVMs with a feeding artery of 2 mm diameter or greater should undergo embolization. After successful embolization of all treatable pulmonary AVMs, the CT angiogram should be repeated in 6 months and 3 years. A person with a negative contrast echocardiogram should have the test repeated every 5 years. Any person with a pulmonary AVM, even an embolized one, should utilize routine endocarditis prophylaxis. Several studies suggest that treatment with anti-estrogenic agents (eg, tamoxifen), thalidomide or its relatives, or anti-vascular endothelial growth factor agents (eg, bevacizumab) can reduce epistaxis and gastrointestinal bleeding and improve hepatic shunting. However, two randomized, controlled clinical trials of intranasal bevacizumab therapy failed to show an improvement in epistaxis.

Musculoskeletal problems account for about 10–20% of outpatient primary care clinical visits. Orthopedic problems can be classified as traumatic (ie, injury-related) or atraumatic (ie, degenerative or overuse syndromes) as well as acute or chronic. The history and physical examination are sufficient in most cases to establish the working diagnosis; the mechanism of injury is usually the most helpful part of the history in determining the diagnosis.

SHOULDER

1. Subacromial Impingement Syndrome

**ESSENTIALS OF DIAGNOSIS**
- Shoulder pain with overhead motion.
- Night pain with sleeping on shoulder.
- Numbness and pain radiation below the elbow are usually due to cervical spine disease.

**General Considerations**

The shoulder is a ball and socket joint. The socket is very shallow, however, which enables this joint to have the most motion of any joint. The shoulder, therefore, relies heavily on the surrounding muscles and ligaments to provide stability. The subacromial impingement syndrome describes a collection of diagnoses that cause mechanical inflammation in the subacromial space. Causes of impingement syndrome can be related to muscle strength imbalances, poor scapula control, rotator cuff tears, subacromial bursitis, and bone spurs.

With any shoulder problem, it is important to establish the patient's hand dominance, occupation, and recreational activities because shoulder injuries may present differently depending on the demands placed on the shoulder joint. For example, baseball pitchers with impingement syndrome may complain of pain while throwing. Alternatively, older adults with even full-thickness rotator cuff tears may not complain of any pain because the demands on the joint are low.

**Clinical Findings**

A. Symptoms and Signs

Subacromial impingement syndrome classically presents with one or more of the following: pain with overhead activities, nocturnal pain with sleeping on the shoulder, or pain on internal rotation (eg, putting on a jacket or bra). On inspection, there may be appreciable atrophy in the supraspinatus or infraspinatus fossa. The patient with impingement syndrome can have mild scapula winging or “dyskinesis.” The patient often has a rolled-forward shoulder posture or head-forward posture. On palpation, the patient can have tenderness over the anterolateral shoulder at the edge of the greater tuberosity. The patient may lack full active range of motion (Table 41–1) but should have preserved passive range of motion. Impingement symptoms can be elicited with the Neer and Hawkins impingement signs (Table 41–1).

B. Imaging

The following four radiographic views should be ordered to evaluate subacromial impingement syndrome: the anteroposterior (AP) scapula, the AP acromioclavicular joint, the lateral scapula (scapular Y), and the axillary lateral. The AP scapula view can rule out glenohumeral joint arthritis. The AP acromioclavicular view evaluates the acromioclavicular joint for inferior spurs. The scapula Y view evaluates the acromial shape, and the axillary lateral view visualizes the glenohumeral joint as well and for the presence of os acromiale.

MRI of the shoulder may demonstrate full- or partial-thickness tears or tendinosis. Ultrasound evaluation may demonstrate thickening of the rotator cuff tendons and tendinosis. Tears may also be visualized on ultrasound, although it is more difficult to identify partial tears from small full thickness than on MRI.

**Treatment**

A. Conservative

The first-line treatment for impingement syndrome is usually a conservative approach with education, activity modification, and physical therapy exercises.

<table>
<thead>
<tr>
<th>Maneuver</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Hawkins impingement sign</td>
<td>Perform with the shoulder forward flexed 90 degrees and the elbow flexed at 90 degrees. The shoulder is then maximally internally rotated to impinge the greater tuberosity on the undersurface of the acromion. The test is considered positive when the patient’s pain is reproduced by this maneuver. Sensitivity is 79%; specificity is 59%.</td>
</tr>
</tbody>
</table>

**Stability Testing**

<table>
<thead>
<tr>
<th>Apprehension test</th>
<th>With persistent anterior instability or a recent dislocation, the patient feels pain or guards when the shoulder is abducted and externally rotated at 90 degrees. With posterior instability, the patient is apprehensive with the shoulder forward flexed and internally rotated to 90 degrees with a posteriorly directed force.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Load and shift test</td>
<td>Perform to determine shoulder instability by manually translating the humeral head anteriorly and posteriorly in relation to the glenoid. However, this test can be difficult to perform when the patient is not relaxed.</td>
</tr>
<tr>
<td>O’Brien test</td>
<td>Performed to rule out labral cartilage tears that often occur following a shoulder subluxation or dislocation. The test involves flexing the patient’s arm to 90 degrees, fully internally rotating the arm so the thumb is facing down (palm down), and adducting the arm to 10 degrees. Once positioned properly, the clinician applies downward force and asks the patient to resist. The test is then repeated in the same position except that the patient has his arm fully supinated (palm up). A positive O’Brien test for labral tear is pain deep in the shoulder with palm down more than the palm up. The O’Brien test can also be used to identify AC joint pathology. The patient would typically complain equally of pain directly over the AC joint with the palm down or up.</td>
</tr>
</tbody>
</table>
Impingement syndrome can be caused by muscle weakness or tear. Rotator cuff muscle strengthening can alleviate weakness or pain, unless the tendons are seriously compromised, which may cause more symptoms. Physical therapy is directed at rotator cuff muscle strengthening, scapula stabilization, and postural exercises. There is no strong evidence supporting the effectiveness of ice and NSAIDs as a prolonged therapy. In a Cochrane review, corticosteroid injections produced slightly better relief of symptoms in the short term when compared with placebo. Most patients respond well to conservative treatment.

B. Surgical

Procedures include arthroscopic acromioplasty with coracoacromial ligament release, bursectomy, or debridement or repair of rotator cuff tears. However, the value of acromioplasty alone for rotator cuff problems is not supported by evidence.

When to Refer

- Failure of conservative treatment over 3 months.
- Young and active patients with impingement due to full-thickness rotator cuff tears.

Most patients complain of weakness or pain with overhead movement. Night pain is also a common complaint. The clinical findings with rotator cuff tears include those of the impingement syndrome except that with full-thickness rotator cuff tears there may be more obvious weakness noted with light resistance testing of specific rotator cuff muscles. Supraspinatus tendon strength is tested with resisted shoulder abduction at 90 degrees with slight forward flexion to around 45 degrees (“open can” test). Infraspinatus/teres minor strength is tested with resisted shoulder external rotation with shoulder at 0 degrees of abduction and elbow by side. Subscapularis strength is tested with the “lift-off” or “belly-press” tests. The affected patient usually also has positive Neer and Hawkins impingement tests (Table 41–1).

B. Imaging

Recommended radiographs are similar to impingement syndrome: AP scapula (glenohumeral), axillary lateral, supraspinatus outlet, and AP acromioclavicular joint views. The AP scapula view is useful in visualizing rotator cuff tears because degenerative changes can appear between the acromion and greater tuberosity of the shoulder. Axillary lateral views show superior elevation of the humeral head in relation to the center of the glenoid. Supraspinatus outlet views allow evaluation of the shape of the acromion. High-grade acromial spurs are associated with a higher incidence of rotator cuff tears. The AP acromioclavicular joint view evaluates for the presence of acromioclavicular joint arthritis, which can mimic rotator cuff tears, and for spurs that can cause rotator cuff injuries. MRI is the best method for visualizing rotator cuff tears. The MR arthrogram can show partial or small (less than 1 cm) rotator cuff tears. For patients who cannot undergo MRI testing or when postoperative artifacts limit MRI evaluations, ultrasonography can be helpful.

Treatment

Partial rotator cuff tears may heal with scarring. Most partial rotator cuff tears can be treated with physical therapy and scapular and rotator cuff muscle strengthening. However, research suggests that 40% of the partial-thickness tears progress to full-thickness tears in 2 years. Physical therapy can strengthen the remaining muscles to compensate for loss of strength and can have high rate of success for chronic tears. Physical therapy is also an option for older sedentary patients. On the contrary, full-thickness rotator cuff tears do not heal well and also have a tendency to increase in size with time. Forty-nine percent of the full-thickness tears get bigger over an average of 2.8 years. When tears get larger, they are also associated with worsening pain. Fatty infiltration is a degenerative process where muscle is being replaced by fat following injury to the rotator cuff tendons. Fatty infiltration progresses in full-thickness rotator cuff tears and it is a negative
Older and sedentary patients with full-thickness rotator cuff tears should be reduced as quickly as possible, using manual relocation techniques if necessary. When to Refer

- Young and active patients with full-thickness rotator cuff tears.
- Partial tears with greater than 50% involvement and significant pain.
- Acute rotator cuff tears and loss of function.
- Older and sedentary patients with full-thickness rotator cuff tears who have not responded to nonoperative treatment.
- Full-thickness subscapularis tears.

**Clinical Findings**

### A. Symptoms and Signs

For acute traumatic dislocations, patients usually have an obvious deformity with the humeral head dislocated anteriorly. The patient holds the shoulder and arm in an externally rotated position. The patient complains of acute pain and deformity that are improved with manual relocation of the shoulder. Reductions are usually performed in the emergency department. Even after reduction, the patient will continue to have limited range of motion and pain for 4–6 weeks, especially following a first-time shoulder dislocation.

Patients with recurrent dislocations can have less pain with subsequent dislocations. Posterior dislocations can be easily missed because the patient usually holds the shoulder and arm in an internally rotated position, which makes the shoulder deformity less obvious. Patients complain of difficulty pushing open a door.

Atraumatic shoulder instability is usually well tolerated with activities of daily living. Patients usually complain of a “sliding” sensation during exercises or strenuous activities such as throwing. Such dislocations may be less symptomatic and can often undergo spontaneous reduction of the shoulder with pain resolving within days after onset. The clinical examination for shoulder instability includes the apprehension test, the load and shift test, and the O’Brien test (Table 41–1). Most patients with persistent shoulder instability have preserved range of motion.

**General Considerations**

The shoulder is a ball and socket joint, similar to the hip. However, the bony contours of the shoulder bones are much different than the hip. Overall, the joint has much less stability than the hip, allowing greater movement and action. Stabilizing the shoulder joint relies heavily on rotator cuff muscle strength and also scapular control. If patients have poor scapular control or weak rotator cuff tendons or tears, their shoulders are more likely to have instability. Ninety-five percent of the shoulder dislocations/instability occur in the anterior direction. Dislocations usually are caused by a fall on an outstretched and abducted arm. Patients complain of pain and feeling of instability when the arm is in the abducted and externally rotated position. Posterior dislocations are usually caused by falls from a height, epileptic seizures, or electric shocks. Traumatic shoulder dislocation can lead to instability. The rate of repeated dislocation is directly related to the patient’s age: patients aged 21 years or younger have a 70–90% risk of redislocation, whereas patients aged 40 years or older have a much lower rate (20–30%). Other risks include male gender and patients with hyperlaxity. Ninety percent of young active individuals who had traumatic shoulder dislocation have labral injuries often described as Bankart lesions when the anterior inferior labrum is torn, which can lead to continued instability. Older patients (over age 55 years) are more likely to have rotator cuff tears or fractures following dislocation. Atraumatic shoulder dislocations are usually caused by intrinsic ligament laxity or repetitive microtrauma leading to joint instability. This is often seen in swimmers, gymnasts, and pitchers as well as other athletes involved in overhead and throwing sports.
B. Imaging

Radiographs for acute dislocations should include a standard trauma series of AP and axillary lateral scapula (glenohumeral) views to determine the relationship of the humerus and the glenoid and to rule out fractures. Orthogonal views are used to identify a posterior shoulder dislocation, which can be missed easily with one AP view of the shoulder. An axillary lateral view of the shoulder can be safely performed even in the acute setting of a patient with a painful shoulder dislocation. A scapula Y view in the acute setting is insufficient to diagnose dislocation. For chronic injuries or symptomatic instability, these recommended radiographic views are helpful to identify bony injuries and Hill-Sachs lesions (indented compression fractures at the posterior-superior part of the humeral head associated with anterior shoulder dislocation). MRI is commonly used to show soft tissue injuries to the labrum and to visualize associated rotator cuff tears. MRI arthrograms better identify labral tears and ligamentous structures. Three-dimensional CT scans are used to determine the significance of bone loss.

Treatment

For acute dislocations, the shoulder should be reduced as soon as possible. The Stimson procedure is the least traumatic method and is quite effective. The patient lies prone with the dislocated arm hanging off the examination table with a weight applied to the wrist to provide traction for 20–30 minutes. Afterward, gentle medial mobilization can be applied manually to assist the reduction. The shoulder can also be reduced with axial "traction" on the arm with "counter-traction" along the trunk. The patient should be sedated and relaxed. The shoulder can then be gently internally and externally rotated to guide it back into the socket.

Initial treatment of acute shoulder dislocations should include sling immobilization for 2–4 weeks along with pendulum exercises. Early physical therapy can be used to maintain range of motion and strengthening of rotator cuff muscles. Patients can also modify their activities to avoid active and risky sports. For patients with a traumatic incident and unilateral shoulder dislocation, a Bankart lesion is commonly present. The risk of recurrence is dependent on the age of first shoulder dislocation. Up to 70% of young patients (age less than 27 years) can have a recurrence whereas only 10% of patients older than age 40 have recurrences. However, once the patient has a second dislocation, the recurrence rate is extremely high, up to 95%, regardless of age. Operative intervention is the only treatment that has been shown to decrease recurrence. Open and arthroscopic stabilization have very similar outcomes. Repeated dislocations have been shown to increase the risk of arthritis and further bony deterioration.

The treatment of atraumatic shoulder instability is different than that of traumatic shoulder instability. Patients with chronic, recurrent shoulder dislocations should be managed with physical therapy and a regular maintenance program, consisting of scapular stabilization and postural and rotator cuff strengthening exercises. Activities may need to be modified. Surgical reconstructions are less successful for atraumatic shoulder instability than for traumatic shoulder instability. However, patients with recurrent dislocations have much higher incidence of bone loss or biceps pathology when compared to patients with first-time dislocations. They are also more likely to require open surgery with bone augmentation rather than arthroscopic stabilization.

When to Refer

- Patients who are at risk for second dislocation, such as young patients and certain job holders (e.g., police officers, firefighters, and rock climbers), to avoid recurrent dislocation or dislocation while at work.
- Patients who have not responded to a conservative approach or who have chronic instability.

4. Adhesive Capsulitis ("Frozen Shoulder")

A. Symptoms and Signs

Patients usually present with a painful shoulder that has a limited range of motion with both passive and active movements. A useful clinical sign is limitation of movement of external rotation with the elbow by the side of the trunk...
When to Refer

There are three phases: the inflammatory phase, the freezing phase, and the thawing phase. During the inflammatory phase, which usually lasts 4–6 months, patients complain of a very painful shoulder without obvious clinical findings to suggest trauma, fracture, or rotator cuff tear. During the “freezing” phase, which also usually lasts 4–6 months, the shoulder becomes stiffer and stiffer even though the pain is improving. The “thawing” phase can take up to a year as the shoulder slowly regains its motion. The total duration of an idiopathic frozen shoulder is usually about 24 months; it can be much longer for patients who have trauma or an endocrinopathy.

B. Imaging

Standard AP, axillary, and lateral glenohumeral radiographs are useful to rule out glenohumeral arthritis, which can also present with limited active and passive range of motion. Imaging can also rule out calcific tendinitis, which is an acute inflammatory process in which calcifications are visible in the soft tissue. However, adhesive capsulitis is usually a clinical diagnosis, and it does not need an extensive diagnostic workup.

Treatment

Adhesive capsulitis is caused by acute inflammation of the capsule followed by scarring and remodeling. During the acute “freezing” phase, NSAIDs and physical therapy are recommended to maintain motion. There is also evidence of short-term benefit from intra-articular corticosteroid injection or oral prednisone. A randomized control trial showed that intra-articular corticosteroid injection provided better pain relief than NSAIDs in the first 8 weeks. However, no difference was seen in range of motion or pain after 12 weeks, which is similar to other noncontrolled studies. One study demonstrated improvement at 6 weeks but not 12 weeks following 30 mg of daily prednisone for 3 weeks. During the “freezing” phase, the shoulder is less painful but remains stiff. Anti-inflammatory medication is not as helpful during the “thawing” phase as it is during the “freezing” phase, and the shoulder symptoms usually resolve with time. Surgical treatments, which are rarely indicated, include manipulation under anesthesia and arthroscopic release.

When to Refer

- When the patient does not respond after more than 6 months of conservative treatment.
- When there is no progress in or worsening of range of motion over 3 months.

SPINE PROBLEMS

1. Low Back Pain

ESSENTIALS OF DIAGNOSIS

- Nerve root impingement is suspected when pain is leg-dominant rather than back-dominant.
- Alarming symptoms include unexplained weight loss, failure to improve with treatment, severe pain for more than 6 weeks, and night or rest pain.
- Cauda equina syndrome is an emergency; often presents with bowel or bladder symptoms (or both).

General Considerations

Low back pain remains the number one cause of disability globally and is the second most common cause for primary care visits. The annual prevalence of low back pain is 15–45%. Annual health care spending for low back and neck pain is estimated to be $87.6 billion. Low back pain is the condition associated with the highest years lived with disability. Approximately 80% of episodes of low back pain resolve within 2 weeks and 90% resolve within 6 weeks. The exact cause of the low back pain is often difficult to diagnose; its cause is often multifactorial. There are usually degenerative changes in the lumbar spine involving the disks, facet joints, and vertebral endplates (Modic changes).

Alarming symptoms for back pain caused by cancer include unexplained weight loss, failure to improve with treatment, pain for more than 6 weeks, and pain at night or rest. History of cancer and age older than 50 years are other risk factors for malignancy. Alarming symptoms for infection include fever, rest pain, recent infection (urinary tract infection, cellulitis, pneumonia), or history of immunocompromise or injection drug use. The cauda equina syndrome is suggested by urinary retention or incontinence, saddle anesthesia, decreased anal sphincter tone or fecal incontinence, bilateral lower extremity weakness, and progressive neurologic deficits. Risk factors for back pain due to vertebral fracture include use of corticosteroids, age over 70 years, history of osteoporosis, severe trauma, and presence of a contusion or abrasion. Back pain may also be the presenting symptom in other serious medical problems, including abdominal aortic aneurysm, peptic ulcer disease, kidney stones, or pancreatitis.

Clinical Findings

A. Symptoms and Signs

The physical examination can be conducted with the patient in the standing, sitting, supine, and finally prone
positions to avoid frequent repositioning of the patient. In the standing position, the patient’s posture can be observed. Commonly encountered spinal asymmetries include scoliosis, thoracic kyphosis, and lumbar hyperlordosis. The active range of motion of the lumbar spine can be assessed while standing. The common directions include flexion, extension, rotation, and lateral bending. The one-leg standing extension test assesses for pain as the patient stands on one leg while extending the spine. A positive test can be caused by pars interarticularis fractures (spondylolysis or spondylolisthesis) or facet joint arthritis.

With the patient sitting, motor strength, reflexes, and sensation can be tested (Table 41–2). The major muscles in the lower extremities are assessed for weakness by eliciting a resisted isometric contraction for about 5 seconds. Comparing the strength bilaterally to detect subtle muscle weakness is important. Similarly, sensory testing to light touch can be checked in specific dermatomes for corresponding nerve root function. Knee (femoral nerve L2–4), ankle (deep peroneal nerve L4–L5), and Babinski (sciatic nerve L5–S1) reflexes can be checked with the patient sitting.

In the supine position, the hip should be evaluated for range of motion, particularly internal rotation. The straight leg raise test puts traction and compression forces on the lower lumbar nerve roots.

Finally, in the prone position, the clinician can carefully palpate each vertebral level of the spine and sacroiliac joints for tenderness. A rectal examination is required if the cauda equina syndrome is suspected. Superficial skin tenderness to a light touch over the lumbar spine, overreaction to maneuvers in the regular back examination, low back pain on axial loading of spine in standing, and inconsistency in the straight leg raise test or on the neurologic examination suggest nonorthopedic causes for the pain or malingering.

### B. Imaging

In the absence of alarming “red flag” symptoms suggesting infection, malignancy, or cauda equina syndrome, most patients do not need diagnostic imaging, including radiographs, in the first 6 weeks. The Agency for Healthcare Research and Quality guidelines for obtaining lumbar radiographs are summarized in Table 41–3. Most clinicians obtain radiographs for new back pain in patients older than 50 years. If done, radiographs of the lumbar spine should include AP and lateral views. Oblique views can be useful if the neuroforamina or bone lesions need to be visualized. MRI is the method of choice in the evaluation of symptoms not responding to conservative treatment or in the presence of red flags of serious conditions.

### C. Special Tests

Electromyography or nerve conduction studies may be useful in assessing patients with possible nerve root symptoms lasting longer than 6 weeks; back pain may or may not also be present. These tests are usually not necessary if the diagnosis of radiculopathy is clear.

#### Treatment

### A. Conservative

Nonpharmacologic treatments are key in the management of low back pain. Education alone improves patient satisfaction with recovery and recurrence. Patients require information and reassurance, especially when diagnostic procedures are not necessary. Discussion must include reviewing safe and effective methods of symptom control as well as how to decrease the risk of recurrence with proper lifting techniques, abdominal wall/core strengthening,

Patients with cancer, infection, fracture, or severe spinal deformity. Prognosis is improved when there is true muscle spasm that is painful rather than simply a protective response. Opioids alleviate pain in the short term, but have the usual side effects and concerns of long-term opioid use (Chapter 5). Treatment of more chronic neuropathic pain with alpha-2-delta ligands (eg, gabapentin), serotonin-norepinephrine reuptake inhibitors (eg, duloxetine), or tricyclic antidepressants (eg, nortriptyline) may be helpful (Chapter 5). Epidural injections may reduce pain in the short term and reduce the need for surgery in some patients within a 1-year period but not longer. Therefore, spinal injections are not recommended for initial care of patients with low back pain without radiculopathy.

B. Surgical

Indications for back surgery include cauda equina syndrome, ongoing morbidity with no response to more than 6 months of conservative treatment, cancer, infection, or severe spinal deformity. Prognosis is improved when there is an anatomic lesion that can be corrected and symptoms are neurologic. Spinal surgery has limitations. Patient selection is very important and the specific surgery recommended should have very clear indications. Patients should understand that surgery can improve their pain but is unlikely to cure it. Surgery is not generally indicated for radiographic abnormalities alone when the patient is relatively asymptomatic. Depending on the surgery performed, possible complications include persistent pain; surgical site pain, especially if bone grafting is needed; infection; neurologic damage; non-union; cutaneous nerve damage; implant failure; deep venous thrombosis; and death.

When to Refer

- Patients with the cauda equina syndrome.
- Patients with cancer, infection, fracture, or severe spinal deformity.
- Patients who have not responded to conservative treatment.

2. Spinal Stenosis

ESSENTIALS OF DIAGNOSIS

- Pain is usually worse with back extension and relieved by sitting.
- Occurs in older patients.
- May present with neurogenic claudication symptoms with walking.

General Considerations

OA in the lumbar spine can cause narrowing of the spinal canal. A large disk herniation can also cause stenosis and compression of neural structures or the spinal artery resulting in “claudication” symptoms with ambulation. The condition usually affects patients aged 50 years or older.

Clinical Findings

Patients report pain that worsens with extension. They describe reproducible single or bilateral leg symptoms that are worse after walking several minutes and that are relieved by sitting (“neurogenic claudication”). On
examination, patients often exhibit limited extension of the lumbar spine, which may reproduce the symptoms radiating down the legs. A thorough neurovascular examination is recommended (Table 41–2).

**Treatment**

Exercises, usually flexion-based as demonstrated by a physical therapist, can help relieve symptoms. Physical therapy showed similar results as surgical decompression in a randomized trial, though there was a 57% crossover rate from physical therapy to surgery. Facet joint corticosteroid injections can also reduce pain symptoms. While epidural corticosteroid injections have been shown to provide immediate improvements in pain and function for patients with radiculopathy, the benefits are small and only short term. Consequently, there is limited evidence to recommend epidural corticosteroids for spinal stenosis.

Surgical treatments for spinal stenosis include spinal decompression (widening the spinal canal or laminectomy), nerve root decompression (freeing a single nerve), and spinal fusion (joining the vertebrae to eliminate motion and diminish pain from the arthritic joints). However, a Cochrane review showed surgery was not clearly better than nonsurgical treatment and had complication rates of 10–24% compared to 0% for nonoperative treatments. Thus, the role of surgery for spinal stenosis is limited. In one multicenter randomized trial, subgroups initially improved significantly more with surgery than with nonoperative treatment. Variables associated with greater treatment effects included lower baseline disability scores, not smoking, neuroforaminal stenosis, predominant leg pain rather than back pain, not lifting at work, and the presence of a neurologic deficit. However, long-term follow-up of the patients with symptomatic spinal stenosis who received surgery in the multicenter randomized trial showed less benefit of surgery between 4 and 8 years, suggesting that the advantage of surgery for spinal stenosis diminishes over time. A Cochrane review of 24 randomized controlled trials of treatments for lumbar spinal stenosis showed that various surgeries including decompression plus fusion and interspinous process spacers were not superior to conventional surgical decompression surgery alone.

**When to Refer**

- If a patient exhibits radicular or claudication symptoms for longer than 12 weeks.
- MRI or CT confirmation of significant, symptomatic spinal stenosis.
- However, surgery has not been shown to have clear benefit over nonsurgical treatment for lumbar spinal stenosis.

**3. Lumbar Disk Herniation**

**ESSENTIALS OF DIAGNOSIS**

- Pain with back flexion or prolonged sitting.
- Radicular pain into the leg due to compression of neural structures.
- Lower extremity numbness and weakness.

**General Considerations**

Lumbar disk herniation is usually due to bending or heavy loading (eg, lifting) with the back in flexion, causing herniation or extrusion of disk contents (nucleus pulposus) into the spinal cord area. However, there may not be an inciting incident. Disk herniations usually occur from degenerative disk disease (dissociation of the annulus fibrosis) in patients between 30 and 50 years old. The L5–S1 disk is affected in 90% of cases. Compression of neural structures, such as the sciatic nerve, causes radicular pain. Severe compression of the spinal cord can cause the cauda equina syndrome, a surgical emergency.

**Clinical Findings**

**A. Symptoms and Signs**

Discogenic pain typically is localized in the low back at the level of the affected disk and is worse with activity. “Sciatica” causes electric shock-like pain radiating down the posterior aspect of the leg often to below the knee. Symptoms usually worsen with back flexion such as bending or sitting for long periods (eg, driving). A significant disk herniation can cause numbness and weakness, including weakness with plantar flexion of the foot (L5/S1) or dorsiflexion of the toes (L4/L5). The cauda equina syndrome should be ruled out if the patient complains of perianal numbness or bowel or bladder incontinence.

**B. Imaging**

Plain radiographs are helpful to assess spinal alignment (scoliosis, lordosis), disk space narrowing, and OA changes. MRI is the best method to assess the level and morphology of the herniation and is recommended if surgery is planned.

**Treatment**

For an acute exacerbation of pain symptoms, bed rest is appropriate for up to 48 hours. Otherwise, first-line treatments include modified activities; NSAIDs and other analgesics; and physical therapy, including core stabilization and McKenzie back exercises. Following nonsurgical treatment for a lumbar disk for over 1 year, the incidence of low
back pain recurrence is at least 40% and is predicted by longer time to initial resolution of pain. In a randomized trial, oral prednisone caused a modest improvement in function at 3 weeks, but there was no significant improvement in pain in patients with acute radiculopathy who were monitored for 1 year. The initial dose for oral prednisone is approximately 1 mg/kg once daily with tapering doses over 10–15 days. Analgesics for neuropathic pain, such as the calcium channel alpha-2-delta ligands (ie, gabapentin, pregabalin) or tricyclic antidepressants, may be helpful (see Chapter 5). Epidural and transforaminal corticosteroid injections can be beneficial. A systematic review demonstrated strong evidence that fluoroscopically-guided epidural injections gave short-term benefit (less than 6 months) in acute radicular pain for individuals. However, epidural injections have not shown any change in long-term surgery rates for disk herniations.

The severity of pain and disability as well as failure of conservative therapy were the most important reasons for surgery. A large trial has shown that patients who underwent surgery for a lumbar disk herniation achieved greater improvement than conservatively treated patients in all primary and secondary outcomes except return to work status after 4-year follow-up. Patients with sequestered fragments, symptom duration greater than 6 months, higher levels of low back pain, or who were neither working nor disabled at baseline showed greater surgical treatment effects. Microdiscectomy is the standard method of treatment with a low rate of complications and satisfactory results over 90% in the largest series. A minimally invasive technique is percutaneous endoscopic discectomy, which involves using an endoscope to remove fragments of disk herniation (interlaminar or transforaminal approaches) under local anesthesia, although results are less successful than with microdiscectomy. Disk replacement surgery has shown benefits in short-term pain relief, disability, and quality of life compared with spine fusion surgery.

**When to Refer**

- Cauda equina syndrome.
- Progressive worsening of neurologic symptoms.
- Loss of motor function (sensory losses can be followed in the outpatient clinic).

**ESSENTIALS OF DIAGNOSIS**

- Chronic neck pain is mostly caused by degenerative joint disease; whiplash often follows a traumatic neck injury.
- Poor posture is often a factor for persistent neck pain.

**General Considerations**

Most neck pain, especially in older patients, is due to mechanical degeneration involving the cervical disks, facet joints, and ligamentous structures and may occur in the setting of degenerative changes at other sites. Pain can also come from the supporting neck musculature, which often acts to protect the underlying neck structures. Posture is a very important factor, especially in younger patients. Many work-related neck symptoms are due to poor posture and repetitive motions over time. Acute injuries can also occur secondary to trauma. Whiplash occurs from rapid flexion and extension of the neck and affects 15–40% of people in motor vehicle accidents; chronic pain develops in 5–7%.

Neck fractures are serious traumatic injuries acutely and can lead to OA in the long term. Ultimately, many degenerative conditions of the neck result in cervical canal stenosis or neural foraminal stenosis, sometimes affecting underlying neural structures.

Cervical radiculopathy can cause neurologic symptoms in the upper extremities usually involving the C5–C7 disks. Patients with neck pain may report associated headaches and shoulder pain. Both peripheral nerve entrapment and cervical radiculopathy, known as a “double crush” injury, may develop. Thoracic outlet syndrome, in which there is mechanical compression of the brachial plexus and neurovascular structures with overhead positioning of the arm, should be considered in the differential diagnosis of neck pain. Other causes of neck pain include rheumatoid arthritis, fibromyalgia, osteomyelitis, neoplasms, polymyalgia rheumatica, compression fractures, pain referred from visceral structures (eg, angina), and functional disorders. Amyotrophic lateral sclerosis, multiple sclerosis, syringomyelia, spinal cord tumors, and Parsonage-Turner syndrome can mimic myelopathy from cervical arthritis.

**Clinical Findings**

**A. Symptoms and Signs**

Neck pain may be limited to the posterior region or, depending on the level of the symptomatic joint, may radiate segmentally to the occiput, anterior chest, shoulder girdle, arm, forearm, and hand. It may be intensified by active or passive neck motions. The general distribution of pain and paresthesias corresponds roughly to the involved dermatome in the upper extremity.
The patient's posture should be assessed, checking for shoulder rolled forward or head forward posture as well as scoliosis in the thoracolumbar spine. Patients with discogenic neck pain often complain of pain with flexion, which causes cervical disks to herniate posteriorly. Extension of the neck usually affects the neural foraminal and facet joints of the neck. Rotation and lateral flexion of the cervical spine should be measured both to the left and the right. Limitation of cervical movements is the most common objective finding.

A detailed neurovascular examination of the upper extremities should be performed, including sensory input to light touch and temperature; motor strength testing, especially the hand intrinsic muscles (thumb extension strength [C6], opponens strength [thumb to pinky] [C7], and finger abductors and adductors strength [C8–T1]); and upper extremity reflexes (biceps, triceps, brachioradialis). True cervical radiculopathy symptoms should match an expected dermatomal or myotomal distribution. The Spurling test involves asking the patient to rotate and extend the neck to one side (Table 41–4). The clinician can apply a gentle axial load to the neck. Reproduction of the cervical radiculopathy symptoms should match an expected dermatomal or myotomal distribution. The Spurling test is a positive sign of nerve root compression. Palpation of the neck is best performed with the patient in the supine position where the clinician can palpate each level of the cervical spine with the muscles of the neck relaxed.

B. Imaging and Special Tests

Radiographs of the cervical spine include the AP and lateral view of the cervical spine. The odontoid view is usually added to rule out traumatic fractures and congenital abnormalities. Oblique views of the cervical spine can provide further information about arthritis changes and assess the neural foramina for narrowing. Plain radiographs can be completely normal in patients who have suffered an acute cervical strain. Comparative reduction in height of the involved disk space and osteophytes are frequent findings when there are degenerative changes in the cervical spine. Loss of cervical lordosis is commonly seen but is nonspecific.

MRI is the best method to assess the cervical spine since the soft tissue structures (such as the disks, spinal cord, and nerve roots) can be evaluated. If the patient has signs of cervical radiculopathy with motor weakness, these more sensitive imaging modalities should be obtained urgently. CT scanning is the most useful method if bony abnormalities, such as fractures, are suspected.

EMG is useful in order to differentiate peripheral nerve entrapment syndromes from cervical radiculopathy. However, sensitivity of electrodiagnostic testing for cervical radiculopathy ranges from only 50% to 71%, so a negative test does not rule out nerve root problems.

![Treatment]( tegenian.com/)

In the absence of trauma or evidence of infection, malignancy, neurologic findings, or systemic inflammation, the patient can be treated conservatively. More frequent observation of individuals in whom very severe symptoms are present early on after an injury is recommended because high pain-related disability is a predictor of poor outcome at 1 year even if individuals decline care. Ergonomics should be assessed at work and home. A course of neck stretching, strengthening, and postural exercises in physical therapy have demonstrated benefit in relieving symptoms. A soft cervical collar can be useful for short-term use (up to 1–2 weeks) in acute neck injuries. Chiropractic manual manipulation and mobilization can provide short-term benefit for mechanical neck pain. Although the rate of complications is low (5–10/million manipulations), care should be taken whenever there are neurologic symptoms present. Specific patients may respond to use of home cervical traction. NSAIDs are commonly used and opioids may be needed in cases of severe neck pain. Muscle relaxants (eg, cyclobenzaprine 5–10 mg orally three times daily) can be used short term if there is muscle spasm or as a sedative to aid in sleeping. Acute radicular symptoms can be treated with neuropathic medications (eg, gabapentin 300–1200 mg orally three times daily), and a short course of oral prednisone (5–10 days) can be considered (starting at 1 mg/kg). Cervical foraminal or facet joint injections can also reduce symptoms. Surgeries are successful in reducing neurologic symptoms in 80–90% of cases, but are still considered as treatments of last resort. Common surgeries for cervical degenerative disk disease include anterior cervical diskectomy with fusion and cervical disk arthroplasty. A meta-analysis of 18 randomized controlled trials showed that cervical disk arthroplasty was superior to anterior diskectomy and fusion for the treatment of symptomatic cervical disk disease, with better success and less reoperation rates.

When to Refer

- Patients with severe symptoms with motor weakness.
- Surgical decompression surgery if the symptoms are severe and there is identifiable, correctable pathology.

Diagnosis of tendinopathy is confirmed by pain tenderness over the lateral or medial epicondyle. The proximal tendon and musculotendinous junction can also be sore. To confirm that the pain is due to tendinopathy, pain can be reproduced over the epicondyle with resisted wrist extension and third digit extension for lateral epicondylitis and resisted wrist pronation and wrist flexion for medial epicondylitis. The pain is also often reproduced with passive stretching of the affected muscle groups, which can be performed with the arm in extension. It is useful to check the ulnar nerve (located in a groove at the posteromedial elbow) for tenderness as well as to perform a Spurling test for cervical radiculopathy.

B. Imaging

Radiographs are often normal, although a small traction spur may be present in chronic cases (enthesopathy). Diagnostic investigations are usually unnecessary, unless the patient does not improve after up to 3 months of conservative treatment. At that point, a patient who demonstrates significant disability due to the pain should be assessed with an MRI or ultrasound. Ultrasound and MRI can visualize the tendon and confirm tendinosis or tears.

Treatment

Treatment is usually conservative, including patient education regarding activity modification and management of symptoms. Ice and NSAIDs can help with pain. The mainstay of treatment is physical therapy exercises. The most important steps are to begin a good stretching program followed by strengthening exercises, particularly eccentric ones. Counterforce elbow braces might provide some symptomatic relief, although there is no published evidence to support their use. If the patient has severe or long-standing symptoms, injections can be considered. A randomized trial showed improvement with corticosteroid injection at 1 month as well as evidence of decreased tendon thickness and Doppler changes but no improvement at 3 months. Treatments such as extracorporeal shock wave therapy and other injections have not shown clear long-term benefit. Evidence on platelet-rich plasma (PRP) injections continues to accumulate and it is becoming more commonly used in practice, although it is still considered a second-line treatment. Reviews suggest that PRP and autologous blood injections both have positive benefits in lateral epicondylitis. In a randomized controlled trial comparing PRP injection to controls (n = 119), the PRP-treated patients reported 55.1% improvement in their pain scores at 12 weeks compared to 47.4% in the control patients (P = 0.163). More significant improvement was seen at 24 weeks; 71.5% improvement in the pain scores in the PRP-treated patients compared to 56.1% in the control patients (P = 0.019). (A 25% improvement of pain symptoms was considered to be clinically significant.) However, the varied methods of PRP preparations and varied post-injection recommendations for rest and physiotherapy make interpretation of various study results difficult to summarize.

When to Refer

Patients not responding to 6 months of conservative treatment should be referred for an injection procedure (PRP or tenotomy), surgical debridement, or repair of the tendon.
2. Carpal Tunnel Syndrome

**ESSENTIALS OF DIAGNOSIS**
- Pain, burning, and tingling in the distribution of the median nerve.
- Initially, most bothersome during sleep.
- Late weakness or atrophy of the thenar eminence.
- Can be caused by repetitive wrist activities.
- Commonly seen during pregnancy and in patients with diabetes mellitus or rheumatoid arthritis.

**General Considerations**

An entrapment neuropathy, carpal tunnel syndrome is a painful disorder caused by compression of the median nerve between the carpal ligament and other structures within the carpal tunnel. The contents of the tunnel can be compressed by synovitis of the tendon sheaths or carpal joints, recent or malhealed fractures, tumors, tissue infiltration, and occasionally congenital syndromes (eg, mucopolysaccharidoses). The disorder may occur in fluid retention of pregnancy, in individuals with a history of repetitive use of the hands, or following injuries of the wrists. Carpal tunnel syndrome can also be a feature of many systemic diseases, such as rheumatoid arthritis and other rheumatic disorders (inflammatory tenosynovitis), myxedema, amyloidosis, sarcoidosis, leukemia, acromegaly, and hyperparathyroidism. There is a familial type of carpal tunnel syndrome in which no etiologic factor can be identified.

**Clinical Findings**

**A. Symptoms and Signs**

The initial symptoms are pain, burning, and tingling in the distribution of the median nerve (the palmar surfaces of the thumb, the index and long fingers, and the radial half of the ring finger). Aching pain may radiate proximally into the forearm and occasionally proximally to the shoulder and over the neck and chest. Pain is exacerbated by manual activity, particularly by extremes of volar flexion or dorsiflexion of the wrist. It is most bothersome at night. Impairment of sensation in the median nerve distribution may or may not be demonstrable. Subtle disparity between the affected and opposite sides can be shown by testing for two-point discrimination or by requiring the patient to identify different textures of cloth by rubbing them between the tips of the thumb and the index finger. A Tinel sign may be positive. A Phalen sign is tingling or shock-like pain on volar wrist percussion. The Phalen sign is pain or paresthesia in the distribution of the median nerve when the patient flexes both wrists to 90 degrees for 60 seconds. The carpal compression test, in which numbness and tingling are induced by the direct application of pressure over the carpal tunnel, may be more sensitive and specific than the Tinel and Phalen tests. Muscle weakness or atrophy, especially of the thenar eminence, can appear later than sensory disturbances as compression of the nerve worsens.

**B. Imaging**

Ultrasound can demonstrate flattening of the median nerve beneath the flexor retinaculum. Sensitivity of ultrasound for carpal tunnel syndrome is variable but estimated between 54% and 98%.

**C. Special Tests**

Electromyography and nerve conduction studies show evidence of sensory conduction delay before motor delay, which may occur in severe cases.

**Treatment**

Treatment is directed toward relief of pressure on the median nerve. When a causative lesion is discovered, it should be treated appropriately. Otherwise, patients in whom carpal tunnel syndrome is suspected should modify their hand activities. The affected wrist can be splinted in the neutral position for up to 3 months, but a series of Cochrane reviews show limited evidence for splinting, exercises, and ergonomic positioning. Moderate evidence supported benefit from several physical therapy and electrophysical modalities (eg, ultrasound therapy and radial extracorporeal shockwave therapy). These modalities provided short-term and mid-term relief of carpal tunnel syndrome symptoms in different studies. Oral corticosteroids or NSAIDs have also shown benefit for carpal tunnel syndrome. Methylprednisolone injections were found to have more effect at 10 weeks than placebo, but the benefits diminished by 1 year.

Compared to trigger finger management, which usually includes injections, as many as 71% of patients with carpal tunnel directly undergo surgery without first getting injections. There is strong evidence that a steroid injection to the carpal tunnel is more effective in the short term than surgery. A randomized, controlled trial showed both corticosteroid injection and surgery resolved symptoms but only decompressive surgery led to resolution of neurophysiologic changes. Carpal tunnel release surgery can be beneficial if the patient has a positive electrodiagnostic test, at least moderate symptoms, high clinical probability, unsuccessful nonoperative treatment, and symptoms lasting longer than 12 months. Surgery can be done with an open approach or endoscopically, both yielding similar good improvements.
### When to Refer
- If symptoms persist more than 3 months despite conservative treatment, including the use of a wrist splint.
- If thenar muscle (eg, abductor pollicis brevis) weakness or atrophy develops.

### Treatment
Corticosteroid injection with a percutaneous needle aponeurotomy has shown some promise for Dupuytren contracture. If the palmar nodule is growing rapidly, injections of triamcinolone or collagenase into the nodule may be of benefit; the injection of collagenase *Clostridium histolyticum* lysed collagen, thereby disrupting the contracted cords. Surgical options include open fasciectomy, partial fasciectomy, or percutaneous needle aponeurotomy and are indicated in patients with significant flexion contractures. A multicenter study showed that collagenase injection and limited fasciectomy had similar improvements with contractures at the metacarpophalangeal joints, while surgery had better results for contractures involving the proximal interphalangeal joints. Splinting after surgery is beneficial. Recurrence is possible after surgery with more adverse events compared to nonoperative treatments. Compared to placebo, tamoxifen therapy produced moderate evidence of improvement before or after a fasciectomy.

### When to Refer
Referal can be considered when one or more digits are affected by severe contractures, which interfere with everyday activities and result in functional limitations.

### 3. Dupuytren Contracture

#### ESSENTIALS OF DIAGNOSIS
- Benign fibrosing disorder of the palmar fascia.
- Contracture of one or more fingers can lead to limited hand function.

#### General Considerations
This relatively common disorder is characterized by hyperplasia of the palmar fascia and related structures, with nodule formation and contracture of the palmar fascia. The cause is unknown, but the condition has a genetic predisposition and occurs primarily in white men over 50 years of age, particularly in those of Celtic descent. The incidence is higher among alcoholic patients and those with chronic systemic disorders (especially cirrhosis). It is also associated with systemic fibrosing syndrome, which includes plantar fibromatosis (10% of patients), Peyronie disease (1–2%), mediastinal and retroperitoneal fibrosis, and Riedel struma. The onset may be acute, but slowly progressive chronic disease is more common.

#### Clinical Findings
Dupuytren contracture manifests itself by nodular or cord-like thickening of one or both hands, with the fourth and fifth fingers most commonly affected. The patient may complain of tightness of the involved digits, with inability to satisfactorily extend the fingers, and on occasion there is tenderness. The resulting cosmetic problems may be unappealing, but in general the contracture is well tolerated since it exaggerates the normal position of function of the hand.

#### Treatment
- If thenar muscle (eg, abductor pollicis brevis) weakness or atrophy develops.

### 4. Bursitis

#### ESSENTIALS OF DIAGNOSIS
- Often occurs around bony prominences where it is important to reduce friction.
- Typically presents with local swelling that is painful acutely.
- Septic bursitis can present without fever or systemic signs.

#### General Considerations
Inflammation of bursae—the synovium-like cellular membranes overlying bony prominences—may be secondary to trauma, infection, or arthritic conditions such as gout, rheumatoid arthritis, or OA. Bursitis can result from infection. The two common sites are the olecranon (Figure 41–1) and prepatellar bursae; however, others include subdeltoid,
Baker cysts are imaged easily by sonography or MRI. It may be important to exclude a deep venous thrombosis, which can be mimicked by a ruptured Baker cyst.

C. Special Tests

Acute swelling and redness at a bursal site call for aspiration to rule out infection especially if the patient is either febrile (temperature more than 37.8°C) or has prebursal warmth (temperature difference greater than 2.2°C) or both. A bursal fluid white blood cell count of greater than 1000/mcL indicates inflammation from infection, rheumatoid arthritis, or goat. The bursal fluid of septic bursitis characteristically contains a purulent aspirate, fluid-to-serum glucose ratio less than 50%, white cell count more than 3000 cells/mL, polymorphonuclear cells more than 50%, and a positive Gram stain for bacteria. Most cases are caused by *Staphylococcus aureus*; the Gram stain is positive in two-thirds.

Treatment

Bursitis caused by trauma responds to local heat, rest, NSAIDs, and local corticosteroid injections. Chronic, stable olecranon bursa swelling usually does not require aspiration. Repetitive minor trauma to the olecranon bursa should be eliminated by avoiding resting the elbow on a hard surface or by wearing an elbow pad. For chronic aseptic bursitis or when there are athletic or occupational demands, aspiration with intrabursal steroid injection can be performed. Aspiration of the olecranon bursa runs the risk of creating a chronic drainage site, which can be reduced by using a “zig-zag” approach with a small needle (25-gauge if possible) and pulling the skin over the bursa before introducing it. Applying a pressure bandage may also help prevent chronic drainage. Ultrasound-guided aspiration and injection can improve the accuracy of the procedures. Treatment of a ruptured Baker cyst includes rest, leg elevation, and possibly injection of triamcinolone, 20–40 mg into the knee anteriorly (the knee compartment communicates with the cyst). However, corticosteroid injections in nonseptic bursitis have more complications and skin atrophy than simple symptomatic treatment.

Treatment for septic bursitis involves incision and drainage and antibiotics usually delivered intravenously.

When to Refer

- Surgical removal of the bursa is indicated only for cases in which repeated infections occur.
- Elective removal for persistent symptoms affecting activities of daily living can be considered.

HIP

1. Hip Fractures

**ESSENTIALS OF DIAGNOSIS**

- Internal rotation of the hip is the best provocative diagnostic maneuver.
- Hip fractures should be surgically repaired as soon as possible (within 24 hours).
- Delayed treatment of hip fractures in older adults leads to increased complications and mortality.

**General Considerations**

Approximately 4% of the 7.9 million fractures that occur each year in the United States are hip fractures. There is a high mortality rate among older adult patients following hip fracture, with death occurring in 8–9% within 30 days and in approximately 25–30% within 1 year. Osteoporosis, female sex, height greater than 5-feet 8-inches, and age over 50 years are risk factors for hip fracture. Hip fractures usually occur after a fall. High-velocity trauma is needed in younger patients. Stress fractures can occur in athletes or individuals with poor bone mineral density following repetitive loading activities.

**Clinical Findings**

**A. Symptoms and Signs**

Patients typically report pain in the groin, though pain radiating to the lateral hip, buttock, or knee can also commonly occur. If a displaced fracture is present, the patient will not be able to bear weight and the leg may be externally rotated. Gentle logrolling of the leg with the patient supine helps rule out a fracture. Examination of the hip demonstrates pain with deep palpation in the area of the femoral triangle (similar to palpating the femoral artery). Provided the patient can tolerate it, the clinician can, with the patient supine, flex the hip to 90 degrees with the knee flexed to 90 degrees. The leg can then be internally and externally rotated to assess the range of motion on both sides. Pain with internal rotation of the hip is the most sensitive test to identify intra-articular hip pathology. Hip flexion, extension, abduction, and adduction strength can be tested.

Patients with hip stress fractures have less pain on physical examination than described previously but typically have pain with weight bearing. The Trendelenburg test can be performed to examine for weakness or instability of the hip abductors, primarily the gluteus medius muscle; the patient balances first on one leg, raising the non-standing knee toward the chest. The clinician can stand behind the patient and observe for dropping of the pelvis and buttock on the non-stance side. Another functional test is asking the patient to hop or jump during the examination. If the patient has a compatible clinical history of pain and is unable or unwilling to hop, then a stress fracture should be ruled out. The back should be carefully examined in patients with hip complaints, including examining for signs of sciatica.

Following displaced hip fractures, a thorough medical evaluation and treatment should be pursued to maximize the patients’ ability to undergo operative intervention. Patients who are unable to get up by themselves may have been immobile for hours or even days following their falls. Thus, clinicians must exclude rhabdomyolysis, hypothermia, deep venous thrombosis, pulmonary embolism, and other conditions that can occur with prolonged immobilization. Delay of operative intervention leads to an increased risk of perioperative morbidity and mortality.

**B. Imaging**

Useful radiographic views of the hip include AP views of the pelvis and bilateral hips and frog-leg-lateral views of the painful hip. A CT scan or MRI may be necessary to identify the hip fracture pattern or to evaluate non-displaced fractures. Hip fractures are generally described by location, including femoral neck, intertrochanteric, or subtrochanteric.

**Treatment**

Almost all patients with a hip fracture will require surgery and may need to be admitted to the hospital for pain control while they await surgery. Surgery is recommended within the first 24 hours because studies have shown that delaying surgery 48 hours results in at least twice the rate of major and minor medical complications, including pneumonia, pressure injuries (formerly pressure ulcers), and deep venous thrombosis. High-volume centers have multidisciplinary teams (including orthopedic surgeons, internists, social workers, and specialized physical therapists) to comanage these patients, which improves perioperative medical care and expedites preoperative evaluation leading to reduced costs.

Stress fractures in active patients require a period of protected weight bearing and a gradual return to activities. Although it may take 4–6 months before a return to normal activities. Femoral neck fractures are commonly treated with hemiarthroplasty or total hip replacement. This allows the patient to begin weight bearing immediately postoperatively. Peritrochanteric hip fractures are treated with open reduction internal fixation, where plate and screw construct or intramedullary devices are used. The choice of implant will depend on the fracture pattern. Since fracture fixation requires the fracture to proceed to union, the patient may need to have protected weight bearing during the early postoperative period. Dislocation, periprosthetic fracture, and avascular necrosis of the hip are common complications after surgery. Patients should be mobilized as soon as possible postoperatively to avoid pulmonary complications and pressure injuries. Supervised physical therapy and rehabilitation are important for the patient to regain as much function as possible. Unfortunately, most patients following hip fractures will lose some degree of independence. Patients with hip fracture surgery when compared with elective total hip replacement have been shown to have higher risk of in-hospital mortality.
Prevention

Bone density screening can identify patients at risk for osteopenia or osteoporosis, and treatment can be planned accordingly. There is strong evidence that bisphosphonates, denosumab, and teriparatide reduce fractures compared with placebo, with relative risk reductions of 0.60–0.80 for nonvertebral fractures. Nutrition and bone health (bone densitometry, serum calcium and 25-OH vitamin D levels) should be reviewed with the patient (see Chapter 26). However, there is no evidence that increasing calcium intake prevents hip fractures. For patients with decreased mobility, systemic anticoagulation should be considered to avoid deep venous thrombosis (see Table 14–14). Fall prevention exercise programs are available for older adult patients at risk for falls and hip fractures. Hip protectors are uncomfortable and have less use in preventing fractures.

When to Refer

- All patients in whom hip fracture is suspected.
- All patients with hip fracture or in whom the diagnosis is uncertain after radiographs.

Clinical Findings

A. Symptoms and Signs

OA usually causes pain in the affected joint with loading of the joint or at the extremes of motion. Mechanical symptoms—such as swelling, grinding, catching, and locking—suggest internal derangement, which is indicated by damaged cartilage or bone fragments that affect the smooth range of motion expected at an articular joint. Pain can also produce the sensation of “buckling” or “giving way” due to muscle inhibition. As the joint degeneration becomes more advanced, the patient loses active range of motion and may lose passive range of motion as well.

Patients complain of pain deep in the groin on the affected side and have problems with weight-bearing activities such as walking, climbing stairs, and getting up from a chair. They may limp and develop a lurch during their gait, leaning toward the unaffected side as they walk to reduce pressure on the arthritic hip.

B. Imaging

An anterior-posterior weight-bearing radiograph of the pelvis with a lateral view of the symptomatic hip are preferred views for evaluation of hip OA. Joint space narrowing and sclerosis suggest early OA, while osteophytes near the femoral head or acetabulum and subchondral bone cysts are more advanced changes. However, not all patients with radiographic hip OA have hip or groin pain; the converse is also true. Radiographs have low sensitivity for hip pain (sensitivity 36.7%, specificity 90.5%, positive predictive value 6.0%, and negative predictive value 98.9%). Findings of femoroacetabular impingement are commonly reported on radiograph reports with arthritic changes and anatomic variations involving the acetabulum and femoral head neck junction. After age 35, MRI of the hips already show labral changes in almost 70% of asymptomatic patients.

Treatment

A. Conservative

Changes in the articular cartilage are irreversible. Therefore, a cure for the diseased joint is not possible, although symptoms or structural issues can be managed to try to maintain activity level. Conservative treatment for patients with OA includes activity modification, proper footwear, therapeutic exercises, weight loss, and use of assistive devices (such as a cane). A 2014 randomized study found that physical therapy did not lead to greater improvement in pain or function compared with sham treatment in patients with hip OA. Analgesics may be effective in some cases. Corticosteroid injections can be considered for severe OA.

B. Surgical

Joint replacement surgeries are effective and cost-effective for patients with significant symptoms and functional limitations, providing improvements in pain, function, and

General Considerations

In the United States, the prevalence of OA will grow as the number of persons over age 65 years doubles to more than 70 million by 2030. Cartilage loss and OA symptoms are preceded by damage to the collagen-proteoglycan matrix. The etiology of OA is often multifactorial, including previous trauma, prior high-impact activities, genetic factors, obesity, and rheumatologic or metabolic conditions. Femoroacetabular impingement, which affects younger active patients, is considered an early development of hip OA.
quality of life. Various surgical techniques and computer-assisted navigation during operation continue to be investigated. A review of nine randomized controlled trials concluded that a direct anterior approach for hip replacement was associated with a shorter incision, lower blood loss, lower pain scores, and earlier functional recovery. However, there was no significant difference in complication rates between groups for the direct anterior or posterior approaches.

Hip resurfacing surgery is a newer joint replacement technique. Rather than use a traditional artificial joint implant of the whole neck and femur, only the femoral head is removed and replaced. Evidence to date suggests that hip resurfacing is comparable to total hip replacement and is a viable alternative for younger patients. The cumulative survival rate of this implant at 10 years is estimated to be 94%. Concerns following resurfacing surgery include the risk of femoral neck fracture and collapse of the head. In a systematic review of national databases, the average time to revision was 3.0 years for metal-on-metal hip resurfacing versus 7.8 years for total hip arthroplasty. Dislocations were more frequent with total hip arthroplasty than metal-on-metal hip resurfacing: 4.4 vs 0.9 per 1000 person-years, respectively.

Guidelines recommend prophylaxis for venous thromboembolic disease for a minimum of 14 days after arthroplasty of the hip or knee using warfarin, low-molecular-weight heparin, fondaparinux, aspirin, rivaroxaban, dabigatran, apixaban, or portable mechanical compression (see Table 14–14).

**When to Refer**

Patients with sufficient disability, limited benefit from conservative therapy, and evidence of severe OA can be referred for joint replacement surgery.

**ESSENTIALS OF DIAGNOSIS**

- Effusion can occur with intra-articular pathology (eg, OA, meniscus and cruciate ligament tears).
- Acute knee swelling (due to hemarthrosis) within 2 hours may indicate ligament injuries or patellar dislocation or fracture.

**General Considerations**

The knee is the largest joint in the body and is susceptible to injury from trauma, inflammation, infection, and degenerative changes. The knee is a hinge joint. The joint line exists between the femoral condyles and tibial plateaus. Separating and cushioning these bony surfaces is the lateral and medial meniscal cartilage, which functions as a shock absorber during weight bearing, protecting the articular cartilage. The patella is a large sesamoid bone anterior to the joint. It is embedded in the quadriceps tendon, and it articulates with the troclear groove of the femur. Poor patellar tracking in the trochlear groove is a common source of knee pain especially when the cause is atraumatic in nature. The knee is stabilized by the collateral ligaments against varus (lateral collateral ligament) and valgus (medial collateral ligament) stresses. The tibia is limited in its anterior movement by the anterior cruciate ligament (ACL) and in its posterior movement by the posterior cruciate ligament (PCL). The bursae of the knee are located between the skin and bony prominences. They act to decrease friction of tendons and muscles as they move over adjacent bony structures. Excessive external pressure or friction can lead to swelling and pain of the bursae. The prepatellar bursae (located between the skin and patella) and the pes anserine bursa (which is medial and inferior to the patella, just below the tibial plateau) are most commonly affected. Joint fluid, when excessive due to synovitis or trauma, can track posteriorly through a potential space, resulting in a popliteal cyst (also called a Baker cyst). Other structures that are susceptible to overuse injury and may cause knee pain following repetitive activity include the patellofemoral joint and the iliotibial band. OA of the knees is common after 50 years of age and can develop due to previous trauma, aging, activities, alignment issues, and genetic predisposition.

**Clinical Findings**

**A. Symptoms and Signs**

Evaluation of knee pain should begin with general questions regarding duration and rapidity of symptom onset and the mechanism of injury or aggravating symptoms. Overuse or degenerative problems can occur with stress or compression from sports, hobbies, or occupation. A history of trauma, previous orthopedic problems with, or surgery to, the affected knee should also be specifically queried. Symptoms of infection (fever, recent bacterial infections, risk factors for sexually transmitted infections [such as gonorrhea] or other bacterial infections [such as staphylococcal infection]) should always be elicited.

Common symptom complaints include the following:

1. Presence of grinding, clicking, or popping with bending may be indicative of OA or the patellofemoral syndrome.
2. “Locking” or “catching” when walking suggests an internal derangement, such as meniscal injury or a loose body in the knee.
3. Intra-articular swelling of the knee or an effusion indicates an internal derangement or a synovial pathology. Large swelling may cause a popliteal (Baker) cyst. Acute swelling within minutes to hours suggests a hemarthrosis, most likely due to an ACL injury, fracture, or patellar dislocation, especially if trauma is involved.

4. Lateral "snapping" with flexion and extension of the knee may indicate inflammation of the iliotibial band.

5. Pain that is worsened with bending and walking downstairs suggests issues with the patellofemoral joint, usually degenerative such as chondromalacia of the patella or OA.

6. Pain that occurs when rising after prolonged sitting suggests a problem with tracking of the patella.

A careful history coupled with a physical examination that includes observation, palpation, and range of motion testing, as well as specific tests for particular anatomic structures is frequently sufficient to establish a diagnosis.

When there is a knee joint effusion caused by increased fluid in the intra-articular space, physical examination will demonstrate swelling in the hollow or dimple around the patella and distention of the suprapatellar space.

Table 41–5 shows the differential diagnosis of knee pain, and Table 41–6 outlines possible diagnoses based on the location of pain.

### B. Laboratory Findings

Laboratory testing of aspirated joint fluid, when indicated, can lead to a definitive diagnosis in most patients (see Tables 20–2 and 20–3).

### C. Imaging

Knee pain is evaluated with plain (weight-bearing) radiographs and MRI most commonly, but CT and ultrasound are sometimes useful.

An acute hemarthrosis represents bloody swelling that usually occurs within the first 1–2 hours following trauma. In situations where the trauma may be activity-related and not a result of a fall or collision, the differential diagnosis most commonly includes ACL tear (responsible for more than 70% in adults), fracture (patella, tibial plateau, femoral supracondylar, growth plate [physeal]), and patellar dislocation. Meniscal tears are unlikely to cause large hemarthrosis.

### 2. Anterior Cruciate Ligament Injury

#### ESSENTIALS OF DIAGNOSIS

- An injury involving an audible pop when the knee buckles.
- Acute swelling immediately (or within 2 hours).
- Instability occurs with lateral movement activities and going down stairs.

#### General Considerations

The anterior cruciate ligament (ACL) connects the posterior aspect of the lateral femoral condyle to the anterior aspect of the tibia. Its main function is to control anterior translation of the tibia on the femur. It also provides rotational stability of the tibia on the femur. ACL tears are common with sporting injuries. They can result from both contact (valgus blow to the knee) and non-contact (jumping, pivoting, and deceleration) activities. The patient usually falls down following the injury, has acute swelling and difficulty with weight bearing and complains of instability. ACL injuries are common in skiing, soccer, football, and basketball among young adolescents and middle-aged patients. Prepubertal and older patients usually sustain fractures instead of ligamentous injuries.
Clinical Findings

A. Symptoms and Signs

Acute ACL injuries usually lead to acute swelling of the knee, causing difficulty with motion. After the swelling has resolved, the patient can walk with a "stiff-knee" gait or quadriceps avoidance gait because of the instability. Patients describe symptoms of instability while performing side-to-side maneuvers or descending stairs. Stability tests assess the amount of laxity of the knee while performing these maneuvers. The Lachman test (84–87% sensitivity and 93% specificity) is performed with the patient lying supine and the knee flexed to 20–30 degrees (Table 41–7). The clinician grasps the distal femur from

the lateral side and the proximal tibia with the other hand on the medial side. With the knee in neutral position, stabilize the femur, and pull the tibia anteriorly using a similar force to lifting a 10- to 15-pound weight. Excessive anterior translation of the tibia compared with the other side indicates injury to the ACL. The anterior drawer test (48% sensitivity and 87% specificity) is performed with the patient lying supine and the knee flexed to 90 degrees (Table 41–7). The clinician stabilizes the patient's foot by sitting on it and grasps the proximal tibia with both hands around the calf and pulls anteriorly. A positive test finds ACL laxity compared with the unaffected side. The pivot shift test is used to determine the amount of rotational laxity of the knee. The patient is examined while lying supine with the knee in full extension. It is then slowly flexed while applying internal rotation and a valgus stress. The clinician feels for a subluxation at 20–40 degrees of knee flexion. The patient must remain very relaxed to have a positive test.

B. Imaging

Plain radiographs are usually negative in ACL tears but are useful to rule out fractures. A small avulsion injury can sometimes be seen over the lateral compartment of the knee ("Segond" fracture) and is pathognomonic of an ACL injury. An ACL injury that avulsed the tibial spine can be seen in radiographs. MRI is the best tool to diagnose ACL tears and associated articular and meniscal cartilage issues. It has greater than 95% sensitivity and specificity for ACL tears.

Treatment

Most young and active patients will require surgical reconstruction of the ACL. Some data suggest that reconstruction within 5 months of the tear has better outcomes. However, a small randomized trial suggested that acute ACL injuries can be treated nonoperatively and delayed ACL reconstruction had similar outcomes to acute ACL reconstructions but patients for whom the reconstruction is delayed have more cartilage or meniscus problems at the time of surgery. Common surgical techniques use the patient's own tissue, usually the patellar or hamstring tendons (autograft) or a cadaver graft (allograft) to arthroscopically reconstruct the torn ACL. Different patient groups experienced improved results with specific surgical graft choices. However, allografts do have a higher failure rate when compared with autografts. Recovery from surgery usually requires 6 months.

Nonoperative treatments are usually reserved for older patients or those with a very sedentary lifestyle. Physical therapy can focus on hamstring strengthening and core stability. An ACL brace can help stability. Longitudinal studies have demonstrated that nonoperative management of an ACL tear can lead to a higher incidence of meniscus tears. Cost-analysis studies have shown that early ACL reconstruction can be more beneficial than nonoperative treatment and delayed subsequent surgeries.
When to Refer

- Almost all ACL tears should be referred to an orthopedic surgeon for evaluation.
- Individuals with instability in the setting of a chronic ACL tear (greater than 6 months) should be considered for surgical reconstruction.
- Patients with an ACL tear and associated meniscus or articular injuries may benefit from surgery to address the other injuries.

Clinical Findings

LCL or posterolateral corner injuries require urgent surgical repair or reconstruction. Individuals with instability in the setting of a chronic ACL tear (greater than 6 months) should be considered for surgical reconstruction.

Patients with an ACL tear and associated meniscus or articular injuries may benefit from surgery to address the other injuries.

General Considerations

The medial collateral ligament (MCL) is the most commonly injured ligament in the knee. It is usually injured with a valgus stress to the partially flexed knee. It can also occur with a blow to the lateral leg. The MCL is commonly injured with acute ACL injuries. The lateral collateral ligament (LCL) is less commonly injured, but this can occur with a medial blow to the knee. Since both collateral ligaments are extra-articular, injuries to these ligaments may not lead to any intra-articular effusion. Affected patients may have difficulty walking initially, but this can improve when the swelling decreases.

Clinical Findings

A. Symptoms and Signs

The main clinical findings for patients with collateral ligament injuries are pain along the course of the ligaments. The patient may have limited range of motion due to pain, especially during the first 2 weeks following the injury. The best tests to assess the collateral ligaments are the varus and valgus stress tests. The sensitivity of the tests is as high as 86–96%.

B. Imaging

Radiographs are usually nondiagnostic except for avulsion injuries. However, radiographs should be used to rule out fractures that can occur with collateral ligament injuries. Isolated MCL injuries usually do not require evaluation by MRI, but MRI should be used to evaluate possible associated cruciate ligament injuries. LCL or posterolateral corner injuries should have MRI evaluation to exclude associated injuries and to determine their significance.

Treatment

The majority of MCL injuries can be treated with protected weight bearing and physical therapy. For grade 1 and 2 injuries, the patient can usually bear weight as tolerated with full range of motion. A hinged knee brace can be given to patients with grade 2 MCL tears to provide stability. Early physical therapy is recommended to protect range of motion and muscle strength. Grade 3 MCL injuries require long leg braces to provide stability. Patients can weight-bear, but only with the knee locked in extension with a brace. The motion can then be increased with the brace unlocked. Grade 3 injuries can take up to 6–8 weeks to heal. MCL injuries rarely need surgery. LCL injuries are less common but are usually associated with other ligament injuries (such as ACL and PCL). LCL injuries do not recover well with nonoperative treatment and usually require urgent surgical repair or reconstruction.

When to Refer

- Symptomatic instability with chronic MCL tears or acute MCL tears with other ligamentous injuries.
- LCL or posterolateral corner injuries require urgent surgical repair or reconstruction (within 1 week).
4. Posterior Cruciate Ligament Injury

**ESSENTIALS OF DIAGNOSIS**

- Usually follows an anterior trauma to the tibia, such as a dashboard injury during a motor vehicle accident.
- The knee may freely dislocate and reduce.
- One-third of multi-ligament injuries involving the PCL have neurovascular injuries.

**General Considerations**

The posterior cruciate ligament (PCL) is the strongest ligament in the knee. PCL injuries usually represent significant trauma and are highly associated with multi-ligament injuries and knee dislocations. More than 70–90% of PCL injuries have associated injuries to the posterolateral corner, MCL, and ACL. Neurovascular injuries occur in up to one-third of all knee dislocations or PCL injuries. There should be high suspicion for neurovascular injuries and a thorough neurovascular examination of the limb should be performed.

**Clinical Findings**

**A. Symptoms and Signs**

Most patients with acute injuries have difficulty with ambulation. Patients with chronic PCL injuries can ambulate without gross instability but may complain of subjective “looseness” and often report pain and dysfunction, especially with bending. Clinical examinations of PCL injuries include the “sag sign”; the patient is placed supine and both hips and knees are flexed to 90 degrees. Because of gravity, the posterior cruciate ligament-injured knee will have an obvious set-off at the anterior tibia that is “sagging” posteriorly. The PCL ligament can also be examined using the posterior drawer test; the patient is placed supine with the knee flexed to 90 degrees. In a normal knee, the anterior tibia should be positioned about 10 mm anterior to the femoral condyle. The clinician can grasp the proximal tibia with both hands and push the tibia posteriorly. The movement, indicating laxity and possible tear of the PCL, is compared with the uninjured knee (90% sensitivity and 99% specificity). A PCL injury is sometimes mistaken for an ACL injury during the anterior drawer test since the tibia is subluxed posteriorly in a sagged position and can be abnormally translated forward, yielding a false-positive test for an ACL injury. Pain, swelling, pallor, and numbness in the affected extremity may suggest a knee dislocation with possible injury to the popliteal artery.

**B. Imaging**

Radiographs are often nondiagnostic but are required to diagnose any fractures. MRI is used to diagnose PCL and other associated injuries.

**Treatment**

Isolated PCL injuries can be treated nonoperatively. Acute injuries are usually immobilized using a knee brace with the knee extension; the patient uses crutches for ambulation. Physical therapy can help achieve increased range of motion and improved ambulation. Many PCL injuries are associated with other injuries and may require operative reconstruction.

**When to Refer**

- The patient should be seen urgently within 1–2 weeks.
- If the lateral knee is also unstable with varus stress testing, the patient should be assessed for a posterolateral corner injury, which may require an urgent surgical reconstruction.
- Isolated PCL tears may require surgery if the tear is complete (grade 3) and the patient is symptomatic.

---

5. Meniscus Injuries

**ESSENTIALS OF DIAGNOSIS**

- Patient may or may not report an injury.
- Joint line pain and pain with deep squatting are the most sensitive signs.
- Difficulty with knee extension suggests an internal derangement that should be evaluated urgently with MRI.

**General Considerations**

The menisci act as shock absorbers within the knee. Injuries to a meniscus can lead to pain, clicking, and locking sensation. Most meniscus injuries occur with acute injuries (usually in younger patients) or repeated microtrauma, such as squatting or twisting (usually in older patients).
Clinical Findings

A. Symptoms and Signs

The patient may have an antalgic (painful) gait and difficulty with squatting. He or she may complain of catching or locking of the meniscal fragment. Physical findings can include effusion or joint line tenderness. Patients can usually point out the area of maximal tenderness along the joint line. Swelling usually occurs during the first 24 hours after the injury or later. Meniscus tears rarely lead to the immediate swelling that is commonly seen with fractures and ligament tears. Meniscus tears are commonly seen in arthritic knees. However, it is often unclear whether the pain is coming from the meniscus tear or the arthritis.

Provocative tests, including the McMurray test, the modified McMurray test, and the Thessaly test, can be performed to confirm the diagnosis (Table 41–7). Most symptomatic meniscus tears cause pain with deep squatting and when waddling (performing a “duck walk”).

B. Imaging

Radiographs are usually normal but may show joint space narrowing, early OA changes, or loose bodies. MRI of the knee is the best diagnostic tool for meniscal injuries (93% sensitivity and 95% specificity). High signal through the meniscus (bright on T2 images) represents a meniscal tear.

Treatment

Conservative treatment can be used for degenerative tears in older patients. The treatment is similar for patients with mild knee OA, including analgesics and physical therapy for strengthening and core stability. A randomized controlled trial showed that physical therapy compared to arthroscopic partial meniscectomy had similar outcomes at 6 months. However, 30% of the patients who were assigned to physical therapy alone underwent surgery within 6 months.

Randomized studies have shown that arthroscopic surgery has no benefit over sham operations in patients who have degenerative meniscal tears, especially with imaging showing signs of osteoarthritis. Another randomized controlled trial found that patients with degenerative meniscus tears but no signs of arthritis on imaging treated conservatively with supervised exercise therapy had similar outcomes to those treated with arthroscopy at 2 year follow up. There is crossover between the groups; patients can be treated with supervised exercise therapy first, and if they do not respond to nonoperative treatment, they can undergo meniscectomy. Acute tears in young and active patients with clinical signs of internal derangement (catching and swelling) and without signs of arthritis on imaging or patients with acute mechanical locking with a displaced meniscus can be best treated arthroscopically with meniscus repair or debridement. There is also growing evidence that untreated meniscus root tears can lead to accelerated osteoarthritic changes. Surgical treatment before cartilage breakdown is recommended for acute meniscus root injuries.

When to Refer

- If the patient has symptoms of internal derangement suspected as meniscus injury. The patient should receive an MRI to confirm the injury.
- If the patient cannot extend the knee due to a mechanical block, the patient should be evaluated as soon as possible. Certain shaped tears on MRI, such as bucket handle tears, are amenable to meniscal repair surgery.
- If the patient has not responded to physical therapy and nonoperative treatment and continues to have symptoms related to the torn meniscus.
- If the patient has MRI confirmation of acute meniscus root injuries.

General Considerations

Patellofemoral pain, also known as anterior knee pain, chondromalacia, or "runner’s knee," describes any pain involving the patellofemoral joint. The pain affects any or all of the anterior knee structures, including the medial and lateral aspects of the patella as well as the quadriceps and patellar tendon insertions. The patella engages the femoral trochlear groove with approximately 30 degrees of knee flexion. Forces on the patellofemoral joint increase up to three times body weight as the knee flexes to 90 degrees (eg, climbing stairs), and five times body weight when going into full knee flexion (eg, squatting). Abnormal patellar tracking during flexion can lead to abnormal articular cartilage wear and pain. When the patient has ligamentous hyperlaxity, the patella can sublux out of the groove, usually laterally. Patellofemoral pain is also associated with muscle strength and flexibility imbalances as well as altered hip and ankle biomechanics.
Degeneration of joint cartilage.

General Considerations

When to Refer

Pain with bending or twisting activities.

Treatment

Loss of active and passive range of motion in the joint.

A. Conservative

For symptomatic relief, use of local modalities such as ice and anti-inflammatory medications can be beneficial. If the patient has signs of patellar hypermobility, physical therapy exercises are useful to strengthen the quadriceps (especially the vastus medialis obliquus muscle) to help stabilize the patella and improve tracking. There is consistent evidence that exercise therapy for patellofemoral pain syndrome may result in clinically important reduction in pain and improvement in functional ability. Lower quality research supports that hip and knee exercises are better than knee exercises alone. Strengthening the quadriceps and the posterolateral hip muscles such as the hip abductors that control rotation at the knee should be recommended. Support for the patellofemoral joint can be provided by use of a patellar stabilizer brace or special taping techniques (McConnell taping). Correcting lower extremity alignment (with appropriate footwear or over-the-counter orthotics) can help improve symptoms, especially if the patient has pronation or high-arched feet. If the patient demonstrates tight peripatellar soft tissues, special focus should be put on stretching the hamstrings, iliotibial band, quadriceps, calves, and hip flexors.

B. Surgical

Surgery is rarely needed and is considered a last resort for patellofemoral pain. Procedures performed include lateral release or patellar realignment surgery.

When to Refer

Patients with persistent symptoms despite a course of conservative therapy.

Clinical Findings

A. Symptoms and Signs

Patients usually complain of pain in the anterior knee with bending movements and less commonly in full extension. Pain from this condition is localized under the kneecap but can sometimes be referred to the posterior knee or over the medial or lateral inferior patella. Symptoms may begin after a trauma or after repetitive physical activity, such as running and jumping. When maltracking, palpable and sometimes audible crepitus can occur.

Intra-articular swelling usually does not occur unless there are articular cartilage defects or if OA changes develop. On physical examination, it is important to palpate the articular surfaces of the patella. For example, the clinician can use one hand to move the patella laterally, and use the fingertips of the other hand to palpate the lateral undersurface of patella. Patellar mobility can be assessed by medially and laterally deviating the patella (deviation by one-quarter of the diameter of the kneecap is considered normal; greater than one-half the diameter suggests excessive mobility). The apprehension sign suggests instability of the patellofemoral joint and is positive when the patient becomes apprehensive when the patella is deviated laterally. The patellar grind test is performed by grasping the knee superior to the patella and pushing it downward with the patient supine and the knee extended, pushing the patella inferiorly. The patient is asked to contract the quadriceps muscle to oppose this downward translation, with reproduction of pain or grinding being the positive sign for chondromalacia of the patella. There are two common presentations: (1) patients whose ligaments and patella are too loose (hypermobility); and (2) patients who have soft tissues that are too tight, leading to excessive pressure on the joint.

Evaluation of the quadriceps strength and hip stabilizers can be accomplished by having the patient perform a one-leg squat without support. Patients who are weak may display poor balance, with dropping of the pelvis (similar to a positive hip Trendelenburg sign) or excessive internal rotation of the knee medially. Normally, with a one-leg squat, the knee should align over the second metatarsal ray of the foot.

B. Imaging

Diagnostic imaging has limited use in younger patients and is more helpful in older patients to assess for OA or to evaluate patients who do not respond to conservative treatment. Radiographs may show lateral deviation or tilting of the patella in relation to the femoral groove. MRI may show thinning of the articular cartilage but is not clinically necessary, except prior to surgery or to exclude other pathology.

Treatment

A. Conservative

For symptomatic relief, use of local modalities such as ice and anti-inflammatory medications can be beneficial. If
Clinical Findings

A. Symptoms and Signs

OA usually causes pain in the affected joint with loading of the joint or at the extremes of motion. Mechanical symptoms—such as swelling, grinding, catching, and locking—suggest internal derangement, which is indicated by damaged cartilage or bone fragments that affect the smooth range of motion expected at an articular joint. Pain can also produce the sensation of “buckling” or “giving way” due to muscle inhibition. As the joint degeneration becomes more advanced, the patient loses active range of motion and may lose passive range of motion as well.

As the condition worsens, patients with knee OA have an increasingly limited ability to walk. Symptoms include pain with bending or twisting activities, and going up and down stairs. Swelling, limping, and pain while sleeping are common complaints with OA, especially as it progresses.

B. Imaging

The most commonly recommended radiographs include bilateral weight-bearing 45-degree bent knee posteroanterior, lateral, and patellofemoral joint views (Merchant view). Radiographic findings include diminished width of the articular cartilage causing joint space narrowing, subchondral sclerosis, presence of osteophytes, and cystic changes in the subchondral bone. MRI of the knee is most likely unnecessary unless other pathology is suspected, including ischemic osteonecrosis of the knee.

Treatment

A. Conservative

Changes in the articular cartilage are irreversible. Therefore, a cure for the diseased joint is not possible, although symptoms or structural issues can be addressed to try to maintain activity level. Conservative treatment for all patients with OA includes activity modification, therapeutic exercises, and weight loss. Lifestyle modifications also include proper footwear and avoidance of high-impact activities. Optimal exercise programs for knee OA should focus on improving aerobic capacity, quadriceps muscle strength, or lower extremity performance. Ideally, the program should be supervised and carried out three times a week.

Use of a cane in the hand opposite to the affected side is mechanically advantageous. Knee sleeves or braces provide some improvement in subjective pain symptoms most likely due to improvements in neuromuscular function. If patients have unicompartmental OA in the medial or lateral compartment, joint unloader braces are available to offload the degenerative compartment. Cushioning footwear and appropriate orthotics or shoe adjustments are useful for reducing impact to the lower extremities.

There are several oral and intra-articular pharmacologic options. Treatments that have been studied include oral acetaminophen, diclofenac, ibuprofen, naproxen, celecoxib, and intra-articular corticosteroids and hyaluronic acid. All treatments except acetaminophen showed clinically significant improvement in pain. If a traditional NSAID is indicated, the choice should be based on cost, side-effect profile, and adherence. The cyclooxygenase (COX)-2 inhibitor celecoxib is no more effective than traditional NSAIDs; it may offer short-term, but probably not long-term, advantage in preventing gastrointestinal complications. Due to its cost and potential cardiovascular risk, celecoxib should be reserved for carefully selected patients. Topical NSAIDs or capsaicin can be effective in the treatment of OA, since they avoid many of the traditional NSAID complications. Opioids can be used appropriately in patients with severe OA (see Chapter 5). Glucosamine and chondroitin sulfate are supplements that have been widely used and marketed for OA. Despite some initial promise, the best-controlled studies indicate these supplements are ineffective as analgesics in OA. However, they have minimal side effects and may be appropriate if the patient experiences subjective benefit.

Knee joint corticosteroid injections are options to help reduce pain and inflammation and can provide short-term pain relief, usually lasting about 6–12 weeks. Viscosupplementation by injections of hyaluronic acid–based products is controversial. Because reviews suggest that viscosupplementation has a questionable clinically relevant effect size, and has an increased risk of adverse events, the American Academy of Orthopedic Surgeons has recommended that viscosupplementation should not be used in the treatment of knee OA. However, the American College of Rheumatology’s 2012 OA guidelines recommend the use of intra-articular hyaluronic acid injection for the treatment of OA of the knee in adults. Platelet-rich plasma injections contain high concentration of platelet-derived growth factors, which regulate some biologic processes in tissue repair. A meta-analysis of 10 studies demonstrated that platelet-rich plasma injections reduced pain in patients with knee OA more efficiently than placebo and hyaluronic acid injections. However, 9 of the 10 studies had a high risk of bias, and the underlying mechanism of biologic healing is unknown. An FDA safety and efficacy study showed that leukocyte-poor PRP autologous conditioned plasma improved overall Western Ontario and McMaster Universities Arthritis Index scores by 78% from the baseline score after 12 months, compared to 7% for the placebo group, though the sample size was small (30 patients).

B. Surgical

Two randomized trials demonstrated that arthroscopy does not improve outcomes at 1 year over placebo or routine conservative treatment of OA. Joint replacement surgeries are effective and cost-effective for patients with significant symptoms or functional limitations, providing improvements in pain, function, and quality of life. The number of total knee arthroplasty procedures jumped 162% from 1991 to 2010, along with an increase
in complications and hospital readmissions. Minimally invasive surgeries and computer-assisted navigation during operation are being investigated as methods to improve techniques (eg, accurate placement of the hardware implant) and to reduce complication rates; however, major improvements have yet to be demonstrated.

Knee realignment surgery, such as high tibial osteotomy or partial knee replacement surgery, is indicated in patients younger than age 60 with unicompartmental OA, who would benefit from delaying total knee replacement. Knee joint replacement surgery has been very successful in improving outcomes for patient with end-stage OA. Long-term series describe more than 95% survival rate of the implant at 15 years.

When to Refer

Patients with sufficient disability, limited benefit from conservative therapy, and evidence of severe OA can be referred for joint replacement surgery.

A positive test consists of increased subtalar joint inversion greater than 10 degrees on the affected side with loss of endpoint for the calcaneofibular ligament. In order to grade the severity of ankle sprains, no laxity on stress tests is considered a grade 1 injury, laxity of the ATF ligament on anterior drawer testing but a negative tilt test is a grade 2 injury, and both positive drawer and tilt tests signify a grade 3 injury. Difficulty jumping and landing within 2 weeks from the acute ankle sprain, abnormal postural or hip muscle control, or ligamentous laxity noted 8 weeks after injury are poor prognostic signs.

**B. Imaging**

Routine ankle radiographic views include the AP, lateral, and oblique (mortise) views. Less common views requested include the calcaneal view and subtalar view. The **Ottawa Ankle Rules** remain the best clinical prediction rules to guide the need for radiographs and have an 86–99% sensitivity and a 97–99% negative predictive value. If the patient is unable to bear weight immediately in the office setting or emergency department for four steps, then the clinician should check for (1) bony tenderness at the posterior edge of the medial or lateral malleolus and (2) bony tenderness over the navicular (medial midfoot) or at the base of the fifth metatarsal. If either malleolus demonstrates pain or deformity, then ankle radiographs should be obtained. If the foot has bony tenderness, obtain foot radiographs. An MRI is helpful when considering the associated injuries.

**When to Refer**

- Ankle fractures.
- Recurrent ankle sprains or signs of chronic ligamentous ankle instability.
- No response after more than 3 months of conservative treatment.
- Suspicion of associated injuries.

**ESSENTIALS OF DIAGNOSIS**

- Severe and prolonged pain.
- Limited range of motion.
- Mild swelling.
- Difficulty with weight bearing.

**2. Eversion ("High") Ankle Sprains**

**General Considerations**

A syndesmotic injury or "high ankle" sprain involves the anterior tibiotalar ligament in the anterolateral aspect of the ankle, superior to the anterior talofibular (ATF) ligament. The injury mechanism often involves the foot being turned out or externally rotated and everted (eg, when being tackled). This injury is commonly missed or misdiagnosed as an ATF ligament sprain on initial visit.

**Clinical Findings**

**A. Symptoms and Signs**

Symptoms of a high ankle sprain include severe and prolonged pain over the anterior ankle at the anterior tibiotalar ligament, worse with weight bearing. This is often more painful than the typical ankle sprain. The point of maximal tenderness involves the anterior tibiotalar ligament, which is higher than the ATF ligament. It is also important to palpate the proximal fibula to rule out any proximal syndesmotic ligament injury and associated fracture known as a "maisonneuve fracture." There is often some mild swelling in this area, and the patient may or may not have an ankle effusion. The patient usually has limited range of motion in all directions. To perform the **external rotation stress test**, the clinician fixes the tibia with one hand and grasps the foot in the other with the ankle in the neutral position. The ankle is then dorsiflexed and externally rotated, reproducing the patient's pain. *(Note: The patient's foot should have an intact neurovascular examination before undertaking this test.)*

**B. Imaging**

Radiographs of the ankle should include the AP, mortise, and lateral views. The mortise view may demonstrate loss of the normal overlap between the tibia and fibula, which should be at least 1–2 mm. Asymmetry in the joint space around the tibiotalar joint suggests disruption of the syndesmotic ligaments. If there is proximal tenderness in the lower leg especially around the fibula, an AP and lateral view of the tibia and fibula should be obtained to rule out a proximal fibula fracture. Radiographs during an external rotation stress test may visualize instability at the distal tibiotalar joint. MRI is the best method to visualize...
injury to the tibiofibular ligament and to assess status of the other ligaments and the articular cartilage.

» **Treatment**

Whereas most ankle sprains are treated with early motion and weight bearing, treatment for a high ankle sprain should be conservative with a cast or walking boot for 4–6 weeks. Thereafter, protected weight bearing with crutches is recommended until the patient can walk pain-free. Physical therapy can start early to regain range of motion and maintain strength with limited weight bearing initially.

» **When to Refer**

If there is widening of the joint space and asymmetry at the tibiotalar joint, the patient should be referred urgently to a foot and ankle surgeon. Severe or prolonged persistent cases that do not heal may require internal fixation to avoid chronic instability at the tibiofibular joint. Screw fixation remains the gold standard, although newer techniques with bioabsorbable constructs are emerging.

The term sexual and gender minorities (SGM) refers to a broad group including lesbian women and gay men; bisexual, pansexual, and queer people; and transgender and gender non-binary people—also commonly referred to as "LGBTQ." Cisgender refers to people whose gender identity (a person's internal sense of gender) and sex assigned at birth are congruent (ie, they are not transgender). Transgender people may also be sexual minorities (ie, lesbian transgender women or gay transgender men). For the sake of expediency in this chapter, the sections on sexual minority men and women omit the term "cisgender"; however, readers of content in these sections should take into consideration that, for example, gay transgender men may have vaginal receptive sex with their cisgender male sexual partners, and therefore should be screened for contraception needs, and cisgender lesbian women may have transgender female partners who retain their penis. A growing number of people identify as pansexual, which describes an attraction to people of any gender, male, female, or on the spectrum between the two. The term queer, historically a pejorative term, has been reclaimed by many SGM people to represent someone with a sexuality or gender identity or expression that differs from that of a cisgender (ie, non-transgender), heterosexual person. Sexual orientation refers to a deep-seated sense of one's sexuality that encompasses three dimensions: identity, behavior, and desire. Sexual identities include gay or homosexual (those who are predominantly attracted to and/or sexually active with members of the same gender), bisexual (those who are attracted to and/or sexually active with both men and women), and heterosexual or straight; however, several other terms may be used, and terminology may change over time.

The three dimensions of sexual orientation—identity, behavior, and desire—do not necessarily overlap. For example, less than 50% of men who have sex with men (MSM) in one national, probability-based survey identified as gay. MSM who identify as heterosexual rather than as gay or bisexual may be more likely than their gay-identified counterparts to be married to women, foreign-born, of minority race, and of lower socioeconomic status. The incomplete overlap of identity and behavior means that clinicians cannot rely upon self-reported identity to infer sexual behavior, and vice versa. It is important to distinguish sexual orientation from their gender identity. Knowing someone's gender identity does not identify one's sexual orientation. Just as cisgender people may be sexually attracted to and have sex with people of any gender, so too can transgender men, transgender women, and non-binary people have partners of any gender. Routinely asking about sexual orientation, and when relevant for the clinical issue at hand, sexual behavior, helps build trust between the patient and clinician, ensures appropriate medical care (for example, appropriate screening tests for sexually transmitted infections [STIs] and family planning), and contributes to better health outcomes. To inquire about gender identity, the following two questions are recommended: "What is your current gender identity?" and "What sex were you assigned at birth?"

Sexual orientation may also change over time or be situational (such as during periods of limited mobility or during incarceration). People may also hide their sexual orientation from others, including clinicians, in order to avoid stigma and discrimination. Revealing one's sexual orientation is called "coming out." This process may occur at any point in life and may vary by context (for example, being "out" to family but not to coworkers).

Sexual and gender identity can be fluid throughout a person's lifetime, and the binary concept of gender is not evidence based. Some legal policies are moving to reflect this fluidity. In California, the choice of gender on legal documents is female, male, or non-binary. These choices have implications for health screening for patients who receive care in health systems with pop-up reminders for sex-specific screening examinations such as mammography or prostate examinations.

Providing compassionate and informed health care for SGM patients, which include but are not limited to people...
who identify as lesbian, gay, bisexual, transgender, and queer, involves the acknowledgment of the negative effects on health caused by discrimination and stigma. LGBTQ people are underserved by the medical community and under-studied, with worse health outcomes compared to the heterosexual and cisgender population. One reason for these disparities is that a previous negative experience in a clinician’s office influences whether the patient will repeat a visit even for an acute medical event, which can delay care and result in advanced disease. One in three transgender people report delays in seeking care due to prior discrimination, and one in five report being refused medical care due to their transgender identity. Some of the compromised health outcomes are related to limited access to the health care system due to financial issues as well as previous negative experiences in society at large. These structural issues will take time to change. However, clinicians can impact the health outcomes of LGBTQ people by ensuring that the clinical space is welcoming to people of all genders and sexual orientations (see below), obtaining comprehensive data on sexual orientation and gender identity, and being aware of the specific health needs of LGBTQ people in order to advance the health of LGBTQ patients.

The vast majority of SGM patients would like to “come out” to their clinician. Many clinicians, however, are concerned that their patients would be offended if asked about sexual orientation and identity. It is important that clinicians overcome any discomfort and ask appropriate questions of their patients. There are useful video resources to help clinicians with these issues; one example is “Acknowledging Sex and Gender” Online Training video from the University of California, San Francisco Center of Excellence for Transgender Health http://transhealth.ucsf.edu/video/story_html5.html?lms=1.

Making Clinical Environments Welcoming to All SGM Patients

Part of serving SGM patients is to create a welcoming clinical space where each person is cared for and respected for all of who they are—including their sexual orientation, gender identity, and gender expression. This includes making sure that (1) senior leadership is involved; (2) nondiscrimination policies are in place, are followed, and are prominently displayed; (3) open visitation policies are concordant with patients’ choice of visitors; (4) outreach and engagement efforts are made for LGBTQ patients; (5) staff receive culturally affirming training in the care of LGBTQ people; (6) processes, forms, artwork, and reading materials reflect the diversity of LGBTQ people; (7) data are collected about both sexual orientation and gender identity in an open and nonjudgmental manner; (8) patients are routinely asked about their sexual health histories; (9) clinical care and services include prevention and wellness care with family planning services and behavioral health services available; (10) LGBTQ staff are recruited and trained; (11) preventive care is concordant with clinical practice guidelines, where applicable; and (12) if gender neutral bathrooms are not available, a posting states that patients are welcome to use either the women’s or men’s bathroom and the patient can determine which bathroom to use. One exercise is to look at clinic materials (ie, signs, posters, brochures, magazines, intake forms etc.) and see if materials presume heterosexual behavior and gender conformity. Often, materials discussing anatomy, sex, family planning, conception, pregnancy, and birth presume heterosexuality. If so, find or create more inclusive materials to replace them.

Obtaining Sexual History From SGM Patients

The core history and physical examination is not different for SGM in comparison to other patients. Clinicians should approach each patient as an individual, using patients’ preferred pronouns, using appropriate terminology, respecting the diversity of gender identity as well as the differing desires for gender affirming treatments, and performing a physical examination noting anatomic changes from any prior gender affirming treatment. As with all adolescent or adult patients, a complete medical history should include a comprehensive sexual history. Clinicians may wish to preface discussion of the patient’s sexual history with a statement indicating that this information is confidential and is important in order to provide optimal health care. However, patients should not be expected to discuss their gender identity or transition unless it is relevant to the current visit. In addition, it is crucial that clinicians understand that transgender patients may have physical appearances and/or names that do not reflect their legal names or sex markers. Staff members must learn how to elicit patients’ names and accepted pronouns so that these can be used consistently.

Key data to gather in a relevant sexual history include sexual function and satisfaction; number of partners if the patient is sexually active; and the gender(s) of the patient’s sexual partner(s). In addition, clinicians should determine the types of sexual practices the patient engages in (for example, oral sex, insertive anal sex, and/or receptive anal sex); how often condoms are used, if at all, for the different sexual practices the patient engages in; and whether or not drugs and/or alcohol are consumed in conjunction with sex. Clinicians should also establish whether there is a history of STIs because a positive history may have implications for medical follow-up and sexual risk assessment (eg, frequency of screening, syphilis serologies, and discussion about preexposure prophylaxis [PrEP]). For example, a
Electronic medical record (EMR) systems should include functionality for the recording of gender identity and birth-assigned sex as well as chosen name and pronoun in the case of a transgender person who has not changed their legal identity documents. Chosen name and pronoun functionality should be displayed in all banners, schedules, and legal identity documents. Chosen name and pronoun functionality should be displayed in all banners, schedules, and legal identity documents.

Evidence suggests that most individuals are ready and willing to disclose to sensitive providers who make it clear the intent behind their questions. Additional questions include the following:

1. “Do you have a partner or a spouse?” or “Are you currently in a relationship?”
2. “Are you sexually active?”
3. “When was the last time you had sex?”
4. “What are the genders of your sexual partner(s)?”
5. “What body parts of yours touch which body parts of your partners?”
6. “How many sexual partners have you had during the last year?”
7. “Do you have any desires regarding sexual intimacy that you would like to discuss?”

Rather than considering this a one-time intervention, it should be thought of as a process that is assessed over time and at critical junctures and changes in health status.

**The Electronic Medical Record**

Electronic medical record (EMR) systems should include functionality for the recording of gender identity and birth-assigned sex as well as chosen name and pronoun in the case of a transgender person who has not changed their legal identity documents. Chosen name and pronoun functionality should be displayed in all banners, schedules, and other viewing screens. Transgender people can be identified within the EMR that supports the data collection of gender as separate from sex assigned at birth, by identifying those individuals whose entries for gender identity and birth sex differ. Collecting gender identity and birth assigned sex data is critical to understanding the population of people in care within a health system.

Disclosure in the EMR of a patient’s sexual orientation and gender identity has been advocated in the United States by the National Academy of Medicine, the Joint Commission, and the Health Resources and Services Administration as fundamental to improving access to and quality of care for LGBTQ people. However, there are risks for LGBTQ people with having their sexual orientation and gender identity documented in the EMR. Examples of such risks include loss of employment. In 28 states in the United States, a person can be legally terminated from employment on the basis of sexual orientation, and same-sex relations are criminalized in over 72 countries. Specific issues that limit the adaptability of some medical records to the LGBTQ population are related to “sex-specific” experiences such as the inability to register a male pregnancy episode. There are “work-arounds,” such as having a place for preferred name for all patients that medical assistants can routinely check before inviting a patient into an examination room. The EMR can also be used to gather answers to sensitive questions before an initial visit so that the patient can provide information privately.

---

**Family Planning**

**A. Pregnancy Prevention**

Comprehensive family planning for LGBTQ people is important to address, so that all pregnancies are intended if at all possible. Anyone with a uterus, ovaries, and fallopian tubes can potentially become pregnant if they engage in penis-in-vagina sex. This includes transgender men who are taking testosterone or still amenorrheic from testosterone. Furthermore, transgender women who have a penis and testes may still produce sperm capable of fertilizing an oocyte even if using gender affirming hormones. Since sexual orientation and gender identity do not predetermine sexual partners, all individuals should be asked about family building intentions as well as contraception if pregnancy is undesired.

The majority of lesbians have been sexually active with men at some point in their lives (85–90%), and 30% of self-identified adult lesbians are currently sexually active with men as well as with women. Fewer lesbian youth use hormonal contraception than heterosexual female youth. On
multiple surveys, one of the reasons that lesbians do not follow up for gynecologic care is the assumption by the clinician that they are heterosexual, and the (insensitive) advocacy of birth control in that assumptive atmosphere about their sexuality (ie, heteronormative). On the other hand, multiple studies show that the unintended pregnancy rate of self-identified lesbian youth is higher than that of the comparison heterosexual female youth. Unintended pregnancy risk continues into adulthood with one sample from the Chicago Health and Life Experiences of Women survey reporting 24% of sexual minority women having had unintended pregnancies. The reasons for disproportionate unintended pregnancy rates have not been fully elucidated but may involve discrimination and family rejection leading to higher-risk behaviors, increased alcohol and other substance use, less effective birth control usage, and multiple sexual partners. Another reason may be attempts to prove one’s “straightness” by engaging in penis-in-vagina sexual activity. It has been determined that the patient self-identifies as a lesbian and is having (penis-in-vagina) sex with men, one suggested question might be, “Are you planning to get pregnant this year?” If the answer is no, this is an opportunity to explain that studies show a higher unintended rate of pregnancy in lesbian youth and to review effective contraception options. It is also a good time to talk about protection from STIs when having sex with men (ie, discuss condoms). As with any person engaging in penis-in-vagina sex, experts recommend additional contraceptives to condoms. Condoms are only 80% reliable in preventing pregnancy with typical use. Long-acting reversible contraceptives, which are not patient or sexual act dependent and function effectively despite alcohol or other substance use, are especially important to consider. Long-acting reversible contraceptives such as an etonorgestrel subdermal implant in the arm (0.05% annual failure) or either the copper (0.8% annual failure) or levonorgestrel (0.2% annual failure) intrauterine devices are highly effective and typical use is generally equivalent to ideal use.

For transgender men and non-binary individuals who were assigned female sex at birth, contraception is important even if testosterone is being used, since testosterone is not a reliable form of contraception. To underscore the points, transgender men taking testosterone (even if amenorrheic) who have a uterus and ovaries and are sexually active with sperm involved should use a standard contraceptive method if they want to avoid a pregnancy. There are multiple case reports in the literature of transgender men who have unintended pregnancies while taking testosterone. Little is known about contraceptive preferences and use profiles among transgender men and non-binary people who were female sex assigned at birth. This is, however, an emerging field and new studies suggest unmet contraceptive need and diverse contraceptive method usage type, including long-acting reversible contraceptives (eg, intrauterine devices).

B. Family Building

Family building should be discussed with all patients, regardless of sexual orientation or gender identity. Options include foster-parenting or adoption (in some countries these options are not open to LGBTQ persons), co-parenting a partner’s child/children, becoming pregnant, contracting with a surrogate, or step-parenting. Some fertility practices refuse to assist LGBTQ people with conception even if it is legal. The American College of Obstetricians and Gynecologists published Committee Opinion No. 749 in 2018, reaffirming their stance that no matter how a child comes into a family, all children and parents deserve equitable protections and access to available resources to maximize the health of that family unit. “Obstetricians-gynecologists should recognize the diversity in parenting desires that exists in the lesbian, gay, bisexual, transgender, queer, intersex, asexual and gender nonconforming communities and should take steps to ensure that clinical spaces are affirming and open to all parties, such that equitable and comprehensive, reproductive health care can meet the needs of these communities."

Lesbian and bisexual cisgender women have many options to consider for conception and may ask the clinician for an opinion and to guide them to resources. Many lesbian women decide to have inseminations with an unknown donor (some unknown donors sign a release so that the child may contact the donor when the child reaches 18 years old), and some lesbian women decide to involve a known sperm donor. Most sperm banks are regulated in regard to the administration of medical history forms, the testing of sperm for STIs, and the performance of genetic screening. Known donors may have risk factors but are not routinely screened. It is important for a woman to be as informed as she can be about the legal implications of each option. In some states and countries, unless the insemination with known donor sperm takes place in the office of a physician, the known donor has full legal rights as well as financial responsibilities for the offspring. In one study of 129 lesbian mothers with 77 index offspring, 77.5% of the mothers were satisfied with the type of donor chosen (36% had chosen known sperm donors, 25%
open-custody concerns were the primary themes mentioned by lesbian mothers regarding their (dis)satisfaction with the type of sperm donor they had selected.

Some lesbian women who are partnered decide to do “co-in vitro fertilization (IVF),” which is also known as “reciprocal IVF” or “co-maternity” in which one partner provides an egg, it is fertilized in the laboratory with sperm of a known or unknown donor, and then the other partner carries the pregnancy. Lactation for the nonestating mother can sometimes be induced by using a protocol that stemmed originally from the experiences of adoptive mothers who were motivated to breastfeed. Many lesbian women delay childbearing until later in life, and then the issues of fertility, pregnancy loss, and birth defects increase. Pregnancy outcomes of bisexual and lesbian women compared to heterosexually identified women include increased risk of miscarriage (odds ratio [OR] 1.77) and stillbirth (OR 2.85), as well as very preterm birth (OR 1.84). There have been many studies on the overall outcomes of children of lesbian women, all of which have been positive when comparing their children to children raised by heterosexual parents, despite the stigma the children experience of having same-sex parents. Using the 2011–2012 National Survey of Children’s Health data set from the United States, children with female same-sex parents and different-sex parents demonstrated no differences in outcomes (spouse-partner relationships, emotional difficulties, coping behaviors, and learning behavior).

Biologic options for pregnancy for cisgender gay men include conceiving with a cisgender woman who may or may not be interested in co-parenting with them, or contracting with a surrogate to carry the pregnancy after the sperm and a donor egg are fertilized and placed in the uterus of the surrogate. For transgender people, there are also options. Prior to initiation of any gender affirming hormones or gender affirming surgical procedures, a consultation with a reproductive endocrinologist to discuss fertility preservation and future genetic offspring is encouraged. Reproductive planning is often not a priority for a transitioning youth but may become a desire in the future and may also be a priority for potential grandparents. Options are limited for transgender youth who have not undergone endogenous puberty before either starting gender affirming hormones (with estrogen or testosterone) or puberty blockers and then going directly to estrogen or testosterone. The only future fertility option is either testicular or ovarian tissue cryopreservation, which is still considered experimental. For transgender women and gender non-binary individuals who were male sex assigned at birth and who have reached adulthood after endogenous puberty, sperm can be stored ideally prior to the initiation of estrogen. Of note, though some transgender women still produce sperm even after long-term estrogen exposure, it is recommended that sperm cryopreservation occur prior to hormone start because the effect on fertility is hard to quantify and coming off hormones can often be dysphoric. For transgender men and non-binary individuals who were female sex assigned at birth and have gone through endogenous puberty, next steps in genetic parentage will be predicated on the desire to carry a pregnancy and whether or not they have started gender affirming hormones. Options include penis-in-vagina sex, intravaginal insemination, intrauterine insemination, and egg cryopreservation for the individual, a partner, or surrogate to carry. Of note, if a transgender man wishes to carry a pregnancy and is using testosterone, testosterone should be stopped for the duration of the pregnancy. If a transgender man desires future genetic parentage, the consultant might recommend egg aspiration and freezing prior to the start of testosterone. If a hysterectomy is planned as part of gender affirmation, discussion of whether ovaries are left in place should occur in light of consideration of future genetic parentage as well as future hormone regulation. Although in one study in Australia, only 7% of transgender and non-binary adults had undertaken fertility preservation, 95% said that fertility preservation should be offered to all transgender and non-binary people. Participants who viewed genetic relatedness as important were more likely to have undertaken fertility preservation.

All LGBTQ persons planning a pregnancy should be encouraged to consult with a family attorney prior to conception, and if partnered, the partner needs to be aware of their rights and responsibilities. The law has not kept up with the variety of family constellations that are seen in LGBTQ families. Examples of these constellations can include two gay cisgender dads parenting together each using the same egg donor so that their children are half-siblings biologically, a lesbian couple composed of a transgender woman and cisgender woman where one mother provides the sperm and another provides the egg and carries the pregnancy, a straight cisgender dad parenting with a lesbian cisgender mom, a lesbian cisgender couple with the sperm donor being the brother of the parent who did not provide the egg so one mother is the genetically related via the egg and the other mother is the related to the child via being a biologic aunt, two cisgender lesbians each carrying a pregnancy conceived with their own eggs and using the same sperm donor so that their children are half-siblings, two gay men where one is a cisgender man and provides the sperm and one is a transgender man and provides the egg and surrogate carries the pregnancy, and so on.

Baiocco R et al. Same-sex and different-sex parent families in Italy: is parents’ sexual orientation associated with child health outcomes and parental dimensions? J Dev Behav Pediatr. 2018 Sep;39(7):555–63. [PMID: 29781831]

Prevention of CVD

The risk of CVD is higher in sexual minority women compared with heterosexual peers. Though many studies lack objective measures such as biomarkers, a systematic review demonstrated greater CVD among sexual minority women. Ultimately this outcome seemed most influenced by societal conditions (ie, cumulative minority stress) that impact the CVD risk. In one study, lesbian and bisexual women were 14% older in vascular terms than their chronological age, which was 6% greater than that of heterosexual counterparts.

Health disparities exist across the life span for lesbian and bisexual women compared to heterosexual women. The following are increased among lesbian and bisexual women: childhood physical abuse in the home, childhood sexual abuse, substance use including alcohol and tobacco, chlamydial infection as teens and young adults, sexual assault, depression, disabilities, body mass index (BMI), intimate partner violence, threats and violence outside the home, asthma, and cardiovascular disease (CVD). Sexual dysfunction for lesbian and bisexual women is seen less often or as often as heterosexual women but is understudied and likely assessed at rates lower than among heterosexual women. A high risk of sexual dysfunction can be detected by a single question regarding sexual function: “Do you have any questions or concerns about your sexual identity or sexual health?” Studies of Irish LGBTQ elders reveal concerns about residential care outside of their own home as well as respect by health professionals; similarly, there are concerns about home services for lesbian and bisexual women in Canada and the United States. Lesbian and bisexual women have fewer children available to help them as they age compared to heterosexual women. Therefore, it is critical that health care providers identify health decision makers for all patients including lesbian and bisexual women who may have more “family of choice” members versus “family of origin” members who may be estranged. This is especially important since same-sex/same-gender marriage is not allowed in many countries and is still considered socially unacceptable in many areas of the United States. To avoid conflict during critical decision-making moments, the health decision maker needs to be identified on the medical record after a private conversation with the patient. In one survey, only about 50% of same-sex couples who desired their partner to be the health decision maker had appropriate forms, and even if married, advance directives should be completed given past visitation denials.

Many notable legal cases, including that of Sharon Kowalski and Karen Thompson, have documented the struggles that same-sex partners can face regarding visitation and appropriate recognition during end-of-life care or critical medical decision making when these documents have not been completed. Elder abuse screening also needs to be done, since the incidence is unknown.

Cigarette smoking is more common among lesbian and bisexual women than in heterosexual women. While estimates vary, the National Adult Tobacco Survey noted 22% of lesbian women and 32% of bisexual women smoke compared with 13% of heterosexual women. The National Health Interview Survey, a United States Centers for Disease Control and Prevention (CDC) sponsored and administered study, noted that lesbian and bisexual women are also heavier smokers. The tobacco industry’s well-documented targeted marketing to LGBTQ groups and the use of cigarette smoking to decrease social stress are probable factors. Significant racial and ethnic differences exist with Asian and Pacific Islander lesbian and bisexual women, who have four times higher odds of smoking than heterossexual Asian and Pacific Islander women. In high school, LGB adolescents reported a higher prevalence of daily cigarette use (22%) compared with heterosexual youth (11%). Protective factors against smoking behaviors for young LGB women included connections with other LGBTQ people. Another study demonstrated that though desire to quit did not differ between sexual minority women and their heterosexual counterparts, cessation attempts did differ, suggesting that clinicians need to customize cessation interventions for sexual minority women.

Traditional smoking cessation programs and targeted LGBTQ programs are effective for LGBTQ people. A review of smoking cessation programs for LGBTI (I = intersex) people found that with cultural modifications for LGBTI people, 61% had quit at the end of interventions and this stabilized to 39% at 3–6 months. In Canada, 24 focus groups in Toronto and Ottawa detailed eight overarching themes that would be important in a smoking intervention: (1) be LGBTQ+ specific; (2) be accessible in terms of location, time, availability, and cost; (3) be inclusive, relatable, and highlight diversity; (4) incorporate LGBTQ+ peer support and counseling services; (5) integrate other activities beyond smoking; (6) be positive, motivational, uplifting, and empowering; (7) provide concrete coping mechanisms; and (8) integrate rewards and incentives. Other studies have corroborated that both LGBTQ-specific (such as relation to “coming out,” different norms and acceptability of smoking among LGBTQ communities, or LGBTQ-related minority stress) and previously identified factors seen in other populations (such as self-efficacy around quitting) are important to support LGBTQ people in quitting smoking. The LGBTQ people in Ireland have very high tobacco use and exposure to secondhand smoke. Attention should be paid to messaging about smoking warnings because not all messages are perceived as equally effective by sexual minorities when compared with heterosexual people. Encourage patients to check with their community or online resources for smoking cessation programs and encourage participation in LGBTQ tailored programs, if available.

Data regarding obesity and overweight prevalence in lesbians and bisexual women are mixed. Many studies, though, including an analysis of over 60,000 women in the National Health Interview Survey find that being a sexual minority woman is associated with an elevated BMI compared to heterosexual women. The prevalence of obesity may not be uniform across racial and ethnic groups. The odds of obesity among lesbian women in the following groups differed when compared with heterosexual women in the same racial group: Latina lesbian women 1.39 (95% CI, 1.20, 1.61), Asian and Pacific Islander lesbian women 1.22 (95% CI, 0.76, 1.94) vs American Indian/Alaska Native lesbian women 2.06 (95% CI, 1.56, 2.70). Findings also differed between bisexual and lesbian women within racial and ethnic minority groups.

Obesity and overweight may start at a young age in lesbian and bisexual youth, and they may conceptualize their weight differently than heterosexual peers. Among adolescents in the Massachusetts Youth Risk Behavior Survey, lesbian and bisexual females were more likely to self-perceive as being of healthy weight or underweight despite being overweight or obese, and 33% engaged in hazardous weight control behaviors. A high school–based study (grades 9–12) in 22 Wisconsin schools revealed that sexual minority female youth, compared to their heterosexual counterparts, were less likely to participate in team sports, and in college, only one of three lesbian, bisexual, and queer women met national physical activity guidelines. Overweight and obesity may also develop as women age. When women were followed longitudinally, lesbian women were more at risk for developing obesity than heterosexual women. Studies of physical activity have found that while there may be greater physical activity and fitness among some sexual minority women, so is increased sedentary time. There have also been findings of differences in dietary patterns between lesbian, bisexual, and heterosexual women.

Studies about successful weight intervention programs for lesbian and bisexual women are emerging. A United States Centers for Disease Control and Prevention (CDC) sponsored and administered study, noted that lesbian and bisexual women are more likely to self-perceive as being of healthy weight or underweight despite being overweight or obese, and 33% engaged in hazardous weight control behaviors. A high school–based study (grades 9–12) in 22 Wisconsin schools revealed that sexual minority female youth, compared to their heterosexual counterparts, were less likely to participate in team sports, and in college, only one of three lesbian, bisexual, and queer women met national physical activity guidelines. Overweight and obesity may also develop as women age. When women were followed longitudinally, lesbian women were more at risk for developing obesity than heterosexual women. Studies of physical activity have found that while there may be greater physical activity and fitness among some sexual minority women, so is increased sedentary time. There have also been findings of differences in dietary patterns between lesbian, bisexual, and heterosexual women.

There have also been findings of differences in dietary patterns between lesbian, bisexual, and heterosexual women.
Prevention of Diabetes

Lesbian and bisexual women are more likely than heterosexual women to exhibit risk factors for type 2 diabetes. In the Nurse’s Health Study II, lesbian and bisexual women had a 27% higher risk of developing type 2 diabetes than heterosexual women. BMI mediated the relationship between sexual orientation and type 2 diabetes: the incidence rate ratio was completely attenuated when BMI was added to the model. Thus, efforts to prevent, detect, and manage obesity would hopefully decrease this health disparity in female sexual minorities.

Prevention of Pulmonary Disease

Pulmonary disease has not been rigorously studied in lesbian or bisexual women. However, with the increased prevalence of smoking in these women compared to heterosexual women, there may be more acute respiratory illness, chronic pulmonary disease, and lung cancer—especially with increasing age. Lesbian women have a higher prevalence of lifetime and current asthma, even when statistical models are used to correct for current and past smoking, and obesity, all of which are increased in lesbian and bisexual women. Overweight or obese lesbian and bisexual women are more than seven times more likely to report current asthma and three times more likely to report lifetime asthma than lesbian and bisexual women who are not overweight or obese.

Prevention of Sexually Transmitted Infections

STIs occur in lesbian and bisexual women, but little population-based data are available to delineate precise risks. Asking about sexual behaviors in addition to sexual identity is key to identifying STI risk and advising appropriate testing, since risk may vary by specific sexual practice (e.g., digital-vaginal, vaginal-vaginal, digital-anal, oral-vaginal, oral-anal contact) and the specific pathogen. Often data are mixed and inconsistent with respect to whether sources speak to infection risk by identity group or behavior. Both behavior-based risk and identity-based risk are important for assessments and interventions. We use language of identity or behavior as consistent with original research. Women who have sex with women (WSW) are noted by the CDC to have diverse sexual practices and that use of barrier protection in examined studies (e.g., use of gloves, dental dams) was ubiquitously low.

Chlamydial infections were higher in 14- to 24-year-old women who reported same-sex behavior when attending family planning clinics in the US Pacific Northwest compared to women who reported exclusively heterosexual behavior. Possible explanations for this observation include differences in these groups’ use of reproductive health care services, infrequent use of barrier methods to prevent STI transmission with female partners, trends toward higher-risk behaviors, and different social network characteristics. Untreated chlamydial infection places a woman’s future fertility at risk due to potential fallopian tube occlusion. Some women who have a chlamydial infection do not have symptoms. Secondary sequelae of chlamydia include intra-abdominal abscesses, chronic pain, and the need for multiple surgeries. Regardless of sexual orientation, the CDC recommends annual Chlamydia trachomatis (and Neisseria gonorrhoeae) screening from the age of first sexual activity to the age of 25 years for all women.

It is important to ask lesbian and bisexual women about specific sexual practices, as some practices may carry a higher risk of STIs than others, although there has been little research on sexual practices and the risk of STIs in this population. Thus, inferences are drawn from
heterosexual prevention of these infections. "Safer Sex Kits" have occasionally been distributed to WSW and women who have sex with women and men (WSWM) to decrease the risk of STIs, but intervention effectiveness has not been studied. These kits often include dental dams to prevent transmission of bacteria and viruses from oral sex, but the efficacy of dental dams for this function has not been studied. Female latex condoms and latex gloves may provide better protection against infectious transmission from oral sex since latex has been studied as a barrier for prevention of HIV and other STIs. Exchange of blood should be avoided as much as possible, especially in HIV-discordant lesbian couples, since viral genotype analysis has confirmed that HIV can be transmitted sexually between women. The clinician should encourage both partners in new lesbian couples to have comprehensive STI and HIV screening prior to sexual contact and recommend barrier protection for 6 months until the couple is again screened to verify that their HIV status is still negative. If the couple is consistently monogamous and HIV and other STI testing is negative, barrier precautions do not need to be continued. However, lesbian and bisexual women may not follow this advice, since many feel they are at low risk for HIV, which may be correct, but data are lacking. About 20–50% of lesbian women use sexual aids (eg, vibrators, dildos, or other sexual toys); these should not be shared with partners and should be cleaned after use. The human papillomavirus (HPV) can remain on these sexual aids for up to 24 hours after use, even after standard cleaning. Some lesbian and bisexual women are sex workers or have had sexual relationships with high-risk male sexual partners (sometimes gay male friends) and are at increased risk for STIs. Current CDC guidelines recommend that all women should be tested once in their lifetime for HIV, with testing repeated according to risk factors.

The herpes simplex virus (HSV) can be transmitted sexually between women. The same precautions regarding the transmission of HSV should be provided to lesbian, bisexual, and heterosexual women; there should be no sexual contact during any prodromal symptoms that may precede a genital herpes outbreak or during the blister stage of the outbreak. Suppression of lesions can usually be accomplished with antiviral medications, such as acyclovir or valacyclovir, if the lesions are recurrent (see Chapter 6). There is evidence of HPV transmission between female sexual partners. Certain strains of HPV are causally related to many precancerous and cancerous lesions, including cervical dysplasia and cervical cancer (see Chapter 18). Ten percent of lesbian women have never had sex with men, yet cervical dysplasia and cervical cancer develop in some of these women. All women (including lesbian women) need cervical cancer screening, which may include Papanicolaou smears, high-risk HPV strain testing, or both, according to timetables and risk factors provided by professional society guidelines. The rate of HPV vaccination in lesbian women, though previously thought to be less than heterosexual women, has increased recently and is now equal to that of heterosexual women, yet bisexual women are vaccinated more frequently than either lesbian or heterosexual women. However, overall the HPV vaccination rate is low in adult women regardless of sexual orientation, so improvement in all groups should be the goal. Administration of the HPV vaccine is critical to the prevention of cervical cancer, and the age group to receive the HPV vaccine has now been expanded by the FDA to 45 years old. Despite recommendations that cervical cancer screening, usually Papanicolaou testing be performed regardless of sexual orientation, Papanicolaou testing varies according to identity irrespective of behavior and some studies modify screening according to identity and behavior though perhaps suboptimally. In a national probability sample of who underwent Papanicolaou testing, WSWM had the same odds of testing as WSM only, whereas women with lifetime female partners had lower odds of testing. Those who identified as bisexual also had lower odds of testing.

**Trichomonas vaginalis** can be transmitted easily between female sexual partners. One study of women attending an STI clinic in the United States noted that *T vaginalis* was the most common curable STI found in this population with a prevalence of 17% in WSW and 24% in WSWM.

Bacterial vaginosis is common among women and, according to the CDC, even more common among WSW. It is unknown whether bacterial vaginosis can be transmitted between women. A study from Australia found a 27% prevalence of bacterial vaginosis in women and their female partners; risk factors for bacterial vaginosis were four or more lifetime female sexual partners, a female partner with bacterial vaginosis symptoms, and smoking at least 30 cigarettes weekly. Routine screening for bacterial vaginosis, though, is not currently recommended and testing should be based on symptoms. One approach for a WSW who has symptomatic bacterial vaginosis is to treat her and not her female sexual partner. If symptoms recur, her female sexual partner(s) should be evaluated and treated with consideration of re-treating the index woman. This strategy may also be used for treatment of recurrent or hard to treat vulvovaginal candidiasis, which technically is not considered to be sexually transmitted, but anecdotal, improvement has occurred with treatment of the index patient and female partner.

Various strategies for making reproductive and sexual health clinics and providers more amenable to serving LGBTQ people were studied by a group in the United States, but the findings (such as ensuring counseling involves inclusive safe sex discussions that are relevant to LGBTQ people) have broad face validity and relevance for other regional and medical focus settings as well.

**Prevention of Substance Use**

Substance use is higher in lesbian and bisexual women compared to heterosexual women and is especially well-documented for cigarette smoking and alcohol use. A
secondary analysis of alcohol, tobacco, and other drug use among lesbian and bisexual women in the American College Health Association’s National College Health Assessment revealed that bisexual women had greater odds of using alcohol, tobacco, and marijuana than heterosexual women and lesbian women. In addition, bisexual women had greater odds of using all illicit drugs (except steroids) and misusing prescription drugs than heterosexual women. Furthermore, bisexual women had greater odds of using amphetamines other than methamphetamine, sedatives, and 3,4-methylenedioxymethamphetamine (MDMA; Ecstasy) when compared to lesbian women. Lesbian women had greater odds of using tobacco, marijuana, sedatives, hallucinogens, and other illicit drugs and misusing prescription drugs than heterosexual women. This increased rate of substance use persists for bisexual women over the age of 25 but decreases for lesbian women at that time.

Multiple interventions have been initiated to decrease alcohol and other substance use in lesbian and bisexual female youth. In Canada, there were significant lower odds of binge-drinking among lesbian and bisexual youth in schools with longer-established Gay-Straight Alliances. Recommendations for improving substance use treatment for sexual minority persons include providing interventionists with training in LGBTQ cultural sensitivity. Another approach studied in the rural United States looked at training and deploying LGBTQ peer-advocates to support mental health and substance use and “bridge the gap in culturally competent care.” More work is needed to study specific interventions outcomes research, however, comparing LGBTQ adapted materials with routine materials. Some LGBTQ clients in these programs find it hard to “come out” to a group that potentially includes members who may be homophbic. Sexual minority women, compared to heterosexual women, with lifetime alcohol use disorders are at heightened risk for concomitant psychiatric and drug use disorders, underscoring the need for substance abuse programs to provide access to individual counseling with mental health professionals.

Cancer Risk, Prevention, & Treatment

Very little is known about the incidence and prevalence of various cancers in lesbian and bisexual women, since sexual orientation has not been routinely included in cancer screening programs and cancer registries. However, data suggest that sexual minority women may be at a higher risk for cancer-related mortality than heterosexual counterparts. Investigators from the Women’s Health Study compared sexual minority veterans and civilians to their heterosexual counterparts and found that sexual minority women veterans had a higher risk of cancer-specific mortality. Information from the US National Health Interview Survey showed that lesbian and bisexual women have cancer risk factors, such as tobacco use, underscoring the need for vigilant screening. Since lesbian and bisexual women have barriers to accessing health care and may not see a clinician on an annual basis, any visit to a healthcare provider is an opportunity to check on cancer screening status (eg, colonoscopy, mammography, cervical cancer screening). There is also recognition that upon receiving a cancer diagnosis, LGBTQ people face challenges in receiving equitable care throughout the cancer care continuum and may experience cancer differently and have different needs during their care; heterosexual and sexual minority cancer survivors in the UK reported receiving different care. The US National Cancer Care Network Guidelines do not address how SGM status should be considered in site-specific guidelines. One qualitative study with SGM breast cancer survivors underscored the challenges of disclosing sexual orientation during cancer care and the importance of provider recognition that varying social networks are critical to positive experiences of care provision. The 2017 American Society for Clinical Oncology position statement recommends five action steps to enhance SGM cancer care and reduce disparities: (1) patient education and support, (2) workforce development and diversity, (3) quality improvement strategies, (4) policy solutions, and (5) research strategies. All providers need to consider whether their prevention, screening, diagnostic, treatment, and palliative approaches will be equitably experienced by lesbian and bisexual women.

A. Breast Cancer

The literature has been mixed on whether lesbian and bisexual women have a slight increased risk of breast cancer compared to heterosexual women. A 2013 systematic review found the few prevalence studies of breast cancer in lesbians unreliable; however, lesbian women do have an increased prevalence of risk factors predisposing to breast cancer, including nulliparity (and decreased breastfeeding), alcohol use, obesity, and smoking. The literature is also inconsistent regarding the rate of mammography screening in lesbian women; however, a study done in Massachusetts showed that bisexual women were less likely than heterosexual
women and lesbian women to adhere to mammography screening guidelines. Lesbian and bisexual women who have breast cancer may not want reconstruction at the same rate as heterosexual women and often find that breast cancer support groups focus on issues for heterosexual women (such as attractiveness to a male partner).

B. Cervical Cancer

Primary prevention of cervical cancer is essential. All people between the ages of 9 and 45 years (routine recommended age is 11 to 12 years old) should receive the HPV vaccine series. HPV can be transmitted sexually between lesbian or heterosexual partners. Cervical cancer screening, with Papanicolaou smears, primary HPV testing, or both, should be part of lesbian and bisexual women's health care at the same intervals as for heterosexual women according to national guidelines. Lesbian and bisexual women, however, receive Papanicolaou smears at a lower rate than sexually active heterosexual women, in part because many of the Papanicolaou smears are done in reproductive health clinics, lesbians who are not interested in becoming pregnant or avoiding pregnancy may not access these clinical sites. In addition, some lesbian patients as well as their health care providers mistakenly think that lesbian women do not need Papanicolaou smears. All lesbian and bisexual women need cervical cancer screening starting at the age of 21, consistent with recommendations for cervical cancer screening for all women.

C. Lung Cancer

Compared to heterosexual women, the rate of lung cancer is likely higher in lesbian and bisexual women compared to heterosexual women due to their increased rate of smoking. The incidence and prevalence of lung cancer, however, have not been determined in this sexual minority population.

D. Endometrial and Ovarian Cancer

Endometrial and ovarian cancer are increased among those with nulliparity, which is more likely in sexual minority women. Obesity, a known risk factor for both cancers, appears to be more prevalent among sexual minority women. Conversely, the use of oral contraceptives, which is protective against the development of both of these cancers, is lower in lesbian women than in heterosexual women. Vigilance toward and education about presenting signs and symptoms (eg, postmenopausal bleeding, early satiety, unintended weight loss) are important to detect cancers as early as possible. Neither incidence nor prevalence of endometrial or ovarian cancer has been determined in this sexual minority population.

Prevention of Violence

Compared to heterosexual women, lesbian and bisexual women have higher exposures to violence throughout their lifetimes. Lifetime prevalence of sexual assault may be as high as 85%. In a study of four countries in southern Africa, nearly one-third of lesbian and bisexual women experienced forced sex and assault including "corrective rape" by men as an attempt to change the women's sexual orientation. In a study in the state of Sao Paul in Brazil, qualitative interviews were done of youth coming out to their families: The family reactions were often violent, with persecution and even expulsion from the home, which impacted their health and quality of life.

The CDC reports that 61% of bisexual women and 44% of lesbian women experience rape, physical violence, and stalking by an intimate partner. These rates are higher than similar trauma in heterosexual women (35%). Additionally, approximately 20% of bisexual women compared with 10% of heterosexual women have been raped by an intimate partner in their lifetimes. The rate of stalking experienced by bisexual women is twice that of heterosexual women and a higher percentage of bisexual women report being afraid of an intimate partner. Despite alarming rates for women of any identity, lesbian and bisexual women survivors of sexual assault and interpersonal violence may experience unique difficulties when seeking assistance. These problems include a limited understanding of interpersonal violence in the relationships of lesbian and bisexual women, stigma, and systemic inequities (such as shelters unwelcome to this population, perpetrating partners being allowed into the same shelters as the survivor of the domestic violence, " outing" someone as a psychological threat, and staff lacking cultural sensitivity and appropriate training in working with lesbian and bisexual women). Barriers to preventing LGBTQ violence include stigma, systemic discrimination, and a lack of understanding of LGBTQ intimate partner violence.

Community violence is experienced more frequently by LGBTQ persons. In-depth interviews of 19 Flemish sexual minority victims of violence revealed the use of four coping strategies: (1) avoidance, (2) assertiveness and confrontation, (3) cognitive change, and (4) social support. Applying these coping skills and actively attaching meaning to negative experiences helped victims of anti-LGBTQ violence overcome fear, embarrassment, or depressive feelings. The presence of a supportive network was important in facilitating the positive outcomes.

Prevention of Mental Disorders

Lesbians and bisexual women have an increased risk of depression. Many of the health disparities and health risks faced by lesbians and bisexual women, such as depression and cardiovascular risk, have been attributed to Ilan Meyer’s theory of minority stress. This theory proposes that individuals who identify as a sexual minority experience chronic, additive, and unique stresses stemming from living in social conditions that are characterized by prejudice and discrimination. Therefore, rather than identifying mental health problems as synonymous with a sexual minority identity or stemming from in-born association with minority sexual orientation, minority stress causes mental health challenges that stem from societal discrimination and stigma borne by individuals with minority identities (and behaviors). An examination of lesbian and bisexual women veterans from the United States Behavioral Risk Factor Surveillance System found that sexual minority women veterans were three times more likely than heterosexual women to experience “mental distress.” Mortality risk from suicide is also elevated among women with same-sex partners. There is evidence from the United States National Epidemiologic Survey on Alcohol and Related Conditions—III that bisexual women had greater rates of specific psychiatric disorders than lesbians or heterosexual women. Resilience factors that are protective for mental distress and poorer mental health among lesbian, gay, bisexual, queer and questioning youth and adults in Israel included family support as well as other community-level factors, such as friends’ support, LGBT connectedness, and having a steady partner. How parents react to an adolescent’s “coming out” has a profound effect on their child’s health outcomes. For those adolescents whose parents were supportive, there was less homelessness, depression, substance use, and unprotected sex. Interventions for building resilience can be important in achieving a reduction in anxiety and depression. There is some evidence that online friends can serve as a buffer and social support, especially for LGBTQ youth, although in-person social support appears to be more protective against victimization. However, social media can also be a place where LGBTQQ youth experience bullying.

There is evidence that being in a legally recognized same-sex relationship, particularly in marriage, diminishes mental health differences between heterosexual and lesbian, gay, and bisexual persons. In contrast, psychiatric disorders increased among lesbian, gay, and bisexual persons who lived in states in the United States that enacted constitutional amendments to ban same-sex marriage compared to states that did not. One study examined the mental health of individuals living in states before (wave 1, 2001–2002) and after (wave 2, 2004–2005) the enactment of same-sex marriage bans in 2004–2005. Among LGB respondents living in states that enacted the marriage bans, the National Epidemiologic Survey on Alcohol and Related Conditions (N = 34,653), revealed that there was a significantly increased prevalence of any mood disorder (36% increase), generalized anxiety disorder (248% increase), any alcohol use disorder (42% increase), and psychiatric comorbidity (36.3%) between wave 1 and wave 2 of the survey, suggesting that living in sociopolitical environments that do not legally recognize same-sex relationships can have deleterious effects on mental health. Mental health inequities among bisexual and lesbian women are well documented. Compared to heterosexual women, both bisexual and lesbian women are more likely to report lifetime depressive disorders, with bisexual women often facing the worst on mental health outcomes. Risk factors for depression, such as victimization in childhood and adulthood, are more prevalent among bisexual women. Black bisexual and black lesbian women had significantly lower odds of depression than white lesbian women, despite their higher reports of victimization in one Chicago Health and Life Experiences of Women study, an 18-year, community-based longitudinal study of sexual minority women’s health. The rate of depression in Latina bisexual and lesbian women did not differ from white lesbian women.

Gay & Bisexual Men’s Health

Kevin L. Ard, MD, MPH
Kenneth H. Mayer, MD

This section is devoted to the primary care of cisgender (that is, non-transgender) gay, bisexual, and other MSM regardless of their sexual identity. Most health-related research that focuses on MSM categorizes men based on their sexual behavior as MSM, rather than their self-reported identification as gay, bisexual, or other identities. Although sexual identity is not always congruent with sexual behavior, identity is important to recognize in order to optimize health and health care, especially when there is a difference on the basis of sexual identity (for example, gay- vs bisexual-identified men).
### Demographics

The size of the MSM population in the United States is not known with certainty due to variability in the definition of sexual orientation used in surveys and the possibility that some survey respondents do not disclose nonheterosexual orientations because of concerns about discrimination. Nevertheless, based on available data, it is estimated that at least 2.2% of American adult men identify as gay, and an additional 1.4% of men identify as bisexual. The proportion of men who engage in sex with other men or experience sexual attraction to other men is estimated to be higher, with 7.3% and 6.2% of adult men reporting same-sex attraction and sexual behavior, respectively, in one national survey.

### Stigma & Discrimination

Although social acceptance of nonheterosexual orientations is increasing, gay, bisexual, and other MSM may still experience stigma and discrimination based on their sexual orientation and/or gender expression, with significant impacts on health. In one national survey of LGBT Americans, discriminatory experiences were commonly reported: 39% of respondents endorsed experiences of rejection by family or friends, 30% had been physically attacked or threatened, 23% had been treated poorly in public, and 21% reported being treated unfairly at work. These experiences may contribute to adverse health outcomes among MSM and other SGM populations. One model of how this occurs centers on the concept of minority stress. In this model, stressors (such as experiences of prejudice, expectations of rejection, the cognitive burden of deciding whether to come out in different circumstances, and internalized homophobia) lead to anxiety, depression, and maladaptive coping behaviors, including substance use disorders and condomless sexual behavior that increases the risk for HIV and STIs. In adolescents, family rejection has been linked to increased risk of depression, homelessness, suicide attempts, illegal drug use, sexual risk-taking, and HIV/STI acquisition. Avoidance of—or delays in—seeking health care due to concerns about discrimination in medical settings may also contribute to adverse health outcomes in MSM.

### Health Disparities

Gay, bisexual, and other MSM face health disparities stemming from the biologic aspects of their sexual behavior and/or from minority stress. Because of these disparities, MSM have been identified as a priority population for health-related research and improvement in health care by both the National Academy of Medicine and the federal government’s Healthy People initiative. These health disparities are exacerbated if young MSM have experienced early life traumatic events, such as sexual abuse or familial rejection.

### A. HIV and Other STIs

MSM account for approximately 70% of all new HIV infections in the United States, despite representing a small proportion (less than 10% by any metric) of the country’s male population. The high burden of HIV infection among MSM stems in part from the efficient transmission of the virus through receptive anal intercourse, which confers a higher risk of HIV infection than other sexual activities, such as penile-vaginal and oral intercourse. Role versatility can also uniquely potentiate HIV spread among MSM, since the same person can acquire HIV via receptive intercourse and become an efficient transmitter by engaging in insertive anal intercourse with HIV-uninfected partners. The origin of disparate HIV rates between MSM and other populations is not solely biologic in origin, however, as societal stigma and psychosocial problems also contribute to sexual risk behavior among MSM. MSM of color face an increased risk of HIV; the CDC estimates that the lifetime risk of HIV infection is 1 in 2 for African American MSM and 1 in 4 for Latino MSM compared to 1 in 11 for white MSM. Racial and ethnic disparities in HIV infections among MSM do not appear to be due to differences in sexual behavior or substance use but rather factors such as lack of access to medical care, lower rates of recent HIV testing among nonwhite MSM, and assortative mixing (ie, being more likely to have sex with partners from one’s own racial or ethnic group).

Beyond HIV, some STIs are more common among MSM. In 2017, 58% of primary and secondary syphilis diagnoses occurred in MSM or men who have sex with both men and women. Syphilis is associated with a high risk of subsequent HIV acquisition in MSM and may serve as a marker for individuals who could benefit from intensive HIV prevention efforts, such as the initiation of PrEP. In addition, increased cases of ocular syphilis, occasionally resulting in blindness have been reported, with a majority of cases occurring in MSM. The incidence of gonorrhea among MSM exceeds that among men who have sex with women (MSW) and has increased. MSM also are more likely than MSW to be infected with gonorrhea, including antibiotic-resistant strains. Many gonococcal infections in MSM occur at extragenital sites (ie, the pharynx or the

---

---

Rectum) where they may be asymptomatic, underscoring the importance of eliciting a comprehensive sexual history, including an inventory of potential anatomic exposures, in order to provide optimal health care to MSM.

MSM also face increased risks of viral hepatitis. Outbreaks of hepatitis A infection have been documented in MSM, likely due to anal sexual contact, including oral-anal exposure (“rimming”) as well as insertive and receptive practices. Likewise, hepatitis B is more common among MSM than the general population; approximately 20% of MSM have evidence of either current or prior infection with hepatitis B by age 30. This highlights the importance of universal hepatitis A and B vaccination for young MSM, preferably prior to the initiation of sexual contact. Finally, although hepatitis C is generally not efficiently transmitted via sexual contact, hepatitis C infection has been identified as a problem among HIV-infected and high-risk HIV-uninfected MSM and is associated with condomless receptive anal sex, group sex, manual insertion of fingers into the rectum (“fisting”), and recent STIs, which make the rectal mucosa more susceptible to hepatitis C acquisition.

HPV infection, which can cause anogenital warts, anal dysplasia, and anal cancer, is more common among MSM than MSW. A meta-analysis estimated the prevalence of the oncogenic HPV type 16 in the anal canal to be 35.4% among HIV-infected MSM and 12.5% among MSM without HIV. Correspondingly, anal cancer incidence is higher among HIV-infected versus HIV-uninfected MSM. Studies are underway to determine the optimal frequency of screening for anal cellular atypia and follow-up high resolution anoscopy for sexually active MSM.

Enteric infections may be sexually transmitted among MSM engaging in anal sexual contact, especially oral-anal sexual contact, and should be considered in the differential diagnosis of gastrointestinal complaints. These infections include giardiasis, amebiasis, and shigellosis. In addition, Shigella infections are more likely to be antibiotic resistant among MSM than among other individuals.

Clusters of meningococcal disease among MSM in the United States and Europe have also been reported, particularly those frequenting sexualized environments, including saunas and bathhouses, prompting some jurisdictions to recommend meningococcal vaccination for high-risk MSM. Intimate contact with multiple partners has been identified as a risk factor for infection in some of these outbreaks.

B. Mental Health

Likely due to minority stress (ie, growing up in non-affirming societies), MSM experience mental health disorders more commonly than other men. Whether defined by self-reported identity as gay or bisexual or behaviorally by report of sexual activity with other men, MSM have a higher lifetime prevalence of depression and anxiety disorders than men who identify as heterosexual and/or who report sexual activity only with women. Behaviorally bisexual men experience a higher burden of both depression and anxiety disorders, compared to men who engage in only homosexual behavior, in part because bisexual men may not have access to defined communities of choice, like self-identified gay men. The increased prevalence of mental health disorders among behaviorally bisexual men may also stem from dual stigmatization by both the heterosexual and gay male communities, as well as internalized stigma. Among MSM overall, anti-gay violence, community alienation, and dissatisfaction with an idealized body image have all been associated with depression.

C. Substance Use

Compared to men with only female sexual partners, MSM are more likely to report lifetime recreational drug use; they are specifically more likely to have used cocaine, hallucinogens, inhalants, analgesics, and tranquilizers. In addition, men who identify as gay or bisexual are more likely to smoke cigarettes than those who identify as heterosexual. Although it is not clear that MSM are more likely to smoke cigarettes than those who identify as heterosexual. Although it is not clear that MSM are more likely to use methamphetamine, methamphetamine use in MSM communities has been linked to increased sexual risk behavior and transmission of hepatitis C, HIV, and other STIs. Consistent with the minority stress model, experiences of discrimination have been independently associated with substance use among MSM. Several studies have indicated that substance use programs that integrate support for minority sexual identity for MSM can result in long-term successful outcomes.

Clinicians can help address health disparities affecting MSM by following clinical practice guidelines that pertain to this population (Table 42–1). The CDC recommends that sexually active MSM undergo screening for HIV, syphilis, gonorrhea, and chlamydia annually and more often if the risk history warrants more frequent assessment. An HIV antibody-antigen assay is preferred for HIV screening because this test increases the sensitivity for detection of acute or recent HIV infection. Nucleic acid amplification testing (NAAT) provides optimal sensitivity for diagnosis of gonorrhea and chlamydia and can be performed on the oropharynx, rectum, urine, and urethra. Although oropharyngeal testing for chlamydia is not recommended, MSM should otherwise be screened for these infections at any of the aforementioned sites that may have been exposed during sex, regardless of condom use. First-catch urine and urethral specimens for gonorrhea and chlamydia NAAT in men provide comparable accuracy; thus, there is no advantage to the urethral swab for routine screening. Rectal swabs for NAAT can be self-collected.

The CDC also recommends that MSM be screened for chronic hepatitis B infection at least once in their lives and that they be vaccinated against hepatitis A and B. Annual hepatitis C screening with a hepatitis C antibody test is recommended for HIV-infected MSM due to the elevated incidence of this infection in this population and the advent of well-tolerated, curative therapy. HIV-uninfected MSM engaging in traumatic sexual practices, such as group sex, fisting, and any other practice that may abrade the rectal mucosa, may also benefit from annual HCV screening.

Both the CDC and the World Health Organization recommend PrEP for HIV with the fixed-dose combination of tenofovir disoproxil fumarate–emtricitabine for MSM at high risk for HIV infection (see Chapter 31). Individuals at high risk include those who engage in condomless anal sex outside of a monogamous relationship with an HIV-uninfected man; those who have recently been diagnosed with a bacterial STI; and those whose sexual partners are HIV-infected. However, the utility of PrEP is likely low in the latter scenario if the relationship is monogamous and the HIV-infected partner is consistently virologically suppressed on antiretroviral therapy, because antiretroviral therapy significantly reduces the likelihood of HIV transmission through sexual contact. PrEP has been shown in randomized controlled trials to prevent HIV infection in MSM and is addressed in more detail in Chapter 31.

MSM, men who have sex with men; STI, sexually transmitted infection.
Clinicians who care for MSM should also be aware of postexposure prophylaxis (PEP), which consists of antiretrovirals started within 72 hours of a discrete exposure to HIV and taken for 28 days, and either provide PEP themselves or be able to rapidly link patients to PEP care (see Chapter 31).

While HPV immunization with the quadrivalent or nonavalent vaccines is recommended for all boys and young men up to age 21 years, vaccination is recommended for MSM up to age 26. The HIV Medicine Association (HIVMA) recommends routinely screening HIV-infected MSM for anal cancer with anal cytology; however, this approach has not yet been proven to be beneficial in a randomized controlled clinical trial. In addition, the optimal screening interval (ages at which to initiate and cease screening) and management of abnormal results are not clearly defined. Patients with abnormal anal cytology are typically referred for high-resolution anoscopy with biopsy. Colonoscopy performed for colon cancer screening is not considered a substitute for anal cytology or high-resolution anoscopy because colonoscopy does not assess for cellular abnormalities in the anal canal. Anal cytology screening of HIV-uninfected MSM is not currently recommended in any national consensus guidelines, although some clinicians perform this screening due to the elevated risk of anal cancer in these men. Large prospective studies are underway in the United States and Australia to attempt to address the questions related to optimal timing of anal HPV screening for MSM.

Finally, clinicians should ensure that MSM are offered preventive care recommended for all individuals, including smoking cessation counseling and pharmacotherapy, screening for depression, and assessment for and counseling about alcohol misuse (see Lesbian and Bisexual Women’s Health, above). Some studies have found that behavioral health programs tailored specifically for MSM are more effective in promoting healthy behaviors than those that are not culturally sensitive.

Madeline B. Deutsch, MD, MPH

Terminology

Transgender (abbr: “trans”) people have a gender identity that differs from the sex they were assigned at birth. Gender identity describes a person’s internal sense of gender. Sex refers to the sex assigned at birth typically by the attending medical provider, based on assessment of external genitalia. In everyday language “sex” and “gender” are used interchangeably; however, in the context of transgender people, the meanings differ. Gender expression describes the outward manner in which an individual expresses or displays gender, including choices in clothing and hairstyle, speech, and mannerisms. Gender identity and gender expression may differ; for example, a woman (transgender or non-transgender) may have an androgynous appearance, or a man (transgender or non-transgender) may have a feminine form of self-expression. Transgender people may not feel comfortable, or be unable to, outwardly express their internal felt sense of gender due to societal, work, or family pressures. Transgender people who have a well documented and persistent gender identity that differs from their sex assigned at birth and are experiencing distress as a result of this mismatch, meet the diagnostic criteria for gender dysphoria as described in the Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-5).

A transgender man is someone with a male gender identity and a female birth-assigned sex; a transgender woman is someone with a female gender identity and a male birth-assigned sex. A non-transgender person may be referred to as cisgender (Latin root cis = near/next to), which refers to people whose gender identity and birth sex are the same, ie, non-transgender. Non-binary, gender nonconforming, or genderqueer describes a person whose gender identity differs from that assigned at birth but may be more complex, fluid, multifaceted, or otherwise less clearly defined than purely male or female. Non-binary people may use neutral pronouns such as “they,” “them,” or “their.” The term transsexual is an older term that has fallen out of favor and referred specifically to a transgender person who seeks medical interventions. Other related terms include cross dresser, which describes someone who may wear clothing of the opposite gender without a clear identification with that gender, and drag, which describes cross dressing for performance purposes. For the purposes of this text, “transgender” will be inclusive of those who identify with the terms gender non-binary, nonconforming, genderqueer, and transgender.

Sexual orientation, which describes sexual attraction and behaviors, is not directly related to gender identity.
The sexual orientation of transgender people should be described based on the lived gender; a transgender woman attracted to other women would be a lesbian, and a transgender man attracted to other men would be a gay man.

Transgender people may seek any one of a number of gender affirming medical, surgical or related interventions. Based on research demonstrating positive effects on multiple psychosocial measures, such interventions are recognized as medically necessary by the World Professional Association for Transgender Health (WPATH), an international, multidisciplinary professional organization that publishes widely recognized standards of care. Not all transgender people seek all interventions, and some may seek none; the current standard of care is to allow each transgender person to seek only those interventions they desire to affirm their own gender identity.

Medical Interventions

Many, but not all, transgender people will seek gender affirming hormone therapy and/or surgery (genitals, chest, or face). Transgender women commonly seek facial hair removal and may also seek voice feminization training. Hormone therapy allows the acquisition of secondary sex characteristics more aligned with an individual's gender identity. The WPATH Standards of Care recognize that hormone therapy is within the scope of practice for primary care providers. The Standards also permit medical providers to prescribe hormone therapy under an informed consent approach without a mental health assessment if the medical provider feels comfortable making the diagnosis of gender dysphoria.

A. Feminizing Hormone Therapy

The goal of feminizing hormone therapy is the development of female secondary sex characteristics and suppression/minimization of male secondary sex characteristics. The general approach of therapy is to obtain physiologic premenopausal female range estrogen and testosterone levels through the combined use of an estrogen with an androgen blocker, and in some cases a progestagen. Clinical endpoints include breast development (often maximum Tanner stage 2/3), reduction of body hair, reduced muscle mass, and female redistribution of body fat.

The most commonly used estrogen is 17-beta estradiol, in pill, patch, or, less commonly, injected form. The choice of route is based to some degree on patient preference (Table 42–2). Transdermal estradiol has a well-established safety profile based on studies in menopausal cisgender women. Injected estradiol is the least studied route and can be associated with both supratherapeutic levels as well as cyclical levels over the dosing interval. Estrogens should be continued after gonadectomy without reduction in dose. There is no direct evidence to guide decision making regarding the discontinuation of estrogen once a patient arrives at a menopausal age, though most experts believe initiating or continuing hormone therapy in transgender women after age 50 is appropriate. Ethinyl estradiol (found in combined oral contraceptives) should be avoided due to thrombogenicity and a lack of need for suppression of ovulation.

The most commonly used anti-androgen is spironolactone, a potassium-sparking diuretic that is frequently used for female hirsutism or adult acne. Spironolactone inhibits both the synthesis of and action of testosterone. In higher doses (100–200 mg orally daily), spironolactone can lead to suppression of androgen levels into the female physiologic range. Common side effects include orthostasis and polyuria. Monitoring should include periodic assessment of kidney function and serum potassium. Other options for those who cannot tolerate spironolactone include a gonadotropin-releasing hormone (GnRH) analog, orchietomy, or the use of a progestagen. Finasteride and dutasteride (5-alpha-reductase inhibitors) are sometimes used as an alternative; however, they have limited effects. After gonadectomy, anti-androgens can be discontinued.

No studies have been conducted on the role of progestagens in transgender women. Some believe there is benefit to breast development, mood, or libido, and there is no evidence to suggest any harm related to progestagens. Progestagens may be an effective anti-androgen, particularly cyproterone acetate, which is used widely outside the United States as the primary androgen blocker in feminizing regimens. If used, progestagens should be initiated after at least several months of estrogen plus anti-androgen.

The primary risk associated with estrogen therapy is venous thromboembolism (VTE). However, when using 17-beta estradiol at physiologic estrogen dosing, the risk is minimal. Prior studies showing 20- to 40-fold increased risk of VTE involved the use of ethinyl estradiol at doses of up to 200 mcg/day and did not control for tobacco use. More recent data found no increased risk of VTE in transgender women using transdermal 17-beta estradiol. Thus, transdermal estradiol is the preferred route for those who smoke or with risk factors for or a personal history of VTE.

**B. Masculinizing Hormone Therapy**

The goal of masculinizing hormone therapy is the development of male secondary sex characteristics, and suppression/minimization of female secondary sex characteristics. The general approach involves the use of one of several forms of parenteral testosterone using an approach similar to that in hypogonadal or agonadal cisgender men (Table 42–3). Blockade of estrogen is not needed.

Testosterone may be injected or applied as a topical gel or patch. Two studies support the use of subcutaneous (rather than intramuscular) injections, which allow the use of a smaller needle. The use of topical testosterone or using a weekly (vs biweekly) injection interval can help maintain even hormone levels in those with cyclical mood symptoms or pelvic cramping. Clinical endpoints include the development of facial hair, deepening of the voice, clitoral growth, male body fat redistribution and muscle growth, and induction of amenorrhea by 6 months.

Prior concerns of testosterone-induced hepatotoxicity were based on the use of oral methyltestosterone. There is no evidence to support a concern of hepatotoxicity in transgender men using parenteral bio-identical testosterone.

Common side effects of testosterone therapy in transgender men include acne and male pattern baldness, both of which can be approached as in cisgender men. Hemoglobin and hematocrit should be monitored, and if the levels are elevated, consider reducing testosterone dose or changing to a transdermal form or weekly injections to maintain more even levels. Polycystic ovarian syndrome and obesity have been found to be at an increased prevalence in transgender men prior to beginning testosterone therapy. Testosterone is not contraindicated in the presence of these conditions; instead, related metabolic disorders can be managed concurrently.

**C. Monitoring Therapy**

Hormone effects should be monitored both by clinical results as well as hormone levels, if available. Patients should be reminded that results may vary and can take up to 5 years to reach maximal effect; supraphysiologic hormone levels are not likely to enhance results but may incur

\(^1\)Initial, low-dose regimen is recommended for genderqueer and non-binary persons.
\(^2\)Maximum dosing does not mean maximal effect. Furthermore, these dosage ranges do not necessarily represent a target or ideal dose. Dose increases should be based on patient response and monitored hormone levels. Some patients may require less or more than this amount.
\(^3\)Available as standard US Pharmacopia (USP) as well as compounded products.
\(^4\)Doses of less than 20.25 mg with 1.62% gel or less than 30 mg with 2% axillary gel may be difficult, since measuring one-half of a pump or packet can present a challenge. Patients requiring doses lower than 20.25 mg and whose insurance does not cover 1% gel may require prior authorization or an appeal.
\(^5\)Testosterone creams are prepared by individual compounding pharmacies. Specific absorption and activity varies and consultation with the individual compounding pharmacist is recommended.
\(^6\)Testosterone undecanoate has been associated with rare cases of pulmonary oil microembolism and anaphylaxis; in the United States, the drug is available only through the AVEED Risk Evaluation and Mitigation Strategy (REMS) Program (https://www.aveedrems.com/AveedUI/rems/preHome.action). All injections must be administered in an office or hospital setting by a trained and registered health care provider and monitored for 30 minutes afterward for adverse reactions.

risks. Note that reported laboratory reference range values may differ depending on the sex of registration of the patient; in general, clinicians should use the reference ranges driven by the current hormonal status of the patient. For example, female reference ranges will be included on automated laboratory reports of a transgender man taking testosterone while still legally registered as female. The interpreting clinician should use the male reference ranges for any tests run on this patient that have sexually dimorphic reference ranges. Tables 42–4 and 42–5 describe general monitoring recommendations, rationales, and “sex-specific” laboratory values that may require individualized interpretation.

D. Long-Term Health Outcomes

Well-designed, large, long-term studies of health outcomes in transgender people are lacking. The largest existing study of mortality is in a retrospective cohort of 966 transgender women and 365 transgender men who were treated with cross-sex hormones from the Netherlands, which did not control for a number of risk factors. All-cause as well as cardiovascular, cerebrovascular, and other disease-specific mortality among transgender men did not differ from the general Dutch population of cisgender women. Among transgender women, all-cause mortality was 51% higher than cisgender men in the general Dutch population, with the overwhelming majority of the difference due to HIV, drug overdose and suicide; a 64% increased risk (95% CI 43% to 87%) in cardiovascular mortality was seen; however, no significant difference was seen for cerebrovascular mortality. It should be noted that this study did not control for tobacco use. Any decisions to provide hormone therapy should include a detailed informed consent discussion and consideration, including recognizing the significant risks of withholding treatment on psychological well being which can have negative impacts on physical health as well as suicidality or substance abuse.

> Surgical Interventions

A wide range of gender-affirming surgeries are available to transgender people. These include surgeries specific to gender affirmation as well as procedures commonly performed in cisgender populations (Table 42–6).

> Cancer Risk & Screening

Several retrospective studies have not identified an increased risk of cancer in transgender people compared to birth-sex matched controls. However, because of the numerous barriers to care as well as to identifying transgender people in clinical databases, underscreening and underreporting are likely. In general, an organ-based approach to screening should be taken. There are no modifications to screening recommendations (or recommendations not to screen) for ovarian, uterine, or cervical cancer in transgender men. Breast cancer screening for transgender men who have not undergone mastectomy should be performed based on guidelines for cisgender women. The role of screening for breast cancer in transgender men who have undergone mastectomy is unknown and depends on the technique used as well as technical limitations on screening small amounts of residual breast tissue. In transgender women, breast cancer screening using guidelines for cisgender women is recommended, with the modifications starting at age 50 and only after a minimum of 5 years of lifetime estrogen exposure. Screening for prostate cancer in transgender women is complicated beyond the current debate over the utility of prostate cancer screening in cisgender men by the effects of feminizing hormones on prostatic hypertrophy and interpretation of tests of prostate-specific antigen.

While screening transgender women for pituitary adenoma with serum prolactin levels has been done in the past, this is not recommended in asymptomatic patients since current guidelines for the management of incidental prolactinomas is watchful waiting. Prolactin screening should occur in transgender women with galactorrhea, visual disturbances, or a new headache pattern.

**HIV**

Transgender women in the United States are 34 times more likely to be infected with HIV than the general population. This disparity is driven by a number of factors, including lack of both employment opportunities and legal protections in the workplace and elsewhere, all of which can result in survival transactional sex and sex work, and an association between unaffirmed gender identity and high-risk sexual behavior. Based on studies of hormonal contraception, gender-affirming hormone therapy is not believed to have negative interactions with antiretroviral medications, although direct studies are lacking. A subanalysis of transgender women within a larger study of HIV PrEP with a daily fixed-dose combination of tenofovir disoproxil fumarate 300 mg and emtricitabine 200 mg suggested efficacy when taken as prescribed but demonstrated poor adherence in comparison to control MSM. Such findings support the notion that HIV services and programs targeting transgender populations should be developed and implemented distinctly from those targeting MSM, and that bundling of HIV care with gender-affirming care may improve HIV outcomes.

Anterior (patellofemoral) knee pain, 1729, 1736–1737
Anterior talofibular ligament, in ankle sprains, 1739, 1740
Anterior tibiofibular ligament, in ankle sprains, 1740
Anticholinergic syndrome/effects/agents.
Antidepressant drug interactions and, 264
for COPD, 273
for nausea and vomiting, 597
for Parkinson disease/parkinsonism, 1034
for asthma, 261–262t, 264t, 265
for COPD, 273
for irritable bowel syndrome, 662
for nausea and vomiting, 597
overdose/toxicity of, 209t, 210, 1601t, 1610–1611
for Parkinson disease/parkinsonism, 1034
Anticoagulant, lupus.
Antidepressant drug interactions and, 407, 407–410, 408
for GIRD, 623, 625
integrate inhibitor therapy and, 1384
for peptic ulcer disease, 641
Anterior chest wall syndrome, 376
Anterior cruciate ligament (ACL), 1728, 1729, 1729–1734, 1730t
Anterior cruciate ligament (ACL), 1728, 1729, 1729–1734, 1730t
Anterior cruciate ligament (ACL), 1728, 1729, 1729–1734, 1730t
Anterior drawer test
ACL injury and, 1730t
Anterior hypopituitarism, 1127–1132
Anterior interosseous syndrome, 1060
Antiphospholipid antibody
for antiphospholipid antibody syndrome, 833, 860
in DVT/PE (venous thromboembolic disease), 308
in SLE, 857t, 858t
Anti-CAD/CDM 140 antibody, 866
Anti-(constitutive) smooth muscle antibodies, 157–158
Antibiotics; Antimicrobial therapy
specific type
for C difficile
clinical response to, 1334
CSF analysis and, 1319, 1320
duration of treatment and, 1334
in fever management, 35, 1314
dysfunction and, 1334
in hemodialysis/pertum transplantation, 585, 586t, 587t, 588t, 589t, 590t
See also specific agent or disorder and Antiplatelet therapy
for ACS (NSTEMI/STEMI), 384f, 385, 391, 392–393
for acute arterial limb occlusion, 492
antidepressant drug interactions and, 1104r
for antiphospholipid antibody syndrome, 833–834, 861
for atrial fibrillation/stroke prevention, 408t, 407–410, 408t, 409t, 1016–1017
in hyperthyroidism, 1155
in mitral stenosis, 351, 352, 368t
prominent in response to, 1334
prophylactic. See Antimicrobial chemoprophylaxis
resistance to. See Drug resistance
rout of administration for, 1337–1338
susceptibility testing and, 1334
thrombocytopenia/platelet function and, 570t, 573t
Antipolyclonal antibodies. See Immunoglobulins
Antibody deficiency disease (specific/functional antibody deficiency), 901
Antiemetics. See Antiparkinsonian therapy
in feminizing hormone therapy, 1758, 1759
in gynecosmatia and, 1213
for prostate cancer, 1679, 1679–1680, 1680t
for postinfarction, 396
for poisoning/drug overdose, 398–399
in poisoning/drug overdose, 1599
in prediction of, 570t
Antioxidant agents.
Antithrombotic agents: see Anticoagulant therapy
for antiphospholipid antibody syndrome, 833, 860
in DVT/PE (venous thromboembolic disease), 308
in SLE, 857t, 858t
Anti-Casp2 antibody, 1028
Anti-CCP antibodies, 853, 882
Anticentromere antibody, 858t, 863
Anticholinergic agents. See also specific disorder
for allergic disorders/rhinitis, 232
drug interactions and, 1104r
for asthma, 261–262t, 264t, 265
for COPD, 273
for irritable bowel syndrome, 662
for nausea and vomiting, 597
overdose/toxicity of, 209t, 210, 1601t, 1610–1611
for Parkinson disease/parkinsonism, 1034
Anticholinergic syndrome/effects/delirium, 1603
tidepressants causing, 1099, 1626
antipsychotics causing, 1089, 1090t, 1091
hallucinogens causing, 1618, 1619
Anticholinergic-type mushroom poisoning, 1610
Anticholinesterases/acyethylcholinesterase inhibitors, 60, 1041, 1066, 1601t, 1621–1622
Antidepressant drug interactions and, 1104r
Antidepressant drugs, 47, 376–379, 378f
Antithrombotic agents: See Anticoagulant therapy
Anticoagulant therapy; Thrombolytic therapy
Anticoagulant, lupus.
Anterior interosseous syndrome, 1127–1132
Anterior interosseous syndrome, 1060
Anterior ischemic optic neuropathy, 202
Anterior talofibular ligament, in ankle sprains, 1739, 1740
Anterior tibiofibular ligament, in ankle sprains, 1740
Anticholinergic syndrome/effects/agents.
Antidepressant drug interactions and, 407, 407–410, 408

Monoclonal protein.

Monoclonal antibodies

Monoamine oxidase inhibitors (MAOIs),

Monkeypox, 1447–1448

Monge disease,

Mönckeberg medial calcific sclerosis, 491

Mometasone, 108

MOLST forms, 77

Mollaret meningitis, 1391

Molecular adsorbent recirculating system (MARS), 721

Mobitz type I (Wenckebach)

atrioventricular block, 393–394,

402

Mobitz type II atrioventricular block, 402

MoCA (Montreal Cognitive Assessment), 59, 1040

Modafinil, 38, 74, 726, 1044, 1112

Model for End-Stage Liver Disease (MELD/MELD-Na) score,

723–724, 724t

in alcoholic liver disease/cirrhosis, 72,

712, 713

hepatocellular carcinoma and, 1650

in liver failure/hepatic encephalopathy, 703, 704

postoperative complications and, 51

Modic changes, 1716

Modified Duke criteria, 1482–1483

Modified Marshall scoring system, 746

Modified McMurtry test, 1732, 1736

Moexipril/moexipril HCTZ, 466

Modified Marshall scoring system, 746

Monge disease, 556, 1057

Moods

Molecular adsorbent recirculating system (MARS), 721

Mollaret meningitis, 1391

Molecular adsorbent recirculating system (MARS), 721

Mollaret meningitis, 1391

Molecular adsorbent recirculating system (MARS), 721

Mollaret meningitis, 1391

Molar pregnancy,

Molecular adsorbent recirculating system (MARS), 721

Mole (skin).

Mole, hydatidiform.

Molds

household, 1579

opportunitistic infections caused by, 1313, 1365, 1579

Mole, hydatidiform. See Hydatidiform mole

Mole (skin). See Nevi

Molecular adsorbent recirculating system (MARS), 721

Mollaret meningitis, 1391

Molluscum contagiosum, 150, 152f, 152f,

1364–1365, 1447

MOLST forms, 77

Mometasone, 108f, 229, 232, 263t, 264t

Mönckeberg medial calcific sclerosis, 491

Monge disease, 1595

Monkeypox, 1447–1448

Monoamine oxidase inhibitors (MAOIs),

1098, 1099f, 1102–1103, 1289t

for Parkinson disease, 1033

serotonin syndrome and, 1101

Monoclonal antibodies

against calcium ion–related peptide,

998, 998f

in cancer chemotheraphy, 1636–1637t.

See also specific agent

for Ebola viral disease, 1425, 1426

Monoclonal gammopathy of unknown significance (MGUS), 553–554,

556, 1057

Monoclonal immunoglobulin-mediated glomerulonephritis, 941

Monoclonal protein. See also Paraproteins in plasma cell myeloma, 551, 551–552,

552

in Waldenström macroglobulinemia, 554

Monocular visual loss, transient, 198–199

Monocytic ehlichiosis, 1453t, 1459–1460

Monomethylhydrazine mushroom poisoning, 1620–1621

Mononeuritis multiplex, 1055–1059, 1057.

See also Neuropathies in diabetes, 1256–1257

in Lyme disease, 1057, 1523

polyarteritis nodosa and, 873

See also Mononeuritis (mononeuropathy) multiplex

Neuropathies

in diabetes, 1256–1257. See also

Diabetic neuropathy in HIV infection/AIDS, 1360

in sarcoidosis, 1057

Mononeuritis multiplex

CMV, 1402, 1403

Epstein-Barr virus, 214, 1941, 1399–1400

pharyngitis in, 241, 1400

Mononeuritis-like syndrome, 1402, 1403, 1404

Montelukast, 232, 264t, 265

Montenegro (leishmanin) skin test, 1531

Montgomery-Asberg scale, 1097

Montreal Cognitive Assessment (MoCA), 59, 1040

Mood disorders, 1095–1108, 1099f,

1100f, 1102f, 1104t, 1107t. See also Depression; Mania
dementia and, 1040, 1041–1042

Moraxella/Moraxella catarrhalis infections, 280f, 1331f, 1336f,

1489

Morbidly adherent placenta (placenta accreta/increta/percreta), 831

Morbiliform skin disorders, 107t

Morganella, 1332t

Moricizine, toxicity of, 400

Morning sickness. See Vomiting, of pregnancy

Morphaea, 864

Morphine, 89, 93f, 94f, 97

for dyspnea, 73–74, 274

intraheal delivery of, 103

for myocardial infarction, 392, 394

overdose/toxicity of, 93t, 210f, 1621

for pulmonary edema, 428

Mosaic HIV vaccine, 1372

Mosaicism

premature menopause and, 1218

Turner syndrome and, 1224, 1225

Mosaics/mosquito control chikungunya fever and, 1434, 1435
dengue and, 1428, 1429

encephalitis and, 1415, 1416

filariasis and, 1563, 1564

hemorrhagic fever and, 1427, 1428,

1429, 1431

malaria and, 1533, 1540

yellow fever and, 1431, 1432

Zika virus infection and, 1433, 1434

MOTOR TREATMENT FORMS, 77

Moths, skin lesions caused by, 161

Mollaret meningitis, 1391

Motive disorder. See also specific disorder

esophageal. See Esophageal motility disorders

testinal, 654–657. See also Intestinal obstruction

constipation and, 599, 599f

diarrhea and, 604t, 607

irritable bowel syndrome and, 607,

609

vomiting and, 596, 596t

Motivational interview, at-risk drinking and, 1116

Motor conduction velocity studies. See Conduction velocity studies

Motor neuron diseases, 1053–1054

spasticity and, 1046

spinal trauma and, 1052

Motor vehicle accidents. See Automobile accidents

Mountain sickness acute (AMS), 1593, 1594

chronic (Monge disease), 1595

subacute, 1595

Mouth. See Oral cavity

Movement disorders, 1030–1038. See also specific type

drug-induced, 1037

Movalastat, 573t

Moxifloxacin. See also Fluoroquinolones for anaerobic infections, 1501, 1502t

for bite wounds, 1322

for ophthalmic disorders, 182

for pneumonia, 281t, 283, 284, 1470

MPL mutation, 535, 537, 538

MPSV4 vaccine, 1345f, 1488. See also

Meningococcal vaccine

MRI. See Magnetic resonance imaging

MSH2/MSH6 genes in GI cancer, 685

in pancreatic/periampullary carcinoma, 1654

mtTOR inhibitors, 774, 1665, 1685

Mucin deficiency, 179

Mucocutaneous (mucosal) candidiasis,

141–142, 141f, 1567,

1568–1569

Mucocutaneous herpes simplex, 130–131,

130f, 1390, 1391f

Mucocutaneous leishmaniasis (espinula),

1530, 1531, 1532

Mucocutaneous lymph node syndrome (Kawasaki disease), 1394f,

1462–1464

Mucocutaneous syphilis, 1511f, 1513,

1514, 1515f, 1516

Mucosimetitics, for dry eye, 179

Mucormycosis/Mucor infection, 231, 1577

Mucosa-associated lymphoid tissue lymphoma. See MALT lymphoma

Mucosal biopsy

in celiac disease, 650

in diarrhea, 609

Mucosal protective agents, for peptic ulcer disease, 641

Mucositis, oral, chemotherapy-induced, 1693t, 1696

Mucous membranes

diabetes mellitus affecting, 1258–1259

leishmaniasis involving, 1530, 1531,

1532

melanoma involving, 115

thrombocytopenia, 568
for intracranial venous thrombosis,
1021
in mirtal stenosis, 352
in nephrotic syndrome/nephrotic
spectrum disorders, 960
overdose/toxicity of, 314, 579, 587,
589t, 1608
perioperative management and, 52,
52t, 367–368
pregnancy and, 367, 369, 450–451
for pulmonary hypertension, 448
switching to from DOAC, 581t
switching to DOAC from, 408–410,
581t, 588
for TIAs, 1012
vitamin K epoxide reductase complex
(VKORC1) and, 586
Warts (verrucae), 150–152, 150f, 1361.
See also Venerale (genital) warts
Washout time, 1103
Wasting
chronic, 1421
in HIV infection/AIDS, 1353
in malabsorption, 648t
in protein-energy malnutrition, 1286
Watchful waiting/surveillance
for benign prostatic hyperplasia, 991,
992f, 992t
after orchectomy for testicular cancer,
1687
for prostate cancer, 1678
for thyroid microcarcinoma,
1162–1163
Water, body. See Body water
Water deficit, calculation of, 909
Water-hammer pulse, 362
Water/fluid intake. See also Fluid
management/hydration
in diabetes insipidus, 1132, 1133
in diabetes mellitus, 1231, 1232
disorders of/inappropriate, 911t.
See also Polypsia
hyponatremia caused by, 904–905,
904f, 906
in schizophrenia/psychotic
disorders, 904–905, 904f, 906, 1088
replacement of/requirements for, 930,
1303
restriction of
for chronic kidney disease, 947
for hyponatremia, 906, 907, 908
urinary stone formation and, 981, 982
Water vapor thermal therapy, for benign
prostatic hyperplasia, 995
Waterhouse-Friderichsen syndrome,
1188
WDHA (Verner-Morrison syndrome),
1198, 1204
Weakness/muscle weakness, 864, 865,
866–867. See also Myopathies;
Myositis; Paralysis
